Chapter 86

Optical Imaging of Seizure Activity

Michael M. Haglund

Daryl Hochman

Arthur W. Toga

Introduction

Recent advances in imaging techniques have provided the clinician with new methods to identify epileptic foci, rolandic cortex, and eloquent language areas. The best method for understanding how these imaging techniques, such as magnetoencephalography (MEG), positron emission tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI), and optical imaging, fit together is to examine briefly their temporal and spatial resolutions.[11,14,18,30,31,53,55,57] Accurate maps of brain function and the spread of epileptiform activity require excellent spatial resolution to identify interictal activity and the site of onset of ictal activity and to find the source of the epileptic activity and the pathways by which the seizure activity spreads.[13,47,49] Unfortunately, although each of these new methods holds significant promise, none stands alone to provide the unique answer for identifying epileptic foci and mapping functional activity. PET (Chapter 80) provides three-dimensional information regarding functional activity but has a temporal resolution of only 40 seconds and a spatial resolution of 5 to 7.5 mm^2, limiting its ability to identify ictal onsets and individual interictal activity.[1,38,41] SPECT has similar limitations, although newer imaging compounds have allowed identification of epileptic foci and ictal-onsets zones.[14,53] Functional MRI (Chapter 83) is rapidly advancing, and provides three-dimensional identification of rolandic cortex and has been shown to have the potential to localize eloquent regions, especially Broca area; however, identification of epileptic foci and seizure spread awaits further advancements.[2,11,14,55] MEG (Chapter 78) has the fastest temporal resolution, which is necessary to identify epileptic foci, but is somewhat limited by its overall spatial resolution and the methods necessary to identify rolandic cortex and eloquent regions.[15,18] Optical imaging is one of the latest imaging techniques to be used on human cortex with potential advantages of being the only technique used for intraoperative localization of epileptic foci, rolandic cortex, and eloquent language regions.[26,38,44] This chapter focuses on the use of optical imaging in identifying epileptic foci and the spread of seizure activity in human patients undergoing epilepsy surgery.

Background Studies in Optical Imaging

The foundational work that allowed optical imaging to be used in the operating room to identify speech and sensory cortical regions began more than 50 years ago. Using the nerve trunk of the crayfish, Hill and Keynes[27] found optical changes in the nerve trunk that correlated with stimulation of the nerve. The â€œintrinsic signalâ€ changes (without any voltage-sensitive dyes) in the nerve trunk recorded by a photocell showed an increase in the transmission of light during stimulation and a more prolonged undershoot following the stimulation. The potential uses of optical recordings have been advanced during the last 20 years by the work of a small group of investigators including, but not limited to, Waggoner, Davila, Salzberg, Grinvald, Ross, and Orbach.[7,8,9,10,16,19,36,41] These investigators have made vital contributions to the techniques of optical imaging by screening and developing optical probes of membrane potential (voltage-sensitive dyes) as well as by pioneering different technologies for their use.

Blasdel and Salama[5] expanded on these techniques by using a television camera to obtain greater spatial resolution (120 Ã— 100) than had been previously possible with the standard photodiode arrays (24 Ã— 24) by previous investigators. Blasdel went on to use optical imaging and voltage-sensitive dyes to visualize functional domains of visual cortex in nonhuman primates such as ocular dominance columns and orientation preferences.[3,4] Frostig et al., Grinvald et al., and Ts'o et al.[16,19,54] were later able to identify similar functional regions in the primate visual cortex without voltage-sensitive dyes by using the intrinsic signal changes in the optical reflectants from the cortical surface. These advances led to the first human epileptiform and functional images of language and sensory cortex obtained by Haglund et al.[26] There are a vast number of questions that can be addressed with optical imaging techniques; however, this chapter focuses on the basics of the technique and how the technique can be used to identify epileptic foci and follow the spread of seizure activity across neocortex. The use of optical imaging to localize rolandic cortex of cortical regions involved in higher cognitive functions such as language, memory, or phrase processing is not covered in this chapter and has been reviewed by Pouratian et al.[38] and Suh et al.[50]

Fundamentals of Optical Imaging

Much of the fundamental work on optical imaging concerns the correlation of optical changes observed with voltage-sensitive dyes and electrophysiologic changes.[3,4,5] The voltage-sensitive dyes were known to bind to cell membranes and their absorption properties change when the cell membrane voltage changes. The work on the invertebrates established that the optical changes observed with voltage-sensitive dyes were tightly correlated with action potential depolarization recorded by the means of intracellular electrodes. Correlation of optical changes to functional regions in cortex was developed from work on the rat somatosensory cortex with the identification of individual barrels using single-unit recordings and optical images.[32,34] Blasdel and Salama added to the correlative information on optical imaging and single unit recordings by demonstrating that in the intact nonhuman primate visual cortex, the peak optical changes for the specific orientations correlate with peak optical imaging changes

for that specific orientation stimulus. Anatomic studies also confirm that these optical changes correlated with anatomic boundaries.[3,4,5]

The understanding of the mechanism underlying the intrinsic signals still awaits more detailed studies, but some information has been presented in the last several years. Initially, Frostig et al.[16] demonstrated in a monkey visual cortex that ocular dominance orientation preferences that correlated with anatomic substrates could be found using the intrinsic signal. These studies have shown that the intrinsic signal changes can be used for mapping functional activity during visual-evoked changes.[12,46,47,48,54,56] Using an in vitro slice preparation, MacVicar and Hochman[33] have shown that there was a broad range of wavelengths over which the intrinsic signal changes allow more light transmission through the slice when the Schaffer collaterals are stimulated in the hippocampal slice. They went on to show that the intrinsic signal depends on a Na-K-2Cl cotransport mechanism, which is blocked by furosemide. Because the intrinsic signal is abolished by the Na-K-2Cl cotransport inhibitor, the mechanism underlying the intrinsic signal in the bloodless brain slice preparation appears to be a consequence of cellular swelling. However, Frostig et al.[16] have shown that the intrinsic signal also depends on blood volume and oxygen delivery changes. More recent studies from Haglund and Hochman[23,24] demonstrated that in the human neocortex, the changes in the intrinsic signal could be either due to blood volume or blood oxygenation changes, depending on the wavelength used. Using a wavelength at the isobestic point for hemoglobin (535 nm), changes in the negative direction (the tissue getting darker) are localized to pial arterioles that are dilating during functional or epileptic activity. In contrast, imaging done at a wavelength where the oxy-deoxy-hemoglobin absorption curves are maximally separated shows blood oxygenation changes restricted mainly to the draining veins. These blood oxygenation changes are more likely to go along with the BOLD (blood oxygen levelâ€"dependent) signal that is part of the fMRI imaging paradigms.[29,31,37,40] Using this technique, Haglund and Hochman were able to demonstrate spontaneous ictal activity in the human cortex and more recently interictal activity in the human cortex that correlated with intrinsic signal changes. The most localized changes appear to go along with the blood volume at the isobestic point for hemoglobin (green light, 535 nm).

Optical Imaging of Epileptiform Activity in Animal Models

Visualization of the spread of epileptiform activity has been accomplished in the brain slice preparation.[52] In neocortical slices, stimulation of the white matter demonstrated a certain area of cortical activation in an area increased in its spatial extent when bicuculline, a Î³-aminobutyric acid ($GABA_A$) antagonist, is added to the bathing medium. These studies point toward a baseline inhibition that leads to a larger area of activation when the slice is disinhibited. However, most of these studies do not demonstrate localization of the seizure focus or how the seizure activity spreads from its site of origin. Intact neocortical preparations have shown an increase in the area of cortex activated when $GABA_A$ antagonists are superfused in the cortex. These studies do not specifically address localization of the epileptic focus or the spread of ictal seizure activity. Grinvald et al.,[20] using a photodiode array and voltage-sensitive dyes (with high temporal resolution but limited spatial resolution), showed the rapid spread of interictal spikes (paroxysmal polarization shift) across the cortical surface. With the advent of CCD (charge coupled device) cameras for identifying functional areas of visual cortex,[4] Haglund and Blasdel[22] used the visual cortex as a model for localizing acute epileptic foci. After the optical imaging of voltage-sensitive dyes was used to map the ocular dominance column (Fig. 1B), an acute epileptic focus was created by placing a 0.5-mm^2 pledget of bicuculline-soaked Gelfoam on the cortical surface for 5 minutes at site No. 5 (Fig. 1A). This application of the convulsive bicuculline created an epileptic focus that persisted for 2 to 3 hours and was well localized to the area of application. By activating the visual cortex with the moving grading for 250 msec, which resulted in the single large interictal spikes, the area of epileptic discharge was identified (Fig. 1C). The area surrounding the epileptic focus was hyperpolarized, consistent with surround inhibition. When the cortex was activated with visual stimulation for 500 msec, multiple interictal spikes occurred and an interesting pattern of alternating hyperexcitability and inhibition was evident (Fig. 1D). The development of an acute epileptic focus is shown in FIGURE 2. A new epileptic focus was created at site No. 6 (Fig. 2A). Five and 10 minutes after bicuculline application, the site could be identified (Fig. 2B,C). However, 30 minutes after the epileptic focus was created, brief stimulation of the visual cortex elicited a pattern of depolarization in the epileptogenic region (Fig. 2D) with an area of probable surround inhibition.[39] Spreading out from the epileptic focus were alternating patterns of excitation and inhibition. These patterns are reminiscent of the patterns previously found with intercortical stimulation.[17,21,57] Whether these patterns are spreading via the horizontal connections involving the color blob system, which is known to run orthogonal to the ocular dominance columns, awaits further study. These preliminary studies demonstrate the power of the high spatial resolution of optical maps. The entire images shown in Figures 1 and 2 with a spatial resolution of 120 Ã— 100 pixels would most closely represent a single voxel in an individual PET scan. The pattern of seizure activity in the optical imaging map suggests the complexity that would not be appreciated with other imaging modalities, such as PET or SPECT, because of their lesser temporal resolution. These studies in nonhuman primates led to attempts to identify seizure onset and spread of human cortex during neurosurgical procedures in awake patients for the treatment of intractable epilepsy. The human studies could be performed on a much larger scale (4 to 5 cm^2) compared to the primate studies, which were carried out in an area of 0.6 to 0.8 cm^2. The spatial resolution for these optical imaging studies is on the order of 100 Âµm^2 per pixel.

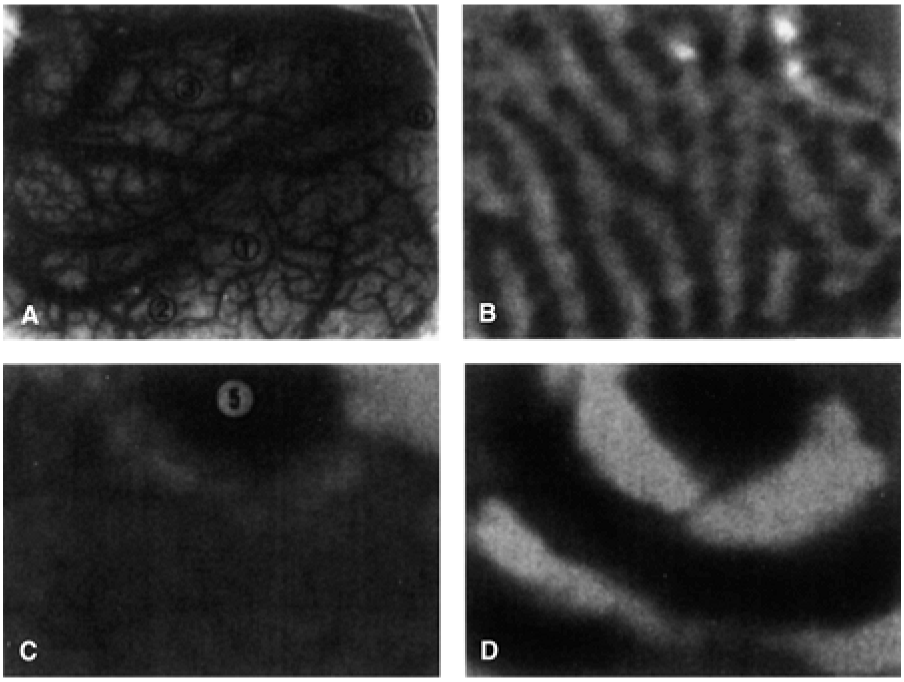

FIGURE 1. A: A 6 Ã— 8-mm area of monkey primary visual cortex with the bottom region just behind the lunate sulcus, such that ocular-dominance columns should intersect perpendicular to that region. The numbers in circles represent regions where epileptic foci were created. **B:** Ocular-dominance columns obtained by staining the cortical surface with merocyanine voltage-sensitive dye and stimulating the right eye for 3 seconds and then the left eye for 3 seconds. After six trials of right- and left-eye stimulation, the optical images collected during left-eye stimulation (1,000 frames) are subtracted from the right-eye images and the pattern of ocular-dominance columns is shown. Note that the width of the image is 8 mm, and there are approximately eight right-eye columns (*black*) and eight left-eye columns (*white*). **C:** After creation of an epileptic focus at site No. 5 **(A)**, stimulation of only the right eye for 250 msec evoked a single large interictal burst; after six stimulations were averaged, the baseline control images were subtracted from the stimulation images. The black area represents areas of intense activation, whereas the white surrounding regions represent areas below baseline. **D:** If the stimulation of the right eye is prolonged (500 msec) to elicit multiple interictal bursts, an interesting pattern of alternating excitation and inhibition is evoked. See text for further details.

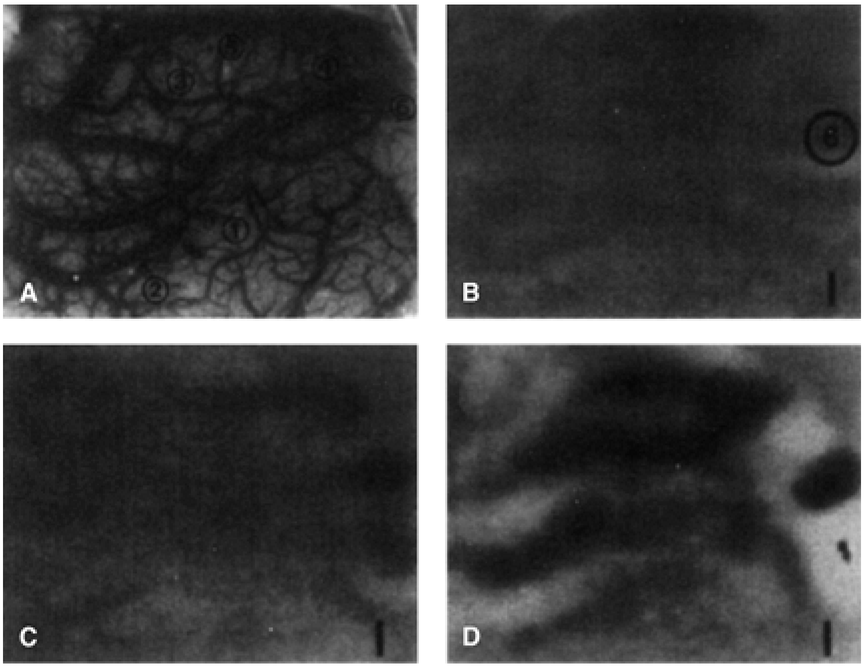

FIGURE 2. **A:** Same area of monkey visual cortex as for FIGURE 1, except a new epileptic focus has been created at site No. 6. The development of the epileptic focus is followed for 5, 10, and 30 minutes after its creation. **Bâ€"D:** The stimulations of the right eye were carried out for 125 msec, just enough to elicit a single interictal burst. After the epileptic focus is well established **(D)**, the area of the seizure onset is noted with its surrounding inhibitory region and the alternating pattern of excitation and inhibition.

Optical Imaging of Epileptiform Activity in Humans

By using the intrinsic signal in human cortex and stimulating at just above the afterdischarge threshold, seizure activity can be elicited and recorded by a surface electrode (electroencephalogram [EEG]) (Fig. 3Aa). In a large area of cortex (4 cm^2), stimulating electrodes separated by 1 cm (Fig. 3Ab) evoked either short afterdischarges (lower left, Fig. 3B) or a longer series of seizure activity (lower right, Fig. 3B). The optical imaging changes at baseline (one control image subtracted from another) demonstrate the noise present in the system (Fig. 3Ab). At the end of the stimulation during the shorter seizure episode, the area of optical changes is shown in FIGURE 3Ac, whereas a much greater spatial extent of cortex activation is found in the more intense seizure episode (Fig. 3Ad). In addition to examination of the spatial extent of activation, the magnitude of optical changes during the seizure episode can be measured. The sites at FIGURE 3B correlate with the regions of interest in

P.1027

P.1029

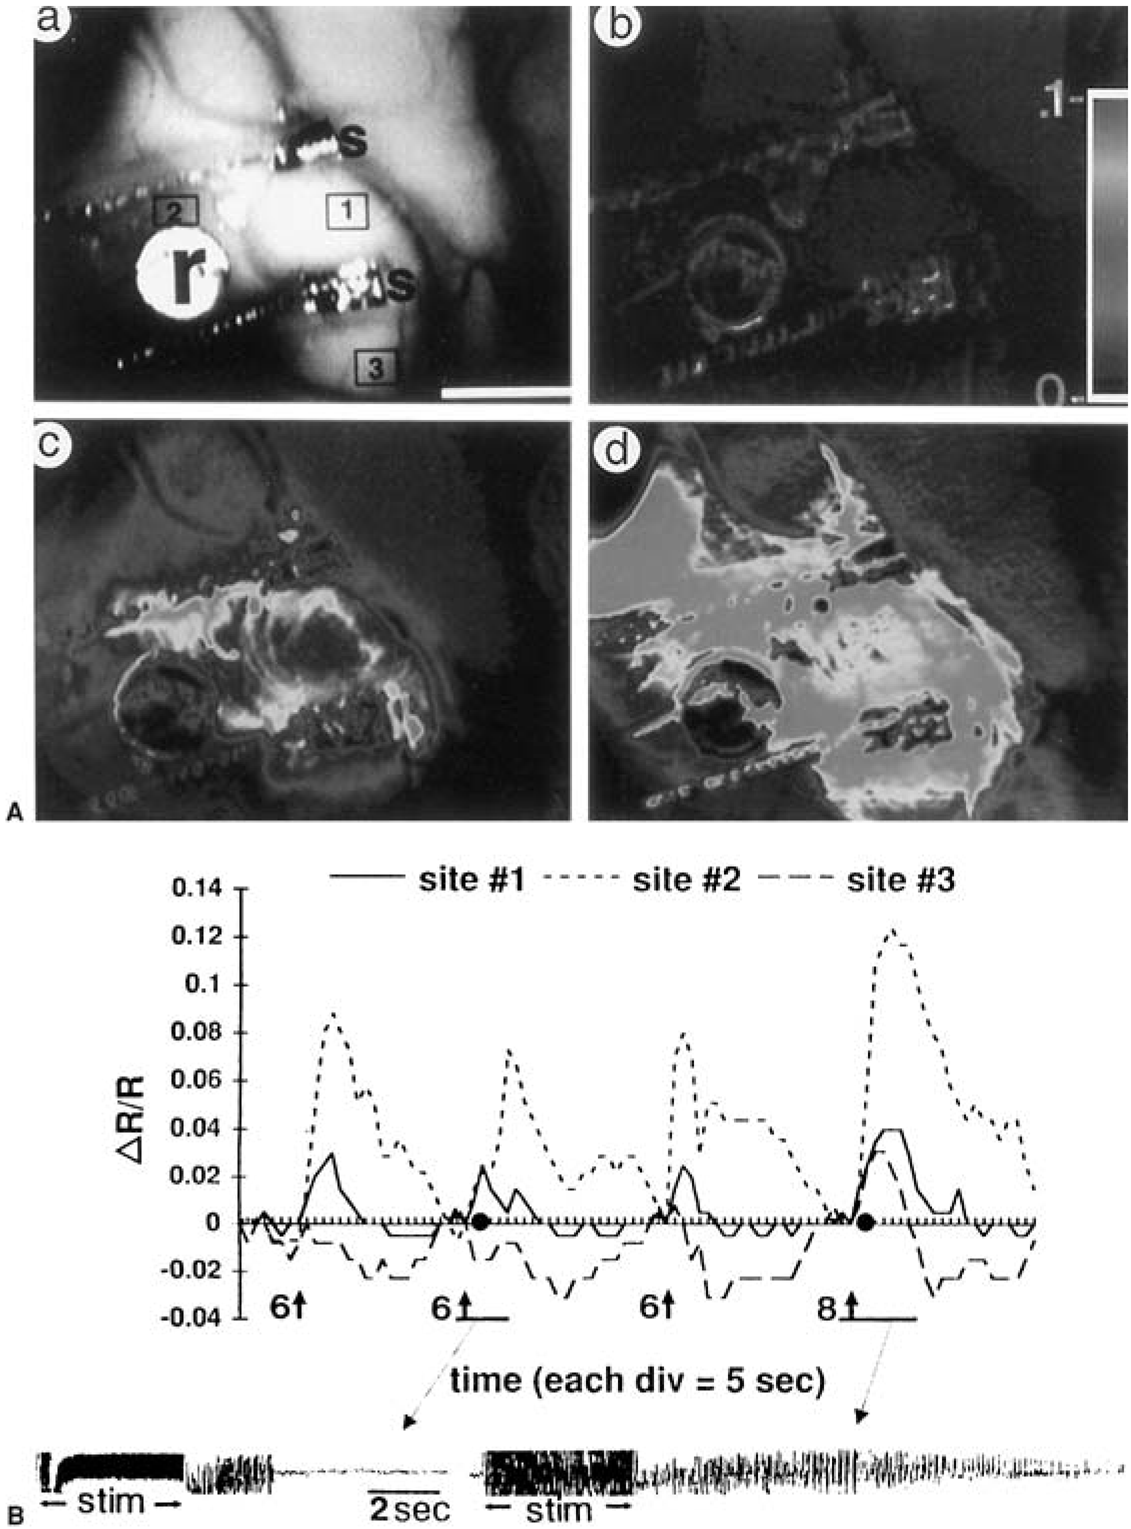

FIGURE 3. A: Human frontal cortex exposed at the time of a neurosurgical procedure for treatment of medically intractable epilepsy. Recording surface electroencephalographic (EEG) electrode is represented by *r*, the two stimulating electrodes by *s*. *Boxes 1, 2, and 3* are regions of interest where the optical changes in the intrinsic signal were measured for FIGURE 3B. Scale bar = 1 cm. **Ab:** Control image subtracted from another control image showing the baseline noise. The pseudocolor scale bar (*right*) shows the intensity of the optical changes, with black being below baseline, blue near baseline, and red maximal. **Ac:** Optical changes at the end of the second stimulation at 6 mÃ…, which evoked a

short seizure â€œafterdischargeâ€ episode. The peak changes are near the recording electrode with a surrounding region that is black, suggesting that the optical changes in that region are below baseline. **Ad:** Optical changes after the fourth stimulation are at 8 mÃ…, which evoked a more prolonged and intense seizure episode compared with the other intense optical change. **B:** The optical changes from the three boxes shown in FIGURE 3Aa are shown, as well as the surface EEG recording from the second stimulation (optical changes in Fig. 3Ac; *lower left*) and the surface EEG recording from the second stimulation (optical changes in Fig. 3Ad; *lower right*). From Haglund MM, Ojemann GA, Hochman DW. Optical imaging of epileptiform and functional activity from human cortex. *Nature*. 1992;358:668â€“671, with permission. (See color insert.)

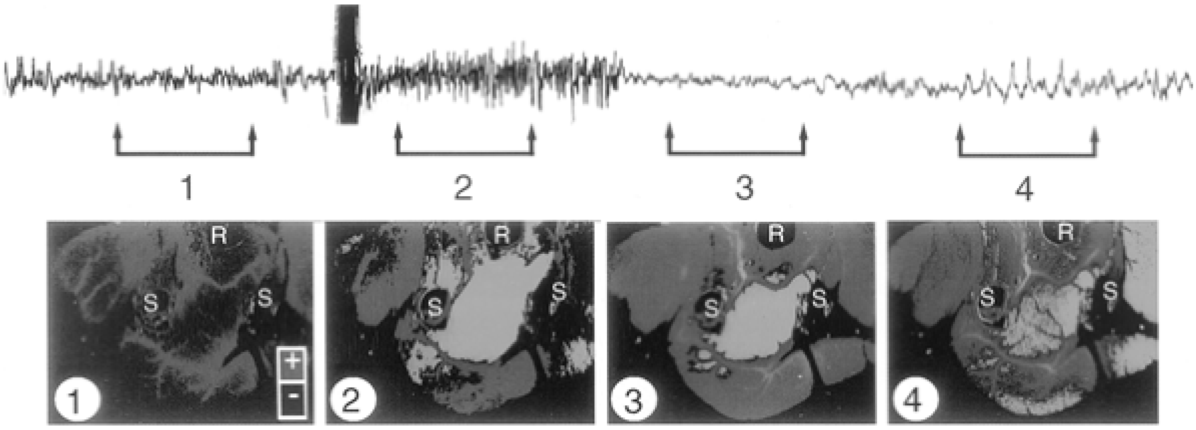

FIGURE 4. Upper trace: Surface electroencephalographic (EEG) trace from the recording electrode (*r* in the *lower images*). The brackets represent the period during which the optical images in the *lower panel* were collected and a baseline image was subtracted from each of the images. The four brackets show the baseline, seizure, postictal, and recovery electrical recordings, respectively. **Lower panel:** Optical changes before and after electrical stimulation at the afterdischarge threshold (stimulating electrodes represented by *s*). The optical changes are shown in a two-color scheme, so positive changes correlated with increases in neuronal activation are shown in red, whereas optical changes in the intrinsic signal below baseline are shown in blue. The optical changes in the positive direction correlate with the increases in electrical activity, especially the seizure activity in bracket No. 2. The optical changes also correlate with the quiescent postictal surface EEG recording in bracket No. 3, where the optical changes are below baseline. (See color insert.)

Figure 3Aa. Site No. 1 represents the area between the stimulating electrodes and shows the positive change in optical signal during four stimulations. The first three stimulations were performed at 6 mAA and the last stimulation at 8 mAA. Of the three stimulations at 6 mAA, the first seizure episode was the longest electrically, whereas the second and third were of shorter duration and intensity. The last stimulation at 8 mÃ… led to the longest and most intense seizure episode as measured by the surface EEG electrode. The optical changes near the recording electrode are measured at box No. 2, mimicking the electrical changes, with large darkening of the optical changes occurring after the four stimulations (Fig. 3B, lower right).

Of interest, but still without clear mechanisms, are the surrounding opposite changes measured at box No. 3. During each of the first three stimulations, the optical changes are in the opposite direction of neuronal activity activation, whereas during the fourth and most intense seizure episode, the change is initially along with neuronal activation but then goes in the opposite direction. Whether these intrinsic signals in the opposite direction from a neuronal activation actually represent surround inhibition as seen in the monkey visual cortex or is some type of surrounding shunting of cellular swelling or blood volume changes needs to be studied with more detail. However, studies in the ferret neocortex have shown that the surrounding intrinsic signal changes are active inhibition.[42,43,50]

Closer comparison of the electrical and optical changes can be accomplished by studying surface EEG activity in different stages of seizure activity. In FIGURE 4, the surface electrode (red) measures the baseline No. 1, the seizure No. 2, postseizure quiescent No. 3, and return to baseline No. 4 activities while the optical imaging was performed. By comparing those areas colored red, associated with increases in neuronal activity, and those colored blue, having a decrease in neuronal activity, the optical changes can be compared with a concomitant surface EEG recording. During baseline activity, the region around the recording electrode is black, whereas during the seizure episode, the area is clearly activated (red). During the postseizure period, when the electrical activity is quiescent compared with baseline, the area around the recording electrode shows a signal in the opposite direction of activation (blue), which gradually returns to near baseline in the last image (No. 4). These preliminary studies indicate that those changes associated with neuronal activity also correlate with increases in electrical activity, whereas changes in the opposite direction correlate with decreases in the baseline electrical activity.

Recent advances have allowed investigators to image the neocortical surface in the operating room during spontaneous seizures and interictal activity. By using specific wavelengths, Haglund and Hochman[23] were able to compare optical changes during a spontaneous seizure in the neocortex. These changes were confirmed clinically and the intrinsic signal changes at the blood volume wavelength (535 nm) and the blood oxygenation wavelength (660 nm) were compared. The blood volume changes were closely associated with the site of the seizure activity, whereas the blood oxygenation changes were more variable. It appears that the blood volume wavelength will be more precise in localizing epileptic foci, while the blood oxygenation wavelength may be more variable and have more to do with the draining venules from the area than localizing the exact site of neuronal activity.

Summary and Conclusions

The use of optical imaging to identify epileptic foci and the spread of seizure activity in the operating room is still in its earliest stages.[28,38,49] However, if it is to be used in a noninvasive manner, infrared cameras and lasers will likely be required. Optical imaging of rat and monkey visual cortex has been accomplished through a thin skull,[6,34,35,45,46,47,50,54] and implanted brain tumors have been identified through the rat skull by means of optical imaging.[25] Since these technologies can be carried out noninvasively, the potential exists for using optical imaging to identify sources of epileptic activity.

The most significant application of optical imaging is its capacity to identify functional regions intraoperatively that are important to preserve and localize the epileptic focus and the pathways of seizure spread. By using these optical imaging techniques, the more precise surgical treatment of medically intractable epilepsy could be performed. As optical imaging emerges from being a purely research tool, the technique will fulfill its future potential as an adjunct to three-dimensional fMRI and PET techniques. Additional advantages over PET and fMRI include the capacity be formed intraoperatively,

P.1030

better spatial and temporal resolution than PET, and functional maps that have been compared with precise electrical stimulation maps of language and higher cognitive functions.[1,2,51,55]

Chapter 87

Microdialysis

Idil Cavus

Charles L. Wilson

Introduction

Microdialysis is a method that allows continuous in vivo sampling and neurochemical analysis of brain extracellular fluid (ECF) for extended periods of time. Although brain extracellular (EC) space comprises only 15% of brain volume, the neurochemical changes in this compartment are critical for the functioning of the various cellular receptors and transporters. Brain microdialysis was first introduced in animal research in the 1970s[32,125] and applied to human research in the 1990s. This method has been used in numerous animal models of disease, including epilepsy, to measure the EC levels of ions, drugs, neurotransmitters, and other small molecules and peptides under anesthetized as well as awake behaving conditions. In humans, brain microdialysis is used primarily to monitor or study the neurochemistry of brain injury related to trauma, stroke, or ischemia in neurointensive care and tumors in the neurosurgical setting, and it has also been used during intracranial electroencephalographic (EEG) monitoring of epilepsy patients (for reviews, see Benjamin et al.[11] and Hillered et al.[51]). Recently, significant advances in clinical microdialysis research have allowed the technique to be used not only for the study of disease neurochemistry, but also as a bedside monitoring and diagnostic tool in neurointensive care patients.[10]

Microdialysis Methodology

The microdialysis setup is relatively simple, involving a probe/catheter, a perfusion pump, and a collection system. The microdialysis probe (~1 mm in diameter) consists of a concentric or side-by-side dual catheter with a semipermeable membrane attached to its tip and connected to inlet and outlet tubing. The probe membrane is usually 1 to 3 mm long in rodent studies and 5 to 30 mm in humans, with typically 10- to 20-kDa molecular weight cutoff. Microdialysis membranes with small pore sizes have the advantage of acting as an additional barrier to likely infectious agents, and may be preferable in human research. A recently introduced probe for human research with 110-kDa molecular cutoff,[54] however, allows for sampling of larger proteins and can be useful in studying the proteomics of the brain microdialysate.[70] A microdialysis probe with even larger membrane cutoff (3,000 kDa) has been used in tumor patients to sample neurotrophins and inflammatory factors.[136] Usually, the commercially available CMA 70 (molecular cutoff 20 kDa; CMA Microdialysis, North Chelmsford, MA) has been the probe of choice for human research in brain trauma, stroke, and tumor patients. In human epilepsy research, however, in which stereotaxic placement and simultaneous electrophysiologic monitoring are desired, probes with smaller diameters and longer shafts are preferred. The earlier homemade designs[35] have been replaced by custom-made probes. These probes can be inserted inside the depth electrode (Spencer probe) for simultaneous EEG[35] or single unit activity monitoring.[43] In human epilepsy research, patients with refractory epilepsy who are evaluated with intracranial electrodes for localization of their seizure onset site are implanted with microdialysis or Spencer probes after obtaining institutional review board approval and the necessary informed consents.

Spencer probes can be stereotaxically implanted into the brain area of interest and their position confirmed with magnetic resonance imaging (MRI) and computed tomography (CT). The probe is perfused with sterile artificial ECF through the inlet at relatively slow rates (usually 0.1â€"2.5 ÂµL/min) allowing for diffusion of molecules across the membrane down their concentration gradient. The dialysate fluid is collected either manually or automatically (typical sampling rates 1â€“60 min) and can be analyzed on-line or off-line using high-performance liquid chromatography (HPLC), mass spectroscopy, or enzyme-based methodologies.[78] The more recently developed and highly sensitive capillary electrophoresis analysis allows for relatively high (5â€“60 seconds) temporal resolution,[71,80] which is more useful in tracking fast neurochemical changes during seizures.

The amount of brain chemical recovered in the dialysate represents only a fraction of its actual interstitial concentration. This relative recovery depends on many factors, including the molecular weight, charge, uptake, and metabolism of the measured compound, diffusion, tortuosity factors in the interstitial microenvironment, length and composition of the dialysis membrane, flow rate, temperature, and composition of the perfusion fluid.[12,15] Usually, higher relative recovery is obtained at lower perfusion rates and with longer membranes.[123] The absolute EC concentration of the measured neurochemicals can be estimated using quantitative microdialysis methods such as no-net-flux[65] and extrapolation-to-zero-flow methods.[55] These methods have been rarely used in clinical research, for example, in epilepsy patients,[1,20] and in neurointensive care,[53,62] because of their cumbersome nature.

The insertion of the microdialysis probe causes local tissue damage, transient disruption in the bloodâ€“brain barrier, and gliosis around the probe tract.[13,134] Some of this damage is attributed to the relatively large, nonsterile probes inserted in small animals' brains. Postmortem studies in sheep brain using sterile probes approved for human use reveal minimal disturbance to the cerebral parenchyma.[134] Similarly, implantation of small, flexible, sterile catheters in epileptic patients[35] has been reported to leave only a small track with minimal gliosis in the brain tissue. After the probe insertion, there is an initial period of disturbed metabolic function that can last up to 24 hours.[12,14] The disruption in the bloodâ€“brain barrier usually heals within 2 hours,[15,52] although a widespread leakage of albumin into the rat brains 24 hours after probe implantation has been also reported.[131] In humans, several clinical studies cite stabilization of dialysate levels within 20 to 60 minutes of probe insertion.[52] In contrast to microdialysis in rodents, in which dynamic exchanges across the dialysis membrane are lost relatively rapidly after probe implantation and in which experiments frequently must be conducted on the same day as the

probe implantation, human microdialysis parameters appear remarkably stable over many days. This stability is attributed to the minimal tissue damage and gliosis associated with the implantation procedure, which is most likely due to the use of sterile, relatively small, and flexible probes that are floating rather than rigidly secured to the skull, decreasing the trauma to the brain parenchyma.[35]

In epilepsy patients, microdialysis can be performed intraoperatively or during the intracranial EEG monitoring phase, on an intermittent or continuous basis (usually up to 2 weeks). In our experience, continuous bedside microdialysis for several days at low flow rates can be used safely in epilepsy patients and in neurointensive care.[10,49,50,81] The microdialysis probe can be also used for drug delivery to the brain (reverse dialysis), and this technique is often used in animal experimentation. In humans, drug delivery through microdialysis has been used for local brain tumor therapy[96] and for research purposes in epilepsy[37,38] and stroke patients.[58] Microdialysis can be applied simultaneously with other methods, such as positron emission tomography (PET)[41,52] and Doppler flowmetry,[56] to study the relationship between the neurochemical changes in the EC milieu and changes in brain metabolism and blood flow.

The Cellular Origin of the Dialysate Neurotransmitters

Microdialysis typically samples neurochemical changes and volume transmission in the immediate vicinity of the probe, and it may provide information only indirectly on the changes within the synapse.[12,34,133] The probe is much larger than the synaptic cleft, and the time resolution is orders of magnitude slower than that for synaptic events. The extrasynaptic concentration of a transmitter reflects a balance between its rate of neuronal and glial release and reuptake, together with its diffusion outside the synapse. In addition, these parameters are affected by the neuroanatomic location and density of terminals, receptors, and transporter molecules. As such, the measured ambient neurotransmitter levels may be most relevant for the function of the extrasynaptic receptors.

Although there is evidence that dialysate dopamine, norepinephrine, serotonin, and acetylcholine are primarily of neuronal, calcium-dependent origin, the cellular origin of glutamate and Î³-aminobutyric acid (GABA) has been disputed.[117,132] In most cases, glutamate and GABA in dialysate are insensitive to tetrodotoxin and to calcium depletion, raising the possibility of glial metabolic release.[117] Indeed, recent evidence indicates that glia are capable of releasing both glutamate and GABA through a variety of mechanisms, calcium dependent and independent, including tonic nonvesicular release and transporter reversal, via the cystine/glutamate antiporter and in response to neuronal stimulation.[9,19,31,89] Thus, the basal microdialysate levels of glutamate and GABA may be most relevant to our understanding of volume transmission and the regulation of tonic excitation and inhibition through activation of the extrasynaptic receptors, which can in turn affect excitability.[19,31,88] EC glutamate and GABA may be also of neuronal origin, particularly in response to stimulation. Synaptically released glutamate and GABA can spill over into the EC space and become accessible to the microdialysis probe during intense physiologic and electrical stimulation, particularly when glial reuptake or coverage is reduced.[3,34] Improvements in microdialysis method (smaller probes, increased temporal resolution, minimal tissue trauma) and in analytical procedures may enhance the detection of synaptically released neurotransmitters.[34,87]

Role of Microdialysis Studies in Animal Models of Epilepsy

Although the primary utility of microdialysis in animal models has been to further our understanding of the basic mechanisms of epilepsy, these studies have also provided data that may have potential diagnostic value for patients.[17] Measurement of brain anticonvulsant levels in animal models and their effect on electrographic, neurochemical, and behavioral expression of seizure activity only provides approximations of effective brain levels of antiepileptic drugs (AEDs) because of differences in AED absorption and breakdown between rodents and humans.[130] Although the effective levels may differ, the mechanisms of action can more easily be determined in animal models of epilepsy, which provide important information for identification of AED targets by measurement of neurotransmitters and transporters that are modulated by seizures. This provides a means for evaluating the potential for effective use of an AED in patient treatment[25,26] or identification of receptor agonists or antagonists with anticonvulsant potential by providing in vivo data complementary to in vitro electrophysiology.[109]

Initial in vivo microdialysis studies of neurotransmitter modulation in epilepsy published in the 1980s and 1990s largely focused on the amino acids (AAs) glutamate, aspartate, taurine, and GABA in attempts to determine their role in seizure genesis as reflected by changes in AA release in rodent brain during seizures evoked by excitotoxins or stimulation (for review, see Chapman[21]). The use of microdialysis specifically in animal epilepsy research has increased from about 90 studies in the first 10 years of its use to >170 animal studies in an equivalent period since 1997, and these studies have focused on an ever-wider range of topics related to a variety of epilepsy-related neurotransmitters and neuromodulators, receptor agonists, and antagonists, as well as AEDs.

The animal models employed in these microdialysis studies are extremely varied but can be roughly divided into acute, chronic, and genetic. Acute models (such as systemic, intra-cerebral, or reverse dialysis administration of substances that induce depolarization, afterdischarge, and status epilepticus) are useful for evaluation of anticonvulsants, whereas chronic models (such as kindling models, which usually require several weeks of electrical or chemical stimulation; the status epilepticus model; and the genetic models) have the potential of identifying antiepileptic properties of drugs and perhaps more faithfully simulate the interictal and ictal clinical expression of epilepsy.

Microdialysis Research in Epilepsy in Animal Models

Amino Acid Studies

Investigation of the roles of excitatory and inhibitory amino acids in seizure generation has been a primary focus of microdialysis research. Naive rats generally show little change in AAs in response to a single acute electrical stimulation or chemical administration of picrotoxin (PTX), bicuculline (BMI), pentelynetetrazol (PTZ), or kainate (KA).[74,106] Systemic administration of 4-aminopyridine (4-AP)[72] is effective in evoking a two-to sixfold increase in hippocampal glutamate or glutamine, and local reverse dialysis of pilocarpine produces significant release of glutamate as well as dopamine,[108] accompanied by seizures. Seizure-related increases in EC glutamate similar to the ones observed in humans[39,135] have been observed more reliably in chronic models of epilepsy, such as kindling with electrical stimulation[120] or intrahippocampal[135] or amygdalar KA injection.[119] Paradoxically, in a PTX kindling model, ictal

discharges were associated with initial decrease in glutamate and aspartate,[104,105] which was followed by delayed, long-lasting increase in glutamate,[107] again indicating the need for rapid measurement to detect transient glutamate change and suggesting an important role for glia in slower glutamate modulation.

Repeated bursts of high-potassium stimuli in the rat hippocampus[118] or electrical stimulation in kindled rats[121] were associated with graded increases in glutamate release, suggesting that repeated short-term increases in EC glutamate levels results in enhancement of excitatory neuronal systems, causing propagation of seizure activity and culminating in secondary generalized seizures. In KA-kindled rats, the hippocampus had elevated interictal glutamate, which increased sharply in response to potassium-induced depolarization,[119] findings that were again similar to reports in humans.[20,39] Ueda and colleagues[119] identified a parallel downregulation in hippocampal glial glutamate transporters GLAST and GLT-1 as the basis of the increased interictal basal glutamate levels.

Not only are kindling models more responsive, but chronic rat models and genetic models also show AA increases that are absent in naive rats.[64,83,99,113] Changes in metabotropic glutamate receptors have also been identified as important mediators of AA release.[22,76,109]

Amino Acid Transporter Studies

Given the normally rapid reuptake of glutamate by its transporters and the resistance to glutamate elevation during transient evoked seizures in normal rat brain,[63,73] the observation of glutamate elevation with microdialysis during spontaneous seizures in the human hippocampus[37,39,135] has generated interest in the possible reduction or loss of glutamate transport in epilepsy. The glutamate transporters GLAST, GLT-1 (glial), and EAAC1 (neuronal) have received substantial study using the combination of microdialysis to detect changes in glutamate or GABA levels and quantitative immunoblotting or in situ hybridization to measure changes in transporters that might be associated with seizure models.[73] The genetically epilepsy-prone rat (GEPR) shows reduced GLAST, GLT-1, and EAAC-1 mRNA but not protein,[5] whereas results of kindling in normal rats have been variable depending on the measure used,[6,44,75,120] but usually showing less change in GLT-1. Rats receiving chronic administration of antisense oligonucleotide probes, which drastically reduce the expression of glial glutamate transporter GLT-1, respond with elevated EC glutamate levels and signs of excitotoxic neuronal degradation, whereas rats receiving antisense probes against the neuronal glutamate transporter EAAC-1 show no elevation of EC glutamate but do develop seizures.[97] Chronic KA[119] or iron chloride[100] rat models are consistent in showing reduced GLT-1, and although most glutamate uptake is mediated by GLT-1 into glia, GLT-1 also transports glutamate into neuronal terminals,[112] making interpretation of transporter data more complex.

Antiepileptic Drug Pharmacokinetics and Effects on Neurotransmitter Release

Microdialysis has been used for pharmacokinetic analysis of AEDs,[46,129,130] and methodologic issues related to such studies have been discussed extensively by de Lange et al.[28,29,30] Studies using microdialysis in rat models of epilepsy to investigate the change in glutamate and GABA levels in response to AEDs usually report decreased glutamate levels and variable effects on GABA.[3,4,57,61,98,107] Monoamine response to AEDs has also been investigated[4,27,79] to determine whether increases in serotonin or dopamine may be associated with AED efficacy. Although changes in serotonin have been associated with action of these AEDs, dopamine's role is less clear. Monoaminergic changes were preceded and are generally secondary to the role of GABA increase or Na^+ channel blockade by AEDs.

Monoamine Modulation of Epileptic Activity

The most heavily studied endogenous neuromodulator that might have antiepileptic properties is serotonin. A good deal of work has been done in the GEPR rat by Dailey and Jobe in a long series of studies with a number of coauthors (see review by Dailey et al.[27]). They found that both norepinephrine and serotonin are reduced in GEPRs, and that administration of serotonin agonists reduces seizures, whereas serotonin depletion prevents the anticonvulsant effects of agonists.[141] Recently, a rat seizure model using reverse dialysis of pilocarpine has been used to evaluate anticonvulsive effects of focal microdialysis perfusion of serotonin and dopamine.[24,25] Both serotonin and dopamine suppressed pilocarpine seizures, but the effect was lost when glutamate was coperfused prior to seizures.[23] The authors concluded that although increase in glutamate does not necessarily induce seizures, interictal or preictal elevation in glutamate can exacerbate seizure activity, even in the presence of monoaminergic protection.

Microdialysis Evaluation of Other Neuromodulators

In addition to the studies of adenosine release during seizures in humans described earlier, Michotte and colleagues used their pilocarpine rat model to test the anticonvulsant effect of adenosine A1 receptor agonists in hippocampus,[59,60] finding a decrease in glutamate release but only a small degree of seizure suppression. Other studies showed that seizures evoked by PTZ, KA, or bicuculline evoke a small but significant adenosine release,[16] and perforant path kindling was reported to increase hippocampal adenosine and its metabolites xanthine and hypoxanthine.[2]

Several studies using microdialysis in rats have found increases in opioid peptides,[92,93,94] nociceptin/orphanin FQ opioid peptides,[8] and somatostatin[68] in response to kindling or chemical induction of seizures, changes that may have differential influences in excitability depending on the receptor type activated. Microdialysis has been also used to evaluate the relation of nitric oxide (NO) or NO synthesis to seizure generation or glutamate levels in a variety of models.[7,90,122,142]

Wu, Schwarcz, and colleagues[137,139] used in vivo microdialysis to investigate the role of kynurenic acid, an endogenous agonist of the glycine site of the *N*-methyl-D-aspartic acid (NMDA) receptor, in suppressing epileptic activity. Recently, they reported that although poor brain penetration of kynurenate limits its use as an anticonvulsant, systemic administration of its precursors in the pilocarpine rat with chronic seizures causes increase in the kynurenate levels in epileptic brain regions, likely through increased synthesis due to astroglial incursion.[138]

New Directions in Use of in Vivo Microdialysis in Animal Models of Epilepsy

Several recent studies have shown the potential of in vivo microdialysis for evaluating diverse antiepileptic approaches. For example, the antiepileptic mechanism of anterior thalamic electrical stimulation in epileptic patients has received little study, but catecholamine release during thalamic deep brain stimulation was evaluated in the rat during PTZ administration, and significant differences in norepinephrine, serotonin, and 5-hydroxyindolacetic acid (5-HIAA) levels were found

between controls and stimulated animals.[144] In seeking more effective antiepileptic drugs, administration of selective antagonists of the GLU_{K5}(GlutamateR5) kainate receptor subunit was found to block seizures induced by intrahippocampal pilocarpine in rats[108a]. Microdialysis monitoring showed that pretreatment with the GLU_{K5} antagonists LY377770 and LY382884 both prevented the pilocarpine administrationâ€"associated increases in glutamate and GABA and blocked the electrographic seizures.

Microdialysis has been used extensively to measure AED levels in the epileptic hippocampus, where AEDs are found to be significantly reduced in the presence of endogenous P-glycoproteins and multidrug-resistant transporters (MDRs).[85,91] Reviews of the effects of MDRs in reducing the effectiveness of AEDs have been published by Loscher and Potschka,[66,67] and a complete description of these investigations can be found in Chapter 115.

Microdialysis in Humans

Clinical Applications

The most common clinical use of microdialysis is in neurointensive care patients following severe head trauma, subarachnoid hemorrhage, and occlusive stroke (for review, see Hillered et al.[51]). Most commonly, hypoxia/ischemia events have been associated with dramatic and persistent (hours to days) release of excitatory AAs and changes in the markers of glucose metabolism. In these settings, massive increase in EC glutamate can result from hypoxia/ischemiaâ€"related cellular depolarization or damage, leakage across the bloodâ€"brain barrier, and inhibition or reversal of the glutamate transporters. The changes in the microdialysate glucose and its metabolites (profound decrease in glucose, and increase in lactate, lactate/pyruvate, and lactate/glucose ratios) have been interpreted to indicate decreased glucose delivery and utilization, increased anaerobic glycolysis, and energy failure in the affected hypoxic/ischemic tissue. Seizures in patients with traumatic brain injury are a cause for even higher increases in EC glutamate that can last for hours[128] and to additional membrane injury as reflected by elevated EC glycerol levels.[127] In general, the extent of glutamate release and the disturbance in glucose metabolism appear to correlate with the severity of the pathology and the clinical outcome (reviewed by Hillered et al.[51]). Conversely, therapeutic interventions such as barbiturate coma[45] and hypothermia[140] result in decrease in the pathologically elevated glutamate and lactate levels. In recent years, microdialysis has moved from preclinical evaluation and validation to clinical applications. Ungerstedt and colleagues[110,111,124] pioneered the use of bedside around-the-clock microdialysis analysis as a tool for monitoring the clinical development in neurotrauma and stroke patients. This monitoring has allowed the detection of neurochemical changes in the brain hours before their clinical manifestation, thus allowing for early therapeutic intervention.[101,110,111,126] The Swedish clinical experience with neurotrauma and stroke patients confirms that neurochemical changes in the human brain can be detected with microdialysis long before the clinical signs of a disease. No similar studies to investigate markers heralding the development of epileptogenicity, however, have been performed.

Microdialysis Studies in Epilepsy Patients

Intraoperative Studies

Several centers have carried out acute microdialysis in patients undergoing epilepsy surgery under generalized anesthesia and maintained on their usual antiepileptic pharma-cotherapy.[18,47,95,114,115,116] Equilibration and sampling periods were necessarily short to conform with the surgical procedure. First, Hamberger et al.,[47] using a dialytrode (an early version of microdialysis probe) placed on exposed cortical surface, reported that several AAs (glutamate, alanine, glycine, serine, and phosphoethanolamine) are higher interictally at the epileptiform cortical regions compared to the nonepileptic regions. More recently, Thomas et al.,[116] using simultaneous intraoperative electrocorticography (ECoG) and microdialysis in hippocampus in a limited number of patients, related the increase in glutamate, aspartate, and GABA levels to increased epileptiform activity. Another group[18,95] measured the amino acid changes during spontaneous or electrically evoked seizures (following a standard clinical electrical stimulation protocol to verify the location of the epileptogenic focus) in the epileptic cortex or hippocampus of seven intraoperative patients. Both spontaneous and electrically evoked seizures were associated with sharp rises in the EC levels of aspartate and glutamate, as well as in glycine, serine, and lactate.

Microdialysis in Ambulatory Epilepsy Patients

The group led by Dr. Dennis Spencer at Yale has been pioneering microdialysis in ambulatory patients with refractory complex partial epilepsy (CPS) undergoing intracranial EEG monitoring, with continuous perfusion and sample collection for up to 16 days to determine interictal steady-state levels of AAs and neurometabolites and their elevation with spontaneous seizures.[1,20,36,37,38,39,69,102,103] Table 1 shows EC levels of various neurochemicals measured with microdialysis in the nonepileptic brain areas of awake patients with refractory epilepsy and comparisons obtained from animal studies. In patients with bilateral hippocampal probes, the epileptogenic hippocampus had higher glutamate at baseline. With the onset of seizure, there was a sharp increase in dialysate glutamate in both sides, with much larger and more prolonged (up to 18 minutes of sampling) increase in the epileptogenic hippocampus. Dialysate GABA also increased with seizure bilaterally; the GABA increase in the epileptogenic hippocampus was small and short lasting, however, compared to the nonepileptogenic site. The large seizure-related glutamate release together with relatively small GABA increase (high glutamate/GABA ratio) was proposed to lead to neurotoxicity and further seizures in the hippocampus. This first observation of seizure-related glutamate release in the human hippocampus was very significant because such elevations were seen in some but not all animal models of epilepsy. Wilson et al.[135] at UCLA replicated the study in a group of ambulatory patients and noted that the seizure-related glutamate increase was not seen in all of them; they speculated that the extent of glutamate release may depend on the extent of the hippocampal sclerosis. Furthermore, they verified that the same AAs (aspartate, glutamate, GABA, and taurine) that increase with spontaneous seizures in the human hippocampus increase with seizures in a chronic kainate rat model of temporal epilepsy, which also has evidence of mossy fiber sprouting in the dentate gyrus. Thus, for the large and prolonged EC glutamate transients to occur, a certain degree of chronic axonal and synaptic reorganization over long periods of time may be necessary. It is of interest that the increase in glutamateâ€"which is usually thought to be of neuronal originâ€"is seen paradoxically in patients with pronounced hippocampal sclerosis in which a majority (70%â€"90%) of the neurons are lost. The origin of the increased glutamate efflux in the epileptogenic hippocampus both at baseline[20] and with seizures remains to be elucidated.

Table 1 Brain extracellular neurotransmitter and neurometabolite levels

Substance	Species	Brain area	Extracellular fluid concentration	Method	Authors
Glutamate	Rat	Hippocampus	2.9 Â± 0.4	Recirculation	Lerma et al. 1986[63a]

Values (mean Â± SEM) are expressed as ÂµM, except for glucose and lactate (mM). Human values are from the nonepileptogenic brain areas in awake patients with medication-resistant epilepsy. GABA, Î³-aminobutyric acid.
[a]Values in men.

Subsequent microdialysis experiments in patients with CPS have explored the basis of the diminished seizure-evoked GABA release in the epileptogenic hippocampus.[37] In a unique set of experiments, potassium (56 mM, 30 minutes) and

P.1035

glutamate (5 mM, 30 minutes) in a calcium-free or physiologic calcium medium were perfused through the microdialysis probe to investigate the mechanism of GABA release in the human hippocampus. Results suggested that although the calcium-dependent, potassium-induced GABA release in the epileptogenic hippocampus is intact, the glutamate-induced, calcium-independent GABA release is diminished. Parallel studies in amygdala-kindled rats that had 50% reduction in their GABA transporters further suggested that the glutamate-induced GABA release is nonvesicular (calcium independent) and mediated by transporter reversal. Thus, the authors concluded the diminished GABA release with spontaneous seizures in the epileptogenic hippocampus is largely due to the decrease in the transporter-mediated nonvesicular GABA release limiting inhibition and contributing to epileptogenicity in human temporal lobe epilepsy.

Other studies in epilepsy patients implanted with bilateral hippocampal probes showed large transient increases in adenosine[38] and lactate[36] with the onset of spontaneous seizures. The persistent bilateral (larger in the ipsilateral hippocampus) increase in adenosine, a potent inhibitory neuromodulator with anticonvulsant activity, was proposed to mediate the seizure arrest and the postictal refractoriness in epilepsy patients. However, interictal baseline adenosine levels have not been found to differ between the mesial temporal lobe of seizure onset and the contralateral side.[143] Lactate, a product of nonoxidative glucose metabolism, is released from both neurons and glia with increased cerebral activity.[33] Lactate, monitored with an online method (lactography) in patients with CPS, fluctuated with the interictal spiking rate and increased sharply with seizure onset in the ipsilateral hippocampus for up to 60 to 90 minutes.[36] This prolonged rise in lactate was proposed not only to be a product of increased nonoxidative glycolysis with seizures, but also to endogenously mediate the seizure arrest and postictal refractoriness through acidification of the EC compartment.

Lactate has been also proposed as an alternative energy source in the brain.[42,82] Using the zero-flow microdialysis method in a group of fasting, medication-resistant epilepsy patients, Abi-Saab et al.[1] reported that although brain glucose levels are only 30% of that found in the plasma, brain lactate is much higher than brain glucose or than in the plasma, suggesting that lactate is synthesized locally in the brain. During a hyperglycemiaâ€"hypoglycemia insulin clamp in the same patient population, the change in brain glucose lagged behind the change in the plasma by 20 to 30 minutes, which may be protective to the brain during hypoglycemia.

Epilepsy has been associated with impaired energy metabolism,[48] decreased glutamateâ€"glutamine cycling,[84] and decreased glutamine synthase levels in the epileptogenic hippocampus.[40] Cavus et al.[20] used the zero-flow microdialysis method to estimate the absolute interictal in vivo concentrations of glutamate, glutamine, and the energy metabolites glucose and lactate in the epileptogenic and nonepileptogenic cortex and hippocampus of 38 awake patients with medically refractory CPS. The epileptogenic hippocampus had significantly higher basal glutamate levels (12.1 Â± 3.4 ÂµM, mean Â± SEM; in some cases up to 35 ÂµM), low glutamine/glutamine ratio (~100 vs. 350 in the nonepileptogenic sites), and high lactate levels. Higher EC glutamate correlated with higher EC glucose only within the epileptogenic hippocampus in which basal glutamate was elevated, suggesting that glucose utilization, which is driven by glutamate reuptake,[82] is also impaired. The authors concluded that interictal energy deficiency could result in poor glutamate reuptake, lower glutamine synthesis, and increased glial glutamate release. This could lead to glutamate-induced glial and neuronal toxicity, as well as to cellular deprivation of glutamate and glutamine as substrates

P.1036

for energy, and to poor utilization of the available glucose and lactate. Thus, a cycle of events triggered by energy deprivation could lead to worsening of energetics in mesial temporal lobe epilepsy.

Microdialysis Assessment of Antiepileptic Drug Pharmacokinetics in Humans

Whereas peripheral microdialysis (e.g., probe insertion into subcutaneous adipose layer) has become a relatively common procedure for evaluating drug pharmacokinetics,[77] central nervous system microdialysis evaluation of AEDs in epilepsy patients has been very limited. Early studies measuring the absolute ECF brain levels of carbamazepine, phenytoin, and valproate with zero-flow microdialysis in a limited number of refractory epilepsy patients chronically implanted with microdialysis probes reported that brain interstitial drug levels closely mirrored their unbound plasma concentrations.[69,102,103] Recently, to explore the hypothesis that drug resistance in epilepsy is related to lower interstitial concentrations of AEDs mediated by upregulated drug efflux transporters in affected brain regions,[66,67] Loscher and colleagues[66] measured the concentrations of several AEDs in the epileptic neocortex that was to be resected using intraoperative microdialysis in a series of 22 patients with refractory epilepsy. Although the EC AED levels showed great intraindividual and interindividual variability, they appeared significantly lower than their cerebrospinal fluid levels. The limitations of the study, however, which included lack of control data obtained from nonepileptic cortex and inexact determination of the absolute EC drug concentration, precluded any conclusions related to the authors' hypothesis.

Summary and Conclusions

It is evident from this brief review that microdialysis has provided a wealth of information from both animal and human studies that have aided in the investigation of basic mechanisms of brain physiology relevant to epilepsy as based on measurement of neurotransmitters and neuromodulators in the extracellular space. Although microdialysis has found clinical application in stroke and neurotrauma rather than epilepsy, the use of microdialysis for understanding both transient and chronic changes in epileptic brain tissue has been fruitful in several areas of study. These include rapid measurement of glutamate and GABA increases associated with concurrent EEG recording of spontaneous seizures in humans, as well as long-term differences in levels of these neurotransmitters measured interictally. Similar in vivo microdialysis measures in both the human and rodent brain of the participation of catecholamines, monoamines, purines, peptides, and other endogenous neuromodulators have enhanced our understanding of their roles in epilepsy.

In addition, microdialysis has been used to study glutamateâ€"glutamine cycling and glucose/lactate levels in relation to chronic impaired energy metabolism in the epileptic human cortex and hippocampus. These investigations provide evidence in human epilepsy for reduced glutamate uptake and glutamine synthesis and increased glial glutamate release that may be responsible for glutamate-induced neuronal toxicity. As newer techniques for rapid in vivo measurement of neurotransmitter release are developed, increased understanding of the role of phasic excitatory and inhibitory neurotransmitter participation in the preictal evolution of seizure genesis and subsequent ictal events may also be anticipated.

Transcranial Magnetic Stimulation

Charles M. Epstein

Roberto Michelucci

Mark Hallett

Introduction

Transcranial magnetic stimulation (TMS) depolarizes neural elements through electromagnetic induction. It might more properly be called â€œtranscranial electromagnetic stimulation.â€ However, emphasizing the magnetic component distinguishes TMS more clearly from direct electrical stimulation and highlights the easy penetration of the magnetic field through skin, skull, and cerebrospinal fluid. TMS provides unique, non-invasive measures of neurologic function, along with the possibility of focally augmenting or inhibiting cortical activity.

Principles of Transcranial Magnetic Stimulation

The fundamental principles of electromagnetic induction are that an electric current produces a magnetic field *B* and a *changing* magnetic field induces a flow of electric current in nearby conductorsâ€" including human tissue. A static magnetic field, however large, produces no current in the brain. Thus, the key parameter for a magnetic stimulator is not the absolute magnetic field strength in teslas but its first time derivative, dB/dt, combined with the duration of the stimulating pulse. Typical magnetic stimulators operate at a few thousand volts and several thousand amperes per pulse. Peak power output is measured in megawatts and lasts a few score microseconds. The very high peak currents are obtained by discharging a large capacitor directly into the stimulation coil (Fig. 1).

The resulting pulse waveforms are determined by the resonant frequency of the capacitor plus coil. These waveforms fall into two categories: (a) monophasic and (b) biphasic. â€œMonophasicâ€ magnetic pulses have the general shape illustrated in FIGURE 2A, with a large initial peak and a much smaller, longer-lasting tail that presumably has no biologic effect. Biphasic pulses form a cosine wave, as shown in FIGURE 2B, with the later peaks smaller than the first because of energy losses in the circuitry.

These induced voltage waveforms mirror the voltage across the stimulation coil during the course of the discharge cycle. They do not reflect the actual coil current, which lags the coil voltage by 90Â°. The biphasic waveform appears to stimulate neurons maximally at the second (downgoing) shaded region, which represents the longest epoch of induced voltage across neuronal membranes.

Monophasic pulses have prominent directional effects, which may be important for some applications. They can be produced with circuitry that is lighter and cheaper than that needed for biphasic pulses. However, simple monophasic stimulators dissipate the entire capacitor charge with every pulse, incurring a high energy cost. This power loss translates into additional heating of the stimulation coil and other components, making monophasic stimulators more difficult to adapt for sustained repeat stimulation. Biphasic stimulators conserve energy by recapturing much of the original charge in the capacitor, and the biphasic wave shape has somewhat greater biologic effect for a given output voltage. This makes biphasic stimulators three to four times more efficient than monophasic devices, and the most practical choice for rapid repetitive stimulation.

TMS pulses may be single, paired, or repetitive (rTMS). rTMS can be fast (more frequently than once per second) or slow (less than once per second). Paired-pulse TMS most commonly involves passing two separate pulses through the coil within a few milliseconds. The large capacitors used for TMS cannot be recharged that rapidly, so paired-pulse stimulation requires two separate power modules coupled to a single coil.

Transcranial Magnetic Stimulation Coils

Circular Transcranial Magnetic Stimulation Coils

The simplest TMS coil is a circular loop. As shown in FIGURE 3, the changing current in the coil loop induces an antiparallel current flow of opposite direction in the underlying brain. Although the magnetic field is maximum directly under the center of the coil, the induced current is maximum near the outer edge of the coil. This discrepancy is an occasional source of confusion and may lead to the erroneous assumption that the site of magnetic stimulation is beneath the coil center.

Large circular TMS coils have good penetration to the cerebral cortex. They are commonly placed at the cranial vertex, where they can stimulate both hemispheres simultaneously. However, the effect on motor cortex tends to be asymmetric, especially with monophasic pulse waveforms. The main drawback of circular coils is their lack of focality. Not only does the circumference of the coil overlie a large area of brain, but in addition the radius of strongest stimulation is difficult to specify.

Figure 8 Transcranial Magnetic Stimulation Coils

If two round coils are placed side by side so that the currents flow in the same direction at the junction point, the induced electric fields will add together and be maximum below the junction (Fig. 4). This design, known as a â€œfigure-8,â€ â€œbutterfly,â€ or â€œdouble-Dâ€ coil, allows focal stimulation at a limited and clearly definable location. Because of this greater focality, figure-8 coils are chosen much more often than round coils for research and clinical applications. In typical use, the area of stimulated cerebral cortex is several square centimeters and its contours resemble an oval or rounded rectangle. The long axis of the rectangle parallels the junction of the two coils.

P.1042

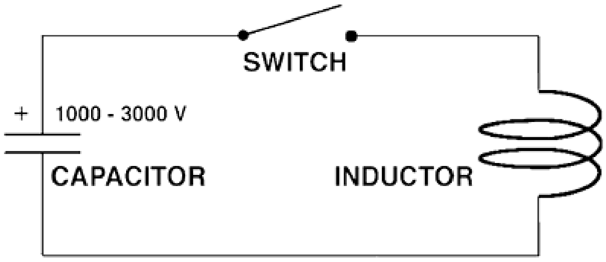

FIGURE 1. Simplified transcranial magnetic stimulation (TMS) circuit. The capacitor is first charged to a high voltage and then is discharged into the inductor (the stimulation coil) when the switch is closed. Additional components are needed to shape monophasic TMS pulses and to stop biphasic TMS pulses after a single cycle.

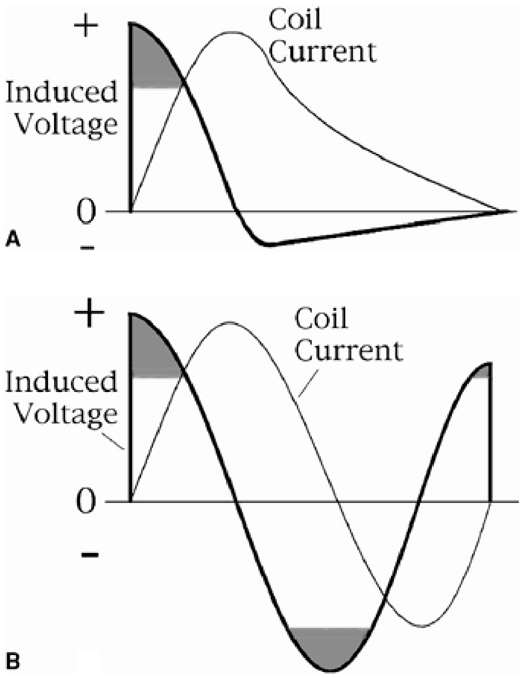

FIGURE 2. Monophasic **(A)** and biphasic **(B)** transcranial magnetic stimulation waveforms. Darker curves represent the induced voltage in the brain, and lighter curves the simultaneous current in the stimulation coil. Shaded areas are the periods of highest induced voltage, when neuronal membranes are most likely to be depolarized.

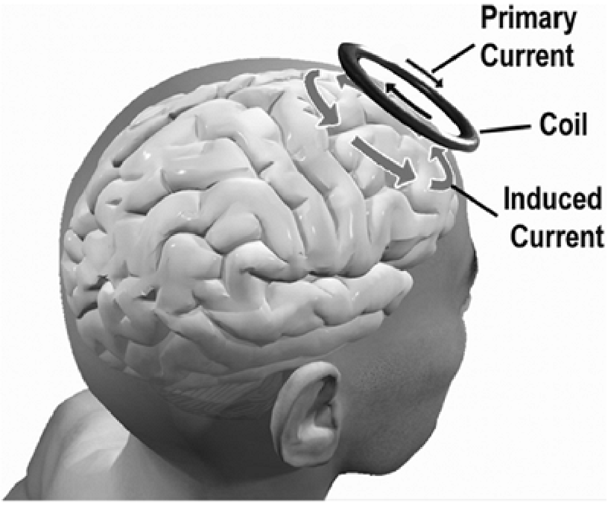

FIGURE 3. Round transcranial magnetic stimulation coil. Small dark arrows show the primary current in the coil. Large arrows show the path of maximum induced current, which lies below the outer coil edge.

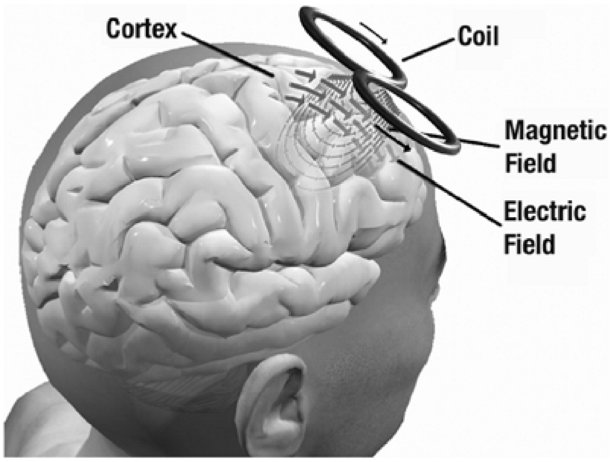

FIGURE 4. Figure-8 type transcranial magnetic stimulation coil. Small dark arrows show the primary current in the coil. Very small gray arrows (forming loops and penetrating into the brain) show the position and orientation of the maximum magnetic field, which lies perpendicular to the coil junction. Larger gray arrows show the position and orientation of the maximum electric field, which lies parallel to the junction and largely tangent to the cortical surface.

Iron-core Transcranial Magnetic Stimulation Coils

The efficiency of energy transfer from TMS coils to tissue is extremely small, on the order of 0.0001%. This striking inefficiency is responsible for the high power requirement of magnetic stimulation, bulky power supplies, and an annoying tendency to overheat with repeated firing. Ferromagnetic cores have much greater magnetic permeability than air, and consequently produce equivalent magnetic fields with much lower coil currents, increasing efficiency by a factor of four and reducing heat production by a factor of 5 to 10. In return for this improved performance, iron-core coils may be several pounds heavier.

Sham Transcranial Magnetic Stimulation Coils

The need for placebo stimulation in TMS research has led to the development of sham TMS coils, which are intended to prevent the subject and even the operator from knowing whether a given session involves real or sham stimulation. Ideally, sham stimulation should reproduce the external appearance of the coil and lead wires, the auditory click and mechanical tapping when it fires, and the complex sensations of scalp muscle contraction and electrical paresthesias that accompany real TMS, without actually projecting a magnetic field into the brain. The most advanced sham coils are integrated with scalp electrodes, which deliver a small current and produce subjective scalp paresthesias at the moment of sham stimulation. Most

P.1043

placebo coils have been less complex. Properly designed experiments rely in part on presenting real and sham stimulation to different subjects, or at widely separated times to the same subjects, so that any difference is difficult to detect.

The Site of Transcranial Magnetic Stimulation Activation

The electric currents induced by TMS in brain are strongly constrained to lie parallel to the superficial surface of the cerebral cortex. Evidence from varied sources suggests that TMS induces depolarization of myelinated axons that are aligned parallel to the cortical surface, and lie near the grayâ€"white matter junction. The sites of activation are likely to be branch points or bends, where induced transmembrane currents will be largest. In motor cortex the depolarized axons belong primarily to interneurons, although the axons of large motor neurons can be activated directly in some experimental paradigms.

Transcranial Magnetic Stimulation and the Neurophysiology of Epilepsy

A large number of studies have investigated cortical excitability in epilepsy by means of TMS to gain new insight into the physiopathology of this disorder. As discussed in a subsequent section, however, antiepileptic drugs (AEDs) can influence TMS parameters. Therefore, the optimal methodologic approach to investigating epileptic processes by TMS is to evaluate untreated patients or, if this first-choice approach is not possible, design TMS studies to evaluate at best the possible effects of AED treatment. In this section the results of TMS studies investigating cortical excitability are separated into two main subsections according to the generalized or focal nature of the epilepsies included in the TMS trials.

Generalized Epilepsies

In a group of untreated patients with IGE, Reutens et al.[72,73] found an abnormal motor threshold (MT) reduction. This finding was interpreted as an index of motor cortical hyperexcitability due to the epileptic process. In contrast, Gianelli et al.[39] reported increased MT in untreated patients suffering from idiopathic generalized epilepsy (IGE) with typical absence seizures. Another group found no MT abnormality in IGE patients.[7,52]

Finally, MT increase has been reported in a group of untreated patients who experienced a first generalized tonicâ€"clonic seizure in the previous 48 hours, this finding having been interpreted as a postictal â€œprotective effect.â€[21] The differences reported in these studies may be related to the clinical heterogeneity of IGE patients. In accordance with this view, Reutens et al.[73] found that MT was lower in patients with myoclonic seizures than in patients suffering from absence seizures. In an unusual group of patients with IGE and versive, circling seizures, the interhemispheric difference of the MT was significantly higher than in IGE patients without circling and in normal controls, suggesting an explanation for the clinical phenomena.[3] The cortical silent period (CSP) was found to be increased or normal in untreated patients with IGE.[21,54,63]

According to the finding of increased excitability as demonstrated by MT in generalized myoclonic seizures, an abnormal intracortical inhibition (ICI) reduction and a normal intracortical facilitation (ICF) were found in both treated and untreated patients with juvenile myoclonic epilepsy (JME).[10,42,56] ICI suppression suggests impaired functioning of inhibitory circuits in JME, which may result in hyperexcitability of the corticospinal pathways. Increased facilitation at interstimulus intervals of 200 to 300 msec, but not at 100 to 150 msec, corresponds to the mean interdischarge interval of spike-wave activity on the electroencephalogram (EEG).[7,54] Patients with progressive myoclonus epilepsies (PMEs) have reduced long-ISI paired-pulse inhibition[47,94] as well as exaggerated facilitatory effect of peripheral stimulation on motor-evoked potential (MEP), suggesting a markedly increased influence of afferent input on motor cortical excitability.[73] Digital stimulation markedly facilitated conditioned MEPs, suggesting cortical and subcortical components of abnormal sensorimotor integration in addition to hyperexcitability of the sensory and motor cortex.[54]

Focal Epilepsies

Normal MT was reported in untreated patients with benign rolandic epilepsy (BRE)[53] and cryptogenic focal epilepsy (FE),[61] as well as in a group of patients with focal seizures in which AED treatment was discontinued at least 48 hours prior to TMS as part of an evaluation for epilepsy surgery.[103]

Alterations in MT and CSP prolongation have been reported, mostly in patients suffering from seizures involving the motor cortex. In these cases, CSP prolongation may indicate that the mechanisms underlying CSP contribute to the compensatory phenomena in the interictal phase. In contrast, CSP has been shown to be usually normal in FEs localized outside the motor cortex.[8,15,17,103] Nevertheless, in a patient with FE due to a lesion within the supplementary motor area[19] and in two patients with FE secondary to cortical dysgenesis not involving the motor cortex,[16] the CSP was greatly lengthened in the contralateral hand, this effect being more likely related to the structural brain lesions rather than to the epileptic process. One study reported a shortened CSP after high-intensity TMS of the affected hemisphere in a group of patients with cryptogenic focal epilepsy, whose characteristics indicated that the epileptogenic area did not correspond to the motor cortex.[14] More recently, a single- and paired-pulse TMS study performed in 23 patients with focal epilepsies not including the primary motor area disclosed that CSP was shorter in epileptic hemispheres of extratemporal epilepsies than in controls, suggesting that FEs chronically influence distant cortex, leading to decrease inhibition in the ipsilateral motor cortex even when the epileptogenic zone is apart from it.[42]

In FE, studies of ICI and ICF have led to inconsistent findings that may be due to subject heterogeneity and AED fluctuations. Overall, most studies have reported ICI reduction and ICF increase in FEs involving or not the motor cortex but without any clear lateralization value.[8,37,95,103,104]

Studies Performed by Stimulating During the Seizures

Single-pulse TMS performed during the seizures captured by long-term EEG monitoring may disclose a variety of alterations of MT and MEP amplitudes, which are likely to reflect the influences of different seizure types on the motor system.[86] In four IGE patients, Gianelli et al.[39] compared the size of MEPs following test magnetic pulses delivered during normal EEG segments and during typical 3-Hz spike-and-wave EEG complexes. MEP size was reduced when TMS was time-locked to the slow-wave component, suggesting a transient decrease in excitability of corticospinal pathways.

In a group of BRE patients presenting extreme somato-sensory-evoked potentials, an abnormal MEP facilitation was seen when the test magnetic pulse was delivered during the ascending phase and the peak of the spike evoked by electrical digital nerve stimulation.[54] In contrast, peripheral nerve stimulation produced no abnormality of MEP size modulation in IGE patients.[74]

Effects of Anticonvulsants

Although TMS can be a useful method for evaluating a patient with epilepsy, it is crucial to note that anticonvulsants have a major influence on brain excitability and, therefore, TMS effects. Hence, it is necessary to understand these effects in order to interpret TMS studies. In fact, some of the information on mode of action of anticonvulsants was actually determined in part from TMS studies.

Before looking at anticonvulsant effects, we review the types of information that can be obtained from TMS studies. Virtually all the data come from stimulation of the primary motor cortex, where TMS produces MEPs in muscles topographically related to the site of stimulation.[1,41,88] Stimulation can excite the descending axons from M1 directly, called the D-wave, and indirectly by a series of intracortical synaptic influences that produce a number of indirect or I-waves.[23] At lowest stimulation intensity, typically the earliest effect comes from the first I-wave, I1.

The *threshold* for producing an MEP reflects the excitability of a central core of neurons that arises from the excitability of individual neurons and their local density. It can be influenced by drugs that affect Na and Ca channels, and must indicate membrane excitability. Because the MEP is small, the threshold measure reflects the influence of mainly the I1 wave. Threshold can be measured with the muscle at rest, rMT, or with an active background contraction of the muscle, aMT.

The *recruitment curve* is the growth of MEP size as a function of stimulus intensity and/or background contraction force. This measurement is less well understood because there are many effects, but it must involve neurons in addition to the core region activated at threshold. These neurons have higher threshold for activation because either they are intrinsically less excitable or they are spatially further from the center of activation by the magnetic stimulus. These neurons would be part of the â€œsubliminal fringeâ€ and contribute to I2 and later I-waves. D-waves are also recruited with higher intensities of stimulation.

Intracortical inhibition and facilitation are obtained with paired-pulse studies and reflect interneuron influences in the cortex.[108] In such studies, an initial conditioning stimulus is given, enough to activate cortical neurons but small enough that no descending influence on the spinal cord can be detected. A second test stimulus at suprathreshold level follows at a short interval (Fig. 5). Intracortical influences initiated by the conditioning stimulus modulate the amplitude of the MEP produced by the test stimulus. At very short intervals, <5 msec, there is inhibition, and at intervals between 8 and 30 msec, there is facilitation. ICI is likely largely a GABAergic effect, specifically Î³-aminobutyric acid A ($GABA_A$).[24] This type of inhibition is also referred to as â€œshort ICIâ€ or SICI to contrast it with ICI studied at longer time intervals, called LICI.[78]

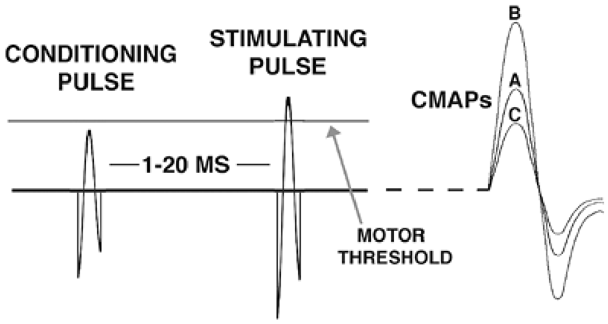

FIGURE 5. Intracortical inhibition and facilitation with paired-pulse stimulation. The first, conditioning pulse is just below motor threshold; the second, stimulating pulse, is just above. Depending on the time interval between the two pulses, the recorded compound muscle action potential (CMAP) may be **(A)** normal, **(B)** facilitated, or **(C)** inhibited.

The *silent period* (SP) (or cortical silent period, CSP) is a pause in ongoing voluntary EMG activity produced by TMS. Although the first part of the SP is due in part to spinal cord refractoriness, the latter part is entirely due to cortical inhibition. There is evidence that this type of inhibition is mediated by $GABA_B$ receptors.[102] SICI and the SP reflect different aspects of cortical inhibition.

Intracortical inhibition can also be assessed with paired suprathreshold TMS pulses at intervals from 50 to 200 msec. This is called LICI to differentiate it from SICI as noted previously. LICI and SICI differ, as demonstrated by the facts that with increasing test pulse strength, LICI decreases but SICI tends to increase, and that there is no correlation between the degree of SICI and that of LICI in different individuals.[78] In addition, LICI appears to inhibit SICI and shows some interaction of inhibitory mechanisms within the human motor cortex.[78] The mechanisms of LICI and SP may be similar.

Short afferent inhibition (SAI) is produced at short latency by somatosensory stimulation of the hand.[24] This has been demonstrated to be mediated by muscarinic synapses because it is selectively blocked by scopolamine.

The data on the influence of anticonvulsant drugs on TMS measures were reviewed in depth by Ziemann.[106] Only the highlights are addressed here and summarized in Table 1. As he noted, the literature is not completely consistent, and the acute and chronic effects of these agents may differ, which makes the interpretation of the literature a bit more complex.

Certain anticonvulsants affect mainly Na channels and thus should influence the threshold for the MEP selectively. This is true of carbamazepine (CBZ),[106] phenytoin (PHT),[11] and la-motrigine (LTG).[106] These agents do not affect MEP recruitment, SP, SICI, or ICF.

Some anticonvulsants, such as lorazepam[107] and diazepam,[67] appear to facilitate the action of $GABA_A$ in a straightforward fashion. These drugs do not influence the motor threshold, but they suppress MEP recruitment, increase SICI, and depress ICF. On the other hand, a more recent finding is that these two agents have different effects on SAI.[26,27] Lorazepam decreases SAI and diazepam increases it. This result shows how complex interneuronal networks are and that even similar compounds might have differing effects.

Other anticonvulsants that are supposed to facilitate GABA do not have the fully expected effect. Valproate was initially reported to elevate MT in patients with primary generalized epilepsy,[73] but in subsequent studies it had no clear influence on any measure.[109] In one study, vigabatrin suppressed ICF but did not affect SP or SICI.[106] In another study, vigabatrin increased LICI and SP but not SICI.[70] This result would be compatible with a selective effect on $GABA_B$ receptors. Tiagabine has paradoxical effects in suppressing SICI and facilitating ICF, but it does lengthen the SP.[102] This suggests that its inhibitory effect is also mediated largely by $GABA_B$ effects.

Table 1 Effects of AEDs on TMS Measures

AED	MT	SICI	LICI	SAI	ICF	REC	sp
Carbamazepine	â†‘						
Lamotrigine	â†‘						
Phenytoin	â†‘						
Levetiracetam	(â†‘)					â†“	
Lorazepam		â†‘		â†“	â†“	â†“	
Diazepam		â†‘		â†‘	â†“	â†“	
Tiababine		â†“			â†‘		â†‘
Gabapentin		â†‘			â†“		â†‘
Vigabatrin			â†‘		â†“		(â†‘)
Valproate		(â†‘)					
Topiramate		â†‘					

Some anticonvulsants have unknown, incompletely known, or multiple modes of action. In this situation, the TMS studies can give some information about how they might have

their most important actions. Gabapentin has several modes of action, including increasing GABA synthesis, and its effect is consistent with facilitating GABA effects in that it increases both the SP and SICI and suppresses ICF but has no effect on threshold.[106] Topiramate also has several modes of action, but its effect on TMS measures is limited to increasing SICI, which likely indicates a prominent $GABA_A$ influence.

Levetiracetam has an uncertain mode of action, although some basic studies suggest an effect at the GABA synapse. Multiple TMS measures in one study revealed only a suppression of MEP recruitment and no effect on threshold, SP, ICI, or ICF.[81] As noted earlier, this is difficult to interpret in isolation. Another study, however, did find an elevation in rMT.[71] Levetiracetam was also studied in a special way, via a motor learning task, which might be a method for assessing long-term potentiation.[82] Pinch force and acceleration and motor cortex excitability were studied before and after 30 minutes of pinch practice at 0.5 Hz. Either 3,000 mg of levetiracetam or placebo was administered 1 hour before the experiment. After practice, pinch acceleration was significantly increased with placebo but not with levetiracetam. All other measures showed no significant change. The finding is consistent with a negative influence on long-term potentiation.

Given the influence of anticonvulsants on the brain, it should be possible to use TMS as a functional measure of drug levels. In some ways, this makes more sense than just the serum level of a drug. On the other hand, there needs to be some caution because the anticonvulsant efficacy may not be linearly related to a TMS effect. This has been attempted in several studies. For example, the relationships among LTG oral doses, serum levels, and rMT were assessed by TMS.[90] With a single dose, rMT elevation showed a poor but significant correlation with serum levels, but with a graded dose, serum levels as well as rMT increased in a dose-dependent fashion with significant linear correlation. However, there was a high interindividual variability in the relationship, resembling a sigmoid correlation.

Another study investigated the correlation between serum levels of CBZ and several different measures of motor excitability in patients at the beginning of antiepileptic treatment.[93] Recording sessions were performed before treatment and after 7, 15, and 60 days. There was a progressive increase in rMT and aMT until the serum levels of CBZ reached a steady-state condition. On the other hand, no significant changes were observed in MEP amplitude, SP, SICI, and ICF. This study confirms both the selective effect of CBZ as well as the correlation with serum levels. A third study examined TMS measures and relationship to serum levels with both LTG and CBZ during drug administration and withdrawal.[51] rMT increased with increasing total and free CBZ and LTG levels during drug administration. After acute drug withdrawal, rMT elevation persisted in most individuals with CBZ despite undetectable plasma levels, whereas there was a rapid normalization with LTG. Another interesting finding was that acute drug withdrawal resulted in a transient decrease in rMT in 3 of 10 individuals with CBZ and 2 of 10 with LTG. The authors concluded that plasma levels provide information on motor cortical function during active treatment phases but not during drug withdrawal, and noted that the transient decrease in rMT associated with acute drug withdrawal could represent a physiologic substrate contributing to drug withdrawal seizures.

Induction and Inhibition of Seizures

The potential role of TMS in inducing or inhibiting seizures has long been debated, and a number of experimental studies have been devoted to this issue. In this section we discuss the induction and inhibition properties of TMS separately, as well as the effects of single-pulse (sp), paired-pulse (pp), and repetitive (r) TMS.

Transcranial Magnetic Stimulation and Induction of Seizures

Single-pulse and Paired-pulse Transcranial Magnetic Stimulation

At the time of its introduction in clinical practice, the use of sp TMS was limited by the hypothetical risk of inducing epileptic seizures.[2] However, there are only a few reports dealing with the accidental induction of seizures in patients with neurologic disorders of the brain, while the causative role of TMS remains questionable in most of these cases.[34,43,50] Only Homberg and Netz[43] reported a stroke patient who had his first tonicâ€“clonic seizure during the stimulation procedure.

Table 2 Maximum safe duration (in seconds) of single trains of repetitive transcranial magnetic stimulation based on the National Institute of Neurological Disorders and Stroke experience

Frequency (Hz)	Intensity (% of motor-evoked potential threshold)												
	100	**110**	**120**	**130**	**140**	**150**	**160**	**170**	**180**	**190**	**200**	**210**	**220**
1	>1,800	>1,800	360	>50	>50	>50	>50	27	11	11	8	7	6
5	>10	>10	>10	>10	7.6	5.2	3.6	2.6	2.4	1.6	1.4	1.6	1.2
10	>5	>5	4.2	2.9	1.3	0.8	0.9	0.8	0.5	0.6	0.4	0.3	0.3
20	2.05	1.6	1.0	0.55	0.35	0.25	0.25	0.15	0.2	0.25	0.2	0.1	0.1
25	1.28	0.84	0.4	0.24	0.2	0.24	0.2	0.12	0.08	0.12	0.12	0.08	0.08

Numbers preceded by > are the longest durations tested. No afterdischarge or spread of excitation has been encountered with single trains of repetitive transcranial magnetic stimulation at these combinations of stimulus frequency and intensity.
From Wassermann EM. Risk and safety of repetitive transcranial magnetic stimulation: report and suggested guidelines from the International Workshop on the Safety of Repetitive Transcranial Magnetic Stimulation, June 5â€“7, 1996. *Electroencephalogr Clin Neurophysiol*. 1998;108(1):1â€“16.

Single-pulse TMS has not been shown to induce seizures consistently in epileptics.[58,59] In 1990, Tassinari et al.[85] studied 58 patients with recurrent seizures (either partial or generalized) resistant to AEDs. The patients were subdivided into three groups according to seizure frequency (rare, weekly, or daily seizures). Each patient received an average of 25 stimuli, ranging in intensity from 50% to 90% of the maximum stimulator output, with a rate not exceeding one shock every 10 seconds. Neither the short-term (for 2 hours after TMS) or long-term (for 2 months after TMS) clinical monitoring disclosed any

P.1046

TMS seizure-triggering effect in any group of patients. Only one patient with 5 to 10 complex partial seizures (CPS) a day experienced one of his habitual seizures during the TMS investigation. Similarly, Hufnagel et al.[45] reported that 2 of 53 patients with three to five spontaneous CPS a day had a typical seizure during the course of the TMS investigation. Other cases of seizures temporally related to sp TMS in epileptics have been reported,[29,44,46] but these ictal events may have been coincidental. For at least one patient, however, there is clear-cut evidence of focal seizures triggered consistently and reproducibly by single-pulse TMS.[19] Recently, Schrader et al.,[79] reviewing published data and their own experience with three additional seizures in epilepsy patients, estimated that the crude risk of a TMS-associated seizure ranges from 0.0% to 2.8% for sp TMS and from 0.0% to 3.6% for pp TMS in patients with epilepsy. Medically intractable epilepsy and lowering AEDs were associated with increased incidence. In most cases, however, the patients experienced their characteristic seizure semiology, and doubt was expressed in the original reports as to whether the seizures were induced or merely coincidental.

Repetitive Transcranial Magnetic Stimulation

By the end of 1996, six seizures had been elicited by rTMS in 6 nonepileptic individuals (5 volunteers and 1 with depression). Four of these seizures occurred in 4 of 250 volunteers studied at the National Institute of Neurological Disorders and Stroke (NINDS) during the program of clinical development of the technique.[68,97,99] On the basis of these induced seizures and safety studies that monitored the occurrence of post-TMS EMG activity and spread of excitation,[12] limits of stimulation parameters were recommended and proposed for a correct and safe use of the technique in clinical practice (Table 2). These safety margins supplemented and outweighed those previously published by Pascual-Leone et al.[69] on the basis of their studies on spread of cortical excitation along the motor cortex.

Although high-frequency rTMS may induce accidental seizures in normal subjects, it has been rarely associated with seizures in epileptics. So far, only three epileptic patients have been reported to experience a seizure during rapid rTMS procedures (Dhuna et al.[22]; Cohen, personal communication;

Michelucci, Valzania, and Tassinari, personal communication). In view of the seizures occurring in normal subjects, the difficulty of producing seizures in epileptic patients seems paradoxical, especially given that many studies used combinations of settings that were outside of the safe zone (Table 2). A possible explanation is that all of the epileptic subjects were treated with anticonvulsants at the time of stimulation. Special epileptic conditions, however, seem more prone to develop seizures following rTMS. Of 60 patients with various types of epilepsy studied by means of rTMS, Tassinari et al.[87] observed apparently rTMS-induced seizures in 2 of 10 patients with PME and in 1 of 4 patients with epilepsia partialis continua. Persistent jerking of the contralateral arm following cessation of motor cortex rTMS, indicating the presence of afterdischarges, was reported by Michelucci et al.[60] in 2 patients with cryptogenic FE.

Transcranial Magnetic Stimulation and Inhibition of Seizures

In normal subjects, application of low-frequency trains of rTMS produces a relatively long-lasting suppression of cortical excitability.[13] In addition, 0.5-Hz rTMS prolonged the latency for development of pentylenetetrazol-induced seizures in rats.[4] These data provide a rationale for using low-frequency rTMS to treat patients affected by epilepsy and epileptic myoclonus.

In an open pilot study, Tergau et al.[89] investigated the effects of 0.33-Hz rTMS delivered on five consecutive days in nine patients with drug-resistant FE (two temporal, seven extratemporal). Each day, two trains of 500 pulses at 100% of the RMT were applied by means of a large circular coil placed over the vertex. During the follow-up period (4 weeks before and 4 weeks after the rTMS application) the AED treatment was kept constant. Seizure frequency was significantly reduced in the postintervention period compared with the preintervention period.

In a patient with intractable partial seizures due to a focal cortical dysplasia in the left parasagittal parietal region, Menkes and Gruenthal[57] used 0.5-Hz trains of 100 subthreshold magnetic stimuli twice a week for four consecutive weeks. rTMS was delivered by a round coil. During the month of observation, the seizure frequency and the interictal spikes were reduced by 70% and 77%, respectively. Similarly, Fregni et al.[38] observed a significant antiepileptic effect after one session of 0.5-Hz trains of 600 pulses in eight patients with refractory epilepsies due to malformations of cortical development.

These effects of 0.3- to 0.5-Hz rTMS on seizure frequency have yet to be replicated in randomized, blinded trials. In contrast, a controlled study was performed to assess the therapeutic potential of 1-Hz rTMS.[91] Twenty-four FE patients were randomized to blinded active or placebo stimulation delivered

for 15 minutes twice daily for 1 week. Active stimulation was administered at 120% of MT using a figure-8 coil placed over the EEG focus. For the â€œplaceboâ€ stimulation, the coil was angled at 90 degrees away from the scalp. A trend toward a short-term reduction of seizure frequency was observed in the active group, whereas placebo stimulation had no effect. However, this difference was not significant. These findings do not necessarily indicate that the seizure reduction observed in the previous reports was merely due to observer expectations and placebo effects. For instance, distinct effects of different rTMS frequencies (0.3â€"0.5 vs. 1 Hz) could also explain this discrepancy. Cincotta et al.[18] provided evidence that suprathreshold 0.3-Hz rTMS but not 0.9- to 1-Hz rTMS produces a relatively long-lasting enhancement of the inhibitory mechanisms responsible for CSP.

A preliminary report suggested that low-frequency rTMS could reduce epileptic cortical myoclonus.[101] However, the same group performed a sham-controlled study of a larger case series and found no significant beneficial effect with 10 days of 1-Hz rTMS of the motor cortex.[100] In patients with epilepsia partialis continua due to cortical dysplasia, 0.5- to 1-Hz rTMS applied over the motor area induced a marked reduction or temporary disappearance of the jerks.[62,75] In conclusion, the available data are too preliminary to establish whether low-frequency rTMS may be an effective adjunctive treatment in epileptic processes. Randomized trials with realistic shams reproducing as far as possible the physical sensation of the active stimulation should test different rTMS parameter combinations (frequency and intensity of stimulation, train duration, number and frequency of applications, focal vs. nonfocal stimulation). Larger and homogeneous case series are essential to increase sensitivity and to identify the specific epileptic conditions that could be alleviated by rTMS. Finally, appropriate endpoints and long-term follow-up are necessary to evaluate the clinical relevance of the results.

Mapping Speech, Language, and Memory

From the time of its introduction, many researchers in TMS have focused on replicating or replacing the intracarotid amobarbital test (Wada test).[96] The requirements for doing so are straightforward. The new procedure should be safe, tolerable, and robust, producing obvious effects in virtually all subjects and allowing test paradigms that epilepsy patients can comply with in the face of anxiety, medications, and structural encephalopathies. Finally, of course, the new procedure should have excellent concordance with Wada test results, and when discordant, should be at least as good at predicting surgical outcomes. TMS has provided a wealth of information about language and memory mechanisms but has not yet fully satisfied the requirements for a clinical language test.

Initial attempts to affect language with rTMS were hampered by the use of round stimulation coils and colored by the belief that stimulation parameters should match those used in operative electrocorticography. Prior to the existence of safety guidelines,[99] stimulation frequencies ranged up to 50 Hz; stimulator output was commonly set between 80% and 100% of maximum, with stimulus trains up to 10 seconds in duration. Pain, crying, and even seizure were among the outcomes.[20,35,48,60,69] Pascual-Leone et al.[68] reported lateralized interference with speech output using TMS in 6 of 6 epilepsy patients; all results matched the Wada test. Others found speech disruption difficult to induce with round TMS stimulation coils. Jennum et al.[48] achieved complete speech arrest in only 7 of 14 subjects, whereas Michelucci et al.[61] reported 14 of 21. Epstein et al.,[30] using a more focal figure-8 coil, induced speech arrest with frequencies as low as 4 Hz and train durations of 5 seconds or less. These stimulation parameters produced more consistent results while reducing the discomfort of rTMS and allowing compliance with safety guidelines.

TMS-induced speech arrest is now safe and robust enough to produce obvious effects in almost all epilepsy patients and normal volunteers. However, it appears to represent a disruption of motor speech output rather than a true aphasia and to occur in the vicinity of facial motor cortex.[32] Like simple speech arrest in the Wada test itself, it is not fully accurate for language lateralization.[6] Jennum et al.[48] and Epstein et al.[32] each reported a patient with left hemisphere language lateralization by Wada testing but apparent right lateralization by rTMS speech arrest. We have encountered a third such patient in the course of additional testing. When compared directly in 17 epilepsy surgery candidates, rTMS showed a significant correlation with the Wada test but also showed a significant bias toward right hemisphere or bilateral lateralization.[32] Most patients in this series underwent resection of the epileptic focus; the Wada results corresponded more closely than TMS with postoperative language deficits.

In retrospect, it might have been predicted that TMS speech effects would be obtained most easily over motor cortex. Ojemann's classic studies of verbal interference sites during electrocorticography show the most common locus to lie at the foot of the precentral sulcus.[66] In these studies, there is no evidence for a more anterior cluster of speech arrest sites corresponding to Broca's area. Furthermore, despite occasional observations of transient aphasic phenomena, it has not been possible for TMS to produce consistent Broca's or Wernicke's aphasia.

Stewart et al.[84] demonstrated in normal volunteers that magnetic stimulation of two different, nonoverlapping inferior frontal sites could result in speech arrest. Stimulation of the more posterior site was accompanied by mentalis muscle activity; stimulation of the more anterior site was not. The anterior, nonmotor site was more clearly lateralized to the left hemisphere but was also more uncomfortable and more difficult to activate in all subjects. The finding of two separate sites for TMS speech interference has been replicated,[5] but it is not yet clear whether the anterior site represents interference with language as opposed to simply motor speech.

A large number of studies have in fact demonstrated TMS effects on language function. Most of these effects have been subtle, however, consisting of group changes in reaction time rather than accuracy of performance. Picture naming and a variety of other language tasks can be both delayed and facilitated by rapid rTMS over left posterior temporal, left superior temporal, dorsal frontal, and inferior frontal lobes.[9,28,63,76,77,83,92] It is interesting that some of the facilitatory effects can be obtained from stimulation of the nondominant hemisphere[65,100] and can be demonstrated in aphasic patients.[64]

In the present era, lateralization of memory function probably has greater practical importance than lateralization of speech. A few TMS studies have shown interference with verbal memory by TMS over the temporal lobe.[29,40,69] However, the hippocampus represents a daunting target for TMS. Focal stimulation of such deep structures without overstimulation of overlying cortex remains a technical challenge. The granular cortex of the prefrontal lobe is now known to be intimately involved in both working memory and encoding of novel stimuli and represents a far more accessible target. Several reports have described interference or facilitation of episodic memory encoding by TMS over dorsolateral prefrontal cortex. In general, the results are consistent with classic models of hemispheric specialization: Verbal encoding is disrupted by stimulation over the left prefrontal region, and nonverbal encoding is impaired by right prefrontal stimulation.[9,33,36,49,63,77,80] Virtually all of these studies have been carried out in normal volunteers, for

which the required intensity of stimulation is generally quite tolerable.

New, noninvasive techniques for determining the lateralization of memory function remain desirable for epilepsy practice and research. Recent approaches to memory testing with TMS show promise of eventual clinical application.

Summary and Conclusions

Most of our understanding about the mechanisms of TMS comes from studies of the motor cortex, where the major site of activation appears to be myelinated axons of cortical interneurons, aligned parallel to the cortical surface. TMS findings in different epileptic phenotypes are complex and sometimes contradictory, with the most consistent being decreased MT and ICI in some forms of IGE. Such studies are complicated by time of testing in relation to seizures, the possibility that patients with similar clinical conditions may have different underlying disorders, and the independent effects of AEDs. The AED effects, while occasionally inconsistent, are sufficiently reliable that they can be helpful in exploring AED mechanisms of action and tracking central nervous system changes over time. Application of TMS to mapping language and memory is promising, but not yet sufficiently robust and accurate for general clinical application. Preliminary reports of TMS efficacy in activating and suppressing seizures have yet to be substantiated in clinical trials.

Chapter 89

Cellular Imaging of Epilepsy

Andrew J. Trevelyan

Rafael M. Yuste

Introduction

We are at the start of an imaging revolution that is transforming our view of the brain. The techniques and technology continue to develop, and the benefits are self-evident when studying such a complex network phenomenon as a seizure. Indeed, the complexity of epileptiform activity and our inability to record it with sufficient detail at an appropriate temporal and spatial resolution have been major obstacles to progress in the field. Imaging permits detailed measurements (e.g., membrane potential or calcium [Ca^{2+}] dynamics) to be made at many locations simultaneously, and it has already proved a significant adjunct to traditional electrophysiologic recordings.

Our main goal in this chapter is to present the possibilities that imaging affords, with a focus on imaging neural activity. We start with a brief description of some of the tools of the trade. We then provide an overview of various imaging techniques and their relevance to epilepsy, and we finish with some thoughts on possible future research.

Imaging Hardware

Technological developments have both fed and driven the burgeoning field of imaging in biology. It is tempting to draw comparison with how developments in making lenses fuelled new ways of looking at nature (both literally and metaphorically) at the start of the scientific revolution in the seventeenth century.

Key among these recent developments is the continual improvement in light sensors and cameras. The importance of the camera is obviously in part to make a permanent record of the biology, but also to record things that are not necessarily visible to the naked eye. There are two facets to thisâ€"enhancement of the view, which involves creating an image from light that lacks sufficient contrast or has spectral characteristics beyond visible light (e.g., infrared [IR] or ultraviolet [UV]); and intensification, which involves boosting the signal when the light levels are too low, which is especially important in fluorescence microscopy because it permits much less intense illumination of the specimen.

Most imaging today involves recording fluorescent emissions. There are three main optionsâ€"epifluorescent, confocal, and two-photon microscopy (TPM). Of these, epifluorescent microscopy has been the most conventional and affordable. Its limitation is that the signal of interest, located at the plane of focus, is contaminated with fluorescence from molecules above and below this plane. Consequently, the signal-to-noise level is low, necessitating intense illumination to improve the signal. The intensity of illumination is a severe problem because it causes photobleaching and phototoxicity. Furthermore, these effects occur throughout the path of illumination.

This problem is partly solved by confocal microscopes. The key feature of these microscopes is a pinhole at the confocal plane (the plane of focus of the image located at the other side of the objective lens to the specimen; the pinhole effect also can be achieved with a tilting mirror) through which both the illumination and the fluorescent emission have to pass. Thus, any fluorescence emission from molecules out of the plane of focus will fail to pass back through the pinhole. Consequently, the only signal arises from the focal plane. This is known as focal sectioning. Focal sectioning provides a much-improved signal-to-noise ratio and thus permits lower illumination. Unfortunately, there is still photobleaching and phototoxicity in the path of illumination.

Two-photon microscopy (TPM) produces the least photobleaching and phototoxicity because the excitation of the chromophore occurs at a single point in the plane of focus. The essential physics for understanding TPM is that if a fluorescent molecule can be activated by a single photon at a given wavelength, then it can also be activated by the near-simultaneous absorption of two photons of approximately double the wavelength. However, the intensity of light required to get two photons to hit the same molecule is staggeringly high and is only achieved at the focal point with illumination using a pulsed laser.

The benefit of illumination with long wavelengths (roughly twice the wavelength for two-photon excitation) is that the light is less scattered and consequently penetrates tissue much better, causing less damage as it passes through. One can therefore monitor activity far deeper into slices and, crucially, perform in vivo imaging. This ability is further aided by the fact that fluorescence occurs at a single point, and so all emissions, no matter how scattered, can be attributed to that point. Indeed, it was possible to image dendritic spines on pyramidal cells in vivo without even doing a craniotomy.[15]

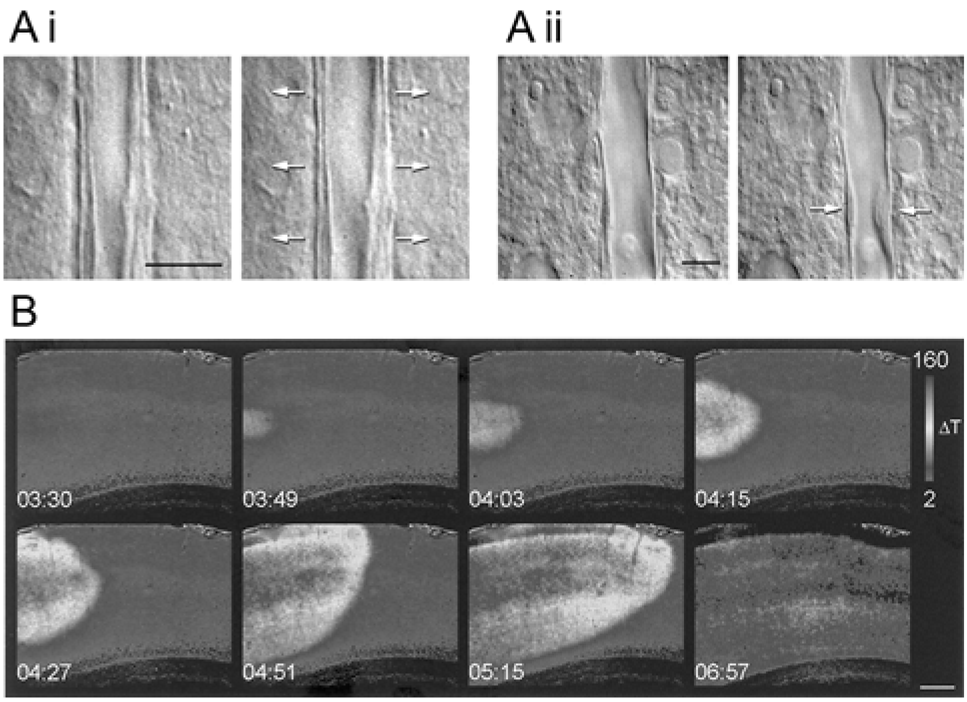

FIGURE 1. Imaging without stains. **A:** Regulation of vascular tone by interneuronal activity. Differential interference contrast images of microvessels before and after electrical stimulation of (**i**) a vasoactive intestinal peptide (VIP)-positive interneuron and (**ii**) a somatostatin-positive interneuron. The stimulated interneurons were not in the field of view but were characterized electrophysiologically and, post fixing, with immunocytochemistry. (From Cauli B, Tong XK, Rancillac A, et al. Cortical GABA interneurons in neurovascular coupling: relays for subcortical vasoactive pathways. *J Neurosci.* 2004;24(41):8940â€“8949; with permission.) **B:** Spreading depression in a neocortical slice viewed using intrinsic optical imaging. The spreading depression was triggered by perfusion of 100 ÂµM ouabain. (From Basarsky TA, Duffy SN, Andrew RD, et al. Imaging spreading depression and associated intracellular calcium waves in brain slices. *J Neurosci.* 1998;18(18):7189â€“7199; with permission.)

One further use for TPM is laser uncaging of various biologically active species (e.g., glutamate and Ca^{2+}).

The main drawback of TPM is the slow rate of imaging acquisition. Because only one point is being illuminated at any given time, to get an extended two-dimensional image, the laser has to be scanned through the whole field of view. This usually takes about 1 second, which is clearly a serious impediment when trying to monitor rapidly evolving network activity. Recently, however, the problem of slow image acquisition has been solved in three different ways. The first involves splitting the laser beam into multiple beams.[14] There is a cost in signal-to-noise ratio and possibly spatial resolution and depth of imaging (due to scatter of emitted light), but the potential benefit is, in principle, a doubling in imaging rate each time the beam is split. The second solution is to direct the laser only to those points in the field of view that are of interest. For instance, one maps the location of the neuronal somas with an initial scan, and then directs the laser only to those points.[20] The resulting laser trajectory is a fraction of that in normal raster mode. A

third option is to use acoustooptic scanners, which could be as much as 1,000 times faster than mechanical scanners.[17]

It is important to remember that all modes of imaging entail photobleaching and phototoxicity, the only difference being one of degree. Thus, there is a general overriding principle that applies to all imaging methods: To optimize the protocol so as to reduce the illumination intensity to a minimum. This demands an understanding of the nature of the biological phenomenon being studied and the properties and sensitivity of the tools being used to examine it. Out of necessity, we have given a narrow and simplistic view of the field, and we encourage interested readers to consult more-specialized texts.[10,13,16,37]

Nature of Cellular Imaging

In the following sections we cover the main techniques used to study neural activity. We also introduce some techniques that, although not yet applied to epilepsy, show promise for future research.

Floyd Bloom wryly noted that â€œthe gain in brain lies mainly in the stain.â€ Certainly our ability to visualize and understand biology has been transformed by green fluorescent protein (GFP), Ca^{2+} dyes, and many other labeling methods, and we discuss these in due course. It should be remembered, however, that there are also means of observing brain processes that do so without the potential invasiveness of loading the tissue with dye.

Imaging Without Stains

Brain tissue is not colored, but cells (either isolated or in slices) can be visualized using differential interference contrast (DIC) imaging. In slices, the view is limited effectively to the soma and dendritic stems of neurons, but this has proved to be an excellent way of visualizing neurons for patch clamping. Blood vessels are also easily seen, permitting a beautiful demonstration of the interaction between interneurons and the vasculature (Fig. 1A).[6]

A similarly simple technique is intrinsic optical imagingâ€" the recording of subtle changes in reflectance of the tissue (see Chapter 86). The reflectance changes are secondary to neural activity and are thought to arise from changes in cellular volume and, for in vivo studies, changes in blood flow and hemoglobin oxygenation. In vivo intrinsic imaging has been used to show a prominent inhibitory annulus surrounding a neocortical ictal focus during interictal events and a preceding inhibition in advance of a propagating wave.[27] In vitro imaging of slices has demonstrated activity-induced swelling of neurons,[2] swelling of astrocytes secondary to potassium (K^+) uptake,[22] spreading depression[5] (Fig. 1B), and ischemic depolarization.[4] The limitation of the technique is that it gives only an indirect measure of activity recorded on a relatively slow time scale, but on the plus side, it provides large-scale views of neuronal activity without indicator dyes.

Finally, a handful of biological molecules autofluoresce when illuminated at the appropriate wavelength.[36] Probably the most useful of these is the reduced form of nicotinamide adenine dinucleotide[7](NADH) (other examples include retinol, indoleamines, and collagen), the oxygenated form of which (NAD^+), does not fluoresce. Thus, changes in NADH autofluorescence reflect shifts in the ratio of NADH to NAD^+, which in turn reflect the metabolic state of the cell.[7]

Seizure-like activity or persistent stimulation in vitro causes an initial drop in NADH fluorescence (trough at around 10 seconds) followed by a subsequent overshoot peaking at around 60 seconds.[21] A further in vitro study, using GFP and immunofluorescently labeled astrocytes, identified the early flux as arising from oxidative metabolism in neuronal dendrites, whereas the late rise in NADH occurred in astrocytes (rich in glycolytic enzymes but poor in mitochondria).[19] There is, however, one significant caveat to this interesting metabolic relationship between neurons and glia: Experiments in vivo fail to show the late rise in NADH fluorescence unless the local blood supply is impaired.[18] It seems that in the normal brain, any oxygen debt incurred by neuronal activity is more than offset by an increased supply of oxygen through dilated blood vessels.

Anatomic Stains

Perhaps the most widely discussed imaging development arose from molecular biologyâ€"the ability to genetically engineer green fluorescent proteins. The developments continue apace,

as illustrated by the Gensat project (http://www.gensat.com). This online resource is striving to characterize expression patterns for all genes known to be expressed in the mouse brain, by creating mouse strains in which individual promoters are used to drive GFP expression. In principle, one can then visualize the temporal and spatial pattern of expression by the presence of GFP.

This facility might allow the expression of key genes to be followed during the evolution of ictogenic foci in vivo, for example, following a head injury. Of course, there are easier means of identifying candidate genes ex vivo (e.g., immunolabeling fixed tissue, gene expression profiling using microarray analysis), but the availability of the relevant GFP mouse line would permit detailed analysis of the temporal and spatial patterns of gene expression in living samples.

A further use for anatomic stains is that they provide easy, noninvasive cell identification. One can then target those cells for patching or for characterizing cell-class-specific patterns of activity using Ca^{2+} dyes.

Finally, epileptic activity might induce morphologic changes that can be followed in labeled cells. For instance, dendritic spines, the site of excitatory drive on to pyramidal cells, are known to be restructured by activity, although the degree to which this happens is the subject of intense debate.[15,33] Studies of post mortem tissue have shown reductions in spine density following seizures. However a recent TPM in vivo study of pilocarpine-induced epileptic activity failed to find evidence of spine remodeling, except secondary to other pathologic changes in the dendrites.[25]

Voltage-sensitive Dyes

Optical monitoring using voltage-sensitive dyes has been used to record activity in a single neuron at many locations in the dendritic tree or to record population activity in a bulk-loaded preparation. The signals are rapid, but they are also small. Measurements from a single cell require intense illumination, but the dyes are then very phototoxic, and the cells usually die after firing a handful of action potentials. In population studies, the signal is too weak to record from individual neurons.

An additional problem in interpreting the signal is that it is an average from all neural structuresâ€"axons, somas, and dendrites. This problem is well illustrated by attempts to study epileptiform propagation in neocortical slices. These studies seemed to indicate that activity spreads primarily in the supragranular layers,[1,29,35] in contrast to other work, which concluded that the earliest recruited pyramidal population were the large layer 5 neurons.[8,31] A resolution to this contradiction may come from simultaneous somatic and dendritic patch recordings,[26] which show that the peak membrane potential deflection during a paroxysmal depolarizing shift (PDS) is 10 mV greater in the apical trunk (i.e., supragranular location) than at the soma. This is also consistent with the anatomy of neocortical networks because we know that the most powerful reciprocal lateral connections are in the supragranular layers 2 and 3.[11]

Ca^{2+} Imaging

We come finally to what may prove to be the most useful imaging tool for epilepsy research. Most Ca^{2+} indicators are derivatives of the Ca^{2+} buffer 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*â€²,*N*â€²-tetraacetic acid (BAPTA) and thus are exquisitely sensitive to Ca^{2+}. They work by chelating the ion, with the bound form having different fluorescent properties from the unbound form. A key property is therefore the dissociation constant for Ca^{2+} binding, K_d, which determines the dynamic range of the dye (typically 0.1 to 10 times K_d). The K_d, however, is influenced by temperature, pH, protein binding, the presence of other ions (especially magnesium [Mg^{2+}]), and a number of other factors. Consequently the K_d measured in vitro and that in situ can be rather different. The most useful dyes for monitoring firing patterns have an in vitroâ€"measured K_d in the range 100 to 350 nM and include fura-2, indo-1, Oregon green 488 BAPTA-1 (OGB1), and fluo-4.

Calcium indicators can be loaded into neurons directly via the recording pipette, and this method has been used to explore the role of Ca^{2+} in the PDS during bicuculline-induced events.[26] Ca^{2+} enters primarily through *N*-methyl-D-aspartate (NMDA) receptors and voltage-gated Ca^{2+} channels, and the cytosolic concentration is further boosted from intracellular stores.[26] This rise in Ca^{2+} activates the nonspecific cation channel I_{can}, which is the crucial for sustaining the PDS.

Bulk loading, on the other hand, uses the acetoxymethyl (AM) ester derivatives of the various dyes. These freely cross the cell membrane, and the AM group is then cleaved by intracellular esterases to produce the functional dye. Fura-2 has been the dye of choice for our in vitro studies[3,9,30] for several reasons:

1. It affords a good signal-to-noise ratio, with Ca^{2+} increases causing a drop in emission; thus the quiescent cell is clearly visualized, allowing easy localization of the somas.
2. It can be used in tandem with GFP; the dyes have different absorption and emission spectra.
3. It yields preferential loading of neurons over glia; we estimate that with good loading, about 95% of labeled cells are neurons.

OGB1 also gives good neuronal labeling (70% to 90% neuronal, with glia being easily distinguished using the astrocyte-specific label SR101[23]; see Fig. 2). Brief loading with fluo-4-AM can give good neuronal loading (30% to 70% neuronal), but with longer incubations, the loading is preferentially of glia. The reason for the differential pattern of loading is not clear, but it is most likely caused by some combination of the following: Differences in the intracellular esterases, differences in the internal milieu influencing the effective K_d, and differences in the Ca^{2+} rise triggered by action potentials in different neuronal populations.

Our bulk-loading experiments use what appears to be a universal feature of spiking neurons, which is that their somatic Ca^{2+} levels rise following an action potential. The Ca^{2+} change is detected as a sharp change in fluorescence, occurring in less than 17 msec (one time frame imaged at 60 Hz: Fig. 2). The subsequent decay has a time constant of about 0.5 second, so the signal persists for some time, allowing action potentials to be captured at relatively slow imaging speeds.

How fast can one usefully capture population dynamics with Ca^{2+} imaging? Low-power imaging necessarily reduces the numbers of pixels collecting signal for an individual soma, and consequently the spatial averaging is limited. Furthermore, lower-power objectives have lower numerical apertures, and hence they have poorer focal sectioning and produce a somatic signal contaminated by neuropil signal. The neuropil signal can be large during intense network activity such as epileptiform events. These factors lower the signal-to-noise ratio. Increasing the intensity of illumination helps, but at a cost of increased phototoxicity and bleaching. A second option is to image at higher powers but with a smaller field of view. The final option is to collect each image over a longer period, that is, to image more slowly. For these reasons, we believe that Ca^{2+} imaging of bulk-loaded slices is unlikely to discriminate activation times of neurons activated within much less than 10 msec of each other.

P.1054

P.1055

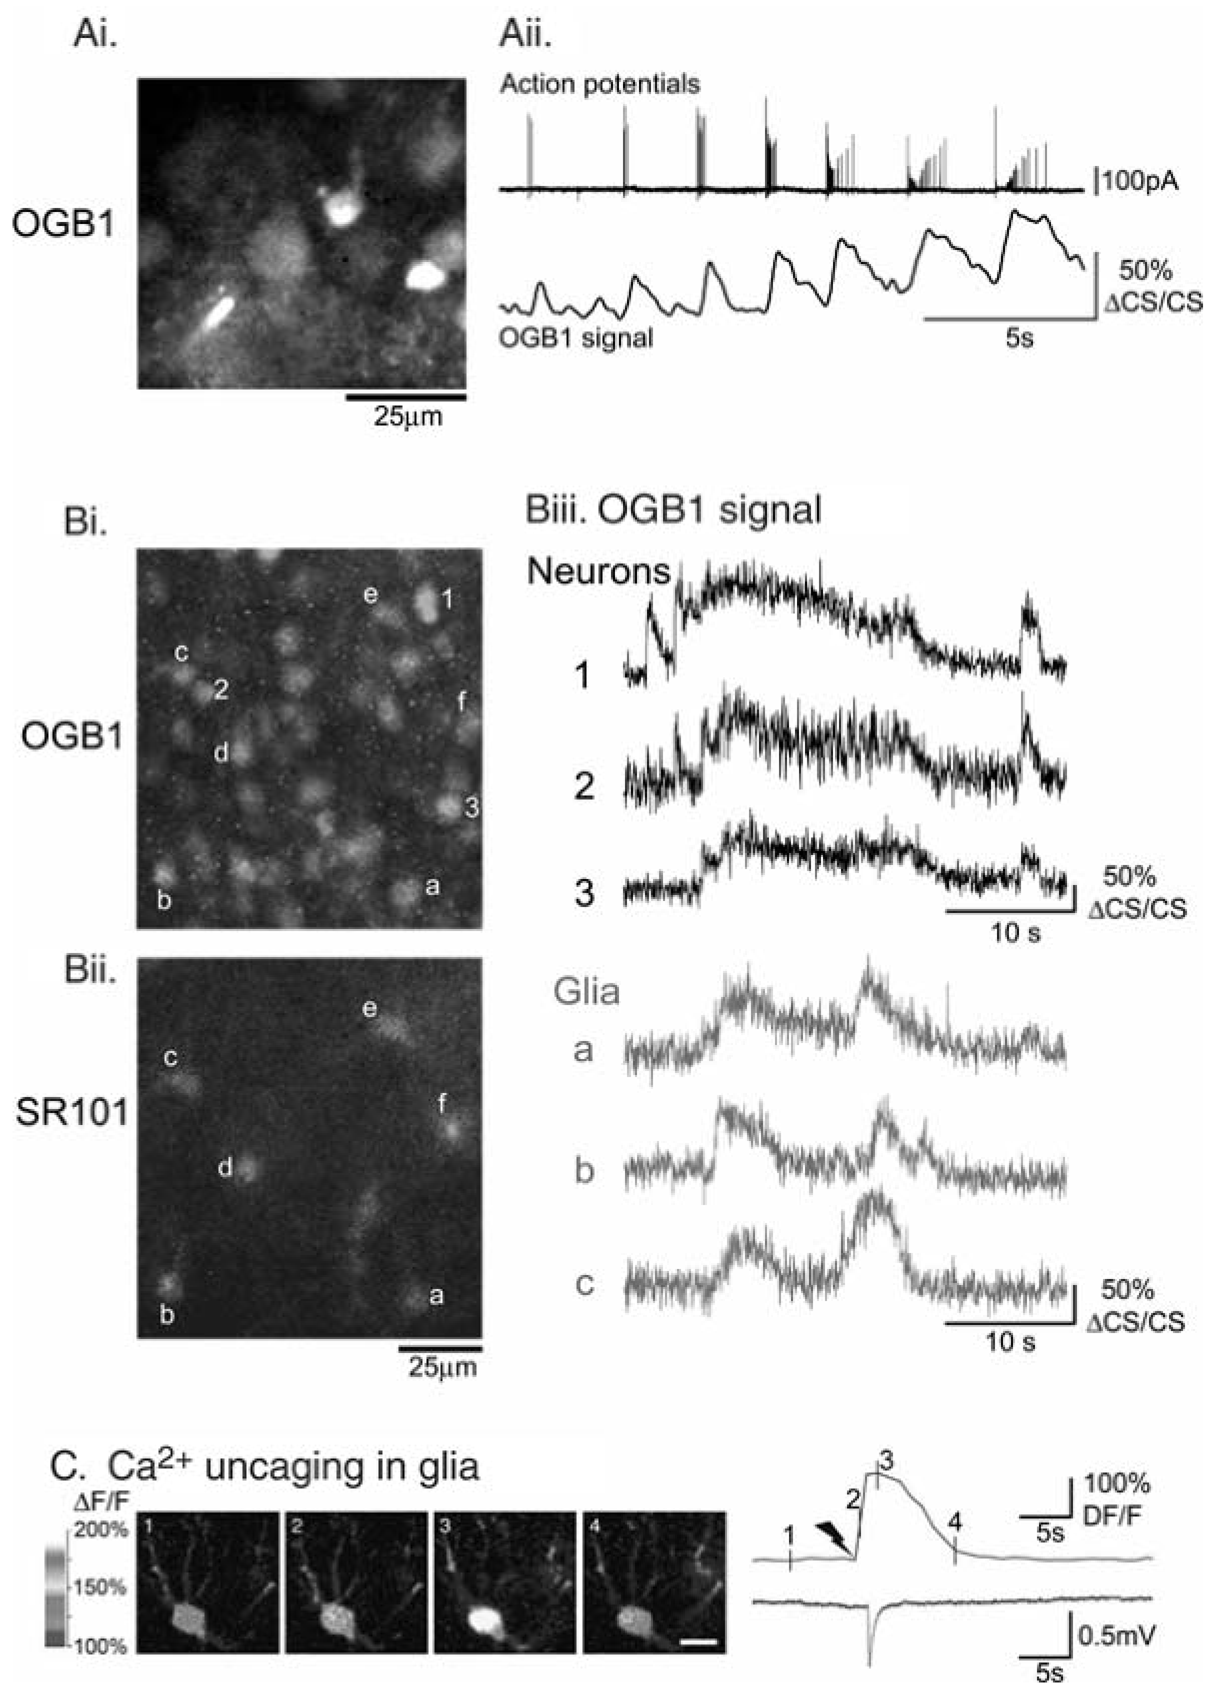

FIGURE 2. Ca^{2+} imaging of epileptiform activity. **A:** Ca^{2+} indicators give a reliable record of action potential trains. A loaded pyramidal cell (**i**, *center*) was recorded in cell-attached mode (electrode is the white flash,

lower left) during the transition into a full ictal event. We know from other recordings that the action potential barrages occur on the crest of successive paroxysmal depolarizing shifts (the PDSs themselves are not apparent in cell-attached recordings). **B:** Neuronal and glial activity. Both neurons and glia take up the Ca^{2+} indicator OGB1 (**i**), but only glial cells take up SR101 (**ii;** glia labeled aâ€"f). **(iii)** The Ca^{2+} fluorescence for three of the glia (aâ€"c) and for three representative neurons (1â€"3). Glia have slower and delayed Ca^{2+} rises compared to the neuronal signal. (From Tian GF, Azmi H, Takano T, et al. An astrocytic basis of epilepsy. *Nat Med.* 2005;11(9):973â€"981; with permission.) **C:** Two-photon uncaging of Ca^{2+} in glial cells provokes glutamate-dependent DC shifts in the local field recordings. The glia were also labeled with the Ca^{2+} dye fluo4. The four sequential micrographs were taken at the times shown in the traces (*right*). The rise in the glial Ca^{2+} consistently was followed by a local network event recorded here using a field electrode.

These techniques have shown patterns of activity in cortical slices bathed in nonepileptogenic artificial cerebrospinal fluid (ACSF),[9] and we have extended these studies to various in vitro models of epilepsy.[3,30] The most interesting results are the propagation patterns of the first epileptiform waves following washout of Mg^{2+} from the bath. The wave propagates by stepwise recruitment of local populations of neurons, seemingly regulated by the local inhibitory elements.[34]

Calcium imaging has also highlighted prominent Ca^{2+} dynamics in glia (Fig. 2). Epileptogenic conditions induce a marked increase in the incidence of large oscillations of intracellular Ca^{2+} in glia.[30,32] These are associated with synchronized NMDA-mediated events in local pyramidal populations. Furthermore, uncaging Ca^{2+} in glia can cause these local depolarizing events.[12,32]

Further evidence of a role for glial Ca^{2+} waves in epilepsy derives from in vivo experiments that demonstrate a surprising action of three different anticonvulsants. Valproate, gabapentin, and phenytoin were all found to reduce the amplitude of glial Ca^{2+} waves triggered by either 4-aminopyridine or ATP.[32] This effect implies that the crucial anticonvulsant action of these drugs, long thought to be mediated through neurons, may in fact be mediated through glia. The ATP-induced waves provide the strongest evidence because ATP is thought to have a much more powerful effect on glia than on neurons. There remain, however, the possibilities that initiation or maintenance of these glial Ca^{2+} waves involves neuronal action, which should warn us against overinterpreting this result. What we really need to demonstrate is a molecular site of action for the anticonvulsants, and furthermore that this is located in glia.

Glia also show interesting Ca^{2+} dynamics during propagating waves recorded in vitro. Their intracellular Ca^{2+} rises very slowly, with a delay of around 1 to 5 seconds after the local neuronal activation (Fig. 2). These glial Ca^{2+} kinetics need to be interpreted in the light of the NADH imaging studies mentioned earlier, and future experiments will show whether they also occur in vivo. Given the apparent role for glia in initiating events, it seems quite possible that glial activity might also influence how the epileptiform activity evolves.

These techniques for bulk loading Ca^{2+} dyes are being applied.[20,24,28] One important goal will be to validate the numerous in vitro studies, but there are also many other possibilities.

Summary and Conclusions

We mentioned the possibility of using imaging to follow gene expression in vivo during epileptogenesis. In this case, the screening of involved genes is best done using molecular biological techniques. In other contexts, it is worth stressing that imaging represents an ideal screening tool in its own right. We documented some of the many ways we can use imaging techniques to observe neural function, often relatively noninvasively. The strength of these techniques lies in the possibility of gathering huge amounts of data from many locations in the neural networks simultaneously. Thus, imaging can highlight quickly where the action lies; which cells are active or behaving in unusual ways; which cells are no longer active or have died; and, if changes in gene expression are involved, in which cells and at what times.

We speculate that there are critical components of the network that underlie the majority of epilepsy phenotypes, and that these represent promising therapeutic targets. We suggest that our best chance of identifying these elements will be to use, in tandem with the more classical electrophysiologic and molecular biology techniques, the many imaging techniques that are now being developed.

Chapter 90

Neuropsychology Evaluation â€“ Adults

David W. Loring

William B. Barr

Marla Hamberger

Christoph Helmstaedter

Introduction

Neuropsychological impairments are common in many epilepsy syndromes and are related to clinical factors such as seizure frequency and severity, age of seizure onset, as well as the underlying pathologic substrate. It is beyond the scope of this chapter to provide a comprehensive review of all epilepsy syndromes and their patterns of neuropsychological impairment. However, we will highlight several consistent neuropsychological principles.

As described by Hughlings Jackson, there are significant and independent contributions of both static and dynamic factors that affect brain function, and by extension, neuropsychological abilities. Morphologic or structural lesions are associated with relatively nonmodifiable neuropsychological deficits. In contrast, electroencephalographic (EEG) discharges, seizures, and epilepsy treatment are associated with more dynamic brain changes that, to varying degrees, are modifiable and are under direct physician management. Depending on epilepsy type (idiopathic vs. symptomatic), the relative contributions of specific factors will differ.

Disentangling the stable and dynamic cognitive influences in epilepsy often poses a major challenge because the causes of impaired neuropsychological function are not fully independent of each other. Treatment effects, for example, act on and interact with morphology and epilepsy. Although altered brain structure and function may result in epilepsy, epilepsy and its underpinnings may also alter functional cerebral organization. Finally, at the highest level, epilepsy-related cognitive impairment must be evaluated within the patient's developmental context. Certain seizure syndromes show peaks at specific developmental stages, and etiology is associated with age at seizure onset. Cognitive profiles vary depending on age of seizure onset, with differences apparent depending on whether epilepsy develops in the maturing brain versus mature brain versus aging brain. However, age of seizure onset may simply reflect the expression of dysfunctional brain maturation.

Epilepsy is often dichotomized according to whether the EEG abnormalities involve the entire cerebrum (generalized epilepsy) or begin focally (partial epilepsy). Generalized epilepsy includes tonicâ€“clonic seizures, juvenile absence epilepsy, and myoclonic epilepsy. Partial epilepsy includes a variety of seizure types including the so called â€œbenignâ€ partial epilepsy (e.g., benign epilepsy with centrotemporal spikes, or BECTS) as well as symptomatic focal epilepsy (e.g., mesial temporal lobe epilepsy and neocortical epilepsy). In this chapter, we describe disease effects on cognition as a function of epilepsy syndromes, age of onset, and epilepsy course. We also discuss the complex issue of whether poorly controlled seizures are associated with progressive cognitive decline. For ease of discussion, we categorize epilepsy subtypes according to whether they are considered to be idiopathic or symptomatic.

Idiopathic Epilepsy

Idiopathic epilepsy, including both generalized and partial epilepsy expression, is characterized by a genetic predisposition and the absence of readily identifiable brain lesions. Although not completely silent behaviorally or cognitively, idiopathic epilepsy is generally easy to treat and is associated with less severe cognitive impairments than are other seizure types. *Idiopathic generalized epilepsy* (IGE) is characterized by generalized EEG abnormalities involving the entire cerebral cortex, whereas *idiopathic partial epilepsy* (IPE) is associated with regional EEG abnormalities (e.g., centrotemporal EEG in rolandic epilepsy).

As would be predicted from generalized EEG abnormalities, diffuse and generalized cognitive impairments are present, including deficits in attention, psychomotor speed, visuospatial skills, and nonverbal memory. Language and verbal memory, in contrast, appear unaffected.[62,102,107]

The epileptiform discharges and cognition are also closely related. Not only does cognitive impairment vary as a function of seizure activity, but cognition may also induce seizures and seizure discharges.[92] Although this relationship has been described in patients with symptomatic temporal lobe epilepsy (TLE),[50] patients with IGE are particularly likely to show neuropsychological EEG activation. Negative effects of spike-and-wave bursts exist for sensory and executive functions. Therefore, tasks requiring sustained attention are best suited to detect the cognitive effects of EEG changes in IGE.[102] Although cumulative attentional effects may ultimately result in diminished level of function when they occur over long periods, decreased IQ is not a primary feature of the disease, with developmental delay and retardation developing from interference with cognitive functions over a long period of time. Absence epilepsy developing in early childhood is generally associated with poorer outcome than juvenile absence epilepsy.

BECTS is a common epilepsy syndrome (10%â€“15%), beginning between 5 and 9 years of age and extending into adolescence. It has a favorable prognosis, and most patients become seizure-free after puberty. Its neuropsychological prognosis, however, is less benign. During its active phase, neuropsychological deficits may include attention, motor functions, short-term memory, visual and perceptive abilities. Language difficulty relating to the interictal dysfunction of the perisylvian language areas, however, is a major characteristic of BECTS.[102] Learning disabilities are common in BECTS,[143] although they are not progressive in nature. Although children rapidly improve in most areas following seizure remission, minor problems in executive functions and verbal comprehension persist.[80,103] Complete seizure remission is generally needed for a favorable cognitive outcome.

Juvenile myoclonus epilepsy (JME) generally begins between 12 and 18 years of age, and is characterized by neuropsychological and behavioral features associated with

P.1058

frontal dysexecutive impairment such as reasoning difficulty, poor concept formation, and decreased mental speed and flexibility.[22,64,65,102,130] Of course, frontal lobe dysfunction is not specific for JME. Whether frontal lobe cognitive dysfunction together with personality change (e.g., limited self-control, suggestibility, indifference, rapid mood changes) form a syndrome characteristic of JME merits further study.[65] The presence of more focal impairments in addition to generalized slowing is consistent with the view that IGE should no longer be considered purely a â€œgeneralizedâ€ epilepsy. EEG, histologic, structural and functional imaging studies suggest a specific involvement of frontal lobes, thalamus, and thalamocortical loops in IGE.[1,75,100,118,147]

In conclusion, a wide range of rather mild impairments may be associated with idiopathic generalized or idiopathic partial epilepsy. Mild generalized impairment and learning difficultly have been observed. These are best understood from the close relationship between active epileptic processes interfering with cognitive networks of lower-order functions, on perceptive and executive functions, and on the interference of epilepsy with critical periods of cognitive development (i.e., before, during, or after language acquisition, or at the time before or during frontal executive function development). Frontal/executive functions are the last to fully develop and therefore may represent a common endpoint for the impairments seen in idiopathic epilepsy. Following epilepsy remission, neuropsychological recovery from active epilepsy-driven impairment can be observed. However, some long-term residual deficits may persist, particularly when epilepsy has significantly interfered with cognitive development.

Focal Symptomatic Epilepsy

In contrast to idiopathic epilepsy, the cognitive profiles of symptomatic epilepsy are more strongly related to epilepsy location and etiology. The temporal lobes and temporomesial structures are particularly vulnerable to seizure development, and TLE accounts for approximately 70% of chronic symptomatic epilepsy. Approximately half of TLE patients have hippocampal sclerosis (HS) or hippocampal atrophy, although whether mesial TLE represents a distinct nosological entity or a syndrome is still a matter of debate.[146] Mesial TLE is characterized by impaired declarative memory.[57] Patients with earlier seizure onset tend to have lower IQs, reflecting the interference of seizures (and perhaps their treatment with antiepileptic medications) with normal cognitive and brain development.[54] Accompanying the IQ with earlier seizure onset is a reduction of total brain volume, including both gray and white matter.[54] Memory impairment occurs independent of the age of seizure onset, although the nature of the memory impairment depends on when seizures begin. A more generalized memory impairment occurs with earlier seizure onset, whereas a more focal and material-specific memory impairment that varies according to seizure onset laterality is seen with later seizure onset.[43]

With later seizure development, left temporal/left temporomesial epilepsy is associated with material-specific impairment of verbal learning and memory. Mesial and neocortical structures differentially contribute to verbal memory, with mesial structures subserving consolidation and retrieval, and neocortical structures being more associated with content processing. Thus, impaired delayed recall is more indicative of mesial rather than neocortical temporal lobe damage.[48] Impairment of verbal learning, short-term memory, and naming (i.e., semantic memory) are less specific but also may reflect left inferotemporal or temporolateral lesions.[39,40,42,125,126] Naming impairment is associated with hippocampal volume,[14] and also related to functional activity reflected by spectroscopy.[123] Like memory, the magnitude of naming impairment is strongly associated with seizure onset age.

In contrast to left TLE, right TLE tends affect performance on figural or nonverbal memory tasks.[34] However, this relationship is less consistent than that between left TLE and verbal memory,[6] an effect that has been attributed to nonverbal memory networks being more bilaterally distributed than verbal memory, covert verbalization during task performance, or the type of test and test materials (abstractness, complexity) used. Consequently, using figural memory tests to infer mesial temporal dysfunction will often falsely lateralize seizure onset. However, false lateralizing figural memory impairment in left TLE may also reflect atypical language dominance or sex differences.[43]

Even though the area of seizure onset in focal TLE is limited, neuropsychological impairment often extends beyond the seizure onset zone.[59,89] These â€œfrontalâ€ deficits imply impaired functional connectivity that is disrupted with a temporal lobe focus, and may be considered to reflect â€œnociferous cortexâ€ effects, in which the negative effects associated with ongoing seizure discharge impair brain function at some distance from the active seizure focus.[134] However, magnetic resonance imaging (MRI) volumetrics have demonstrated prominent disruption in ipsilateral hippocampus and neural connectivity (i.e., white matter volume loss) that extends beyond the temporal lobe, affecting both ipsilateral and contralateral hemispheres.[128] TLE patients with secondary generalized seizures are at higher risk of additional general neuropsychological impairment.[70]

Frontal lobe epilepsy (FLE) is seen in approximately 20% of patients with partial onset seizures, and is associated with a less consistent neuropsychological profile than TLE. In contrast to TLE, in which HS is the predominant morphologic feature, frontal lobe epilepsy is associated with a more heterogeneous array of etiologic factors. Moreover, executive functions mediated by the frontal lobe contribute to most other cognitive functions, resulting in diffuse and nonspecific neuropsychological impairments. Patients suffer from attention problems, problems with working memory, mental flexibility, response inhibition, or planning. Tests of motor coordination appear particularly sensitive to frontal lobe epilepsy. At the highest level, a dysexecutive syndrome may comprise problems with response selection, initiation, execution, and inhibition. No consistent lateralized impairment has been associated with focal left versus right FLE.[25,41,129,139]

The neuropsychological characteristics of *parietal lobe epilepsy* and *occipital lobe epilepsy* have rarely been described in a series using adequate sample sizes. Acute parietal or occipital neuropsychological symptoms become evident in seizure semiology, but in chronic epilepsy (most often those patients exhibiting early lesions or malformations), the classic posterior symptoms of aphasia, alexia, agraphia, acalculia, agnosia, and neglect are very uncommon. Primary or secondary perceptive and sensory problems that may be evident at the beginning of epilepsy are often well compensated for behaviorally. Impairments are diffuse, and, as described with seizure semiology and EEG, often mimic frontal or temporal lobe dysfunction.[52,72] Nevertheless, tests of stereognosis or haptic search may be sensitive to parietal lobe epilepsy.[71,117]

Etiology

Partial epilepsy is associated with a variety of etiologies. Lesions include stationary lesions, such as developmental malformations, HS, or atrophy; traumatic brain injury or vascular malformations; as well as potentially progressive defects such as neoplastic and paraneoplastic tumors, CNS infections, and inflammatory and autoimmunologic processes. Independent of

seizure effects, these lesions themselves are associated with cognitive impairments that range from mild impairment in circumscribed domains to severe generalized neuropsychological impairment. However, cognitive impairments in symptomatic epilepsy are not lesion specific, but rather differ according to age at lesion onset, differences in functionality of the affected tissues, differences in the course and dynamics of the underlying disease, and finally differences in lesion lateralization and localization.[7] Although the lesions themselves are generally not associated with ongoing cognitive function, activation of heterotopic gray matter has been demonstrated using functional MRI (fMRI).[66]

A major concern is the cumulative effects of chronic epilepsy on the brain and on cognition. Seizures, and in particular severe seizures, may result in significant damage, although this is more of an individual patient concern than a concern across all patients. For example, multiple reports exist describing amnestic syndromes following either status epilepticus or a series of generalized tonicâ€"clonic seizures. The cumulative effect of less severe seizures on cognition, however, is less clear-cut. In a review of 20 longitudinal studies in children and adults, 12 of 20 reported a relationship between duration of poorly controlled seizures and neuropsychological decline, 5 of 20 described mixed results, and 3 of 20 described no relationship.[82] For those studies reporting an effect, lower IQ with associated increased seizure frequency, greater performance â€œimprovementâ€ in controls than patients, and more important, neuropsychological declines were associated in nonmemory domains.

Cross-sectional studies of chronic uncontrolled TLE suggest a significant IQ decline after three decades.[67] Comparing the age regressions of memory in healthy subjects to those of epilepsy patients puts such a finding into perspective.[45] In chronic uncontrolled TLE, memory decline in a longitudinal design is very slow, and individually proceeding cognitive decline can be suggested. Presumably, this applies for chronic focal epilepsy, but it remains unclear whether specific domains are affected or whether decline is diffuse and nonspecific. Impairment may be seen in patients with symptomatic focal epilepsy even prior to the onset of epilepsy, and cognitive impairment may develop from the interference of lesions/epilepsy with brain maturation and cognitive development. The impact of additional lesions and the interaction of aging with preexisting damage appear much more relevant for individual cognitive change than for the accumulation of seizures alone.[7,43]

Antiepilepsy Drug Effects

Given the many potential influences on cognition for patients with epilepsy, such as age of onset, disease substrate, or seizure frequency and severity, antiepilepsy drugs (AEDs) occupy a unique position because they are under the direct control of the treating physician and his patients. Although the choice of specific AED is guided by seizure type and epilepsy syndrome,[61] within seizure/syndrome categories, AED selection is typically based on clinical experience rather than evidence-based practice. Most major AEDs used to treat partial epilepsy have comparable efficacy,[76] although many recently introduced AEDs are associated with more favorable tolerability profiles that includes less neuropsychological impairment.[73]

Because AEDs decrease membrane excitability, increase postsynaptic inhibition, or alter the synchronization of neural networks, they are often associated with neuropsychological side effects including decreased motor/psychomotor speed and attention.[96] Adverse AED effects are a significant component of treatment effectiveness. The landmark VA Cooperative study reported that standard AEDs including carbamazepine are associated with significant adverse effects that contribute to initial treatment failure in more than 40% of patients,[93] and a separate European trial reported that tiredness was described by more than 50% and sleepiness by more than 35% of patients on phenytoin or carbamazepine monotherapy.[4] Adverse AED effects are strongly associated with poor health reported by patients[30] and with decreased health-related quality of life.[32] After seizure control, the most important aspect of AED treatment is the side effect profile, including problems with cognition, energy level, school performance, childbearing, coordination, and sexual function. Because of side effects, 20% of patients adjusted their AED dosing.[27]

In young adults, neuropsychological AED profiles are generally comparable for the older-generation AEDs carbamazepine, phenytoin, and valproate, with each AED associated with modest psychomotor slowing accompanied by decreased attention and memory.[96] Neuropsychological side effects generally emerge according to a dose-dependent relationship[96]; however, both quality of life[31] and memory may be affected, even when AED blood levels are within standard therapeutic ranges. Central nervous system (CNS) effects of AEDs are reflected by EEG slowing that not only is correlated with short-term neuropsychological decline,[119,120] but is also related to poorer neuropsychological outcome following 1 year of treatment.[28] With the exception of topiramate[87,96,122,135] and possibly zonisamide,[2,10] most newer-generation AEDs have more favorable tolerability and neuropsychological profiles than their predecessors.[86,97,98,99]

Although direct head-to-head comparisons examining the neuropsychological profiles of newer AEDs have not typically included medications thought to have favorable neuropsychological outcomes, some data suggest differences in this regard. For example, in one study, oxcarbazepine was associated with both neuropsychological impairment and EEG slowing in healthy volunteers.[121] Thus, some data suggest that important differences may exist among AEDs, even across newer agents considered to have favorable neuropsychological side effect profiles. Several recent Class I healthy-volunteer studies suggested increased risk of cognitive impairment associated with topiramate[97,121] Because there may be individuals who are at greater risk for developing cognitive impairment, it may be possible to ultimately predict individuals at increased risk for developing treatment-emergent side effects based on pharmacogenetic or pharmacokinetic patient characteristics.

Subjective Report Versus Objective Performance

In addition to poor performance on memory tests and other neuropsychological measures, epilepsy patients often complain of poor memory.[19] Although both subjective and objective memory findings indicate decreased memory, subjective memory ratings and objective memory performance are poorly correlated.[8,29,46,108,142] In studies with sufficient sample sizes, statistically significant relationships between objective and subjective performances have been reported, although these correlations are generally small and account for a small portion of the variance. In contrast, subjective memory correlates much more highly with mood.[19,23,26,108,109] Depressed or anxious patients tend to rate their memory as poor, whereas patients less burdened by poor mood states rate their memory more favorably. Correlations generally account for approximately half of the variance,[5,26] with mood being the single best predictor of subjective memory functioning.[23,33,108]

The association between subjective memory and mood is informative, yet a large portion of the variance remains to be explained. Most studies show no significant relationship between subjective memory and clinical factors such as sex/gender, chronologic age, seizure-onset age, seizure type, seizure frequency, region of seizure onset, and number of AEDs.[23,109] However, memory â€œcomplainersâ€ may have a later age of

P.1060

seizure onset,[19] and a small inverse relationship between age and subjective memory reports has been described.[26,33] There is a tendency for patients on polytherapy to report greater cognitive difficulty than do patients on monotherapy,[33] although this relationship is well-established using formal neuropsychological measures.[96] Although most studies are restricted to TLE patients, those that included both temporal and extratemporal patients document greater reports of memory impairment than in TLE.[19] Although some investigators report no influence of seizure laterality,[5] others have found significant associations between perceived memory and objective verbal memory in left TLE patients, and with objective nonverbal memory in right TLE patients.[12] Although reports exist of a relationship between perceived and objective language performance,[12] others have not observed this relationship.[5]

Ecologic Validity of Objective Measures

Formal neuropsychological measures are established indicators of lateralized or localized cognitive dysfunction.[14] However, the modest correlation between subjective and objective results raises questions regarding ecologic validity of conventional memory tests. Neuropsychological memory tests typically require learning and recall of word lists or abstract designs, whereas â€œeveryday memoryâ€ typically requires incidental memory for complex events in which the individual is personally involved.[49] In two independent studies utilizing memory tests simulating everyday memory demands,[23,49] more ecologically valid tests correlated weakly with subjective ratings, but correlated more highly with conventional test performance. Although a small but significant correlation was found between ecologically valid memory performance and subjective report in patients â€œwithoutâ€ memory impairment,[49] the absence of a significant correlation in the â€œimpairedâ€ group may be related to the more restricted performance range.

The demands of various activities differ considerably, and cognitive deficits may be more apparent in high- versus low-demand situations. In one postoperative series, patients staying at home (â€œlow demandâ€) reported greater subjective complaints than did employed subjects (â€œhigh demandâ€),[35] and this corresponded with objective memory performance as well (i.e., weaker objective memory in the low-demand situations). Although patients were self-selected for group assignment, these data suggest that patients with poorer objective memory were in less demanding situations due to their genuine memory deficits, as well as feeling more impaired.

Tip-of-the-tongue (TOT) phenomena or â€œword finding difficultyâ€ is one of the top three cognitive complaints among epilepsy patients,[20] although the relationship between objective performance using confrontation naming tests[19] or language composite scores[5,108] with patient self-report is low or nil. However, the absence of a stronger relationship may result from language test selection using measures that poorly correlate with word finding difficulty. For example, in a study addressing the ecologic validity of object naming measures, no correlation was found between self-reported word finding difficulty and traditional visual object naming, although a small but significant correlation was noted with auditory description naming, a task developed to better simulate word finding in the context of everyday speech.[39]

Subjective Memory â€œTheoriesâ€

Several studies suggest that laypersons, (i.e., patients, proxies, and normal controls) have a broader definition of â€œmemoryâ€ than do neuropsychologists and neurologists. Specifically, performances on various language tasks, such as word fluency, expressive vocabulary, and naming, correlate significantly with subjective memory ratings.[26,46,104] Thus, when people are asked to rate their memory, they often consider language fluency and word finding difficulty as well as declarative memory processes.

The poor relationship between subjective performance ratings and objective test results raises the question of whether impaired deficit recognition (e.g., anosognosia) exists. A problem in assessing subjective memory in a population with genuine memory deficits is that the task is retrospective and, therefore, a memory task itself.[46,49] The discrepancy between objective and subjective scores is greater in patients with right hemispheric seizure onset, with a greater tendency in these patients to overestimate their genuine memory abilities.[3] This pattern is consistent with the specialized role of the right hemisphere in deficit awareness reported in lesions of other etiologies.

It has been suggested that some patients, unaware of their real memory conditions, exaggerate their memory failures and report this inaccurate self-perception in questionnaires.[109] Although epilepsy patients with and without memory complaints obtain comparable scores across a range of neuropsychological measures, the â€œcomplaintâ€ group scored significantly higher in neuroticism.[142] Thus, both disease-related and personality factors reduce self-awareness, thereby contributing to the discrepancy between subjective complaints and objective performance.

Subjective Change in Postoperative Patients

Whereas pre- (or non-) surgical epilepsy patients tend to â€œover-reportâ€ memory deficits, the prevalence of memory complaints among patients following temporal lobe resection is quite low.[13,124] In fact, postoperative patients tend to report improved memory functioning despite evidence of memory decline on objective measures.[94,95] Accordingly, most studies report little correlation between changes in objective performance and changes in subjective ratings following surgery. Rather, subjective memory ratings in postoperative patients correlate significantly with seizure outcome (i.e., good seizure outcome associated with improved subjective ratings),[58,94,95,124] AED side effects, and, similar to that demonstrated in preoperative patients, with mood[94,124] and neuroticism.[15] Although a higher prevalence of subjective decline might be expected following left anterior temporal lobectomies (ATL) rather than right ATL given the more consistent objective decline following left surgery,[14] subjective complaints do not appear to predict surgical laterality.[8,15,94,95,124] Because of the overall poor correspondence between performance and complaints after surgery, postoperative memory complaints might be considered a marker of depression or other mood disorder.[124] Nonetheless, there is general agreement that, despite these group findings, individual cognitive complaints should be followed up with both formal mood assessment and neuropsychological evaluation.

Practical Implications

The poor correspondence between subjective report and objective performance suggests caution when drawing conclusions from subjective complaints. This is obviously a concern to the treating physician since, in most cases, the presence or absence of memory complaint is based on questioning the patient, rather than on formal memory assessment. Factors to consider include emotional and psychosocial factors, the

potentially broader definition of â€œmemoryâ€ held by patients and their relatives, the patient's level of daily cognitive demands, and seizure onset laterality. For postoperative patients, one should additionally consider seizure outcome and AED burden. Each of these factors carries a potential influence on cognitive self-appraisal; distinguishing among them on an individual basis is critical, because each implicates a different treatment approach.

Wada Testing and Functional Imaging

One of the primary goals in the preoperative evaluation is to identify patients who may be at increased risk for developing significant postoperative neuropsychological impairment. Patients undergoing temporal lobe resection in the language-dominant hemisphere are at higher risk for experiencing postoperative memory decline than are those undergoing nondominant ATL, and knowledge about language dominance and memory representation is important to establish the relative risks to memory associated with temporal lobectomy.

The Wada test is one of the major procedures to establish relative memory risk following ATL, although not all epilepsy surgery centers perform this procedure routinely on all ATL candidates.[83] Wada testing to assess both language and memory function emerged during the 1950s, when structural and functional imaging was almost nonexistent. Although variability in specific protocols exists, the technique generally involves the introduction of amobarbital (or other anesthetic agent) through a transfemoral catheter into the internal carotid artery, which temporarily anesthetizes the distribution of the anterior and middle cerebral arteries. During the period of hemispheric anesthesia, the patient is presented with language and memory acquisition tasks, with memory tested after the drug effects have worn off. Although the memory component of this task was designed to avoid developing a significant postoperative amnesia, this role has largely been supplanted by current functional neuroimaging using MRI, positron emission tomography (PET), and single-photon emission computed tomography (SPECT). Wada memory results, however, are often used to indicate the risk of significant memory decline that may interfere with a patient's overall quality of life.[85]

The Wada test differs from all other approaches to functional assessment, including neuropsychological testing, in that it tests each hemisphere in isolation. By doing so, it helps to disentangle the effects of large-scale distributed brain networks, and it can assess the specific contributions of the anesthetized region and their functional connections to language and memory function. When the hemisphere ipsilateral to a medial temporal lobe focus is anesthetized, the reserve capacity of the contralateral temporal lobe to sustain memory function in isolation is assessed.[16] Multiple reports demonstrate the contribution of Wada memory results to memory outcome prediction.[18,68,74,77,84,116,133] An aphasia confound occurs when testing memory following dominant hemisphere injection and, because of this confound, a selective procedure for anesthetizing the distribution of the posterior cerebral artery may be used,[131] although this approach is associated with a greater risk of stroke and, consequently, is generally not employed routinely.[148] Selective procedures involving other vascular distributions may be performed based on clinical indications.[38,140]

Because the Wada procedure is invasive, fMRI and magnetoencephalography (MEG) are advanced as noninvasive alternatives. Many language fMRI paradigms reliably identify language representation, and the use of fMRI has decreased the frequency of Wada use in some epilepsy centers.[44] MEG is an alternative measure of functional imaging that, unlike fMRI, which relies on indirect measures of neural activity based on blood flow changes, is a direct measure of neuronal function. MEG is also a reliable noninvasive measure of language lateralization.[105,106]

Imaging the medial temporal lobes has proven to be more difficult. However, several reports demonstrate the effectiveness of fMRI related to seizure onset laterality[21,37,69] as well as memory outcome following surgery.[110,113] As the components needed for successful hippocampal activation continue to be understood,[11] it is likely the fMRI will increasingly be used in preoperative epilepsy evaluation, with a corresponding decrease in Wada use.

Postoperative Outcome

Up to 80% of those patients undergoing ATL resection will become seizure-free following surgery,[145] although some patients will experience specific declines in memory, language, or some other aspect of cognitive functioning. A literature has now developed demonstrating how results from presurgical neuropsychological testing, combined with demographic variables and other neurodiagnostic findings, can predict patients who are at greatest risk for developing postoperative decline.

One of the earliest findings from neuropsychological studies is that epilepsy surgery results in very little change in IQ.[44] The view that patients with lower IQ levels, which can suggest greater generalized brain impairment, do not benefit from surgery has been dispelled by research findings comparing seizure outcomes in both low- and high-IQ groups.[36,44] Patients with higher IQ levels and memory performance tend to experience greater cognitive declines following surgery, although they also continue to exhibit a higher level of postoperative functioning than do patients with lower presurgical cognitive performance.[51] These results support the model of *cognitive reserve* that has gained acceptance in the fields of dementia and traumatic brain injury.[114,132]

The majority of epilepsy surgeries are ATLs that involve resection of areas considered important for normal memory processing; consequently, predicting memory outcome has been emphasized. Different rates of memory decline, ranging from 10% to 60%, following ATL have been reported. The prediction of memory decline has been guided by two basic theoretic approaches. The first model is based on Milner's[101] original observation that material-specific memory deficits in verbal and nonverbal memory are associated with ATL of the left (dominant) and right (nondominant) temporal lobes, respectively. The second approach is based on a more recent model, which predicts that the degree of postoperative memory deficit, as well as seizure outcome itself, will be determined by the â€œfunctional adequacyâ€ of the tissue to be resected.[16,74] The type of surgical procedure (e.g., â€œstandardâ€ ATL vs. selective amygdalohippocampectomy) and postoperative seizure status also contribute to postoperative cognitive outcome.[44]

Laterality Effects

Analyses of material-specific memory findings are included in nearly every neuropsychological study of postoperative outcome. The conclusion drawn from recent literature reviews is that strong empirical support exists for the link between surgery on the left temporal lobe and postoperative deficits in verbal memory.[78] There is, however, substantially less support for the proposed relationship between nonverbal memory impairment and surgery on the right temporal lobe.[78,141]

There has been a recent trend moving from group methods of analysis toward predicting the risk of postoperative change in individual patient prediction. To optimize the prediction of individual risk, investigators have been using statistical

P.1062

processes, such as the reliable change index (RCI) and standardized regression-based (SRB) methods, to control for the reliability of the instruments, practice effects, and regression to the mean. Studies using this methodology have reported that the risk for postoperative decline in verbal memory ranges from 40% to 60% in patients undergoing left ATL, whereas the risk for decline in patients undergoing right ATL ranges from 10% to 30%.[56,91] Significant declines following right ATL are not clearly explained by any simple version of the material-specific memory model. Much less is known about the risk of experiencing a decline in nonverbal memory, a result of methodologic factors and small effect sizes.

Language-dominant ATL has been associated with postoperative naming deficits, although details regarding these deficits are less well known than those associated with memory. Postoperative naming impairment is generally thought to occur in only a minority of patients,[14] although at least one study has found naming declines in 40% of a left ATL sample versus none in those patients undergoing right ATL.[91] The ability to predict postoperative naming deficits through presurgical language mapping using intraoperative or extraoperative methods has been inconsistent. One multicenter study found that the rate of postoperative naming decline was not influenced by the availability of mapping data.[53] Others have found that identification of mapping sites critical for auditory descriptive naming is important for predicting both auditory and visual naming outcome.[40]

There are no consistent findings demonstrating deficits in visual perceptual or spatial functions associated with right ATL. Surgical procedures conducted on patients with frontal lobe epilepsy and other forms of extratemporal epilepsy have been associated with only mild declines in memory, language, or other cognitive functions unless areas of eloquent cortex are involved specifically.[24,47] Laterality effects on cognitive functioning are considered to be less of an issue with pediatric patients than with adults.[7]

Functional Adequacy Model

The functional adequacy model predicts that less postoperative memory decline, as well as a greater likelihood for seizure reduction, will be observed in patients exhibiting lower levels of presurgical functioning in the mesial temporal lobe ipsilateral to seizure onset.[16,74] Functional adequacy is established using both neuropsychological methods as well as measure of structural pathology using preoperative neuroimaging. Most research findings have supported this model, as opposed to the competing â€œfunctional reserveâ€ model that suggests postoperative memory is best predicted by the functional and structural integrity of the contralateral temporal lobe.

Presurgical Neuropsychological Performance

Evidence supporting the functional adequacy model was initially provided by the finding that patients with higher memory performance on presurgical testing were more likely to demonstrate significant memory decline following ATL than those with lower presurgical memory performance.[63,111] These results are not simply the result of statistical â€œregression to the mean,â€ but rather reflect the tendency for the most functional patients at baseline to be more vulnerable to experiencing postoperative memory loss.[17] This is a robust pattern of change following ATL, and it has been observed in many independent series.[55,133,144]

Findings from MRI and Other Studies

Neuropathological studies have consistently demonstrated that memory outcome varies according to the presence of HS ipsilateral to seizure onset.[9,14,60] Not only do individuals with severe unilateral HS exhibit lower levels of preoperative memory, but they are also less likely to exhibit memory decline following surgery.[127] Similar findings have been observed using MRI measures of hippocampal pathology.[137,138] Resection of a relatively nonatrophic left hippocampus generally results in greater memory decline, although memory loss may also occur in some patients with severe presurgical HS.[90] Surgery in patients with bilateral hippocampal pathology, however, does not necessarily cause global amnesia, although greater rates of memory decline are seen in patients with bilateral hippocampal atrophy who undergo dominant-hemisphere ATL.[90] Normal verbal memory in the presence of hippocampal atrophy may also be associated with significant postoperative memory decline.[85] Thus, the functional integrity of the left temporal lobe plays a critical role in predicting memory outcome independent of the presence of structural pathology.[81,85]

Studies using multiple regression methods have demonstrated that prediction of postoperative outcome is best accomplished using a combination of both functional and structural indices.[55,133] The importance of functional adequacy to postoperative change has been demonstrated using both magnetic resonance spectroscopy (MRS) and Wada testing.[74,84] fMRI has been shown to be useful for predicting postoperative naming.[115] Recent presurgical fMRI studies have demonstrated the ability to predict postoperative memory functions.[110,113]

Demographic Predictors

Developmental factors, including age at the time of surgery and the stage of cognitive development at the time of seizure onset, are important factors for predicting postoperative cognitive decline. The risk of cognitive decline following surgery appears to be lower in children younger than age 16 years than in adults.[79] In contrast, older patients may experience greater memory loss, consistent with a profile of accelerated aging.[51] Continuing decline in memory performance may be seen in some individuals 10 years or more following surgery.[112] The postoperative deficit in verbal memory in patients who are seizure free is similar to what is observed over time in nonsurgical patients who are continuing to experience seizures, suggesting normal age-related memory decline.[51]

Age of seizure onset interacts with both functional and structural indices in a manner consistent with the functional adequacy model.[16,88] Those with a younger age of onset will have experienced pathology at an earlier stage of development and will have experienced seizures for a longer period of time. This leads to greater neurologic compromise, which is accompanied by more severe and widespread cognitive impairment. However, earlier seizure onset also permits a redistribution of function to other brain areas, which would lead to less deficit following surgery. In contrast, patients developing epilepsy later in life are not as compromised neurologically, because it does not interfere with cognitive development and maturation, and consequently they do not exhibit the same degree of cognitive dysfunction preoperatively. However, surgery involves resection of more functional brain tissue, which increases the likelihood of developing greater cognitive decline postoperatively. Support for these findings coupling age of onset with function was present in some early studies, but at least one recent study has failed to find a link between severe hippocampal pathology, memory decline, and early onset of seizures.[88]

In general, cognitive deficits become more specific and less reversible with surgery with increasing age. The pattern of findings involving age of onset are generally more consistent for cognitive functions associated with neocortical zones than for those associated with the mesial temporal lobe.[44] For example, more severe naming deficits are observed in older patients. Other studies examining demographic factors have suggested

that women, in general, exhibit less severe cognitive decline following surgery than do men.[136]

Summary and Conclusions

Patients with epilepsy frequently have some cognitive and neuropsychological impairment. Cognitive difficulty may be due to the underlying brain disorder, specific epilepsy syndrome, AED effects, psychiatric comorbidity, and ongoing effects of active seizure discharges. Although the neuropsychological impairment is related to the location of the active seizure focus in patients with localization-related epilepsy, often more subtle impairments in executive functions may be present in both focal and generalized epilepsy syndromes, including those commonly referred to as â€œbenign.â€ Because a poor relationship exists between subject performance ratings and formal neuropsychological test results, formal assessment is often necessary to document the presence and extent of cognitive difficulty experienced in individual patients. Cognitive impairments are broadly related to age of seizure onset and seizure duration. Unfortunately, well-established interventions to treat or modulate cognitive difficulty in patients with epilepsy do not exist.

Chapter 91

Neuropsychological Evaluationâ€"Children

Peter M. Rankin

Faraneh Vargha-Khadem

Introduction

The neuropsychological evaluation of children with epilepsy involves the assessment and interpretation of a broad range of variables that have the potential to alter the natural course of brainâ€"behavior development. These variables include seizure type and frequency, lesion lateralization and localization, type of neuropathology, side effects of anticonvulsants, age of epilepsy onset, and elapsed time since onset. Reliable neuropsychological diagnosis and prognosis of a child or adolescent with epilepsy requires the careful consideration of all of these factors and how they interact to affect future cognitive development and organization within the developing brain. Subsequent neuropsychological deficits can range from relatively specific impairments in one neurocognitive system to severe generalized intellectual disability. A child's ability to compensate for and/or overcome neuropsychological deficits will depend in part on the child's exposure to risk or protective factors within his or her environment, such as quality of educational support, family attitudes toward epilepsy and learning difficulties, socioeconomic status, access to specialist rehabilitative programs, behavioral management strategies, pharmacologic management, and/or surgical management. A combination of these variables interacting with neuropsychological impairments will influence the child's overall quality of life and mental health.

Contemporary pediatric neuropsychology for children with epilepsy plays an important role in both enhancing clinical practice and increasing the knowledge base of developmental cognitive neuroscience. From a clinical standpoint, neuropsychological evaluations in children are carried out to establish cognitive status preoperatively, identify eloquent tissue (subserving language, memory, visuospatial perception, and motor function) that may be at risk during surgical intervention, determine the response of cognitive and/or behavioral systems to neuropharmacologic agents, provide prognostic indicators of cognitive and behavioral outcome to help both clinical management and guide educational support and intervention, monitor postoperative outcome and long-term progress through transitional stages of late childhood and adolescence, and identify children who might be at risk of decline or regression. From a scientific viewpoint, investigations of children with epilepsy using a systems neuroscience approach can advance understanding of the extent and limits of the plasticity and reorganizational capacity of the immature brain, determine the costs of reorganization and the adaptive/maladaptive compensatory responses to brain damage, document the developmental trajectory of functional brain organization in the presence of focal or diffuse pathology, establish brain structure/function relationships, and help identify the neural substrates of cognitive function and dysfunction, with the ultimate goal of translating the basic neuroscience findings to inform clinical diagnosis, prognosis, and management.

Over recent years the neuropsychological study of children with epilepsy has gained considerable momentum due to the rise in neurosurgical procedures conducted at younger developmental ages. Pediatric neurosurgery has increased because of the development of enhanced presurgical investigative techniques (e.g., quantitative methods of structural and functional neuroimaging, electroencephalogram [EEG] telemetry, ictal and interictal single photon emission computed tomography [SPECT], and interictal positron emission tomography [PET] examinations) that help to identify seizure type and focus, site and source of seizures, and type of neuropathology more reliably than before.[5] There have also been improvements in the safety of neurosurgical practice[21] and increasing evidence that early surgery may counteract pronounced restriction or regression of cognitive and psychosocial development due to persisting epilepsy.[23,70]

To reflect the increasing interest in neuropsychological evaluations in relation to pediatric neurosurgery, this chapter will consider many of the developmental issues peculiar to pediatric neuropsychology by focusing on studies of children pre- and post-neurosurgery. Alternative models of the ontogeny of hemispheric specialization are introduced to help understand the potential effects that epilepsy can have on cognitive development early in life. Such models are important for pediatric neuropsychologists to consider when interpreting results of evaluations carried out pre- and post-neurosurgery. The relevance of such models to one of the most common neurosurgical procedures for children with epilepsy, namely hemispherectomy, is discussed based on studies of intellectual function and studies of speech and language. We include data from our series of children who have undergone hemispherectomy to highlight the variables that influence intellectual outcome, in particular the interaction between age at onset of epilepsy and hemispheric side of lesion. The effects on speech and language development in children who have bilateral or unilateral left- and right-sided lesions are outlined, and issues of potential reorganization of speech and language following early left-sided lesions are discussed in relation to recent functional neuroimaging studies that demonstrate the importance of hippocampal involvement in language reorganization. The complexity of understanding brainâ€"behavior development following the onset of epilepsy in childhood will become clear, as will the need for clinical pediatric neuropsychologists to be integrated within multidisciplinary pediatric epilepsy surgery services and work collaboratively alongside developmental cognitive neuroscientists to mutually advance clinical practice and scientific understanding.

The Ontogeny of Hemispheric Specialization

There is often an implicit assumption that brainâ€"behavior relationships identified in adults can be applied to children. For

P.1068

example, it is well known that the adult human brain is relatively asymmetric in function for some cognitive processes: Acquired lesions to Broca's area and the perisylvian regions of the left hemisphere affect speech and language,[17,77] whereas lesions to the right hemisphere more often affect aspects of visuospatial ability.[64,83] However, the application of such knowledge to the pediatric population is usually made in the absence of supporting empirical data[9] and without an understanding of normal and abnormal patterns of brain maturation and functional specialization during the course of development.

Historically, the evolution of ideas relating to the ontogeny of hemispheric specialization has been dominated by three models. The *equipotentiality* model first proposed by Lenneberg[35] states that the two cerebral hemispheres have equal potential at the start to subserve different aspects of cognitive function but gradually acquire specialization with increasing age and learning experience up to adolescence, when the pattern becomes crystallized and resembles that of adults. The major implication of the *equipotentiality* model is that the earlier the lesion, the more effective is the compensatory processes, and, consequently, the better is the cognitive outcome. In fact, it is now recognized that age at injury per se is not the sole determinant of outcome, and other factors (e.g., severity and extent of damage, locus of injury, etiology of the lesion, elapsed time since the onset of the lesion, presence or absence of epilepsy, unilateral or bilateral pathology) each contributes to the eventual outcome. However, this model can account for the impressive recovery of function (especially for speech and language) that ensues after early unilateral lesions and for the emergence of selective deficits (e.g., aphasic symptoms), signifying a relative decline in plasticity, with increasing age.

The *early-specialization* model posits that early onset of unilateral lesions leads to material-specific deficits that correspond to the side of damage, suggesting that the hemispheric division of labor for the processing of verbal and nonverbal information is present at or shortly after birth (for reviews see Bates et al.[3] and Vargha-Khadem et al.[69]). The early-specialization view was invoked by a number of researchers[10,22,32,80,81,82] to provide a post hoc account for a series of empirical findings on children with unilateral lesions, including hemispherectomy, showing material-specific deficits corresponding to the hemispheric side of damage. A major implication of this model is that brain organization in the young child is modular just as it is in the adult, and that the double dissociation of function that is the hallmark of adult neuropsychology is present from infancy before the emergence of different aspects of cognitive function. Despite its appeal because of continuity with adult models, the early-specialization view does not satisfactorily account for the impressive rescue of articulate and grammatically formulated speech that is frequently seen after extensive left hemisphere pathology of early origin or the absence of chronic dysphasic symptoms after such early insult. A more fundamental problem for the model is the dearth of empirical evidence supporting a clear pattern of hemispheric specialization in cohorts of healthy children at different ages or a double dissociation of function in pediatric patients with early unilateral lesions.[2,3,39,69,72]

In an attempt to reconcile the two extreme views, that of *equipotentiality*, which is compatible with developmental plasticity, versus *early specialization*, which is consistent with modular organization of brain function across the developmental span, Satz et al.[55] proposed a compromise position, referred to by Bates et al.[3] as â€œconstrained plasticityâ€ and by Vargha-Khadem et al.[69] as â€œontogenetic specialization.â€ This model assumes that there is a genetically determined anatomic basis to hemispheric specialization, and that during normal brain development, the functional expression of this genetic predisposition can unfold early in life. The model also assumes, however, that during normal development, there is an interaction between environmentally evoked neural activity that becomes progressively complex and nonredundant and neural plasticity that gradually declines with increasing age. Early brain injury can counteract the genetic predisposition toward specialization and change the normal trajectory of the activity/plasticity interaction. Thus, children who sustain brain damage early in life suffer two setbacks, one relating to the direct consequences of the actual lesion and the other relating to an altered developmental trajectory that is likely to be different from normal. The *ontogenetic specialization* model fits well with theories of brain and cognitive development (e.g., Alexander Luria, Jean Piaget) insofar as it conceives of the interactions between neural activity and plasticity emerging in stages of increasing complexity during childhood and adolescence. Furthermore, it also fits well with research on normal development of intelligence and language functions, in which evidence suggests that (a) whole-brain gray matter volume obtained from magnetic resonance imaging (MRI) is strongly correlated with IQ in older but not younger children,[76] (b) the two cerebral hemispheres are more nearly equal in linguistic processing capacity in infancy[7,8] than they are later in life,[45,59] and (c) the degrees of left lateralized functional MRI (fMRI) activation on a verb generation task[25] and blood oxygenation levelâ€"dependent (BOLD) fMRI signal during sensorimotor and language tasks[56] increase with age. Although the fMRI activation patterns on a variety of language tasks performed by normal children are the same as those in adults,[15,16,79] there are qualitative and quantitative differences suggesting that maturational features in functional neuroanatomy and/or differences in ability are distinct in development.[57,79] Finally, the model is also consistent with increasing recognition that in the aftermath of early unilateral injury, many factors can influence and counteract the normal developmental trajectory toward hemispheric specialization. For example, a small unilateral lesion acquired in the second decade of childhood can leave undisturbed the normal crystallization of hemispheric specialization and yield a selective deficit that is consistent with the early-specialization view. In contrast, an extensive unilateral lesion acquired early in life, before the development of complex cognitive repertoires, can lead to extensive interhemispheric reorganization and relative stunting of cognitive development across all domains, consistent with the equipotentiality model. With advances in quantitative neuroimaging techniques delineating the site and extent of neuropathology and functional imaging paradigms revealing activation patterns associated with specific cognitive tasks, it is now possible to examine structure/function relationships in pediatric patients with epilepsy and translate the findings to aid surgical decision making and subsequent management.

Intellectual Outcome After Hemispherectomy

Hemispherectomyâ€"complete or partial removal or disconnection of one cerebral hemisphereâ€"is one of the commonest forms of pediatric neurosurgery for the relief of epilepsy, constituting up to 30% of neurosurgical procedures,[5] particularly during the first decade of life. When children are assessed for hemispherectomy, one of the central questions concerns the status of cerebral lateralization and the consequences of surgery for intellectual functions and speech and language. Candidates for surgery usually present with a unilateral structural lesion and seizures, the origins of which date to pathologic congenital or perinatal processes or events, such as Sturge-Weber syndrome or hemimegalencephaly, although some children have later acquired disorders such as Rasmussen syndrome that can develop from about 1 year of age through to adolescence.[13]

In 2004, Pulsifer and colleagues reported on the neuropsychological outcome of the largest series (*n* = 71) of

hemispherectomized patients studied to date.[51] Patients were divided into groups depending on the etiologic category (cortical dysplasia; Rasmussen encephalitis; vascular malformations or stroke). Mean IQ scores were almost two standard deviations below normal (i.e., ~70) in the Rasmussen and the vascular malformation/stroke groups but considerably lower (i.e., more than five standard deviations below normal) in the group with cortical dysplasia. These results are broadly consistent with those reported in our series of 33 children who underwent hemispherectomy and were divided into developmental, acquired, and progressive etiologic groups.[11] Results from these two recent studies suggest that both cognitive and seizure outcomes are related to the underlying pathology, with most favorable outcomes occurring in those with acquired and progressive etiologies as compared to developmental etiologies (such as cortical dysplasia, hemimegalencephaly, etc.). Based on the comparison between preoperative versus postoperative IQ scores, the decline and/or arrest of intellectual function occurred well before presentation for surgery, with both studies indicating improvements in long-term follow-up in only a small percentage of cases.[11,51]

Table 1 Details of age at onset of epilepsy in hemispherectomy subgroups and IQ details

Group	*N*	Mean age of onset of seizures in months (SD)	Mean age at test in months (SD)	Mean time to test in months (SD)	Mean full-scale IQ (SD)	Mean verbalâ€“performance discrepancy score (SD)
Left congenital (LC)	9	22 (27)	183 (40)	161 (60)	60 (17)	3.44 (4.47)
Left early (LE)	6	32 (13)	141 (49)	109 (52)	58 (13)	5.5 (4.96)
Left late (LL)	4	103 (46)	176 (59)	73 (66)	59 (10)	18.25 (6.18)
Right congenital (RC)	5	6 (7)	98 (44)	92 (44)	53 (9)	6 (11.72)
Right early (RE)	6	34 (17)	211 (102)	177 (115)	65 (15)	10.33 (16.28)
Right late (RL)	6	90 (21)	188 (34)	97 (23)	73 (10)	13.66 (11.5)

The relationship between etiology and hemispheric side of removal was pursued further in the report by Pulsifer et al. Whereas no differences were found between the means of the left and right hemispherectomized groups within the etiologic category of cortical dysplasia or vascular abnormality on any of the cognitive measures, including intelligence, significant effects of side of removal were indicated in the Rasmussen encephalitis groups.[51] The right hemispherectomy group obtained significantly higher intelligence and language scores than the left hemispherectomy group. The absence of an effect of hemispheric side of removal in the group with cortical dysplasia is consistent with the ontogenetic specialization model, and the notion that in the face of extensive early brain abnormality hemispheric specialization (i.e., nonredundancy of function) is sacrificed to enable the development of cognitive abilities at a basic level.

The question of whether intellectual outcome after hemispherectomy is related not only to etiology and hemispheric side of removal but also to age at onset of pathology deserves attention. In contrast to adult studies,[42,74] previous reports based on large cohorts of pediatric patients with unilateral lesions, with or without epilepsy,[3,18,68,69] failed to reveal a significant difference between verbal and nonverbal intellectual outcome as a function of hemispheric side of lesion. However, in those with late-acquired pathology (i.e., >5 years) a pattern of IQ scores at least qualitatively similar to the one reported in adults has been found (i.e., verbal IQ [VIQ] < performance IQ [PIQ] after late left hemispheric lesions; PIQ < VIQ after late right hemispheric lesions).[69] It is not known whether this age-at-injuryâ€"dependent and side-of-injuryâ€"dependent pattern documented in pediatric patients with unilateral lesions is also found in hemispherectomized patients.

We examined the interaction between age at onset of pathology and surgical side of removal on IQ type in a subset (*N* = 36) of hemispherectomized patients drawn from the series operated at Great Ormond Street Hospital[11] and King's College Hospital.[67,68] Admittedly, our postoperative hemispherectomized cohort is not yet large enough to permit assessment of the effects of three variables (i.e., hemispheric side of removal, age at onset of pathology, and IQ type) in the same analysis. Nevertheless, despite the small groups that this comparison inevitably entails, it is informative to examine the pattern of results in patients who have undergone hemispherectomy compared to patients who have not received surgery but have hemiplegia due to unilateral left- or right-sided lesions and seizures grouped by age at onset of pathology.[58]

Hemispherectomized patients were selected for this study if they could undergo formal intelligence testing and if they had undergone surgery at least 2 years prior to testing. In each case, both verbal and nonverbal IQs were obtained using the age-appropriate Wechsler Scales of Intelligence. The left- and right-hemispherectomized patients were each divided into three groups on the basis of age at onset of pathology (congenital; early, â‰¤5 years; late, >5 years; see Table 1). Therefore we had six subgroups: left congenital (LC), left early (LE), left late (LL), right congenital (RC), right early (RE), and right late (RL). Relevant details regarding the etiology of the seizure disorder leading to hemispherectomy are presented in Table 2. As indicated in Table 1, the full-scale IQs of the six hemispherectomized groups ranged from 53 (RC group) to 73 (RL group). These mean IQ scores are between two to three standard deviations below normal and are consistent with results reported in previous studies.[51,72] The pronounced restriction in overall intellectual ability is the most striking cost of severe intractable epilepsy leading to hemi- spherectomy.

Prior to statistical analysis, the two variables of IQ type were reduced to one by subtracting verbal IQ from nonverbal (performance IQ), thus yielding a discrepancy score. This reduced the number of analyses carried out on a relatively small sample. A discrepancy score above zero indicated a verbal IQ score that was higher than nonverbal IQ, whereas a discrepancy score below zero signified the opposite. FIGURE 1 presents the mean discrepancy scores for each of the six hemispherectomy groups. As indicated, five groups show positive mean discrepancy scores and the LL group shows a strongly negative mean discrepancy score.

Table 2 Etiology of the seizure disorder leading to hemispherectomy

Etiology	â‰¤5 years	5â€"16 years	Total

Cortical dysplasia	3	1	4
Cerebrovascular accident	1	0	1
Cyst	2	0	2
Encephalopathy	1	0	1
Epilepsy of unknown origin	2	0	2
Hemimegalencephaly	1	0	1
Hemistatus	1	0	1
Infarct	3	0	3
Megalencephaly	1	0	1
Mesial temporal sclerosis with cortical dysplasia	1	0	1
Rasmussen encephalitis	6	9	15
Sturge-Weber syndrome	0	1	1
Scar tissue	2	0	2
Vasculitis	1	0	1
Total	25	11	36

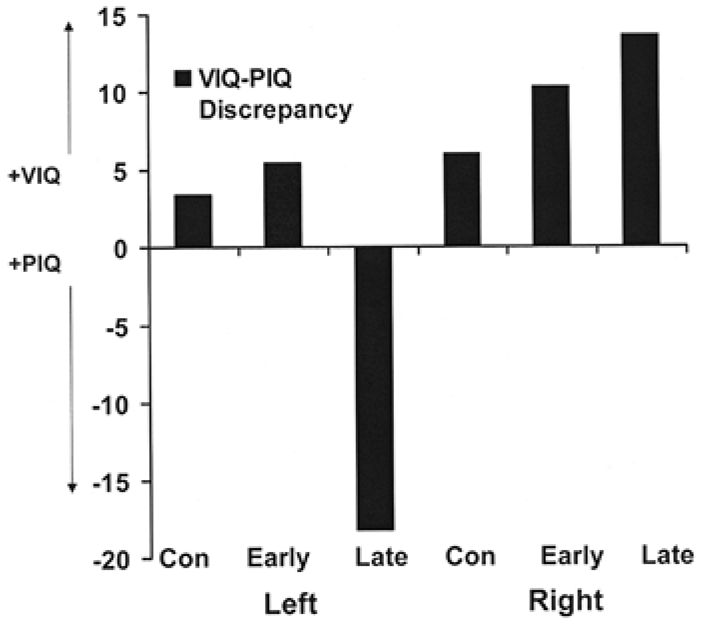

FIGURE 1. Discrepancy scores for verbal minus performance IQ (VIQ and PIQ, respectively) for each of the hemispherectomy subgroups (higher score indicates V > P discrepancy). Con, congenital.

To determine the effects of hemispheric side of removal and age at injury on IQ type, a univariate analysis of variance was performed on the discrepancy scores of the six groups. There was a significant effect of hemispheric side of removal ($F = 14.88$, $p < .001$) and a significant interaction of hemispheric side of removal by age at onset of pathology ($F = 7.11$, $p < .003$). Because these were discrepancy scores, a series of

one-sample t-tests was performed to test the hypothesis for each subgroup that the discrepancy was significantly different from zero. The mean discrepancy scores of the LC, LE, and RL groups (LC $t = 2.30$, $p = .05$; LE $t = 2.71$, $p = .04$; RL $t = 2.91$, $p = .03$) were significantly above zero, suggesting a relatively stronger verbal IQ compared to nonverbal (performance) IQ in these subgroups. The mean discrepancy scores of the RC and RE groups were actually greater than those of the LC and LE group, but there was considerable variability within the right subgroups (see Table 1). In contrast, the discrepancy score of the left late group was significantly below zero (LL $t = -5.90$, $p = .01$) indicating the reverse relationship. FIGURE 2 presents mean verbal and nonverbal IQ scores of the six groups highlighting the double dissociation of function between IQ type and side of hemispherectomy in relation to age at onset of pathology.

To compare this pattern of results with one obtained from pediatric patients with unilateral lesions and seizures but without neurosurgery, IQ data from the six subgroups ($n = 52$) reported by Vargha-Khadem et al.[69] were selected and are illustrated here. These subgroups are selected on the basis of hemispheric side of damage and age at injury using the same three categories indicated previously for hemispherectomized patients (i.e., congenital; early, â‰¤5 years; late, >5 years) (Table 3). Table 4 presents details of etiologic factors for the groups with acquired hemiplegia and seizures. As indicated in Table 3, the full-scale IQs of the six hemiplegia-with-seizure subgroups ranged from 81 (RE group) to 91 (LL group). These mean IQ scores are within one standard deviation of the normal range and, as such, do not constitute an impairment. The relatively well-preserved level of overall intellectual ability in the hemiplegia-with-seizure groups (Table 3 and Fig. 3) stands in marked contrast to that of the severely deficient level achieved by the hemispherectomized groups (Table 1 and Fig. 2).

As with the hemispherectomy subgroups, IQ discrepancy scores were calculated and are presented in FIGURE 4. Univariate analyses of variance revealed no significant effects of side of lesion ($F = 3.411$, $p = .071$), age at onset of pathology ($F = 2.19$, $p = .12$), or age at onset by side of pathology ($F = 2.77$, $p = .073$). It seems likely, however, that with increased sample size, a pattern similar to the one in the hemispherectomized groups will emerge because the overall profile of the six groups with hemiplegia and seizures is qualitatively similar to that of the hemispherectomized groups (see Fig. 4).

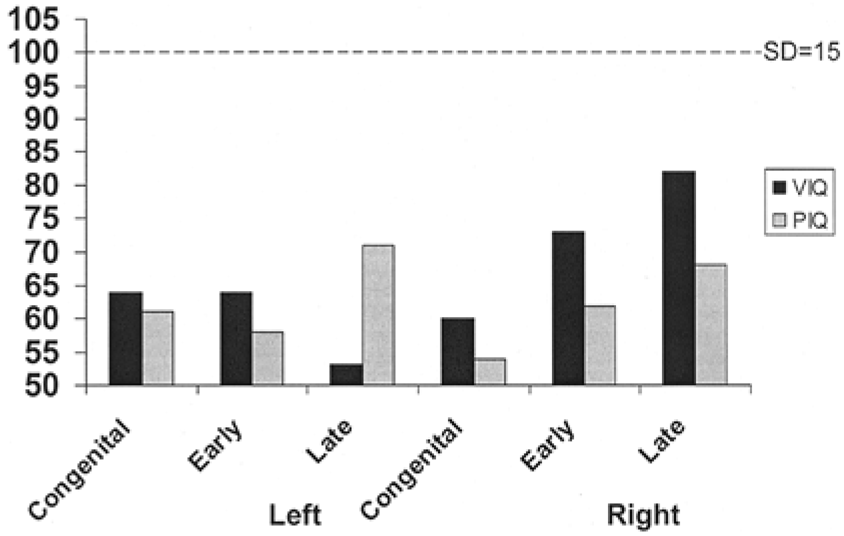

FIGURE 2. Verbal and nonverbal (performance) IQ (VIQ and PIQ, respectively) by age at onset and side of removal in the hemispherectomy group. SD, standard deviation.

Table 3 Details of age at onset of lesion in hemiplegia subgroups and IQ details

Group	*N*	Mean age at injury in months (SD)	Mean age at test in months (SD)	Mean time to test in months (SD)	Mean full-scale IQ (SD)	Mean verbalâ€“performance discrepancy score (SD)
Left congenital (LC)	13	0 (0)	143 (33)	143 (33)	85 (13)	3.28 (6.96)
Left early (LE)	6	32 (10)	148 (61)	116 (60)	90 (10)	0.83 (11.85)
Left late (LL)	5	144 (41)	180 (48)	36 (27)	91 (21)	-16.60 (12.72)

Right congenital (RC)	16	0 (0)	139 (43)	139 (43)	89 (12)	-0.12 (15.24)
Right early (RE)	6	20 (17)	152 (46)	133 (48)	81 (6)	8.33 (20.7)
Right late (RL)	6	108 (44)	147 (34)	39 (33)	90 (13)	2.66 (15.77)

In summary, the data presented here suggest that extensive lesions with seizures leading to hemispherectomy have the profound effect of lowering overall intelligence by more than 2.5 standard deviations below the population mean. Patients in the late left- and right-hemispherectomy subgroups demonstrate an intellectual profile suggestive of a double dissociation of function consistent with the adult pattern. Hemiplegia-inducing lesions with seizures may have a mild effect on reducing overall intelligence (by about one standard deviation below the population mean), irrespective of hemispheric side of lesion and age at onset of seizures. The IQ profile in the hemiplegia with

P.1071

seizures subgroups, however, suggests that in larger cohorts, children with late onset of epilepsy (5 years and beyond) may demonstrate a similar double dissociation of function to those with late hemispherectomy and to adults with acquired lesions. These findings seem consistent with a model of constrained plasticity[3] or ontogenetic hemispheric specialization,[69] suggesting that the functional expression of the genetically determined process of hemispheric specialization gradually unfolds during early childhood, slowly acquiring the adult form from middle childhood onward.

Speech and Language

As was indicated for intellectual outcome, the level of speech and language competence achieved in the face of early unilateral insult is determined by the combination of a number of variables, most notably etiology and age at onset of pathology and, in the case of acquired lesions, hemispheric side of lesion. The primary focus of neuropsychological assessment for speech and language outcome after hemispherectomy is to guard against the development or exacerbation of any existing speech and language deficits by providing a detailed profile of linguistic abilities against the background of cognitive status, identifying the pattern of lateralization of language, defining the territory of eloquent tissue subserving motor speech functions, predicting the course and timing of any interhemispheric reorganization, and identifying rehabilitation and remediation techniques that may improve recovery and reorganization of speech and language function.

Pathology Affecting the Speech and Language Areas Bilaterally

Bilateral lesions restricted to the perisylvian speech and language areas are exceedingly rare, especially so in children. When such pathology occurs, in the context of either acute injury[34,73] or congenital or acquired pathology with epilepsy (i.e., Worcester-Draught syndrome, bilateral perisylvian/ frontal opercular syndrome, Foix-Chavany-Marie syndrome, Landau-Kleffner syndrome), it marks the limits of the reorganizational capacity of the immature brain to rescue speech and language functions. Children with this type of bilateral damage either fail to develop articulate speech[33,73] or lose the ability to speak and become mute after the onset of the acute injury.[34] The severe and chronic absence of spontaneous and clearly articulated speech is analogous to a severe expressive aphasia and/or dyspraxia of speech and contrasts sharply with the rapid resolution of such symptoms following unilateral lesions sustained in childhood. The persistence of the aphasic symptoms in pediatric patients with epilepsy raises the possibility of bilateral pathology and suggests that a viable neural substrate for the development of speech and language function does not exist within either hemisphere.

Table 4 Etiology of the acquired hemiplegia-with-seizures groups

Etiology	â‰¤5 years	5â€“16 years	Total

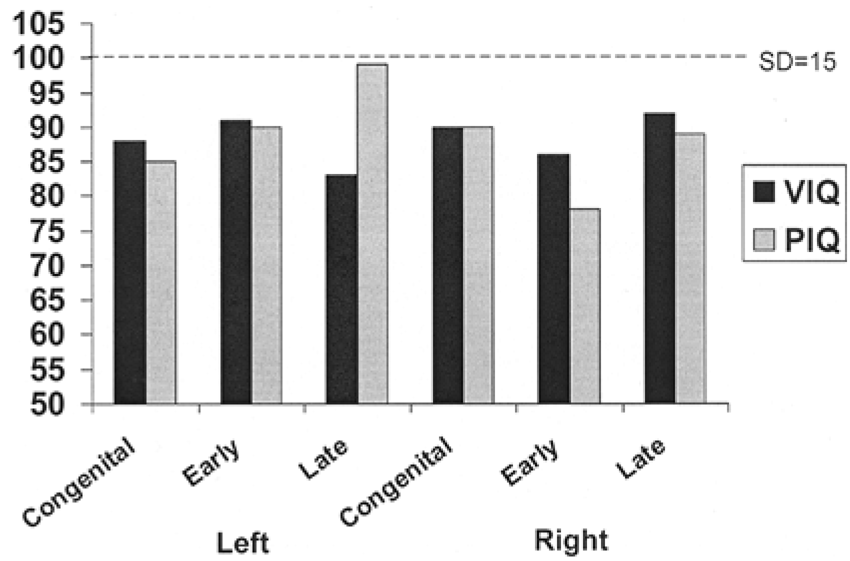

FIGURE 3. Verbal and nonverbal (performance) IQ (VIQ and PIQ, respectively) by age at onset and side of lesion in the hemiplegia group. SD, standard deviation.

Landau[33] described a boy who had cyanotic congenital heart disease. Until the age of 6, he had only developed a limited comprehension but no speech. He was judged to have normal nonverbal intelligence and no hearing impairment. Because his impairment appeared to be an aphasic disorder, at the age of 7, he received speech and language therapy and was reported to develop some useful, albeit limited speech and language.

At the age of 10, the patient died from complications of his cardiac abnormalities. At autopsy, examination of his brain revealed old, bilateral infarctions in the perisylvian regions with retrograde degeneration in the medial geniculate nuclei. The persistent aphasic disorder that failed to resolve with intensive therapy appeared to be the result of bilateral pathology of the perisylvian regions and the thalamocortical pathways.

Similarly, Vargha-Khadem et al.[71] described a young boy who sustained a traumatic birth injury that was reported to be limited to the frontal operculum (including Broca's area) on the left and the inferior precentral motor area on the right. This boy also received speech and language therapy but never developed intelligible speech or sign language.

Bilateral perisylvian polymicrogyria (BPP) is a malformation of cortical development frequently associated with severe dysarthria or anarthria. Patients with BPP have traditionally been considered to have severe learning difficulties. However, Jansen et al.[28] recently conducted a neuropsychological study of 14 adult patients with this diagnosis and demonstrated that only a minority had extremely low intelligence, and that some aspects of their cognitive function correlated with the extent of the cortical disorganization. In this cohort, early age of seizure onset correlated positively with nonverbal intelligence and negatively with the extent of the lesion. Receptive and expressive language skills were found to be equally impaired, but memory abilities and executive functions were relatively well preserved. This study provides further evidence that a malformation of cortical development in the bilateral perisylvian regions can lead to relatively specific aphasic symptoms in both children and adults.

Unilateral lesions also can produce aphasia if epileptiform activity spreads from one hemisphere to the other and thus acts like a functional bilateral lesion. This situation has been seen in pediatric patients with Landau-Kleffner syndrome, Sturge-Weber syndrome, and hemimegalencephaly. Typically, in children with Landau-Kleffner syndrome, speech appears to develop normally until seizure onset, when they become progressively or acutely aphasic as a result of bilateral interference with activity in the perisylvian regions by seizures emanating, in some cases, from the auditory cortex of one temporal lobe.[43,47] That the disorder is partly due to functional interference is demonstrated by the dramatic recovery of speech and language following successful abolition of the epileptiform activity by subpial cortical transection at the primary epileptogenic site.

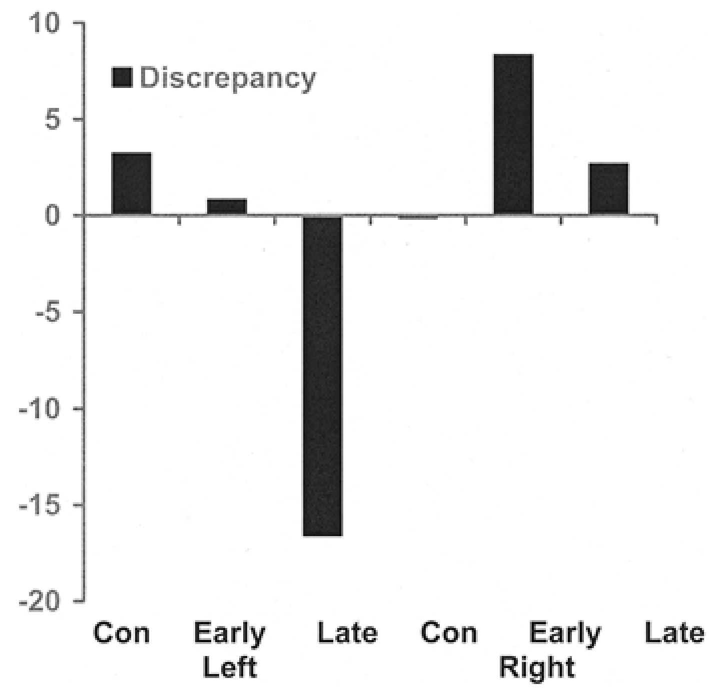

FIGURE 4. Discrepancy scores for verbal (V) minus performance (P) IQ for each of the hemiplegia subgroups (higher score indicates V > P discrepancy). Con, congenital.

Two cases of unilateral pathology resulting from Sturge-Weber syndrome in one and hemimegalencephaly in the other associated with mutism deserve mention. In both cases, mutism was resolved after hemispherectomy and successful abolition of seizures. Fusco and Vigevano[14] described a young girl who had left hemimegalencephaly, which resulted in epileptic discharges that at the age of 3 years spread from the left hemisphere to the frontocentral regions on the right, causing mutism in association with a bilateral frontal operculum syndrome. A few months later, she underwent a left hemispherectomy, which resulted in the abolition of her seizures, and the operculum syndrome resolved, as did her mutism.

Vargha-Khadem et al.[70] described an unusual case (Alex) that challenges the notion of an early critical period for the development of speech and language.[66] Alex had Sturge-Weber syndrome with a pial angioma over the left hemisphere. He did not develop speech as a young child, and at the age of 9.5 years had a mental age and receptive language skills of a 3- to 4-year old. He underwent a left hemispherectomy when he was aged 8.5 years and became seizure free. Shortly after prophylactic anticonvulsant medication was withdrawn, Alex started to speak for the first time in his life at age 9.4 years. Longitudinal examinations of Alex's speech and language functions into the second decade of his life showed that by the age of 15 years he had acquired linguistic abilities of a child aged 10 years. It is significant that Alex generated complex and grammatically formulated sentences, and his articulation was clear with very little evidence of dyspraxia or dysarthria.

The likely explanation of these reversible seizure effects is that the electrographic abnormalities (or their pharmacologic treatment) cause bilateral interference or even bilateral pathology.[70] Therefore the immature brain only has the potential for functional reorganization of speech and language if the thalamocortical systems are preserved and operational in at least one hemisphere.

Interhemispheric Reorganization

The combination of fMRI, neuropsychological assessments, structural MRI, and electrophysiology has made it possible for clinicians to evaluate the status of intra- and interhemispheric organization and reorganization of cognitive and motor function in pediatric patients undergoing epilepsy surgery.[24,26,37,38,41,54,61] The development of these convergent methodologies has reduced the need for some types of invasive investigations to determine lateralization of language and memory functions, such as the Wada test, and has paved the way for longitudinal investigations to track the processes of brain reorganization in the face of early onset epilepsy. In particular, the use of these noninvasive convergent methodologies has helped with (a) delineation of eloquent cortex that needs to be spared during resective surgery, (b) identification of abnormal cortex that is functionally active, and (c) tracking the process of interhemispheric reorganization of function.[38]

Traditionally, interhemispheric shifts in language dominance were thought to result from epileptic lesions encroaching on one or both of the classical language-eloquent regions rather than from lesions located remotely from Broca's and/or Wernicke's areas.[52] Clinical neuropsychologists may have used this evidence alongside handedness, dichotic fused words tests,[30] age at onset of chronic epilepsy, and site of EEG abnormality for predictors of language lateralization. This hypothesis has been recently challenged, however, by functional neuroimaging evidence indicating that in both pediatric and adult cohorts with early onset epilepsy, left- to right-hemisphere shifts in language dominance are more likely to occur in patients who have lesions encroaching the left hippocampus.[29,31,36,75] Hypotheses as to why this might be the case have been reviewed by Weber et al.[75] and include (a) the high degree of interictal epileptiform activity associated with temporal lobe epilepsy,[20,50] which leads to stronger involvement of the nondominant hemisphere in language,[53] (b) the diffuse ipsilateral hemispheric dysfunction that lesions in the hippocampus may cause due to its multiple reciprocal connections,[12,62] and (c) a potential role for the hippocampus in the acquisition of language.[65] It is interesting that neither handedness, age at onset of chronic epilepsy, nor site of EEG abnormality appears to be good predictors of language lateralization,[36] which highlights the need for links between cognitive neuroscience paradigms and techniques such as functional neuroimaging and traditional behavioral testing. Although the shift in language lateralization may be influenced by left hippocampal pathology,[75] the efficacy and speed with which reorganization is achieved may also depend on the frequency, severity, and spread of seizures.[29,75] For example, the catastrophic epilepsy associated with Rasmussen encephalitis (e.g., case PD[27]) may force right hemisphere mediation of linguistic function rapidly compared to seizure activity that is less frequent and less severe (e.g., case MPD[63]). Indeed, the shift in language dominance in the case PD occurred in a matter of weeks. Thus, from the onset of left hemisphere partial motor seizures at age 3.7 up to 4.1 years, each episode was accompanied by complete speech arrest with preservation of consciousness. When PD presented for hemispherectomy at age 4.2 years, however, the frequency of seizures (approximately 200 per day) continued unabated, but now during each episode the child was able to speak in clearly articulated short sentences. Following hemispherectomy, there was no deterioration in speech and language function, and PD continued to develop linguistic abilities in line with predictions based on his intellectual status. Clearly, reorganization of language function from the left to the right hemisphere in PD had been achieved over a period of 3.5 weeks.

Finally, it is usually assumed that when left hemisphere pathology is congenital or perinatal and is of an extent and severity that ultimately requires hemispherectomy, then there has been no interhemispheric reorganization to track.[70] This is because speech and language development will have been completely dependent on the function of the right hemisphere from the start.

Left Hemisphere Pathology

Unlike the situation in adults, unilateral left-sided lesions causing focal epilepsy in children do not appear to produce aphasia if they occur before speech has developed, provided the homologous areas on the right remain functional.[1,52,83] If extensive left hemisphere damage occurs after the onset of speech

but before the age of 4 or 5 years, then aphasic symptoms can result initially, but the symptoms generally resolve prior to hemispherectomy. There is usually postmorbid development of these functions to the extent that, as in patients with congenital or perinatal injury, there is no longer a selective dysphasia.[70] Indeed, language production in these patients may actually exceed their comprehension ability, which tends to fall together with the pathology-induced reductions in their intellectual level.

A mild version of the adult pattern of aphasia typically emerges when extensive left-hemisphere pathology is acquired after the age of 5 years. In such cases, speech arrest, transient mutism, anomia, and/or agrammaticism are seen, and these symptoms often remain chronic.[48,49,63] Basic speech tends to be a resilient function, however, with the patient usually being able to communicate effectively through short phrases and sentences. As indicated earlier (see section on intellectual outcome after hemispherectomy), none of the 15 left-hemispherectomized patients in the congenital and early groups suffered from dysphasic symptoms, despite very low levels of verbal intellectual ability in some patients. Such was not the case with the 4 patients who had onset of left hemisphere seizures after the age of 5 years, each of whom exhibited some degree of dysphasia (e.g., word-finding problems, mispronunciations, phonological errors, etc.) during free speech. Based on these and other data reported in the literature (e.g., Pulsifer et al.[51]), it is evident that the right hemisphere is capable of supporting *basic speech and language* skills from birth.

In a larger study of 31 children who underwent hemispherectomy (11 left, 20 right) with Rasmussen syndrome, Pulsifer et al.[51] reported that the left-hemispherectomy group scored consistently lower than the right-hemispherectomy group in receptive language and expressive language, despite there being no difference in terms of age at seizure onset (average 6.4 years), age at surgery (average 9.7 years), age at follow-up (average 14.7 years), or interval between surgery and postoperative evaluation (average 5.1 years).[51]

In summary, epilepsy-inducing pathology that occurs to the left hemisphere before the age of 5 years and certainly before the onset of speech appears to have little significance for long-term basic fluent speech and language. Difficulties with more complex aspects of language processing have been reported, but it is not clear whether these are significantly greater than the overall lowering of intelligence that frequently appears following any cerebral insult. Presumably, basic language processes are prioritized and spared due to either inter- or intrahemispheric reorganization so that neural substrates outside of the left hemisphere classical language areas support these functions. It is well documented that such compensatory processes also have a cost for nonverbal cognitive functions. Further studies are required of larger groups of children with different ages at onset of epilepsy to elaborate on the decline in available plasticity over the childhood years as brain organization emerges and cognitive processes become crystallized.

Right Hemisphere Pathology

Provided the left hemisphere is intact, right-sided lesions or removal of the hemisphere does not impair long-term speech and language regardless of age at onset of epilepsy or extent of lesion.[1,19,40,46,60,67,78] Right-sided pathology of congenital/ perinatal onset may result in delayed development of speech and language, but there are no *selective* residual dysphasic symptoms. As with pathology leading to removal of the left hemisphere, pathology and subsequent removal on the right at any age has an indirect effect on linguistic function that is related to the lowering of intelligence.[72]

When right-sided pathology is acquired early but after the onset of speech, there may be some initial language disorder such as disorganized speech or restriction of comprehension, presumably due to interhemispheric spread of epileptic activity, but these effects ordinarily resolve following right hemispherectomy and the arrest of epilepsy.

Compared to the investigation of linguistic functions in children, little attention has been paid to nonlinguistic abilities that are usually associated with right hemisphere impairment in adult-onset pathology. There is some evidence that children with congenitally damaged right hemispheres but without seizures present only with lower nonverbal intelligence compared to normal controls.[44] Groups of children with concurrent epilepsy, however, show both verbal and nonverbal intellectual impairment.[44,67] As discussed earlier, this may be due to the seizures interfering with the contralateral hemisphere, and individual variations are masked in large group studies of epilepsy.

Kohn and Dennis[32] reported that visuospatial processing skills might develop in children who have undergone right hemispherectomy up to a maximum of about a 10-year-old level. In a girl who had early right hemispherectomy, Day and Ulatowska[6] reported relevant difficulties with tasks requiring perception or visual-motor coordination. Chiricozzi et al.[4] reported case GT, who had hemiplegia resulting from neonatal ischemic infarction of the right middle cerebral artery. GT developed epilepsy at the age of 4.5 years that was well controlled with anticonvulsants until 10 years of age. GT underwent right hemispherectomy at almost 15 years of age. There was a significant improvement in GT's visuospatial skills following surgery (although they were still below average), suggesting that just as with speech and language, there may be a functional catch-up period that extends well beyond early development. It is not clear, however, whether the ultimate level of visuospatial processing achieved after successful surgical treatment and arrest of epilepsy is consistent with predictions based on intellectual status.

Summary and Conclusions

Neuropsychological evaluation plays a central role in the multidisciplinary investigation and management of children with epilepsy by providing appropriate assessment and advice to optimize the child's cognitive development, educational achievement, and behavioral and mental health function as well as informing decisions in pharmacologic and surgical treatment plans. By combining the advances in functional magnetic resonance imaging, structural MRI, and event-related electrophysiology with neuropsychological assessment, it has become possible for clinicians to evaluate the status of intra- and interhemispheric organization and reorganization of cognitive and motor function in pediatric patients undergoing epilepsy surgery and document the response of the immature brain to injury.

Unlike adults, children with early unilateral left-sided lesions (before the age of 5 years) and seizures do not show persistent deficits in verbal intellect relative to nonverbal intellect and do not demonstrate aphasic features when the left perisylvian regions are injured, provided the right hemisphere remains intact. It appears that fluent speech and language functions at a basic level are prioritized and rescued through a process of intra- or interhemispheric reorganization. Recent evidence suggests that injury to the left hippocampus may play a significant role in speech and language reorganization to the right hemisphere. The efficacy and speed with which reorganization occurs appear to be related to the frequency, severity, and spread of seizures. However, when the early lesion involves catastrophic epilepsy leading to hemispherectomy, the costs for general cognition are striking, with a dramatic

P.1075

lowering of overall intellectual function by between two to five standard deviations below the population mean. If such an epilepsy-inducing lesion occurs after the age of 5 years, as, for example, in Rasmussen encephalitis, there is still a significant lowering of overall intellect, but left-sided pathology has a relatively greater effect on verbal compared to nonverbal intellect, and the reverse occurs in right-sided pathology.

Epilepsy involving bilateral perisylvian regions in childhood can result in mutism or chronic aphasic symptoms similar to those reported in adults following unilateral left Broca's area and perisylvian injury. This also can occur with unilateral lesions in childhood when seizures and perhaps anticonvulsants impede the function of the contralateral hemisphere, this in effect acting like a functional bilateral lesion. Finally, provided the left hemisphere is intact, right-sided lesions or removal of the hemisphere does not impair long-term speech and language regardless of age at onset of epilepsy or extent of lesion. There is some evidence that late right-sided lesions affect aspects of nonverbal processing, although this has not been studied to the same extent as speech and language.

In summary, the findings discussed in this chapter appear consistent with a model of ontogenetic hemispheric specialization, suggesting that the functional expression of the genetically determined process of hemispheric specialization gradually emerges during early childhood, slowly acquiring the adult form from middle childhood onward, with some potential for plasticity and reorganizational capacity early in life, depending on the nature of the brain injury. Contemporary clinical neuropsychological evaluation of children with epilepsy, particularly for children pre- and post-neurosurgery, depends on close collaboration with cognitive neuroscientists so that convergent methodologies are used to help delineate the relationship of pathology, epilepsy, and cognitive development.

Chapter 92

Options for Long-Term Monitoring

Alan D. Legatt

John S. Ebersole

Introduction

Analysis of the electroencephalogram (EEG) during seizures may be crucial in the management of patients with epilepsy, especially those who are candidates for epilepsy surgery, and essential for the diagnosis of conditions that mimic epilepsy.[4,23] A standard EEG recording, lasting <1 hour, typically does not capture seizures. It may also miss infrequent interictal EEG abnormalities, which themselves contain important diagnostic information.

Long-term monitoring (LTM) permits analysis of infrequent ictal and interictal EEG patterns by recording a patient's EEG continuously for hours, days, or weeks on a storage medium from which selected segments may be subsequently retrieved and analyzed. When it is combined with continuous recording of audio and video signals from a closed-circuit television (CCTV) system, the semiology of the episodes can be examined and correlated with the concurrent EEG patterns. Analysis of seizure semiology is also of great value in the differential diagnosis of epilepsies and the conditions that mimic them.[80,134]

An advantage of LTM, in addition to the increased duration of the recordings, is that it permits EEG analysis during the full sleepâ€"wake cycle. Some patients with epilepsy have almost exclusively nocturnal seizures.[11,31,95,101] The clinical and EEG manifestations in others predominantly occur after[92,95,137] or shortly before[19] they awaken in the morning. Infrequent interictal epileptiform discharges (IEDs) may be activated by sleep, particularly non-rapid eye movement (REM) sleep,[77,86,113] and in some patients may appear only during sleep.[36] However, spikes recorded during slow-wave sleep may have less localizing value than those recorded during REM sleep and wakefulness.[113] Long-term monitoring can also distinguish sleep-related nonepileptic events that resemble epileptic seizures (see Chapter 276).

Applications

Long-term monitoring is used in a variety of clinical settings. The techniques used and the information sought from LTM vary according to the clinical situation in each case.

Seizure Classification and Quantification

Long-term monitoring with CCTV and EEG may facilitate patient management by permitting more accurate classification of seizures and thus more appropriate therapy. For example, complex partial seizures can resemble the absence seizures of primary generalized epilepsy, but they are treated differently. Distinguishing between partial seizures with rapid secondary generalization and primarily generalized seizures also has important therapeutic implications.

Long-term monitoring can be used to distinguish epileptic seizures from intermittent nonepileptic behavioral alterations that resemble epilepsy. Although specific ictal behaviors suggestive of psychogenic seizures have been described,[44] they are absent in many, if not most, patients with psychogenic seizures.[71] It may be impossible to distinguish between psychogenic and epileptic seizures on clinical grounds alone without LTM.

Because epileptiform discharges occur in people who do not have epilepsy,[24,48] including those who have psychogenic seizures,[105] LTM may be required to record seizures and confirm a diagnosis of epilepsy even if a routine EEG shows such epileptiform discharges. Psychogenic and epileptic seizures may coexist. Although some investigators have claimed that this is rare,[72] others report that a substantial percentage[20,65,93,105,132] or even a majority[56,109] of patients with confirmed psychogenic seizures also have, or have had, epileptic seizures. Thus, LTM may be necessary in a patient with known epilepsy if the current episodes are suspected of being nonepileptic. For example, if seizure frequency increases in such a patient despite an unchanged treatment regimen or if new episodes that differ from the previous seizures develop, the nature of the current episodes must be determined. Increased epileptic seizures might require increased doses of antiepileptic drugs (AEDs) or other therapeutic alterations. Increasing the AED dose in a patient with psychogenic seizures does not benefit the patient and may lead to drug toxicity.

Long-term monitoring may be used to quantify seizures such as subtle infantile spasms[43] or frequent brief absences that are not clinically obvious but interfere with a child's school work.[50,69,120] It may also be used to assess the response to AEDs.[97,120] Quantification of seizures and measurement of blood AED levels when the AEDs are being administered by hospital personnel may be of value in cases in which patient compliance with the medication regimen and the validity of information provided about seizure frequency are both questionable.

Identification of Interictal Epileptiform Discharges

Identification of IEDs is useful in the assessment of patients with epilepsy,[29,52,62,111] and it is also important in some patients who have not had seizures (Chapter 73). For example, the presence of IEDs in a child with language regression from a normal baseline but no history of seizures establishes a diagnosis of Landau-Kleffner syndrome.[12]

Interictal epileptiform discharges may be infrequent, and often they do not appear in routine EEG studies of patients who are known to have epilepsy. A single EEG demonstrates IEDs in approximately 30% of adults with partial seizure disorders.[2,112] The yield is higher when the patient is a child[2,22,138] or has a generalized seizure disorder.[121,138]

P.1078

Sleep and sleep deprivation also increase the yield of IEDs.[22,41,84,115,138] Multiple routine EEG studies are of limited value, and may fail to demonstrate IEDs in as many as 41% of patients with partial epilepsies.[112] Of patients in whom IEDs are detected by routine EEG studies, the first EEG shows them in 45% to 81% of cases.[112,114,121,138] Four EEGs identify 92% to 99% of patients in whom IEDs are ultimately found by routine recordings; each subsequent recording offers a minimal additional yield. Long-term monitoring covering the entire 24-hour day may demonstrate rare IEDs in patients in whom the results of repeated routine EEGs are negative.

Presurgical Evaluation

Long-term monitoring is used to record seizures and localize their origin in patients with medically intractable seizures who are candidates for epilepsy surgery (see Chapter 169). Among epilepsy surgery centers responding to a 1991 survey,[76] 81% always used CCTV-EEG monitoring in the preoperative evaluation of patients with limbic epilepsy, 15% used it sometimes, and only 3% reported that they never used it. Multiple seizures must be recorded[103,128] to ensure that they all arise from the same focus or, if they do not, to quantitate the relative activities of the various seizure foci. Seizures that occur in clusters or flurries are more likely to arise from the same focus and thus carry less localizing information than seizures that are widely separated in time.[51] A patient with partial epilepsy with multiple foci may still be considered a surgical candidate if the vast majority of the seizures come from one resectable site.[117] Because seizures are only rarely captured during routine EEG, LTM is a necessary prelude to surgical treatment in most patients. Long-term monitoring using implanted (subdural and depth) electrodes may be necessary if the data from less invasive (e.g., sphenoidal) and scalp electrodes are not sufficiently localizing. In the 1991 survey, 92% of the epilepsy surgery centers reported that they used invasive recordings in at least some cases, although not necessarily in all patients.[39]

Although unilateral IEDs may have substantial localizing value,[62] examination of IEDs is generally not regarded as sufficient for localization of the seizure focus before surgery. In one study,[136] the lateralization suggested by interictal recordings alone was misleading in 8 of 67 patients with clear unilateral temporal lobe epilepsy. Moreover, many patients with good outcomes after temporal lobectomy have independent bitemporal IEDs on preoperative EEGs.[29,117,123,136] Long-term monitoring shows a unilateral origin of the seizures or a strong lateral predominance in about half of the patients with bitemporal IEDs when only extracranial electrodes are used and in approximately 75% when depth electrodes are used.[54,116] The degree of lateralization of IEDs may have prognostic significance for patients undergoing temporal lobectomy[10,29,45,52,104] even if LTM with depth electrodes shows unilateral seizure onsets.

Intensive Care Unit Monitoring

Long-term monitoring is also used in neurological[53,60,96,130] and neonatal[124] intensive care units (ICUs) to identify deterioration of cerebral function, titrate drug doses for barbiturate coma, detect seizure activity in comatose patients, and confirm that treatment for seizures is successful. If a patient in status epilepticus has been treated with high doses of barbiturates, benzodiazepines, or other sedative or anesthetic drugs, continued obtundation could be a consequence of either medication effects or continued seizure activity. Only the EEG can distinguish between these and guide further treatment.

Seizures cannot be identified clinically in patients who have been pharmacologically paralyzed. When status epilepticus is prolonged, continued electrographic seizure discharges may not produce clinical seizure activity, even in patients who are not paralyzed.[25] Because status epilepticus can cause brain damage even in the absence of overt convulsions and metabolic derangements,[61,66,133] it must to be detected and treated. EEG monitoring demonstrates nonconvulsive seizures, including nonconvulsive status epilepticus, in a substantial percentage of neuro-ICU patients.[61,130]

Technical Aspects

Recording Techniques

During LTM, surface electrodes are securely attached to the patient's head, typically with collodion, to permit prolonged EEG recordings. Electrode impedances should be both low and balanced to minimize noise and maximize the effective common mode rejection ratio of the recording system.[70] Open-hole cup electrodes are used for recordings lasting days to weeks, so that the electrodes can be periodically regelled. The quality of the recordings must be continually assessed so that electrode maintenance can be performed as soon as possible if the data deteriorate.

The patient's head is wrapped to protect the electrodes and to prevent infection when implanted electrodes are used. Strain relief loops to secure electrode lead wires are especially important when implanted electrodes are used. In patients who become confused or combative during or after seizures and who might pull on the lead wires of their implanted electrodes, judicious use of restraints may be necessary to prevent self-injury.

Multichannel EEG data are amplified, undergo initial bandpass filtering, and are recorded on a storage medium, most commonly magnetic tape. Guidelines for amplifier specifications for LTM have been published.[7,37] If the EEG signal is digitized, the analog-to-digital converter must satisfy the Nyquist criterion: The sampling rate for each input channel must be at least twice the highest frequency present in the analog data. Long stretches of cable and wire will pick up electromagnetic and movement artifacts. The higher the amplitude of the EEG signals traversing these wires, the better is the signal-to-noise ratio. Therefore, preamplifiers placed close to the recording electrodes, either on the patient's head (within the head wrapping) or in an electronics package attached to the patient with a strap or belt, are preferable to remote preamplifiers. When the EEG signal is carried from the patient to the recording machinery by cables (cable telemetry), careful attention must be given to patient isolation to prevent electrical hazards.

If radio telemetry is used, the data must be multiplexed; sample values from all the input channels are combined into a single radio signal. Multiplexing is also used for storage media in which a single â€œchannelâ€

contains all the EEG data, as in videotape recording systems; successive data values stored on the tape are derived from consecutive input channels, going from the first to the last channel and then back to the first channel again. The maximum frequency of the data stored for each channel, which must also satisfy the Nyquist criterion, is equal to the storage frequency (samples per second) of the tape divided by the number of channels that are multiplexed together.

The EEG may be recorded either in a referential format, with the same electrode connected to the input 2 of each channel's differential amplifier, or in a bipolar montage. The referential recording permits reformatting of the retrieved EEG data to any desired montage.[67] This requires carefully balanced amplifiers and high-fidelity recording and playback so that the calculated bipolar data will faithfully reproduce the signal that a bipolar

analog recording would have provided. A faulty reference electrode can make all of the recorded patient data uninterpretable. Thus, referential recordings are usually confined to a hospital setting (inpatient LTM or daytime intensive monitoring), in which the quality of the data can be assessed frequently and technical problems rapidly fixed. Additional recording channels may be used to record the electrocardiogram, electromyogram, respiratory activity, and other physiologic variables, as well as alarm or marker signals that can be triggered by the patient or hospital staff.

The EEG can be analyzed in real time by a computer program that identifies and marks probable epileptiform patterns (computerized EEG analysis is discussed in Chapter 95) for subsequent analysis. In an inpatient setting, the computer can alert the staff so that the patient's responsiveness, neurologic status, and memory can be tested during a seizure.

The EEG data were formerly stored on magnetic tape, but increases in the speed and capacity of computer disks have made them the preferred storage medium. Data storage in a random-access memory device such as a computer disk also has the advantage that any portion of it can be accessed quickly; with magnetic tape, winding to the desired part of the record can markedly prolong data access times.

When CCTV and EEG data are recorded concurrently, all data should include time markers[57] or other methods that permit them to be correlated or synchronized so that the temporal relationship between EEG changes and behavioral alterations can be examined. Many different kinds of CCTV instrumentation are available.[7,37] Cameras sensitive to low light levels or infrared illumination are useful for monitoring patients at night. Multiple cameras with remote-controlled pan and zoom permit recording of a split-screen image that contains both a close-up of the face and eyes and a view of the patient's entire body and that tracks patients' movements to keep them in view as much as possible.

Types of Long-Term Monitoring: Advantages and Disadvantages

Long-term monitoring procedures can be subdivided according to whether they are performed on an outpatient or inpatient basis and by the specific technology utilized. In outpatient LTM, the patient carries an electronics package and recording device. Initially the EEG was stored on magnetic cassette tape, but advances in semiconductor memory technology now permit ambulatory EEG (AEEG) recordings utilizing solid-state memory arrays. Inpatient LTM involves a hospital admission to a specially equipped monitoring unit in which the patient is monitored continuously for days or weeks. In an intermediate approach, which has been labeled daytime intensive monitoring,[110] the patient undergoes repeated prolonged EEG or CCTV-EEG recordings in the hospital but is not admitted to the hospital and goes home each night. The patient is encouraged to sleep during the recording session; antecedent sleep deprivation may facilitate this. When monitoring is performed in the hospital, either on an inpatient basis or as daytime intensive monitoring, the patient can be connected to the recording equipment with a long cable (an arrangement sometimes referred to as cable telemetry) or the data can be sent by radio or infrared telemetry from a transmitter worn by the patient to a nearby receiver and thence to the recording equipment. During cable telemetry, the same semiconductor memory technology used for AEEG can permit continued EEG recording for a limited time when the cable is disconnected, such as when the patient goes for a procedure in another part of the hospital.

Each of the LTM methods has advantages and disadvantages. For example, considerations of equipment weight and size, recording medium capacity, and battery life place limitations on the number of channels and the duration of recordings that can be obtained during AEEG monitoring, although both have been increased as the technology evolves. The decision about which method to use should include consideration of the particular clinical situation of each individual patient.

Coverage of the Circadian Cycle

Daytime intensive monitoring recordings are longer than standard EEG recordings, but they still cover a relatively small portion of the 24-hour day. Nocturnal seizures and IEDs, as well as those occurring on awakening in the morning, are more likely to be captured during continuous 24-hour recordings, either inpatient or ambulatory. Daytime intensive monitoring may suffice in patients who have frequent daytime events.

Changes in Patient Activity and Environment

One benefit of AEEG monitoring is that patients may be in their usual environments, with their usual patterns of activity, as the EEG is being recorded. Some patients with intractable epilepsies do not have seizures for several days when they are admitted to an epilepsy monitoring unit. This is likely related to the enforced change in daily activities, with decreased physical activity and increased bed rest in a patient who is required to stay in range of the CCTV camera. Less commonly, inpatient monitoring can remove environmental stimuli that trigger seizures. The issue of stress deserves special mention. Although being in an epilepsy monitoring unit itself constitutes a stressful situation for some, hospitalization may remove some of the patient's usual stresses. Patients with epilepsy often report that stress increases their seizure frequency, but studies that quantitatively examined this issue concluded that psychological stress does not increase seizure frequency in most patients, aside from indirect mechanisms such as stress leading to medication noncompliance or sleep deprivation.[90,91]

Closed-Circuit Television Recordings

One advantage of in-hospital LTM is the ready availability of concurrent CCTV monitoring. This is usually not feasible during AEEG monitoring, in which information about the clinical correlates of EEG changes is limited to recorded impressions of the patient and observers. Outpatient monitoring equipment with video recording capability is now available, but the requirement to keep the patient within the field of view of the camera may interfere with normal patterns of activity, limiting one of the benefits of AEEG monitoring. This equipment is most useful during sleep or at other times during the day when the patient remains in a fixed location for an extended period of time. If the camera and the AEEG recording system are separate, careful consideration must be given to time markers and the synchronization/correlation of the EEG and video data.

Number of Channels and Montages

If the number of data recording channels is small, the number of recording electrodes will be limited. This impairs detection of epileptiform abnormalities with restricted topographic distributions, as well as differentiation of brain activity from artifacts by inspection of the fields of the potentials. Extensive coverage of the head is especially important during presurgical evaluation: If a limited number of recording electrodes placed to cover the presumed seizure focus pick up the spread of the seizure discharge, whereas the earliest seizure activity actually begins elsewhere but is not recorded, then the LTM-based localization will be inaccurate.[102]

Early ambulatory cassette recorders had only 3 channels, which severely limited the extent to which the scalp EEG could be sampled. This was subsequently increased to 8 and then to

P.1080

16 channels. Since then, technological improvements have permitted digital AEEG recordings with as many as 32 channels.[46] Because the quality of the data is not monitored during recording, AEEG LTM should use bipolar rather than referential recording techniques. Retrieved data can be successfully reformatted if carefully designed bipolar recording montages are used.[58]

In-hospital cable or radio telemetry permits recording of 32, 64, 128, or more channels of data simultaneously, facilitating the use of electrodes more closely spaced than the 21 electrode positions of the International

10-20 System.[6] These added electrodes may more accurately localize the source of IEDs and electrographic seizures.[88] A large number of channels is generally needed for recordings from implanted electrodes during presurgical evaluation; such recordings are of necessity done on an inpatient basis.

Maintenance of Data Quality

When LTM is performed in a hospital setting, the EEG data are usually displayed in real time on monitors at the nursing station or EEG laboratory. Recording problems that develop during inpatient monitoring may be rapidly detected and corrected because of the real-time EEG display. In contrast, recording problems may remain undetected and invalidate much of the recorded data during AEEG monitoring.

Presence of Trained Observers

In the hospital, specially trained personnel are present to evaluate patients during seizures. They also may recognize behavioral changes that require analysis at times when the patient has not pressed the alarm switch and online computer analysis has not identified an unusual EEG pattern requiring attention.

Computerized Online Electroencephalogram Analysis

Real-time computer analysis of the EEG is usually performed during LTM in a hospital setting. It was not available during AEEG monitoring in the era of cassette tape recordings, but many digital AEEG monitors now incorporate microprocessors that perform real-time analysis of the EEG.[46]

Use of Invasive Electrodes

Invasive monitoring with depth electrodes or subdural electrode arrays (see Chapters 170 and 171) presents a risk for infection and other complications and requires careful medical supervision. Thus, it is always performed in an inpatient setting. Sphenoidal electrodes are also most often used during inpatient LTM, although successful AEEG monitoring with sphenoidal electrodes has been reported.[28,125] When cortical stimulation for localization of eloquent cortical areas is done extraoperatively before epilepsy surgery,[73,107,127] it is performed in an inpatient LTM setting.

Cost of Long-Term Monitoring

One of the major advantages of outpatient AEEG monitoring is economic. This may become an even stronger factor in the era of managed health care. Technical costs and the charges for interpretation of the LTM data are common to both AEEG and inpatient LTM, but the latter also incurs charges for the hospital room and charges related to the nursing and physician staff.

Yield of Seizures and Interictal Epileptiform Discharges

A few studies have compared the diagnostic yield of inpatient CCTV-EEG monitoring with that of AEEG monitoring or daytime intensive monitoring performed in the same patients. Inpatient LTM with cable telemetry identifies seizures and IEDs in the largest number of patients. For example, in a study in which patients were randomized to outpatient AEEG versus inpatient LTM,[49] seizures were captured in 85% of the inpatient monitoring sessions as compared to 61% of the ambulatory monitoring sessions; this difference did not reach statistical significance, however.

In the appropriate clinical settings, other types of LTM can provide the necessary diagnostic information in many patients, with a yield much higher than that of routine EEG. For example, AEEG LTM demonstrates seizures or IEDs in 1.7 to 2.5 times as many patients as do routine EEGs; the yield of AEEG LTM is 83% to 93% of that of CCTV-EEG monitoring with cable telemetry and is highest for patients with generalized EEG abnormalities.[18,34,35] The superiority of LTM over routine EEG is most pronounced when capturing seizures as opposed to IEDs. For example, in one study of 46 patients, none of whom had seizures during routine EEG with antecedent sleep deprivation, AEEG captured seizures in 7 patents; the yield of IEDs did not differ significantly between the two recording techniques.[75] Daytime intensive monitoring captured seizures in ten times as many patients as did routine EEGs in one study; this yield was 82% of that obtained with continuous EEG monitoring with radio telemetry.[98]

Daytime intensive monitoring may be particularly useful for patients with psychogenic seizures whose attacks can be provoked by suggestion.[14,64,82]

Data Analysis

For most of its history, the EEG has consisted of a paper printout, each page of which was scanned by the interpreter. This is not feasible during LTM, because of both the bulk of the resulting records and the time that would be required to scan through them. Long-term monitoring EEG data are stored electronically, and selected segments are displayed on a computer screen. Digital EEG offers several advantages: Data recorded in a referential format can be reformatted into a variety of bipolar and referential montages, permitting greater accuracy in the analysis of the EEG patterns. The filter and gain settings can be adjusted to obtain a more interpretable display; use of digital filters permits the phase shifts inherent in analog filters to be averted. Additional EEG display formats, such as spectral power displays and plots of spatial coherence, are also possible.

When CCTV-EEG monitoring is performed, video and audio records are analyzed and correlated with the EEG data. Seizures in which the onset of a focal electrographic seizure pattern precedes the onset of the clinical seizure provide more compelling evidence about the location of the seizure focus than do seizures in which the EEG is nonlocalizing at a time when the clinical seizure has already begun. The CCTV recordings can be shown to family members, coworkers, and friends of the patient to confirm that the semiology of the events occurring during LTM is the same as that of the patient's usual seizures.

Selection of Electroencephalogram Segments for Analysis

Visual inspection of all recorded EEG data is not feasible during LTM. Segments retrieved for analysis include those identified by the patient and (in the hospital) by nurses, physicians, and technologists as seizures or auras. Computer analysis of the EEG is used to identify additional segments containing possible seizures or IEDs[47]; it is most efficiently performed in real time, during the LTM. Because data segments not marked by alarm signals or by the computer are discarded without further analysis, computer algorithms are usually set to maximize sensitivity for seizure detection. Selectivity suffers as a consequence; many if not most of the EEG segments marked by the

computer will be found to contain no epileptiform abnormalities. Each retrieved EEG segment should begin before the onset of the clinical event or EEG abnormality that triggered its retrieval, to permit detection of subtle EEG alterations preceding the event and to serve as the baseline for recognizing changes in the EEG.

In the era of AEEG using magnetic cassette tape, the EEG waveforms were played though speakers as sounds to detect seizures; rhythmic seizure discharges sound like tones with a progressive change in pitch. The data were played back at a faster rate (speed ratio of 20:1 to 60:1) to bring the EEG background frequencies into the range of human hearing.[33] Real-time seizure detection during AEEG with digital technology obviates the need for such auditory analysis.

Interictal EEG samples in both the awake and asleep states should also be reviewed in patients undergoing LTM. The real-time computer analysis can be used to select the epochs to be examined to maximize detection of IEDs. Periodic review of interictal EEG samples also provides for repeated assessment of the technical aspects of the recording; faulty electrodes or other problems can be recognized and corrected promptly so that recordings of subsequent seizures will be optimal.

Data Storage and Archiving

All data recorded during LTM cannot be stored permanently because of storage costs and physical space requirements, as well as the cost of magnetic recording media (which can otherwise be erased and reused). However, samples of the patient's typical episodes should be stored in the event that they are subsequently needed for clinical or medicolegal purposes. Hard-copy EEG printouts do not have to be stored if they can be reproduced from electronically stored data.

Ancillary Procedures

In patients for whom the goal of LTM is to record seizures, intervals during which no seizures occur contribute little to the diagnostic workup but do increase the duration of hospitalization, the costs of LTM, and (for patients with implanted electrodes) the risks for infection and other complications. Several ancillary procedures can be used to increase the frequency of seizures, both epileptic and psychogenic, during LTM.

Other ancillary procedures, such as ictal single-photon emission computed tomography (SPECT)[13] (see Chapter 81) and measurement of serum prolactin levels[8] (see Chapter 194), help to characterize the patient's episodes more accurately. Because the SPECT radioisotope must be injected or the prolactin blood sample drawn when the seizure occurs, these tests are practical only during in-hospital LTM.

Antipileptic Drug Taper and Proconvulsant Drugs

Antiepileptic drugs may be tapered or discontinued to increase seizure frequency; in some patients, the taper may be started before admission to the epilepsy monitoring unit. Protective AED blood levels should be reestablished before discharge in patients with epilepsy. Concern has been expressed that AED withdrawal may activate seizure foci different from those producing the patient's usual seizures,[38] leading to misleading findings from monitoring. Subsequent studies have shown that, in most cases, the origins of the seizures do not change: Foci that produce seizures during AED withdrawal also do so at other times. However, partial seizures are more likely to become secondarily generalized, or to become generalized more rapidly, as AEDs are tapered and discontinued.[79,118] When AEDs are withdrawn, the semiology of the seizures should be examined to ensure that those that were captured are the patient's usual seizures. Antiepileptic drug withdrawal is discussed more fully in Chapter 118.

Proconvulsant drugs such as pentylenetetrazol were formerly used to activate seizures, but they have been found to have a substantial risk for activating seizure foci different from those producing the patient's usual seizures, thereby leading to false localization.[135]

Other Methods of Promoting Epileptic Seizures

Sleep deprivation is often used to promote seizures in patients undergoing LTM because it increases seizure frequency in some patients with epilepsy,[108,129] although a recent study of a group of patients with medically refractory partial epilepsy undergoing LTM failed to show an effect of sleep deprivation on seizure frequency.[78] Sleep deprivation also activates IEDs[41]; this effect is most pronounced for patients with relatively few IEDs at baseline.[84]

Other maneuvers that reportedly trigger the patient's seizures may be used during LTM. This is particularly useful in a patient with a stimulus-sensitive or reflex epilepsy. It has been estimated that seizures may be evoked by specific external stimuli in about 5% of people with epilepsy.[106]

Spell Induction for Suspected Psychogenic Seizures

During LTM, placebo procedures, such as intravenously injecting normal saline solution, rubbing an alcohol pad on the patient's neck, or placing a vibrating tuning fork on the patient's body or head, have been used in attempts to elicit psychogenic seizures.[64] The placebo is accompanied by the suggestion that it will bring on a seizure. The suggestion that standard EEG procedures such as photic stimulation and hyperventilation can trigger attacks may also increase the yield of psychological seizures, especially in patients who have had their typical attacks in a medical setting.[82]

Patients with epilepsy may be suggestible, and spell induction can trigger nonepileptic episodes in them as well. It must always be determined whether episodes precipitated by spell induction are the patient's typical seizures. Conversely, lack of a response to a trial of spell induction does not rule out the possibility of psychogenic seizures in the patient. Although it is rare, a true epileptic seizure can occur during spell induction, either coincidentally or as a reflex epilepsy triggered by the procedure used for spell induction (see Chapter 207 for further discussion).[132]

Monitoring of Other Biologic Signals

At least one data channel should be used to record the electrocardiogram, both to detect cardiac arrhythmias and to identify electrocardiographic artifacts in the EEG that might otherwise be misinterpreted as epileptiform discharges. Seizures can cause cardiac arrhythmias, which may even be fatal[59] (see Chapter 189), and primary cardiac arrhythmias can cause convulsive syncope.[74] If both EEG and electrocardiographic changes occur during LTM, their temporal relationship should be examined to determine causality.

In a patient with myoclonic jerks, recording one or more electromyographic channels from the involved muscle or muscles can document the timing of the jerks. The simultaneously recorded EEG can then be examined for antecedent spikes, which would signify cortical myoclonus. If facial or cranial muscles are involved, care must be taken that the muscle and movement artifacts produced in the EEG recordings are not misinterpreted as epileptiform discharges of cerebral origin. Accelerometers can also be used to detect limb movement.[42]

Polygraphic recording (Chapter 77) of multiple physiologic signals, including formal polysomnography with sleep staging, may be performed in conjunction with LTM. This can be especially useful in differentiating parasomnias from nocturnal seizures. Respiratory monitoring is also important during LTM

in patients who become apneic during seizures.[85] Polysomnography typically includes recording of electrooculogram, submental electromyogram, electrocardiogram, respiratory effort, air flow, blood oxygenation, expired carbon dioxide, and body or limb movements, with as few as six channels of EEG.[5] The larger number of EEG channels used for concurrent LTM enhances the detection and localization of epileptiform discharges with restricted topographic distributions.

Yield of Long-Term Monitoring

How does one assess the benefits of LTM? Many studies have attempted to do so, using a variety of approaches and definitions of benefit and yield. Comparisons between various reports are complicated by differences in the patient populations studied, the reasons for referral, the duration of the monitoring, and the monitoring techniques used.

Because one purpose of LTM is to capture seizures, one may ask how often this is accomplished. Although a single large study using ambulatory cassette EEG reported a relatively low yield of 34%,[126] most published studies report higher yields, with 50% to 96% of LTM recordings su- ccessfully capturing seizures, either epileptic or nonepi-leptic.[3,9,16,17,21,26,27,30,32,40,49,55,63,81,83,87,89,93,94,99,110,119,120,127] In one study, in which inpatient CCTV-EEG LTM had a 50% yield, routine EEG had captured seizures in only 2% of the patients.[81] Long-term monitoring is also used to record interictal EEG abnormalities. Interictal epileptiform discharges were identified by LTM in 25% to 40% of patients with normal routine EEGs in two studies.[17,87]

When the purpose of the monitoring is classification of a patients' episodes, LTM can establish a diagnosis in 50% to 95% of cases.[9,15,27,83,93] In 30% to 68% of patients, the findings during LTM may prompt revision of the previous diagnosis.[3,17,26,30,40,63,93,100,122,127] (One additional report[98] gives a much higher figure of 84%, reflecting a large number of patients thought to have a single seizure type in whom multiple seizure types were documented.) It should be noted, however, that in patients in whom LTM does not provide â€œnew information,â€ confirmation of the previous diagnosis might also be of clinical value.

Patients are referred for LTM for a variety of reasons, not just for seizure classification. Several studies have examined how often LTM fulfills its objectives by answering questions posed by the referring physician. This is accomplished in 60% to 88% of LTM recordings.[1,15,16,27,30,110,120,127]

The ultimate test of LTM is the degree to which it influences patient management and leads to improved clinical outcomes. Findings during LTM have been reported to lead to changes in treatment in 45% to 80% of cases.[1,15,17,27,63,68,127] Changes include modifications of the AED regimen and initiation of psychotherapy in patients in whom psychogenic seizures are identified. Most authors also consider epilepsy surgery to be a change in treatment resulting from LTM because surgery would not be performed without LTM. Studies that include many surgical candidates therefore tend to report high rates of treatment modification resulting from

LTM.

An improved outcome may reflect a reduction in the seizure frequency, a reduction in drug toxicity, or other factors that improve the patient's life, such as treatment directed at the causes of psychogenic seizures. Patients found to have nonepileptic events may derive benefits equal to or greater than those diagnosed with epilepsy.[81,131] Long-term monitoring has been reported to lead to improved outcomes in 30% to 74% of patients.[1,15,17,81,98,99,100,122] Reductions in seizure frequency and improvements in quality of life have been shown to persist in most patients during long-term follow-up.[100,122]

Summary and Conclusions

Technological advances have substantially improved both the quality and quantity of EEG data that can be recorded during LTM. During AEEG monitoring, which is relatively inexpensive, data can now be recorded from enough EEG channels to provide full coverage of each hemisphere. In a hospital setting, high-quality data from >100 electrodes can be acquired and correlated with CCTV data. Unassisted analysis of the huge amount of data acquired would be overwhelming, but parallel developments in computerized analysis of EEG data have permitted the online identification of suggestive EEG epochs for further analysis. Closed-circuit television recording also permits a detailed analysis of seizure semiology and confirmation that the episodes captured during LTM are the patient's typical seizures.

During LTM, the patient's EEG can be recorded throughout the 24-hour circadian cycle, increasing the probability of recording seizures and IEDs. Changes in the AED regimen, sleep deprivation, spell induction, and other manipulations can be used to increase the yield of epileptic seizures and nonepileptic events so that the desired diagnostic information can be obtained more rapidly. Recordings with depth electrodes and subdural electrode arrays, necessary for the evaluation of some patients before epilepsy surgery, can be performed only during inpatient LTM. Electrical stimulation for localization of eloquent cortical areas can also be performed in this setting.

Long-term monitoring is a valuable, and at times essential, adjunct to the diagnosis and management of patients with epilepsy.

Chapter 93

The Epilepsy Monitoring Unit

Gregory K. Bergey

Douglas R. Nordli Jr.

Introduction

Over the last two decades, advances in electroencephalography (EEG) and video-recording technology have fueled a dramatic evolution in the sophistication and number of epilepsy monitoring units (EMUs).[6,32] This chapter focuses on the specialized utility of such units. Other chapters in these volumes deal extensively with interictal EEG (Chapter 73), ictal EEG (Chapter 74), EEG mapping (Chapter 76), computer-assisted data collection and analysis (Chapter 95), the presurgical evaluation (Chapter 169), invasive monitoring (Chapters 170 and 171), and psychogenic seizures (Chapter 207). As a result, while these topics will be mentioned in the context of the EMU, reference should be made to other chapters for more detailed descriptions.

Previous guidelines for video-EEG monitoring have been published,[8] but the most recent ones are those of the International League Against Epilepsy's (ILAE) Commission on Diagnostic Methods Subcommittee on Neurophysiology for long-term monitoring.[33] The ILAE recommendations address monitoring both within and outside (e.g., intensive care unit [ICU]) the EMU (Table 1).

Purpose of the Epilepsy Monitoring Unit: Advantages and Disadvantages

There are two main groups of patients who benefit from inpatient video-EEG monitoring: (a) those in whom the diagnosis is in question or needs to be confirmed and (b) those in whom epilepsy surgery is being considered. Epileptic seizures are episodic brief events, with each ictus typically lasting 2 minutes or less. While the history remains the most important component of the initial evaluation, there are many instances where the clinical details are ambiguous or insufficiently detailed to allow a definitive diagnosis. Patients rarely have seizures during outpatient visits or, with notable exceptions (e.g., unmedicated absence seizures), during routine EEGs. The history may be vague or uncertain because the patient has limited or no memory of the event, there were no observers, or the seizure occurred at night. Multiple types of episodes are sometimes reported, further confounding accurate diagnosis. Interictal EEGs may be normal or show only nonspecific abnormalities. Indeed, even with repeat EEGs about 30% of patients with epilepsy have normal routine EEGs. While a normal EEG does not exclude epilepsy, it also does not assist in making a diagnosis when the question of epilepsy is unresolved. Increased restrictions on administering conscious sedation have made it much more difficult to obtain routine outpatient sleep recordings, which can increase the yield of interictal abnormalities.

The EMU offers the benefits of prolonged recordings with video correlations in a controlled inpatient environment (Table 2). While the recording setup necessarily restricts a patient's activity, this limitation is outweighed by the ability to reduce or withdraw medications if needed, something that is difficult to do safely in the outpatient setting. Simultaneous video recording greatly improves artifact recognition and reduces the likelihood that rhythmic or sharply contoured artifacts are misinterpreted as â€œepileptiform,â€ something that occurs more commonly with ambulatory recordings that do not include video. In addition to analysis of specific events, longer recordings improve assessment of interictal abnormalities. Medication changes can be implemented much more rapidly in the EMU than is possible in the outpatient clinic. In addition, one can more accurately determine the effects of medication. For example, patients who have their antiepileptic drugs (AEDs) discontinued may become aware of cognitive and other side effects that they had not previously recognized as drug related. Inpatient observation also allows trained professionals to interact and assess patients during seizures. This can provide valuable information regarding the precise nature of the ictal symptomatology and localization of the discharge. Also, if the EEG is screened by trained personnel (a frequent but not universal situation), inpatient monitoring may also help in differentiating and characterizing ambiguous EEG patterns. For example, interacting with children during bursts of diffuse rhythmic slow waves or slow spike-wave discharges permits alterations in responsiveness to be determined more accurately. Finally, inpatient monitoring allows alterations in recording methodology to be made â€œon the flyâ€ depending on the EEG findings. This may be particularly helpful in suggesting the use of additional electrodes or the use of polygraphic techniques in selected patients.

Disadvantages of video-EEG monitoring include the need for hospitalization and the inherent limitations on the patient's normal behavior. Antiepileptic drug withdrawal increases the risk of generalized tonicâ€"clonic seizures and status epilepticus. Even with prolonged recording after AEDs have been withdrawn, events that occur infrequently may not be captured for analysis.

Indications for Monitoring in the Epilepsy Monitoring Unit

Diagnosis

Many seizure disorders or epileptic syndromes can be accurately diagnosed from a careful history obtained from the

patient and family members who have observed the events. When seizures fail to be controlled with antiepileptic drugs, it is usually an appropriate time to reconsider the diagnosis. If additional history and routine interictal EEGs are not sufficiently helpful, inpatient video-EEG monitoring to capture typical clinical events should be considered to clarify the diagnosis. Such information can be very important as it often leads to changes in therapy.

Table 1 Recommendations Regarding the Use of the Long-term Monitoring Report of the International League Against Epilepsy's Commission on Diagnostic Methods Subcommittee on Neurophysiology

- Detection, characterization, and quantification on video-electroencephalography (EEG) of ictal events, including the appropriate activation procedures to elicit them in individual patients in whom the diagnosis of an underlying epilepsy has already been made, and when the type of seizure or syndrome is not clear
- Documentation of the electroclinical manifestations of habitual seizures including noninvasive and invasive video-EEG long-term monitoring during presurgical evaluations
- Differential diagnosis between epileptic and nonepileptic conditions, characterized by frequently and intermittently occurring behavioral changes including psychogenic nonepileptic events and sleep disorders, particularly those involving paroxysmal movement disorders
- Documentation of diurnal or circadian variation in occurrence of epileptiform paroxysms, in conjunction with pharmacologic interventions and/or of the effect of these interventions on diurnal or circadian behavioral changes
- Documentation of specific patterns in the occurrence of epileptiform paroxysms during sleep and/or of disruption of sleep architecture in so-called â€œcognitive epilepsyâ€ cases in the pediatric population.
- Monitoring in the intensive care unit (ICU) for the effectiveness of treatment of status epilepticus and for the identification of subclinical seizures and subclinical status epilepticus,

conditions that have been shown to be more frequent than usually thought in the ICU

From Velis D, Plouin P, Gotman J, et al. Recommendations regarding the requirements and applications for long-term recordings in epilepsy. *Epilepsia.* 2007;48(2):379â€“384.

Table 2 Epilepsy Monitoring Unit

Benefits

- Offers prolonged recordings with various recording arrays
- Provides video-electroencephalographic correlation of events
- Allows for antiepileptic drug withdrawal in controlled environment
- Assesses patient directly during events
- Assists in differentiation between epileptic and nonepileptic events
- Assists in classification of seizure type
- Helps with presurgical evaluations
- Has less artifact than ambulatory recordings
- Offers better identification of artifacts with video correlation

Disadvantages

- Requires hospitalization
- Limits patient activity
- Carries an increased risk of generalized seizures and status epilepticus
- May not capture infrequent events

Table 3 Seizures That May Be Difficult to Diagnose or Classify

- Absence seizures with automatisms vs. complex partial seizures
- Absence seizures vs. complex partial seizures with motionless stare
- Complex partial seizures without aura
- Frontal lobe complex partial seizures
- Juvenile myoclonic epilepsy and other myoclonic seizures
- Nocturnal seizures
- Seizures in infants and neonates
- Convulsive psychogenic seizures
- Nonconvulsive psychogenic seizures

Examples of seizures and syndromes that can be diagnostically challenging are listed in Table 3. Diagnosing frontal lobe seizures can be particularly difficult, as clinical manifestations often first suggest nonepileptic, especially psychogenic, seizures.[17,36] The nighttime occurrence of many frontal lobe seizures often further confounds the diagnosis as nocturnal paroxysmal events are difficult to characterize fully by history alone. Complex partial seizures are sometimes confused with absence seizures if they manifest as brief behavioral arrests with a paucity of automatisms and a short postictal period. Video-EEG monitoring usually makes this distinction readily apparent. Elderly patients with episodic events can also present diagnostic difficulty as alterations in consciousness can have multiple potential causes in this age group. Furthermore, descriptions of clinical semiology by elderly patients and their spouses are often incomplete or confusing. In one series,[22] video-EEG monitoring provided a definitive diagnosis in over 75% of a group of 94 elderly patients.

Classification

Accurate classification of the epileptic syndrome can be critical to effective management. For example, it is important to recognize that onset of generalized tonicâ€“clonic seizures (GTCSs) in adolescence can be a manifestation of juvenile myoclonic epilepsy (JME)[7] (Chapter 244). Myoclonic jerks are often underreported by teenagers and young adults with JME. Video-EEG monitoring, however, will frequently document the specific different seizure types (GTCS, myo- clonic, absence) that can occur in this syndrome. Diagnosis of JME has important treatment implications. Although seizures are readily controlled in 80% of patients, lifelong therapy is usually required even if the EEG normalizes, as sustained remission is uncommon in JME. Furthermore, failure

P.1087

to recognize JME can lead to use of AEDs that exacerbate seizures.

Psychogenic Seizures

The possibility of psychogenic seizures (Chapter 207) is an important indication for inpatient video-EEG monitoring. Patients with psychogenic seizures have often been treated unsuccessfully with multiple AEDs, sometimes for years. The EMU environment allows rapid withdrawal of AEDs and detailed analysis of the clinical events, including correlation with sleepâ€“wake states. This can be important as some patients report that their seizures occur during the night. Psychogenic seizures can occur at night, but they do not arise out of sleep. Any event arising out of sleep has a physiologic basis. It may be nonepileptic, but it will not be psychogenic. Video-EEG monitoring assists in making this determination. Arguably, the diagnosis of psychogenic seizures should not be made without video-EEG confirmation, because the implications for treatment are so very important. Frontal lobe neocortical seizures may have few if any recognizable ictal scalp EEG changes at onset. If no video record is available for review, they may therefore be misdiagnosed as psychogenic seizures. Reviewing the clinical manifestations of frontal lobe seizures reveals a stereotyped semiology that supports the diagnosis even if the EEG is not diagnostic. It must also be remembered that 10% to 40% of patients with psychogenic seizures also have epileptic seizures or epileptiform discharges on EEG.[19] Psychogenic seizures often occur early during the EMU stay, in contrast to epileptic seizures.[24] When the diagnosis of psychogenic seizures is established early in the monitoring stay, additional recording, off AEDs, is advantageous to determine if epileptic seizures coexist. Psychogenic seizures and other nonepileptic events are common in most EMUs, typically accounting for 20% to 30% of admissions.[2] Children in particular can have a variety of nonepileptic episodic events.[23] The video component is usually extremely helpful in allowing an accurate diagnosis to be made in children.

Sleep Disorders

Some sleep disorders include episodic events that can be confused with epilepsy.[21] If the EMU admission suggests a sleep disorder, then a formal sleep assessment with polysomnography should be performed (Chapter 276). Polysomnography cannot substitute for video-EEG monitoring, as the typical very limited number of scalp electrodes used for sleep staging is not sufficient in most instances to diagnose seizure disorders, and many false negatives occur. If sleep studies suggest a possible seizure disorder, then an EMU evaluation is necessary to evaluate this effectively.

Epilepsy Surgery

Candidates for epilepsy surgery require EMU evaluations. Multiple seizures must be recorded to localize the area of seizure onset reliably and to determine if seizures arise from more than one site. While interictal recordings provide useful supportive data (e.g., demonstration of a prominent unilateral anterior temporal spike focus), reliance on interictal recordings alone can be misleading; ictal recordings are necessary to make decisions relevant to epilepsy surgery. Withdrawal of AEDs is often required; seizures may not occur until several days after AED dosage has been reduced or stopped. Patients in whom ictal recordings fail to provide definitive localization, or patients with seizures arising in or near eloquent areas, will usually require placement of intracranial electrodes (depth arrays, subdural strips, subdural grids) (Chapters 170 and 171). Patients with intracranial electrodes, particularly those with subdural strips and grids, must be supervised closely to minimize infection, avoid injury, and preserve recording integrity.

Most patients being considered for treatment with the vagus nerve stimulator (VNS) will have had EMU evaluations to assess their suitability for resective surgery. Such monitoring is also important before VNS implantation to determine seizure type and to confirm that the medically refractory seizures are epileptic in origin, not nonepileptic events.

Components of the Epilepsy Monitoring Unit

Hardware and Software

The development of video technology and its adaptation to medical uses have been extremely important for epileptology. Long-term monitoring was first performed using cameras with mirrors to record the patient and the paper EEG record. Video cassette capability was a major technical innovation, as it allowed the EEG and video image to be stored on the same tape for split-screen viewing. Tapes still needed to be changed every 2 to 6 hours if continuous recording was to be maintained. The development of digital video images was a further important step in the evolution of EMUs. Early on, its main limitation was mainly that of storage: A typical day of 30 channels of EEG recording (200-Hz sampling) requires 1 gigabyte (GB) of storage capability. The addition of digital storage of video adds approximately 30 GB of storage per day. At one time this was a major consideration, and temporary storage on hard drives needed to be dumped routinely every 24 hours if continuous recording was to be maintained.

Today, both video and EEG are easily stored digitally and synchronized. EEG activity is typically sampled at 200 to 1000 Hz; higher sampling rates allow for more accurate analysis of higher frequency signals. Sampling should be at the Nyquist frequency, two times the signal frequency, to avoid aliasing and distortion or misrepresentation of the signal. A number of manufacturers provide equipment specifically designed with these capabilities. No longer do video tapes need to be scanned; digital video allows for rapid review and accession of selected time periods. While storage capabilities on computer servers now are in the terabyte range, the amount needed to store EEG is directly proportional to the number of channels and the sampling frequency. Although video storage requirements are still much greater than those for EEG, the capabilities available today allow for many days of continuous recording. Records are typically edited to reduce these requirements. Storage of 7 days of continuous 32-channel EEG (200-Hz sampling) from a single patient would typically require about 7 GB of storage capacity; storage of continuous EEG (without video) from ~100 channels sampled at 1,000 Hz (e.g., intracranial recordings) requires over 100 GB storage. A week of unedited video would require about 200 GB. Therefore, storage of unedited recordings (even EEG alone) requires transfer to external storage devices (e.g., external hard drives). The typical practice in most EMUs is to edit both the EEG and video portions for storage on a single DVD.

The development of infrared low-light cameras has allowed high-resolution black and white video images to be obtained during the night. During the day, color video is obtained routinely using the same camera. The â€œtwilightâ€ period can still be the most challenging. If the camera is still in the color format, resolution of the video image can be severely compromised. This can become an issue if hospital guidelines require

a light (e.g., a night light) to be on continuously in EMU patients' rooms, because this may prevent high-resolution nocturnal recordings. If lighting is used in patients' rooms, it should be of very low intensity and located so that it does not prevent the cameras from switching to the infrared mode at night. If this cannot be done, then lights should be extinguished at night.

Current cameras are unobtrusive and typically mounted in small ceiling domes so that camera movement is not apparent to the patient. This is in contrast to early setups, where a large camera hung from the ceiling and the patient was always aware of the panning and refocusing adjustments being made by staff. Attempts at developing cameras that can automatically â€œfollowâ€ patients as they move from the bed to chair or around the room are not yet reliable. Therefore, unless the patient is confined to bed (see Safety in the Monitoring Unit), it is necessary for staff to monitor patient movements and move the camera as needed. Autofocus capability is now routine, but manual zoom is still necessary if a specific region of the body (e.g., face) is of interest during the seizure. Multiple cameras can allow for separate but continuous monitoring of the whole body and face (or selected regions).

Amplifiers are designed to record broadband activity and are located off the head. In addition to the specific recording needs, amplifiers need to be able to record during cortical stimulation when stimuli can produce not only artifact, but also changes in capacitance. The ideal amplifier for EMU use is one where the recording can be restored rapidly to baseline after stimulation.

Early video-EEG by some manufacturers did utilize telemetry, but at present hard-wired recordings offer the best quality. Hard-wired recordings are particularly important with multichannel (often >100 channel) recordings using intracranial arrays. While modern equipment no longer makes it necessary for rooms to be electrically shielded, sources of 50- or 60-Hz (depending on the country) interference may be problematic on occasion and need to be removed. The cables for connection remain a vulnerable component as a source of artifact or basis for failure.

Early EMU video-EEG recording often used modified hardware that increased expense. Now off-the-shelf components can generally be used, allowing for easier upgrades and replacements. Different manufacturers use different software for processing and storing video and EEG data; no standard code exists. Manufacturers differ in their willingness to provide source code. Some provide downloadable software that permits review of recordings. There are also software packages now available that allow for review of EEG data from multiple vendors.

Video-EEG recording requires appropriate patient consent. The consent form typically includes statements that give permission to show videos at conferences and for educational purposes. If videos are to be used for enduring materials, there should be specific language in the consent form explaining this. Digitized EEG recordings used for research or study purposes need to be stored in an approved Health Insurance Portability and Accountability Act (HIPAA)â€"compliant data system, typically with all identifying headers removed.

Epilepsy Monitoring Unit Staffing

Patients may not know when they have experienced a seizure. While spike and seizure detection software and review of periodic epochs can assist in identifying unreported events, there is a definite benefit in having trained personnel observing the patient video monitors in real time. This not only allows for more accurate identification of clinical events, but it also permits assessment of the patient during the seizure and whether the patient is at risk for injury. This is particularly important for patients with intracranial electrodes. Qualified EEG technologists are essential to ensure that the recording arrays are properly placed and maintained. Recognition of artifacts and electrode problems, as well as simple daily maintenance, can often be done by other, less specialized personnel.

The Patient's Room

Because most patients admitted to the EMU are not acutely ill, patient rooms should be designed to be pleasant and comfortable. In-room accommodations should include a bed for a family member or friend. This not only makes a patient's stay more pleasant, but it can also greatly assist in seizure identification and minimizing risk of patient injury. The design of the room and bathroom should, in as far as possible, reduce the number of objects with sharp edges that could injure a falling patient. Unfortunately, carpeted floors compromise infection control and should not be used; padded tile is a suitable alternative. Cable TV and DVD players make a patient's stay much more enjoyable. As already mentioned, development of excellent infrared cameras has made it possible for the patient to sleep in low ambient light without compromising recordings.

Methods for Augmenting Seizure Frequency

Some patients, such as those with frontal lobe seizures or atonic seizures, may have sufficient seizures while on medication that an adequate sample of attacks can be readily obtained during a brief stay without AED withdrawal. This is especially true for young children. Other patients, however, although they have medically intractable epilepsy, might have only several seizures per month. They will typically require reduction of AEDs to obtain an adequate number of seizures for diagnosis, analysis, or presurgical evaluation. In years past, EMU stays of several weeks were not uncommon. Now, for a variety of reasons, which include the expense of monitoring and insurance reimbursement, typical EMU stays are much shorter, often less than a week. The requirement for obtaining an adequate number of seizures for analysis remains, however. If the question is one of diagnosis (e.g., determining if seizures are primary generalized or partial onset), then relatively few seizures may be necessary. Presurgical evaluations typically require a number of seizures, and even more if multifocal onsets are a concern. A comprehensive analysis concluded that recording five stereotyped seizures was presumptive indication of a single seizure focus (confidence interval [CI] 95%).[3] As already mentioned, evaluation of psychogenic seizures should include sufficient monitoring after AEDs have been discontinued to determine if there is a concomitant epileptogenic potential.

Antiepileptic Drug Withdrawal

Withdrawal of AEDs results in increased seizure frequency, but the time course of this effect is unpredictable. In patients with partial seizures, not only does the frequency of partial seizures increase, but also the frequency of secondarily GTCSs increases. This is particularly the case if AEDs need to be withdrawn completely. It is more common than not for patients with intractable partial epilepsy on AEDs to have good control of their GTCSs while continuing to have partial seizures. In the EMU, AED withdrawal may result in recurrence of GTCSs. Sometimes AED reduction without total withdrawal may be adequate to prevent GTCS. In diagnostic and presurgical evaluations, GTCSs are often not needed, but the need to obtain

multiple partial seizures for analysis within a reasonable time period may necessitate total AED withdrawal. With AED reduction may come the appreciation that drugs thought to have little benefit on seizure reduction were actually more efficacious (albeit not controlling the seizures) than previously thought. It may be advantageous to start reducing the dosage of drugs with long half-lives (e.g., phenobarbital, zonisamide) before admission, if this can be done safely, because it takes five half-lives to reach a new steady state.

Seizures may cluster.[12,13] Multiple absence and neocortical partial seizures are usually well tolerated, but recurrent mesial temporal regionâ€"onset seizures or multiple GTCSs in a given day may produce cognitive changes that can take days or even weeks to resolve. AED withdrawal carries the risk of status epilepticus, and benzodiazepines should be used appropriately, especially after several GTCSs, to minimize this risk.

An important question is, are the seizures that occur with AED withdrawal similar to those that occur with treatment? The detailed time-frequency patterns of seizure onset from a given seizure focus are not only consistent from seizure to seizure, but also do not change with AED withdrawal.[14] In addition, analyses from intracranial recordings suggest that although AED withdrawal increases the number of complex partial seizures and GTCSs, the duration of the complex partial seizures does not increase.[1,30] This is consistent with the idea that AEDs reduce seizure frequency and secondary generalization, but do not necessarily influence intrinsic seizure dynamics once the seizures have begun. For the most part, seizures that occur with AED withdrawal are similar in site of origin to those that occur on full AED regimens. However, the possibility that additional foci may become active with AED withdrawal should be considered, particularly if multifocal events only occur late in the monitoring period, after significant AED reduction.

Sleep Deprivation

Sleep deprivation is commonly used to increase the likelihood of seizure occurrence (Chapter 94). Interestingly, however, Malow et al.[20] were unable to demonstrate any significant increase in seizure frequency in EMU patients who were sleep deprived compared to those who were allowed to maintain their normal sleep patterns.

Scalp Recording Arrays: Additional Electrodes

The usual 10 to 20 recording array may be sufficient for determining if events are epileptic or nonepileptic events. However, additional electrodes, especially over the frontal, parasagittal, or anterior temporal regions, may be useful in improving seizure detection and localization. Several reports[15,31] have suggested that sphenoidal electrodes improve detection of mesial-onset temporal lobe seizures by 5% to 10% compared to routine scalp arrays. Others, however, have found that sphenoidal electrodes add little when compared to the yield following addition of anterior cheek electrodes.[4,18] Routine use of sphenoidal electrodes, which involves some discomfort, is not necessary in most patients.

Detecting Seizures

Some patients are aware when their seizure occurs and can reliably use the event marker. Many patients, however, may not recognize the occurrence of some or all of their seizures. The presence of friends or family in the room, and staff watching monitors in the EMU control room, can also increase the reliability of seizure detection. Subclinical seizures may still go undetected. These observations do not take into account the possibility that recording arrays may be suboptimal, or that some types of seizures (e.g., frontal neocortical, some mesial temporal) may have a paucity of scalp findings at seizure initiation.

Spike detection and seizure detection software can be linked either to record marking or alarms, or both.[10,27] When seizure detectors are linked to alarms, it is important to have the alarm threshold sufficiently high so that multiple false alarms do not occur.[25] The ideal seizure detection algorithm should be sensitive and specific, because false detections decrease utilization. The seizure detection algorithm should be tailored to the onset characteristics of seizures in individual patients. This is important because the seizure initiation pattern from a given focus in a given patient is stereotyped from seizure to seizure.[14] While detection is much more easily and reliably applied to intracranial recordings[11] where artifacts are minimized, detection algorithms can be tuned for scalp ictal recordings so as to have relatively few false alarms.[27]

Restarting Treatment

After gathering sufficient information for diagnosis or presurgical evaluation, EMU patients, most of whom have intractable epilepsy, need to be stabilized before discharge. One result of the evaluation may be a recommendation that the AED regimen be changed, and implementation of this can be started at the time of discharge.

Not all AEDs can be initiated rapidly. If carbamazepine has been totally withdrawn, then hepatic autoinduction may be reduced or reversed. This can occur within a week, so reinstitution may need to begin at dosages lower than previous maintenance dosages.[28] If the patient has previously been on lamotrigine for a number of months, reintroduction after EMU withdrawal does not require repeating the initial slow titration. Maintenance doses can be started without increased risk of severe hypersensitivity reactions (e.g., toxic epidermal necrolysis, Stevens Johnson Syndrome). Oral loading with phenytoin or valproate is possible. Bioequivalency studies of parenteral levetiracetam included a single dose of 1,500 mg given orally.[26] This demonstrated that a 1,500-mg oral dose reaches a C_{max} in 45 minutes. Studies of loading patients with oral levetira- cetam after EMU stays have shown this to be a well-tolerated approach.[16] Pregabalin can be started at maintenance doses and will reach a steady state in 30 to 42 hours. Reinitiation of topiramate, oxcarbazepine, zonisamide, and phenobarbital may need to be done more slowly and individualized according to patient tolerance. Patients should usually be advised to reduce their activities for the first few days after discharge to minimize risk of injury.

Safety in the Epilepsy Monitoring Unit

Patients being monitoring in the EMU are often at increased risk for falls, especially as their medications are reduced. Each patient should be assessed for this and treatment individualized. Patients with atonic, tonic, or frequent tonicâ€"clonic seizures should be closely attended when out of bed. When the patient is using the bathroom, the approach requires a compromise between appropriate privacy and the individual patient's seizure pattern. Bed rails should be up and padded when patients are in bed. As a general rule, patients should not be restrained. In rare instances, a vest may be used for defined periods; arms and legs should not be restrained, as this increases the risk of injury during a seizure. In limited and specific situations, protective mittens may reduce or prevent

removal or disruption of electrodes (particularly important with intracranial recordings). Staffing should be sufficient so that the majority of clinical seizures are promptly recognized. Many patients are confused postictally, and this is therefore a time when they may wander, attempt to remove electrodes, and are generally at increased risk of injury.

Vertebral compression fractures[34] and shoulder dislo-cations[5] are uncommon but well-recognized potential sequelae of GTCSs. Bone mineral density loss secondary to enzyme-inducing AEDs or other medications (e.g., corticosteroids) increase the risk of compression fractures. While close attention to preventing falls can reduce the risk of fractures of long bones, vertebral compression fractures and shoulder dislocations are a result of the muscular activity caused by convulsive seizures and cannot be prevented by rail padding or even constant nursing attention.

Summary and Conclusions

The utility of EMUs for evaluating patients whose seizures persist despite adequate medical therapy is well established.[9,33] In most patients, video data add considerably to merely obtaining prolonged EEG recordings.[35] In a recent analysis of 213 admissions, 87.8% of patients received a definitive diagnosis, with epilepsy diagnosed in 73.3% and excluded in 21.6%.[29] The EMU evaluation resulted in a change in treatment in 79% of patients. Patients who had only nonepileptic seizures had been treated a median of 9 years before admission for evaluation. This report underscores the fact that delays in accurate diagnosis may result in many years of inappropriate therapy. Patients who have seizures that fail to respond to AED therapy should be considered for EMU monitoring if the diagnosis is not clearly established, or if presurgical evaluation is a consideration. Advances in monitoring technology have contributed greatly to the increase in presurgical evaluations. The utility and benefits of long-term monitoring can improve accuracy of diagnosis, provide for more specific therapy, and avoid the pitfalls of misdiagnosis.

Chapter 94

Drug Withdrawal and Other Activating Techniques

Elson L. So

Bruce J. Fisch

Introduction

Activation in epilepsy refers to the evocation of behavioral or electroencephalographic (EEG) manifestations of epileptic seizures in an established epileptic substrate. In clinical practice, activation is useful if it evokes either behavioral changes or epileptiform EEG abnormalities. In addition, because certain kinds of activation are associated with specific kinds of seizures, successful activation alone can have diagnostic value even in the absence of EEG information. In some instances, identifying an activating stimulus is of therapeutic value to the patient, who can then avoid contact with the stimulus.

Activation is also a valuable tool for investigating human epilepsy. Functional neuroimaging of seizures using positron emission tomography or echoplanar magnetic resonance imaging virtually requires that seizures be activated during the procedure. In the epilepsy monitoring unit, activation can result in tremendous savings in professional and technical resources by facilitating an accurate diagnosis and shortening the length of hospital stay. In that setting, where pseudoseizure is often part of the differential diagnosis, the definition of activation is extended to include the activation of psychogenic nonepileptic seizures (PNES). The following is a review of activation techniques commonly used during long-term epilepsy monitoring.

Pharmacologic Techniques of Activation

Activation by Discontinuation of Antiepileptic Drugs

Studies in the literature concerning antiepileptic drug (AED) withdrawal generally fall into three categories, according to the rate and the purpose of withdrawal: (a) withdrawal during a period of months in patients whose seizures have been well controlled[2]; (b) withdrawal during a number of days to weeks as one AED is switched to another[12]; and (c) abrupt discontinuation to increase the likelihood of recording EEG discharges during long-term monitoring. Because the consequences of AED withdrawal may vary in these different clinical situations, this discussion is limited to rapid AED withdrawal during long-term monitoring.

Activation of Interictal Epileptiform Discharges

Patients with epilepsy often do not have spontaneous interictal epileptiform discharges (IEDs) on their routine EEG recordings. Such discharges are not present on the initial EEG recordings of about 40% of patients with newly diagnosed epilepsy.[52] Approximately 10% of candidates for epilepsy surgery do not have IEDs, even with long-term monitoring.[7] The possibility of suppression of IEDs by AEDs has often been raised.[80] Valproate consistently suppresses generalized spike-wave discharges.[29] Long-term treatment with carbamazepine seems to be associated with less frequent epileptiform discharges.[60] Intravenous phenytoin also can suppress generalized IEDs, but the effect is only transient, lasting for 10 to 20 minutes.[54] A single intramuscular dose of clonazepam has been shown in children to decrease significantly both generalized and focal epileptiform discharges.[8] Selective suppression of some types of epileptiform discharges by AEDs has also been observed. Lamotrigine selectively suppresses long episodes of epileptiform discharges, but not short episodes of discharges.[16] The effect of AEDs on cortical excitability has been studied recently in healthy volunteers by using transcranial magnetic stimulation.[39] The threshold for activating the motor cortex was increased with increasing total and free serum concentrations of carbamazepine and lamotrigine, although acute drug withdrawal decreased the threshold in only a small proportion of patients.

Barbiturate withdrawal in addicted persons who were nonepileptic reportedly has been followed by paroxysmal EEG activities.[86] However, according to currently accepted terminology, many of those reported EEG activities are nonepileptiform. Ludwig and Ajmone Marsan[44] observed that spikes developed after abrupt drug withdrawal in 10 of 13 patients who had had no EEG discharges while taking AEDs. A discrete epileptiform focus developed after drug withdrawal in 57% of all their patients. However, Gotman and Marciani[27] found no correlation between serum AED concentrations and spiking rate after tapering the dose. They showed that spiking activity increased after, and not before, seizure occurrence, and that the increase could last several days. Their findings raised the possibility that increased spike discharges previously attributed to drug withdrawal may have actually been a postictal phenomenon. Their method of computerized detection of spike discharges allowed them to quantitate IEDs continuously during several days. The application of this technology to a kindling model of epilepsy in cats yielded similar findings. Moreover, an earlier study showed that carbamazepine withdrawal in primate models of partial epilepsy failed to intensify spike discharges.[10] Epileptiform discharges that occur after seizure episodes may be more widespread in distribution or contralateral to the focus of seizure onset.[26] Localization of the surgical focus must not rely solely on these discharges.

Activation of Epileptic Seizures

Numerous studies have investigated the effect of discontinuing AEDs on seizure characteristics. The common experience among investigators is that fairly abrupt discontinuation of an AED does increase seizure frequency. However, disagreements exist about the factors most responsible for the increase. Some investigators observed that increases occurred early as AED dosage[50] or concentration declined, rather than when the dose became minimal,[87] and the exacerbation of seizure frequency

P.1092

was self-limited. It did not always persist toward the end of the tapering process. Hence, the increase in seizures has been attributed to a transient â€œrebound phenomenonâ€ similar to that seen in abstinence syndromes of drug addiction,[18,32] rather than to a loss of therapeutic effect. In a study of patients withdrawing from phenobarbital, Theodore et al.[75] also observed that seizure rates were highest when serum concentrations passed below 15 Âµg/mL, but not when concentrations were very low.

Other studies[5,51] have concluded that loss of therapeutic effect, and not rebound phenomenon, is the basis for increased seizures during AED withdrawal. They found that seizure frequency increased when serum drug concentrations became subtherapeutic and not as they were falling from their baseline values. However, it is difficult to compare these studies critically for the following reasons: (a) drug regimens were not the same between studies, (b) the order or rate of withdrawal was not uniform, (c) serum drug concentrations were not determined using identical schedules, and (d) definitions of withdrawal and baseline periods were either not reported or were dissimilar. Furthermore, the contribution of falling serum levels to seizure exacerbation cannot be completely discounted, because the observation periods in patients undergoing video-EEG monitoring are typically limited.

Despite the difficulty in attributing seizure exacerbation during withdrawal to rebound phenomenon, abrupt discontinuation of barbiturates[18] and benzodiazepines[32] is unequivocally known to produce an abstinence syndrome, with withdrawal seizures occurring even in nonepileptic persons. The seizures develop only within the duration of the abstinence syndrome. They almost always are generalized convulsive episodes without focal onset. Animal studies suggest that these seizures are subcortical in origin.[17] Hence, there is a theoretical possibility of nonlocalizing rebound seizures confounding the identification of the onset of seizures recorded during long-term monitoring. However, rebound seizures have been reported only in a setting of acute withdrawal from prolonged exposure to very high doses of barbiturates and benzodiazepines. Most cases involved short-acting barbiturates (e.g., secobarbital and pentobarbital) that are not used for chronic treatment of epilepsy. In patients with epilepsy who are taking clinically appropriate doses, the long half-life of phenobarbital probably prevents acute abstinence syndrome and rebound seizures from developing. In fact, seizures may not increase until several weeks after phenobarbital is discontinued,[75] whereas rebound seizures in persons addicted to barbiturates occur a few days after medication withdrawal.[18]

Concern has been raised about the possibility that AED withdrawal may precipitate seizures that are new and not typical of habitual or baseline seizures. However, the clinical and EEG onset characteristics of seizures following AED withdrawal are not substantially different from those of baseline seizures.[88] AED withdrawal does not affect seizure onset, although it does increase seizure frequency and duration and the chance of secondary generalization. Therefore, seizures precipitated by AED withdrawal are generally reliable for localization for epilepsy surgery, providing that their onset characteristics are verified to be identical to those of habitual seizures. Nonetheless, previously unrecognized seizure foci may appear after AED withdrawal. Spencer et al.[73] evaluated the video and depth electrode recordings of 71 baseline and 89 withdrawal seizures in 18 patients. During AED withdrawal, four patients had seizures with EEG or clinical features that were not typical of habitual seizures. One of these four patients had a poor surgical outcome despite the fact that the habitual seizures during baseline originated from a single focus. The authors warned that new seizure foci unmasked by drug withdrawal may be sources of recurrent seizures after surgery. In contrast, Engel and Crandall[14] reported a patient who did well after right temporal lobectomy despite clinically different seizures developing from the contralateral side during AED withdrawal.

The potential for withdrawal seizures appearing to be falsely localizing was assessed further by Marciani and Gotman[49] in 14 surgical candidates. The majority had bilateral independent foci on baseline scalp and sphenoidal EEG. Only one patient had a seizure that was unlike habitual seizures, and it arose from an independent focus. This particular seizure may not have resulted from AED withdrawal, because it occurred before the AED dose was substantially reduced. This observation was corroborated later by Marks et al.,[51] who found that most of the notably different seizures in their patients actually occurred outside the withdrawal period.

Nearly half of all patients undergoing AED withdrawal during long-term monitoring experience generalized convulsive seizures.[50] These seizures begin clinically and electrographically as partial seizures that are no different from the patients' habitual seizures.[49] The duration of either partial or secondarily generalized seizures is usually unaffected by AED dose reduction.[70,74] Antiepileptic drug withdrawal does not alter the pattern of ictal discharges at the onset of these seizures, nor does it hasten spread to the contralateral hemisphere.

The preceding evidence indicates that, with rare exceptions, seizures recorded during AED withdrawal are reliable for localization of the ictal focus. Nonetheless, regardless of the status of AED medication and the number of foci detected, recorded seizures should always be verified with the patient and with witnesses to ensure that they are the same as the patient's habitual and disabling seizures. If there is evidence of more than one ictal focus, further inquiry should be made to determine which seizures are primarily responsible for the patient's disability. Constant vigilance is needed so that occult seizure foci are not overlooked. In patients with multiple seizure foci, clusters of seizures precipitated by drug withdrawal may arise from only one focus. Haut et al.[30] initially reported that in patients with bilateral seizure foci, seizures that occur within 8 hours of each other are more likely to arise from the same side than seizures that occur more than 8 hours apart. However, their subsequent study demonstrated that mean interseizure intervals were not significantly different for concordant and discordant seizures.[31] The discovery of multiple ictal foci does not preclude surgery if it can be established that habitual seizures originate from one surgically resectable focus.[14,71] The identification of the predominant focus does not appear to be affected by seizure clustering.[31]

The profile of AED withdrawal seizures derived from the literature is based mainly on collective experience with intractable partial epilepsy. Therefore, the information obtained may not be applicable to patients with primary generalized seizures or other specific epilepsy syndromes. The effect of AED withdrawal on seizure types other than partial seizure disorders needs to be studied.

Potential Complications of Antiepileptic Drug Withdrawal and Methods of Prevention

Withdrawal of AEDs can result in major complications, some of which are life threatening. Of patients undergoing AED withdrawal, about half experience generalized convulsionsâ€"many of whom have never had convulsive seizures before withdrawal. Furthermore, seizures exacerbated by AED withdrawal may lead to seizure clustering in 50% of patients[19,66,87] and to status epilepticus in 3%.[61] The risk factors for seizure clustering are history of seizure clustering at home, mesial temporal sclerosis documented with magnetic resonance imaging, and more than one seizure onset zone.[31] The rate of AED withdrawal and the location of the EEG ictal onset are not risk factors for seizure clustering in the epilepsy monitoring unit.

It should be noted that even isolated seizure episodes can result in falls that cause fractures, joint dislocations, and external or internal soft tissue injuries. The elderly are especially susceptible to compression fractures of the vertebrae.[47] They

also may be more vulnerable to the cardiac and respiratory effects of convulsive seizures.

Many of the potential complications of AED withdrawal can be anticipated and prevented if patients are under continuous observation by experienced staff. Patient areas should be designed to minimize the risk for injury from falls or unrestrained postictal behavior. Patients should be accompanied when walking. They should be attended to after every seizure. The time of occurrence and the intensity of each seizure should be noted. When seizures are unacceptably prolonged or increasingly frequent, AED treatment should be considered. Theodore et al.[74] observed that generalized tonicâ€"clonic seizures that stop spontaneously do so within 2 minutes. They advocate the initiation of intravenous AEDs when generalized tonicâ€"clonic seizures last longer than 2 minutes. As a general rule, the authors of this chapter administer an oral dose of AED when two or more generalized tonicâ€"clonic seizures occur within 12 hours. When they occur within 2 hours, either an oral[78,79] or intravenous AED is given at a dose sufficient to achieve the desired serum concentration as promptly and as safely as possible. (As part of the protocol, intravenous access is established and maintained with a heparin lock when the patient is admitted.) The AED used in most instances is preferentially a drug that is being withdrawn. However, if intravenous administration is indicated, phenytoin is generally used, unless immediate cessation of prolonged seizures requires intravenous benzodiazepines. For the treatment of seizure clusters, sublingual lor-azepam in adults[47] or rectal diazepam in children[42] may be used.

To manage life-threatening complications of AED withdrawal, medical staff certified in cardiorespiratory resuscitation must be readily available. The monitoring laboratory must be equipped with instruments and medications for resuscitation. Benzodiazepines and short-acting barbiturates should be withdrawn cautiously, particularly if they are taken at a high dose because of the development of tolerance. Seizures and other symptoms of withdrawal may be particularly severe.[18,72] A state of agitation and dysphoria can follow carbamazepine withdrawal.[11] In our experience, temporary resumption of carbamazepine or the use of an oral benzodiazepine alleviates the symptoms.

If patients must be restricted to bed, complications of prolonged inactivity can be avoided by having them exercise in a recumbent position using a bicycle attached to the bed frame. The risk for major complications generally can be kept below 1% if the above safety measures are used.[47,50]

Procedure for Withdrawing Antiepileptic Drugs for Long-term Monitoring

As mentioned above, the rate and order of AED withdrawal in published studies vary widely. In most instances, the schedule of withdrawal differs according to the clinical judgment of the treating physicians. The approach to AED withdrawal can be individualized to achieve the goal of recording seizures promptly without undue risks for injury. Sometimes, medications can be reduced or discontinued on the day before admission if they unequivocally have had no effect on seizure frequency or if serum concentrations have been clinically negligible. When there is concern about the potential for injury during unattended seizures, at least one concurrent AED can be maintained or drug tapering deferred until after admission.

After admission, all AEDs can be tapered simultaneously by reducing one fourth to one third of the maintenance dose every day. The reason for tapering all AEDs at the same time is that peak activation of seizures can be delayed for weeks when concomitant AEDs are maintained.[5] The only AED that the authors usually discontinue abruptly is valproate. Clinical studies have shown that the pharmacologic effect of valproate persists beyond its complete elimination from the serum.[29,63] Because of the possibility of platelet dysfunction associated with valproate use,[41] it is generally preferable that it be withdrawn before epilepsy surgery is performed.

In some situations, only part of the AED regimen needs to be tapered, or a slower schedule than that mentioned above can be followed. This more cautious approach is warranted when the past history suggests that activation of status epilepticus is highly probable or when the risk for convulsion-related complications is unacceptable. Antiepileptic drugs should not be withdrawn if the patient is already experiencing daily seizures at the time of admission.

Activation with Parenteral Drugs

Before the advent of long-term monitoring, it was not feasible to record adequate amounts of spontaneous ictal and interictal activities for localizing surgical foci. Attempts were made to activate ictal and interictal discharges within a short duration of EEG recording by giving intravenous drugs such as pentylenetetrazol,[60] methohexital,[46] or megimide.[64] However, a retrospective evaluation of 133 patients with depth EEG recordings showed that only 60% of the pharmacologically induced seizures were localized to the same foci as spontaneous seizures. Moreover, resection of the pharmacologically induced seizure foci was associated with a risk for failure twice that associated with resection of spontaneous seizure foci. Thus, pharmacologic activation is not used routinely.

Other Activation Techniques

Sleep Deprivation

According to the literature review by Ellingson et al.,[13] sleep deprivation is effective in activating IEDs in persons with a clinical history of epilepsy. After sleep deprivation, interictal discharges developed in as many as 30% to 70% of those without discharges on the baseline EEG. King et al.[37] evaluated the yields of initial EEG and repeat sleep-deprived EEG in patients with newly diagnosed generalized epilepsy or partial epilepsy. Initial EEG documented IEDs in 68% of generalized epilepsy patients and 44% of partial epilepsy patients. Repeat EEG following sleep deprivation in those with a negative initial EEG detected interictal discharges in 75% of generalized epilepsy patients and 32% of partial epilepsy patients.

The yield of sleep-deprived EEG is higher than the yield of only repeating the EEG.[56,62] Roupakiotis et al.[62] also demonstrated that sleep deprivation is superior to sedation in enhancing detection of interictal discharges. Moreover, activation of discharges is not contingent on the occurrence of sleep during recording. Following sleep deprivation, interictal discharges appear even during awake recordings.[23,38,56,62,68,81] Therefore, sleep deprivation appears to have an inherent, but unexplained, effect on enhancing IEDs.

The benefit of sleep deprivation has also been observed in children,[6] but at least one study cast doubts on the value of sleep-deprived EEG in children. Gilbert et al.[25] reported that the odds of detecting IEDs are not different for sleep-deprived children, partially sleep-deprived children, and nonâ€“sleep-deprived children. However, their study was not blinded and the patients were not randomly assigned to undergo the three degrees of sleep deprivation.

Epilepsy patients commonly report the exacerbation or precipitation of seizures after lack of sleep. A prospective and longitudinal outpatient study of the effect of stressful life events on seizure frequency clearly disclosed sleep deprivation as a significant factor.[55] In another study involving patients who

had temporal lobe epilepsy, an increase in seizure frequency correlated with a decrease in the amount of sleep.[57] To reduce the duration of hospital stays, sleep deprivation is widely used to enhance the probability of seizure occurrence during video-EEG monitoring. Hence, when seizures have not occurred in the first few days of monitoring, we deprive patients of sleep about every other night until seizures begin to appear. Because there is no evidence that partial sleep deprivation is ineffective, 2 to 3 hours of nocturnal sleep and daytime naps are generally permitted. However, the value of sleep deprivation in the video-EEG setting had not been assessed formally until Malow et al.[48] conducted a prospective study that showed every other night of sleep deprivation had no enhancing effect on the frequency of complex partial seizures in patients with intractable epilepsy who were undergoing video-EEG monitoring. Also, sleep deprivation did not increase secondarily generalized seizure occurrence. It is not known whether reversing the sleep cycle by nightly sleep deprivation ameliorated with daytime naps would be effective in precipitating seizures. Furthermore, sleep deprivation may have a more consistent effect on the occurrence of primary generalized seizures than on partial seizures.

Hyperventilation

Hyperventilation is known to be the most effective method for activating ictal and interictal EEG abnormalities associated with typical absence seizures. According to Dalby,[9] hyperventilation activates seizures in more than 80% of children with untreated absence seizures. However, it has also been reported to activate almost any type of seizure.[20,53] Miley and Forster[53] found that hyperventilation activated interictal epileptiform activity in 6% of 255 patients with complex partial seizures and activated clinical seizures in 4%. Guaranha et al.[28] found that performing hyperventilation every 3 hours activated focal seizures in 25% of 97 patients. In each case, the activated seizure was similar to the spontaneous seizure. In contrast, Holmes et al.[33] reported that routine outpatient EEG with hyperventilation only activated seizures in 0.5% of 384 patients with partial epilepsy. Various investigators have emphasized the need for hyperventilation to be prolonged and intensive, particularly for activation of partial seizures.[64] However, hyperventilation should be avoided in patients with recent cerebral infarction, increased intracranial pressure, or poorly compensated cardiopulmonary disorders.

Lapses in consciousness during hyperventilation should not be interpreted as an epileptic phenomenon unless they are accompanied by typical epileptiform patterns. Epstein et al.[15] found that among 12 normal children they tested, all demonstrated an impairment of verbal memory, and eight failed to respond to repeated auditory clicks during periods of hyperventilation-induced EEG slowing. None of their subjects had automatisms or abnormal motor activity. In contrast, Lum et al.[46] found that in 22 normal children in whom hyperventilation induced an impairment of consciousness and high-amplitude rhythmic slowing, fidgeting, smiling, and yawning occurred frequently, as well as arrest of activity, staring, and oral and manual automatisms. It is also well known that hyperventilation at any age can trigger psychogenic pseudoseizures and a range of symptoms that include numbness, dizziness, tingling paresthesias, transient blurring of vision, and ringing in the ears.[24] Thus, it appears that episodes mimicking typical absence seizures, including automatisms, can occur during hyperventilation in normal children and that in such cases, only the EEG can reliably distinguish between those with seizure disorders and normal hyperventilation responses. It is also important to be aware that prominent pseudoepileptiform patterns, such as rhythmic midtemporal discharge, may be triggered by hyperventilation.[34]

Photic Stimulation

Photoepileptiform responses (light-induced responses containing epileptiform spikes or spike-and-slow-wave complexes) can be divided into four main topographic categories: (a) generalized; (b) bilateral, posterior dominant; (c) bilateral occipital; and (d) focal unilateral. Approximately 40% of bilateral responses demonstrate consistent asymmetries, particularly at the onset.[4] Rarely, a unilateral EEG seizure may follow a generalized photoepileptiform response in persons with a history of generalized epilepsy.[43] Most bilateral responses have a peak incidence between 6 and 15 years of age and occur frequently in siblings of probands, whether or not the proband has epilepsy. In most cases, therefore, bilateral photoepileptiform responses occur as variable phenotypic expressions of a genetic process that is independent of the genetic determinants of epilepsy. Photosensitivity is greatest between flash frequencies of 9 and 18 Hz, but nearly 50% of sensitive patients respond to frequencies up to 50 Hz, whereas the range of reactivity extends from 1 to >60 Hz.[36] Infrequently, patients may be sensitive to pattern viewing and not to photic stimulation. The most effective pattern is parallel lines. Responsiveness is increased if pattern movement or simultaneous photic stimulation is applied. Roughly one third of patients with stroboscopic light sensitivity demonstrate pattern sensitivity.[89]

Between 70% and 77% of persons with generalized photoepileptiform responses have epilepsy.[83] However, bilateral responses restricted to the occipital lobes are rarely associated with epilepsy. They usually occur in relatives of patients with photosensitive epilepsy.[84] Although it is traditionally taught that photoepileptiform responses that outlast the stimulus are more likely to be associated with epilepsy, recent studies have not confirmed this.[35,67] Similarly, patients who suffer from alcohol withdrawal without having epilepsy were once thought to have a high incidence of photoepileptiform response, but subsequent studies did not find this to be true.[21]

Nearly all persons with photosensitivity have idiopathic generalized epilepsy. When a seizure is elicited by photic stimulation, it is usually a primarily generalized tonicâ€"clonic, absence, or myoclonic seizure.[36] It is uncommon for photosensitivity to occur in partial seizure disorders.[45] A much smaller number of persons have idiopathic epilepsy with focal-onset seizures, particularly benign occipital epilepsy. Juvenile myo-clonic epilepsy is notable among the idiopathic epilepsies for having the highest occurrence of photosensitivity, with reports ranging from 17.4%[65] to 90%.[1] Photic stimulation rarely activates focal or unilateral occipital spikes. When this occurs, there is often a history of a lesion involving the occipital, parietal, or posterior temporal areas. The activation of a more anteriorly located unilateral lesion is extremely rare.[76]

During epilepsy monitoring, particularly for presurgical evaluations, it is important to note that photic stimulation may activate occipital seizures in patients with absence seizures who do not have occipital lobe lesions, in patients with migraine who do not have a history of spontaneous seizures, and in patients with benign partial epilepsy and exaggerated somatosensory-evoked potentials.[59]

Electrical Stimulation of Intracranial Electrodes

Electric stimulation of intracranial electrodes may produce responses that include (a) an afterdischarge, (b) the habitual aura with or without afterdischarge, or (c) a clinical and EEG seizure (see also Chapters 171 and 175). Afterdischarges appear as a rapid series of repetitive spikes that begin at the termination

P.1095

of stimulation, last at least 1 second, and arise from the stimulated electrode but may also involve adjacent electrodes. The afterdischarge is not a reliable localizing sign in depth electrode studies.[3,69] Indeed, the intensity of depth electrode stimulation necessary to induce an afterdischarge may be increased in the epileptogenic hippocampus. The localizing value of afterdischarge in subdural electrode stimulation is unclear. Our experience suggests that a lowered threshold to prolonged afterdischarges is usually concordant with the site of an anatomic lesion and is suggestive of good postoperative outcome in neocortical epilepsy. Otherwise, the value of afterdischarge is limited.

The localizing value of auras or seizures evoked by subdural electrode stimulation is unknown. In studies with depth electrodes, there is some agreement that neither auras nor seizures evoked by stimulating extratemporal sites have reliable localizing value.[3,22] As for the stimulation of temporal lobe structures, the value of electrically induced seizures is also doubtful. They are not reliable for determining the site of seizure onset in patients for whom results of previous, noninvasive EEG studies have been nonlocalizing.[69] Moreover, temporal lobe resections based on electrically induced seizures have a failure rate twice that of resections based on spontaneous seizures.[85]

Role of Activation in Psychogenic Seizures

Psychogenic nonepileptic seizures are the most common kind of nonepileptic attacks encountered at epilepsy centers (see Chapters 207 and 283 for further discussion). Such seizures typically account for 5% to 15% of inpatient admissions for epilepsy monitoring. The diagnosis of PNES is complicated by the common coexistence of epileptic seizures, which in some series occur in more than half of all patients with PNES.[40] Because most patients with PNES are responsive to suggestion, provoking attacks is usually not difficult. This has led to the common practice of using various methods of suggestion to diagnose PNES. The main argument against this practice is that some patients who do not have PNES, particularly those with psychiatric disorders or low intellectual ability, are also suggestible or may consciously fake an attack. Moreover, depending on how the suggestion is given, certain ethical concerns may arise.

There are many compelling reasons for inducing PNES by suggestion. At centers where this form of activation is not used, some patients have no spells after 10 to 12 days of monitoring. Thus, considerable medical resources are consumed without any apparent benefit. Because the recording of habitual spells is crucial in the evaluation of these patients, it is generally a greater disservice to forego a definitive diagnosis than to exercise the power of suggestion. Moreover, because the authors have not encountered and are unaware of any published report of the compromise of the physicianâ€“patient relationship as a result of the use of suggestion to induce spells, they sometimes employ the method of suggestion in cases of suspected PNES if spontaneous attacks have not occurred after several days of monitoring.

In the experience of the authors, the particular maneuver chosen for activation (e.g., injection of saline solution, pressing on the â€œgreater occipital seizure nerveâ€) is not important so long as the physician presents the suggestion in a credible fashion. This means that the patient must be told that the procedure may potentially cause a seizure. The activation procedure should not be performed without simultaneous video-EEG monitoring. Procedures such as the injection of saline solution may actually provoke epileptic seizures in 10% of patients with epilepsy and new nonepileptic spells in 15%.[82] Furthermore, new types of nonepileptic spells may be induced in 8% of patients with proven PNES. Therefore, it is essential that the recording be studied carefully and videotaped events be shown to witnesses of the patient's typical attacks to verify the relevance and significance of the induced seizures. However, it is important to emphasize that the recording of PNES does not rule out the presence of a coexisting epileptic seizure disorder.

Summary and Conclusions

The drive to reduce the cost of medical care has imposed major constraints on the use and methodology of long-term monitoring. Activation procedures are now used routinely to improve the cost effectiveness of long-term monitoring. Although requirements vary according to clinical situations, the general experience among epilepsy programs is that three or more recorded seizures are needed to help formulate a surgical decision.[77] Todorov et al.[77] also demonstrated that the mean duration of monitoring required to record one seizure is 2.9 to 3.7 days; to record three seizures, 4.5 to 5.5 days; and to record five seizures, 6.1 to 7.6 days. Rak[58] reported that at least 5.2 days are needed to establish the diagnosis of seizure, and 5.5 days to localize seizure foci. In an effort to meet these constraints, patient safety should not be overlooked as activation procedures are earnestly employed. It is best to individualize the AED withdrawal schedule and other activation procedures according to the medical condition of the patient and the type of seizures or epilepsy being evaluated. The monitoring staff must be prepared to address the potential limitations and complications of activation procedures. An important general caveat in the use of all activation techniques, particularly activation of pseudoseizures, is that the event elicited may not be related directly to the patient's spontaneous attacks.

Computer-Assisted Data Collection and Analysis

Pierre LeVan

Jean Gotman

Introduction

When evaluating patients with epilepsy, it is often important to obtain a thorough documentation of ictal and interictal electroencephalographic (EEG) patterns, preferably in conjunction with behavioral patterns. This is critical in the differential diagnosis of epilepsy and in the determination of the seizure type so that adequate medical treatment can be administered. An EEG investigation can also provide significant information for the evaluation of candidates for epilepsy surgery. Long-term monitoring sessions are commonly performed during which the EEG and the patient's behavior are observed and recorded continuously. During this time, all spikes and seizures are recorded, observers can interact with the patient during seizures, and EEG and clinical correlations can be performed fully. In some cases, a patient might be monitored during several days or even a few weeks. This might be necessary if a patient's seizures occur sporadically or if a patient suffers from multiple seizure types that need to be properly characterized. Prolonged monitoring might also be required to measure the effect of various antiepileptic drugs (AEDs). Continuous observation and recording of the EEG, typically with 32 to 64 channels, and of behavior during several days or weeks is an immense task. Continuous monitoring is expensive due to the requirements for considerable personnel and equipment during a prolonged period. If sufficient personnel are not available for constant observation, the following questions arise: Should the entire recording be reviewed, which is a very time-consuming task, or should a selective review be performed? If a selective review is performed, how is the selection to be made? Or should the recording be selective, including only the events of interest? Can these tests be performed efficiently and reliably in an outpatient environment?

It has become clear in recent years that computers can be extremely helpful in making the procedure of long-term epilepsy monitoring less tedious and less expensive. They can also assist in the review and analysis of the EEG of epileptic patients, and they can be used for data archiving. Behavioral video recording also can be performed with the assistance of computers. The first part of this chapter considers how computer-based recordings, particularly automatic methods for detection of spikes and seizures, can facilitate long-term epilepsy monitoring in the hospital and at home. The second part discusses the role of computers in EEG review, analysis, and archiving.

Computer-Assisted Long-Term Electroencephalographic Monitoring

In the past, a continuous recording lasting 12 to 24 hours, with the typical 16 channels, could be performed only with a traditional EEG machine and paper or with magnetic tapes running at very low speed. Both media have a limited channel capacity; paper in such a quantity is obviously cumbersome and expensive, and tapes have the disadvantage of being accessible only sequentially. Today, the capacity of computer disks is such that it is simple to perform a continuous 32-channel, 24-hour recording on a standard computer. A computer-based recording allows a flexible review procedure, with random access to any part of the recording and the availability of numerous methods of data manipulation and analysis (see the later section on analysis).

In most 24-hour recordings, 95% to 99% of the recording offers little useful information for the evaluation of an epileptic disorder. Automatic detection methods, despite their imperfections, can facilitate the recording, and thus the review, of valuable information. The recordings of seizures and of interictal spikes are discussed separately. Several reviews of automatic event detection in epilepsy and applications of computer methods to the analysis of the EEG in epilepsy have been published in the last few years.[30,40,41,52,75,122]

Recording Seizures

In the context of epilepsy monitoring, the term *seizure* must be defined. A behavioral seizure can be defined as the clinical manifestation of an epileptic seizure as perceived by the patient, seen by an observer, or recorded on video. The electrographic or EEG seizure can be defined as an abnormal, paroxysmal EEG pattern. In a large fraction of cases, behavioral and electrographic seizures can be observed simultaneously; this is why it has been possible to characterize the EEG changes specific to seizures. There are many cases, however, in which a discrepancy can be observed between behavior and EEG. Two types of discrepancy are possible:

1. A behavioral seizure can be present in the absence of visible EEG changes. If it is assumed that the seizure is indeed epileptic (the means of differentiating epileptic from nonepileptic seizures are not discussed here), then abnormal EEG activity is actually present somewhere in the brain. It is simply not available to the particular method of observation, that is, to the particular arrangement and location of electrodes. The discharge might, for instance, be limited to mesial frontal regions, whereas electrodes might have been placed only on the scalp or only intracerebrally in the temporal lobes. For the purpose of epilepsy monitoring, it must be clear that such a seizure will certainly be missed by observation, review, or computer analysis of the EEG alone.
2. An EEG seizure can be present in the absence of clinical manifestations. This is commonly referred to as a purely electrographic seizure or a subclinical seizure. It was argued in the previous discussion that an absence of EEG discharges can be a pitfall of the method of measurement

(a discharge can be present but not be discernible to the electrodes). It similarly can be argued that the absence of a behavioral seizure may be a pitfall of the method of observation: If a patient is lying in bed watching television, unresponsiveness, inability to speak or understand, and minor automatism or loss of muscle tone cannot be observed unless active testing is performed. Even giving correct responses to many questions does not exclude clinical signs; seizures involving only memory have been observed.[100] In other words, the presence of clinical signs is a function of the method of questioningâ€"hence the importance of recording all seizures, with and without overt clinical signs, and of observing them as precisely as possible. The importance of subclinical seizures has been discussed with respect to evaluation for epilepsy surgery.[115] It will be shown later how automatic seizure detection and seizure warning systems can be helpful in this situation.

It is thus obvious that all types of seizures, with or without clinical and EEG manifestations, ideally should be recorded.

Continuous Recording and Review

As indicated earlier, it is possible to perform a continuous recording on a computer disk for a period of 24 hours. This represents a large amount of EEG to be reviewed, but computer review on a high-resolution screen can be quite fast; 32 channels of EEG can be presented 10 to 20 times faster than real time, resulting in a review lasting 1 to 2 hours. However, such a fast review can result in small seizures being missed, particularly when the number of channels goes beyond 12 or 16.[101] The period of 1 to 2 hours just mentioned does not include the time required for the analysis of seizures or other potentially interesting events. Therefore, the full review of a 24-hour recording is quite time consuming and strenuous. Alternative strategies have been developed by many institutions.

These strategies consist mainly in using a partial review with an attempt to select the most relevant sections. The most important sections are, of course, those during which the patient or an observer noted a behavioral seizure. In addition, randomly selected sections are often reviewed as well. As discussed previously, this entails the significant risk that seizures of which the patient is unaware and that are not observed will be almost systematically missed. This might be an acceptable compromise if the patient is under close observation, but it could be quite dangerous otherwise.

Automatic Detection of Seizure Patterns

Some methods of seizure detection are based on behavioral manifestations of seizures; mechanical sensors under a mattress can detect the strong rhythmic movements of generalized tonicâ€"clonic seizures. The limitations of this kind of method are obviousâ€"many seizures do not include such strong movements. This discussion concentrates on seizure detection methods based on EEG analysis. As indicated earlier, some seizures do not have EEG changes, and EEG-based methods cannot be expected to detect them. There are also seizures that have mild or nonspecific changes, such as brief desynchronization, or groups of theta or delta waves.[4] These EEG patterns are only interpreted as being abnormal in the context of a concomitant clinical event. This makes it very difficult for an automated seizure detection system to differentiate these seizure discharges from normal EEG patterns because the computer does not take into account clinical information when analyzing the EEG. There are thus limitations to seizure detection by EEG; fortunately, these limitations are not very significant, because the vast majority of seizures are associated with clear and relatively specific EEG changes.

The problem of seizure detection is inherently difficult because seizure activity can comprise a variety of morphologies; unlike spikes, which have relatively well-defined characteristics, seizures can include patterns such as low-amplitude desynchronization, polyspike activity, rhythmic waves at a wide variety of frequencies and amplitudes, and spikes and waves.[13] In extracranial recordings, seizures are often obscured by electromyographic, movement, and eye blink artifacts. From the point of view of pattern recognition, the problem is therefore complex. We first discuss the methods of detection, and then address the complex issue of establishing these methods in a practical clinical context.

Methods of Seizure Detection

Early methods for seizure detection relied on relatively simple measurements of amplitude. Because an increase in amplitude is fairly common in the ictal EEG, such systems could successfully detect many seizures. Prior et al.[103] described the use of their cerebral function monitor to identify generalized tonicâ€"clonic seizures; these could be recognized on the tracing as a large increase followed by a clear decrease in EEG amplitude (the postictal depression) and by increased electromyographic activity. Such large seizures with major changes could also be identified in monkeys with experimentally induced epilepsy by a characteristic pattern on slow paper tracings (0.25 mm/s).[38] Ives et al.[63] described a method in which 16 channels of EEG were added, bandpass filtered, and subjected to amplitude discrimination. This technique could detect large seizure discharges but was quite insensitive. Babb et al.[8] implemented an electronic circuit for the detection of seizures in recordings from intracerebral electrodes. A seizure was recognized when a rapid succession of large-amplitude spikes, lasting at least 5 seconds, was found.

More sophisticated systems computed several features of the EEG to recognize seizure activity. Murro et al.[93] described a method based on spectral parameters and discriminant analysis. Gotman[37,43] presented a computer method that attempted to recognize a wide variety of seizure morphologies, identifying patterns that might represent seizure activity for later examination by traditional visual inspection. The method was therefore designed to be as sensitive as possible. False detections, as long as they were not extremely frequent, were not detrimental because they could be removed in an ensuing visual review of the detected events. Observation of numerous seizures led to the conclusion that most seizures, at some time during their development, included activity that was paroxysmal compared with the background (the paroxysm could consist of increased amplitude or increased frequency); activity also had to be rhythmic (with frequencies varying from 3 to 20 cycles per second) and relatively sustained in duration (lasting several seconds).

Measurements of these characteristics were obtained by breaking down the EEG into half-waves; for every 2-second epoch, the average amplitude of the half-waves relative to that of the background (indicating whether an epoch was paroxysmal), the average duration of the half-waves (indicating frequency), and the coefficient of variation of half-wave duration (indicating the regularity of duration or the rhythmicity) were measured. The background was constantly updated and included EEG sections before and after the active epoch. Comparing the amplitude, frequency, and rhythmicity measurements of the background to those of the active epoch allowed definition of a decision tree for the detection of seizure activity. It is often forgotten that it is not necessary to detect the onset of a seizure; a detection occurring at any time during the course of the seizure is sufficient because the computer simply marks the time of the detection and the interpreter can page back to determine the exact time of seizure onset. This method of seizure detection has been made available commercially and is

in widespread use throughout the world. It has also been used to monitor experimental animals.[12,88]

Harding[57] presented a method specifically designed for intracerebral recordings based on the detection of a repetitive spiking pattern as well as of possible flattening at seizure onset. This method was implemented online and was subject to an extensive evaluation (see later discussion). Another approach for seizure detection was proposed by Schindler et al.[112] They simulated neuronal cells processing each EEG channel and used leaky integrators to assess increases in amplitude and slope over a certain time.

Artificial neural networks (ANNs) have found broad applications in many areas of pattern recognition, including seizure detection. Jando et al.[64] showed the utility of neural networks for detecting bursts of spike-and-wave in experimental models of epilepsy. Since then, several methods have been presented involving the use of various EEG features as inputs to an ANN.[6,32,116,120] By being presented with a sufficiently large number of training examples comprising seizure and nonseizure data, the ANN can learn to differentiate seizures from normal EEGs. A representative set of features characterizing the EEG needs to be specified in advance (e.g., amplitude, rhythmicity, dominant frequency, and so on), but it is not necessary explicitly to describe the seizure patterns. The ANN automatically determines which combinations of features are characteristic of seizures by adapting its internal structure to reflect the training data. The performance of ANN methods depends on the selection of an appropriate set of features and on the use of a sufficiently large training set containing a wide variety of seizure patterns. It is also necessary to specify a priori the structure of the ANN; large networks can handle complex classification tasks but may risk overfitting the training data and thus be unable to generalize to other types of seizures. It is also very difficult to investigate the operation of a large ANN; the network essentially acts as a black box that outputs classification values depending on the features it receives as inputs. To circumvent this issue, Wilson et al.[124] presented an algorithm based on a general set of rules in which each individual rule was implemented using a small ANN. By using several simple rules, it became easier to analyze the operation of the system.

Recent developments in automatic detection have demonstrated that performance can be improved significantly by incorporating a wide context in detection algorithms. Rather than defining the event only locally (e.g., comparing the characteristics of a 5-second epoch in one channel with the 30 seconds that precede it), it is important to include measurements of the spatial context (activity in other channels) and the temporal context (state of the subjectâ€"awake, stages of sleep, previously recorded events). Qu and Gotman[104] used this philosophy to greatly reduce the false detection rate by allowing the method to remember the patterns that caused frequent false detections in each subject. Klatchko et al.[68] presented a method for spatial and temporal clustering of elementary detections initially made on individual channels and epochs, which resulted in a more global representation of seizures. This reduced the number of false detections by only asserting the occurrence of a seizure if there were a minimum number of elementary detections adjacent in space and time. The system of Khan and Gotman[67] was based on wavelet decomposition to detect seizures in the intracerebral EEG. Wavelet methods allow the analysis of the temporal evolution of the frequencies of a signal; they are thus well suited for the identification of paroxysmal rhythmic activity, which often characterizes seizures. However, intracerebral EEGs also frequently feature rhythmic bursts associated with normal background activity. Therefore, Khan and Gotman's algorithm automatically adapted to the background of each patient by deactivating the detection of paroxysmal activity occurring consistently in the same channels and at the same frequencies. This resulted in an important decrease in the number of false detections (see later discussion).

Methods of Seizure Warning

Seizure detection systems can significantly reduce the load of EEG interpretation during long-term monitoring by requiring only the review of the detected events rather than the entire EEG record. Another purpose of seizure detection could be to warn the medical personnel, patient, or relatives that a seizure is starting, which could be particularly useful if the electrographic onset of the seizure precedes its clinical onset. In the context of long-term monitoring, a seizure warning system would allow close clinical observation early in the seizure and the taking of necessary precautions to avoid injuries that might otherwise occur in sudden unexpected seizures. It could also be useful for increasing the applicability of ictal single-photon emission computed tomography (SPECT) scans.[11] A seizure warning system could also be implemented as an implantable device, and one could even conceive of rapid intervention in the form of electrical stimulation or drug injection to abort the seizure.[80] The seizure monitoring systems described here were designed primarily to mark EEG records at any point during seizures so that the detected events could be reviewed at a later time. In contrast, seizure warning applications are meant to be used in real time and require detections that occur very early in the seizure. Moreover, the false detection rate should be very low because false alarms can be very disruptive in a clinical setting. Promising results were obtained by Qu and Gotman[105,106]; for each patient, a first recorded seizure was used as a template to train the detection system. This approach clearly results in the introduction of a bias in detection performance toward seizures similar to the template. Therefore, this system is highly patient specific and cannot warn of new or different types of seizures. It thus cannot be used for seizure monitoring purposes, but is still useful to assess the occurrence of a particular seizure type. The system was able to generate a warning within an average of 10 seconds of the electrographic seizure onset, with a relatively low false alarm rate. Shoeb et al.[114] designed a system for seizure warning in scalp EEGs. By training the system with wavelet features specific to each patient, they could obtain a high sensitivity and a low rate of false detections.

Although patient-specific systems can be useful, more general methods are more practical in a clinical setting because they do not need to be retrained for each patient. The system of Osorio et al.[98] used a wavelet filter followed by a median filter to detect the onset of seizures in intracerebral recordings. The best performance was achieved when the system was tuned to each patient, but good results were still obtained without this patient-specific adjustment. Saab and Gotman[108] designed a system based on measurements of amplitude and rhythmicity in the wavelet decomposition of scalp EEGs. The wavelet features were then used in a Bayesian classifier to obtain the probability that a seizure had begun. Various criteria were used to automatically reject epochs containing alpha activity, electromyographic artifact, or abnormal signals due to defective electrodes; this allowed the system to ignore these sources of false detections, which are common in scalp EEG recordings. FIGURE 1 shows examples of seizures detected by the warning system. The classifier was trained using a large data set containing a wide variety of seizures; the system is thus sufficiently generic to be useful for seizure monitoring applications. For seizure warning purposes, it is also possible to further reduce the false alarm rate without significantly increasing the detection delay, by manually tuning the system for each patient.

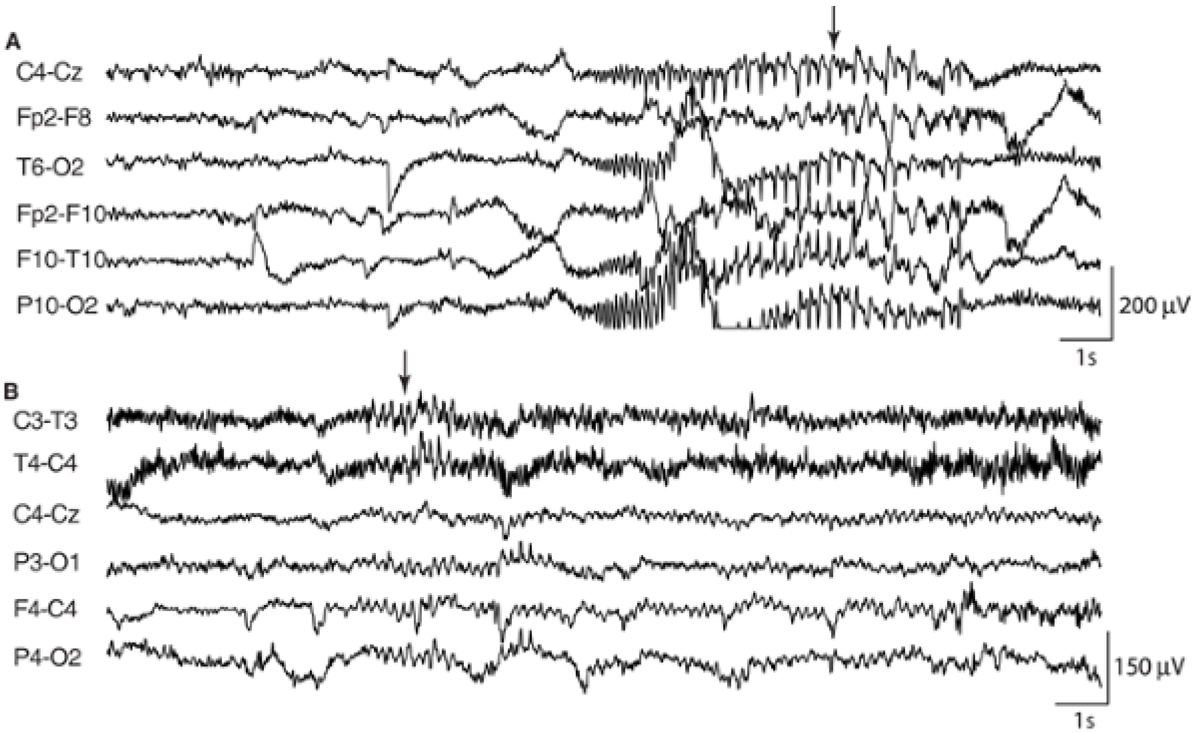

FIGURE 1. Seizures recorded by scalp electrodes that were detected automatically by the seizure warning system of Saab and Gotman.[108] Arrows mark the earliest detections. **A:** Seizure featuring clear rhythmic spikes lasting <8 seconds. **B:** Subtle seizure characterized by somewhat rhythmic discharges of low amplitude.

Whereas the system just described was specific to scalp recordings, a similar methodology was employed by Grewal and Gotman[56] to process intracerebral recordings. They used spectral features in several frequency bands and integrated

P.1102

measures of spatiotemporal context to detect the onset of seizures. To aid in the detection process, the harmonics of identified rhythmic signals were also examined for the presence of sustained activity. Epochs containing abnormally large amplitude signal or activity at the mains frequency of 60 Hz were automatically rejected, thus reducing the rate of false detections due to artifacts. The system was trained on a wide variety of seizures, resulting in a general detector useful for seizure monitoring, which also provided a tuning mechanism to improve its performance for use as a seizure warning system. Examples of seizures recorded by intracranial electrodes and detected by the method are shown in FIGURE 2.

The seizure warning systems described here aim to detect seizures in real time just as they are starting. On the other hand, recent studies[18,61,79,87,91,95] have indicated that it is sometimes possible to detect changes in the EEG well before the actual onset of clinical and electrographic changes. These results are preliminary, but it might be possible to develop methods for seizure prediction if reliable algorithms can be designed (see Chapter 85).

Detection of Seizures in the Neonate

The detection of seizures in neonates is quite different from that in adults; discharges are often much slower (down to 0.5 Hz), seizure onset can be very gradual, seizures can last several minutes, and waveforms of seizures and of interictal background show a high level of variability. Because of this, several seizure detection systems have been developed specifically for neonates. Liu et al.[84] presented a method based on the autocorrelation function for the detection of rhythmic slow patterns of any morphology. Gotman et al.[47] also developed a system specifically for newborns, based on a combination of various techniques. Spectral analysis was used to detect paroxysmal bursts of rhythmic activity. Spike detection methods were also integrated in the system to detect seizures that consist of irregular spiking patterns. Very slow rhythmic discharges were detected by applying a low-pass filter to the neonatal EEG and then using the seizure detection method of Gotman[43] on the filtered signal. By using a combination of several methods, the system was able to detect a wide variety of patterns occurring during neonatal seizures. Roessgen et al.[107] proposed a different approach to neonatal seizure detection based on a neuronal model of EEG generation. The model takes into account the generation of seizure activity and of background activity. By fitting the model to the EEG data under investigation, it is possible to determine how much of the signal is due to seizure activity. Celka and Colditz[17] presented a method based on singular spectrum analysis, also aimed specifically at seizures in infants. They used the minimum description length (MDL) principle to estimate the signal complexity, which was then used as a detection measure. Their system also implemented an autoregressive moving average (ARMA) model of the EEG as a preprocessing step to separate background activity from seizure activity. Altenburg et al.[7] described a method of detecting neonatal seizures based on interchannel synchronization. They noted that the onset of seizures is often characterized by a sudden increase in synchronization. The method of Hassanpour et al.[58] used time-frequency representations of the signal to detect low-frequency rhythmic activity as well as high-frequency bursts of spikes. Aarabi et al.[1] designed a multistage system for seizure detection in the newborn based on a large number of features. The relevance of each feature was then analyzed, so that only the most appropriate features were selected and used in an artificial neural network to classify seizure and nonseizure EEG.

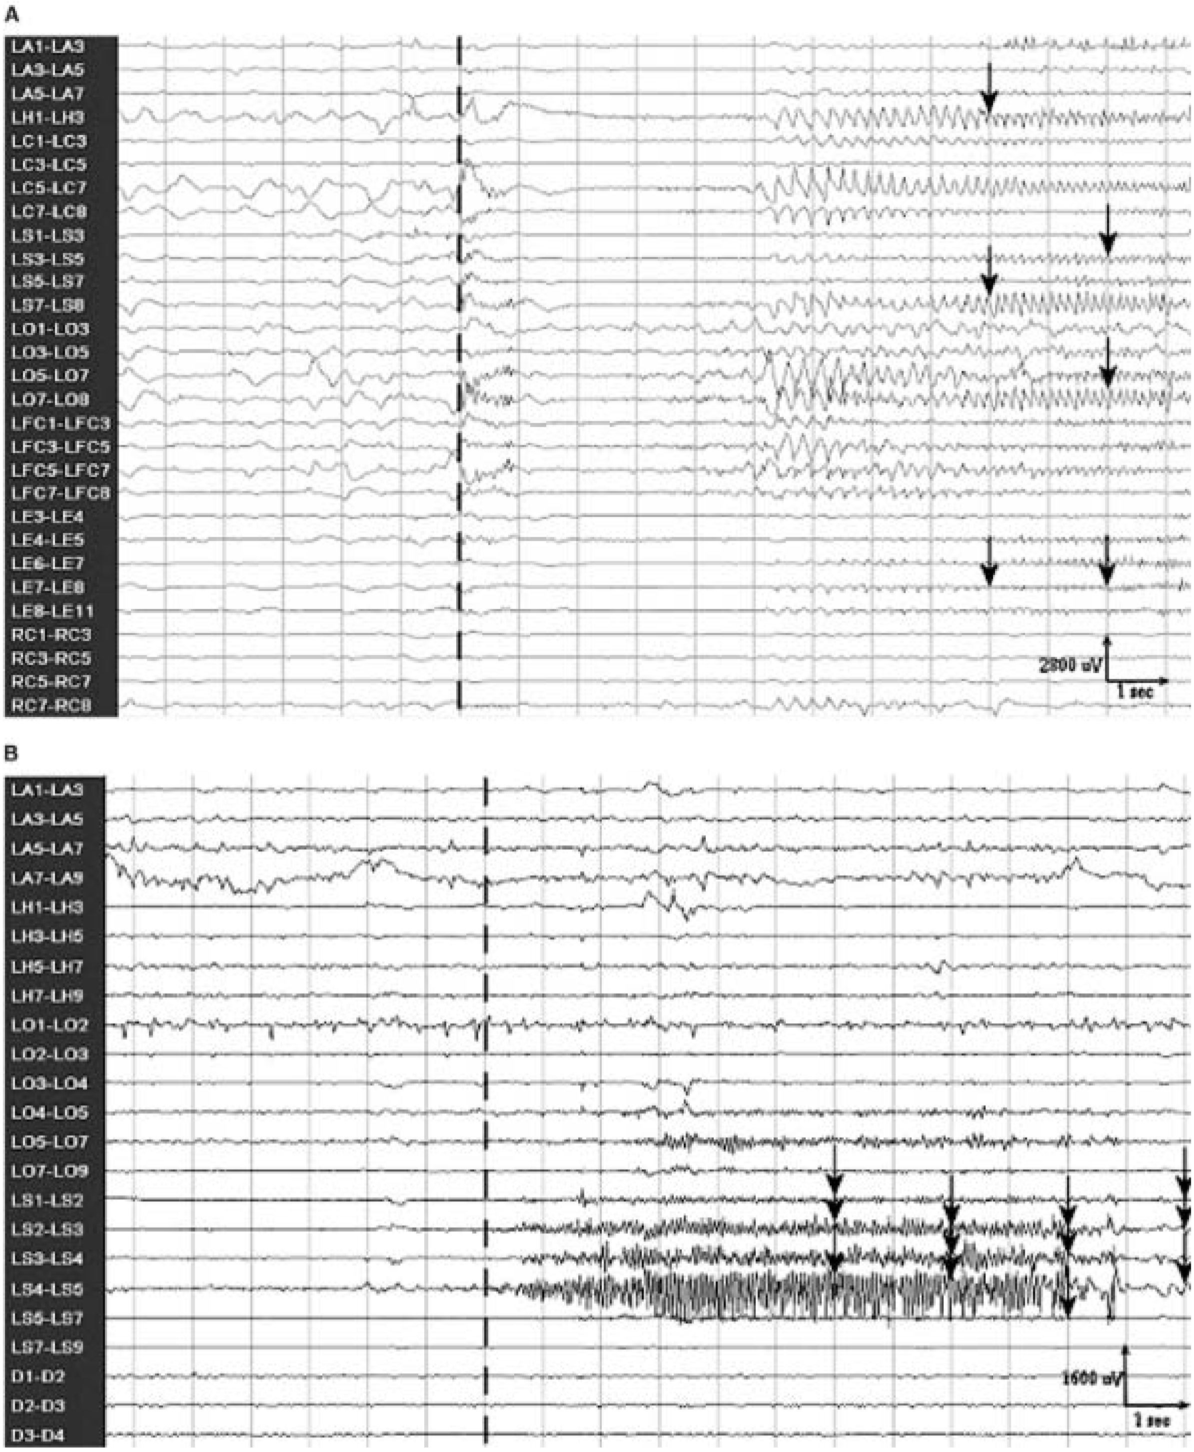

FIGURE 2. Seizures recorded with intracerebral electrodes that were detected automatically by the seizure warning system of Grewal and Gotman.[56] The dashed vertical lines indicate the onset of the seizures. Arrows mark the seizure epochs that were detected by the system. **A:** Seizure featuring typical sustained rhythmic activity, which was detected 9 seconds after the onset. **B:** Seizure characterized by fast rhythmic activity. This seizure was detected only 6 seconds after its onset.

Clinical Validation of Seizure Detection Methods

Evaluating the performance of automatic detection methods is very difficult because results may depend more on the selection

of EEGs included in the evaluation set than on the detection method itself; for instance, a seizure detection method may work well when the patient is resting with eyes closed, perform less well when eye blinks are present, and fail totally if electromyographic and movement artifacts are also included. To give a fair impression of performance, what type of EEG should be included in the evaluation? Several requirements should be met to obtain an accurate validation that corresponds to a realistic clinical setting:

- EEGs used in the validation should be independent of EEGs used in developing the method.
- EEGs should not be preselected, especially with respect to quality. A subjective selection of the EEGs could strongly bias the results. Ideally, the records should be obtained consecutively.
- A large variety of seizure patterns from several patients should be included.
- A large amount of nonseizure data should also be included, to be representative of all conditions that might occur in long-term monitoring.

The performance of the seizure detection methods described earlier will be reviewed. Methods that did not use an extensive amount of independent EEG during their validation will not be considered in detail in this section. This does not mean that these methods do not perform well; in fact, most of them show very promising results. However, their validity in a realistic clinical context has not yet been established.

In evaluating the seizure detection method of Gotman,[43] all efforts were made to avoid bias in data selection. EEGs were recorded from 293 consecutive monitoring sessions totaling 5,303 hours from 49 patients, most of them having medically refractory epilepsy and being considered for surgical treatment. All EEGs were included, independent of EEG patterns and technical quality. Of the 244 seizures in the validation data set, 24% were recorded by the alarm button but were missed by the computer, 35% were detected by the computer and were accompanied by an alarm button press, and 41% were detected by the computer alone. Pauri et al.[101] performed an independent evaluation of the same method and came to very similar conclusions. In a third evaluation, Salinsky[109] concluded that the use of automatic seizure detection made it possible to catch a large number of seizures missed by the patient and observers and to reduce significantly the length of the hospital stay. As in the previous study, approximately 20% of seizures were not detected by the computer but were detected by the patient or an observer.

It is thus clear that one cannot rely exclusively on either human observation (the alarm button) or automatic detection. Using both approaches can considerably increase the yield of long-term monitoring. In addition, the average detection rates given here reflect poorly the reality of individual patients. Some patients had most of their seizures recorded by the alarm button alone, whereas others had most of their seizures detected by the computer without an accompanying press of the alarm button. The computer can be extremely helpful when seizures go unnoticed, such as when they consist of quiet automatisms. All seizures can be detected if a nurse and an EEG technologist observe the patient and the EEG at all times. This procedure is obviously expensive and difficult to achieveâ€"hence the importance of automatic seizure detection methods.

False-positive detection rates were around one to two false detections per hour of monitoring,[43,101] increasing in some patients with intracerebral electrodes to up to four or five false detections per hour. In the majority of cases, the number of false detections is small enough not to be disruptive: False detections merely cause the EEG to be marked unnecessarily and can be removed at the time of review by visual inspection. This selective visual review is clearly preferable to reviewing the entire EEG recording without the benefit of data reduction.

The wavelet-based and context-based method of Khan and Gotman[67] was evaluated on recordings from 10 consecutive patients with intracerebral electrodes, each having 20 hours of recording and at least three seizures. It was compared to the original method of Gotman.[43] Sensitivity was 90% for the original method and 86% for the new method. It thus appears that the original method, even when applied exclusively to intracerebral electrodes, had an excellent performance. The new method had marginally lower sensitivity, but its main advantage was its low rate of false detection of 0.3/hour, compared to 2.4/hour for the original method.

Harding[57] performed a thorough evaluation of his method of seizure detection for intracerebral recordings, also by using large amounts of unselected dataâ€"almost 1,600 hours from 40 patients. He obtained few false negatives and a very acceptable level of false positives. The results are difficult to compare directly with other methods because detection parameters were altered slightly according to the results after the first seizure was recorded. Gabor[31] performed an extensive evaluation of his neural network method using 4,500 hours of scalp EEG from 65 patients. The data were not preselected, so that even low-quality EEGs were included in the analysis. The original method of Gotman[43] was also evaluated using the same data set, resulting in a sensitivity of 74.4% and an average false-detection rate of 3.02/hour. The neural network method yielded an improved performance, with a sensitivity of 90.0% and a false-detection rate of 1.29/hour. Osorio et al.[97] evaluated their method on recordings from 15 patients with intracerebral electrodes. Their results are not presented in the traditional fashion and cannot easily be compared to those of other methods. They indicate that 100% of the 39 seizures were detected, but they only considered seizures for which there was an alarm from the nurse or the patient, and they excluded poor-quality EEGs. Purely electrographic seizures or seizures of which the patient was not aware were not considered. In addition to the 39 detected seizures, their system yielded another 866 detections that were subsequently reviewed; 92% were then reclassified as true detections, including short electrographic bursts, leaving a low rate of false detections. Saab and Gotman[108] tested their seizure warning method on an independent, unselected data set including seizure and nonseizure data from 16 patients totaling 360 hours of scalp EEG. They reported a sensitivity of 77.9%, a false-detection rate of 0.86/hour, and a median detection delay of 9.8 seconds. For use specifically as a seizure warning system, it was possible to tune the system for patients with a large number of false detections. This resulted in a false-detection rate of 0.34/hours, and the sensitivity and median detection delay were almost unchanged at 76.0% and 10 seconds, respectively. Grewal and Gotman[56] tested their intracerebral seizure detection method using an independent testing data set from 19 patients totaling 389 hours of intracerebral EEG. They indicated a sensitivity of 86%, a false-detection rate of 0.47/hour, and a median delay time of 16.2 seconds. They also provided a patient-specific tuning mechanism to reduce the number of false detections for seizure warning purposes. This resulted in a false-detection rate of 0.22/hour, with a sensitivity of 89.4% and a median delay time of 17.1 seconds.

Gotman et al.[46] evaluated their newborn seizure detection method on a large set of data (55 newborns) obtained from three hospitals. Results showed seizure detection rates that were a little lower than those of scalp recordings in adults (around 70%) and false-detection rates of approximately 2/hour. This study illustrated that it can be difficult to extrapolate results from one patient group to another: The performance varied considerably between the data sets of the three hospitals, reflecting the variability of recording conditions, technical quality, and types of pathologic conditions.

Faul et al.[25] performed an independent evaluation of the methods of Liu et al.,[84] Gotman et al.,[47] and Celka and Colditz,[17] using a common data set consisting of EEGs from 13 newborns. Using the default parameters from each algorithm, it was found that the three methods did not perform as well as expected on this particular data set. This again reflects the difficulties in designing a general seizure detector to handle variable conditions. To obtain better results, it might be necessary to adjust the parameters of each method specifically for each hospital. An improved performance was noted when the algorithm parameters were appropriately tuned.

Current seizure detection programs are not perfect and would benefit from significant improvements. It would be extremely difficult, however, to detect all seizures because some seizures have almost no EEG accompaniment, and the discharge morphology is often nonspecific.[4] Nevertheless, computer assistance is almost indispensable for the detection of epileptic events during long-term monitoring. There is no single economical method that ensures the detection of all seizures in every patient: All available help must be used, including staff and patient reporting, and computer detection. In some patients, one method may prove to be more useful than others, but this is not known in advance of the monitoring sessions. Automatic methods of seizure detection can be especially useful in the context of human validation. Moreover, newer methods, relying on a broader contextual analysis of the EEG, can yield a significantly improved performance compared to traditional methods. They can also reliably be used as seizure warning systems, detecting seizures close to their electrographic onset.

Recording Interictal Activity

The interictal activity specific to epilepsy consists of spikes, sharp waves, and bursts of spike-and-wave. Patients with epilepsy also have abnormalities of background, which can be analyzed by computer methods. Paroxysmal interictal activity occurs unpredictably and sometimes infrequently. To obtain a full documentation of the different types of abnormalities, the traditional short recording might not be sufficient. Long-term monitoring might be required, including periods of the different stages of sleep, which most often activates and modifies interictal patterns.[110] The reduction of AED doses, often done during long-term monitoring to precipitate seizures, also results indirectly in increased spiking; it has been shown that spikes are more frequent after seizures.[44,50,53] It is clear that complete review of recordings lasting days and nights is an awkward way to document interictal activity: Automatic detection methods can be very helpful.

Past Methods

The usual approach in early systems for automatic spike detection consisted in (1) selecting EEG sections lasting 1 or 2 minutes, free of artifacts, and including a sufficient number of spikes; (2) devising a method for their detection; and (3) comparing results of automatic detection to what qualified electroencephalographers considered â€œtrueâ€ spikes. Details of the various detection methods have been reviewed extensively.[45] In general terms, these methods relied on one of two approaches: In the first, the EEG is broken down into elementary waves, and the method then attempts to identify waves having morphologic characteristics normally associated with spikes (amplitude, duration, sharpness). In the second, the EEG is analyzed to find statistically improbable events of short duration. With most methods, very acceptable performance was obtained, usually with 80% to 90% of â€œtrueâ€ spikes detected and a low rate of false-positive detection. Many publications ended with statements such as, â€œAs computers become more powerful and less expensive, practical implementation of this method will be simple.â€ Computers did in fact become more powerful and less expensive faster than anybody had expected, but most methods did not reach practical implementation. One major reason is that the detection problem became much more complex when longer sections were analyzed; artifacts and normal transients had to be included, and they caused numerous false detections. In addition, some methods were not readily adaptable to online analysis and were therefore of limited practical utility. For short recordings, human inspection generally performs sufficiently well, so that there is little use for spike detection in these cases. Automatic methods would thus be most useful for prolonged recordings. It should be noted, however, that perfect performance is unlikely ever to be obtained by automatic systems. After all, EEG experts also show a less-than-perfect sensitivity; there is some inherent variability associated with the subjective interpretation of EEG records.[123]

Difficulties of the Problem

The major difficulty of spike recognition methods is their reliance on a very incomplete definition of a spike. The definition quoted by many publications is â€œa sharp transient, easily distinguishable from the background, having a duration of less than 70 msec for a spike and 70 to 200 msec for a sharp waveâ€ (adapted from Chatrian et al.[19]). This definition is extremely incomplete because it lacks features for differentiating transients with the same local morphology that are not spikes, such as eye blinks, vertex sharp waves, isolated alpha or spindle waves, electrode artifacts, and movement artifacts. Such transients are common during prolonged EEG recordings, when automatic spike detection is useful. Because of this, results of standard spike detection methods usually include genuine spikes mixed with false detections caused by nonepileptiform transients.

Which characteristics allow a human interpreter to distinguish an epileptiform sharp wave from an eye blink, even though the waves themselves may have the same morphology and emerge from a similar background? These characteristics most likely relate to the context in which the waves appear; this context likely encompasses a much wider space and time than the background activity surrounding the spike. When interpreting a wave having the morphology of a spike, the human observer takes into account events in other channels (spatial context) and in earlier and later parts of the recording (temporal context), and even non-EEG information, such as the age or clinical state of the subject. Optimism about early detection methods was based on a failure to appreciate how much spike identification relies on context.

It must be noted that these problems do not affect the ability to detect most epileptiform spikes, but they do result in a large number of false-positive detections. For this reason, it is possible to make practical use of an automatic spike detection method, as long as it is conceived as a method for detecting a high proportion of the spikes along with a possibly large number of nonepileptiform transients, rather than as a method to detect only spikes. Such a practical implementation was made with the spike detection algorithms developed at the Montreal Neurological Institute.[40,48] Pietila et al.[102] presented a system including automatic segmentation of the EEG followed by feature extraction. Compared with Gotman's system, this system showed a higher sensitivity but a lower specificity.

Newer Approaches

As in seizure detection systems, artificial neural networks have also become a popular method for spike detection. The process usually requires a large number of sample patterns for training; the ANN then automatically adapts to the discrimination task at hand. This method was used by Gabor and Seyal,[33] who

P.1106

obtained a good performance but evaluated their method on a very small sample.

When designing a neural network method, it is crucial to select an appropriate set of features to use as inputs to the ANN. The relatively short duration of spikes offers the opportunity to use the raw EEG data points as network inputs, thus foregoing the extraction of features. Webber et al.,[121] using a relatively small data set for evaluation, compared the use of the raw EEG to that of preprocessed variables in the ANN and concluded that a better performance was obtained by using the preprocessed parameters. Ozdamar and Kalayci[99] obtained good performance with an ANN trained on raw EEG, but Ko and Chung[69] revisited the data and suggested that the results were erroneous due to inappropriate data preparation.

When using raw EEG instead of preprocessed parameters, the ANN needs to recognize all combinations of the data that can be relevant for the classification task. A very complex ANN will thus be required to obtain a satisfactory performance. It is possible to simplify the problem by using only a small amount of raw EEG as input, as was done by Kurth et al.,[76] who used a data window of only 100 msec. However, the use of such a short window prevents their method from taking into account characteristics such as the slow wave that often follows interictal spikes. The lack of temporal context makes it difficult to prevent false detections caused by transients whose morphologies are locally similar to spikes. Their results are difficult to compare with other methods because they only used a limited data set for validation, and they had separate ANNs trained and tested individually on the same patients. To reduce the complexity of spike detectors using raw EEG as inputs, Acir and Guzelis[2] proposed a multistage approach in which the data are first reduced by identifying nonstationary transients using an autoregressive linear predictor. Only the identified transients are then further examined, by using the raw signal in a support vector machine for classification as spike or nonspike. A sensitivity of 90.3% with 9.5% of false detections was reported after validation with 4.2 hours of EEG from seven patients.

The use of extracted features instead of raw data can result in simpler classifiers for spike detection. Wilson et al.[125] designed several simple rules for spike detection and then used small ANNs to learn each rule. It was then easier to interpret how each small ANN implemented the individual rules. Wilson et al. also used a training set in which EEG data epochs were marked with a probability value rather than a dichotomous classification as a spike or nonspike. This allowed the system to process ambiguous spikes without having to decide on a definitive classification. Hellmann[59] used cross-correlation to identify candidate spikes that resembled a given template, followed by classification using an ANN with various features. The use of a template results in a system that is patient specific and can only identify one type of spike. Nevertheless, this method could be useful if the time of occurrence of known spike morphologies is desired, such as in functional imaging applications. In addition to ANNs, other data mining models can also be used to automatically generate classifiers for spike detection. Valenti et al.[119] implemented C4.5 decision trees and naive Bayesian classifiers with good results, but EEGs from only three patients were used for training and validation.

There has been some interest recently in using wavelet analysis to identify interictal spikes in EEG records.[21,77,111,113] Wavelet features can be useful for describing the time and frequency relationships that exist between the spike and the following slow-wave. These methods are well suited to the characterization of transient signals such as spikes.

Another approach to improving detection performance is to make automatic methods use information from a wider context. This is a simple concept, but it is difficult to implement because the context encompasses a very large amount of information and it must be decided which part of that information is relevant to spike detection. It is this selection process that human interpreters do so well. Glover et al.[35] described a context-based system aimed largely at reducing false spike detections by making use of a wide spatial context; information from all EEG channels, as well as from electromyographic, electrooculographic, and electrocardiographic channels is used to assess whether a transient in a particular channel is likely to be epileptiform.

An approach has been proposed by Gotman and Wang[54,55] in which a wide temporal and spatial context is used to decide on the nature of a sharp event. The method is termed state-dependent spike detection because criteria for spike detection are rendered dependent on the state of the EEG. Five states were defined in which spike detection should be performed differently: (1) active wakefulness, (2) quiet wakefulness, (3) desynchronized EEG, (4) phasic EEG, and (5) slow-wave EEG. In fact, in these different states it is not so much that spike detection has to be done differently as that false detections have to be handled by different means. In active wakefulness, for instance, one must be particularly aware of symmetric frontal sharp waves that may be caused by eye blinks, whereas there is no such concern in the phasic EEG state; in that state, sharp waves maximal at the vertex are a problem (Fig. 3). The method was evaluated in 20 patients, each having close to 2 hours of EEG covering all states; it showed a reduction in false detection of 65% and an increased sensitivity of 35% compared with the original method. Flanagan et al.[27] suggested an improvement to this method by using an equivalent current dipole to model each detection. The goodness of fit and the position of the dipole were then used as features to reject nonspike artifactual transients. It was not necessary to obtain an accurate localization of the spike generator; a simple dipole model provided sufficient information to reject many false detections. Using an independent data set of 20 patients to validate the method, Flanagan et al. reported a 53% decrease in false detections while only removing 4.3% of true spike detections compared to the original method of Gotman and Wang.[54,55]

Whether neural networks or more traditional methods are used, it is unlikely that local wave morphology is sufficient to differentiate epileptiform transients from other transients. Some form of context sensitivity appears to be necessary.

Recording Behavior

The analysis of behavioral manifestations of seizures is obviously a critical element. It can be performed by an observer or by video recording (often by both). It is now possible to record and store a few days of continuous video directly on a computer; the recording can then be reviewed at a later time. Computer networks can greatly facilitate this process by allowing the direct transfer of EEGs and simultaneous video from the recording computer to the review computer. Reviewers can choose to examine only specific sections of the recording, such as those marked by the automatic detection systems described earlier. The entire data set can also be reviewed at an accelerated speed to identify events of interest. For long-term archival purposes, only the sections of interest are usually kept due to limitations in archiving media capacity.

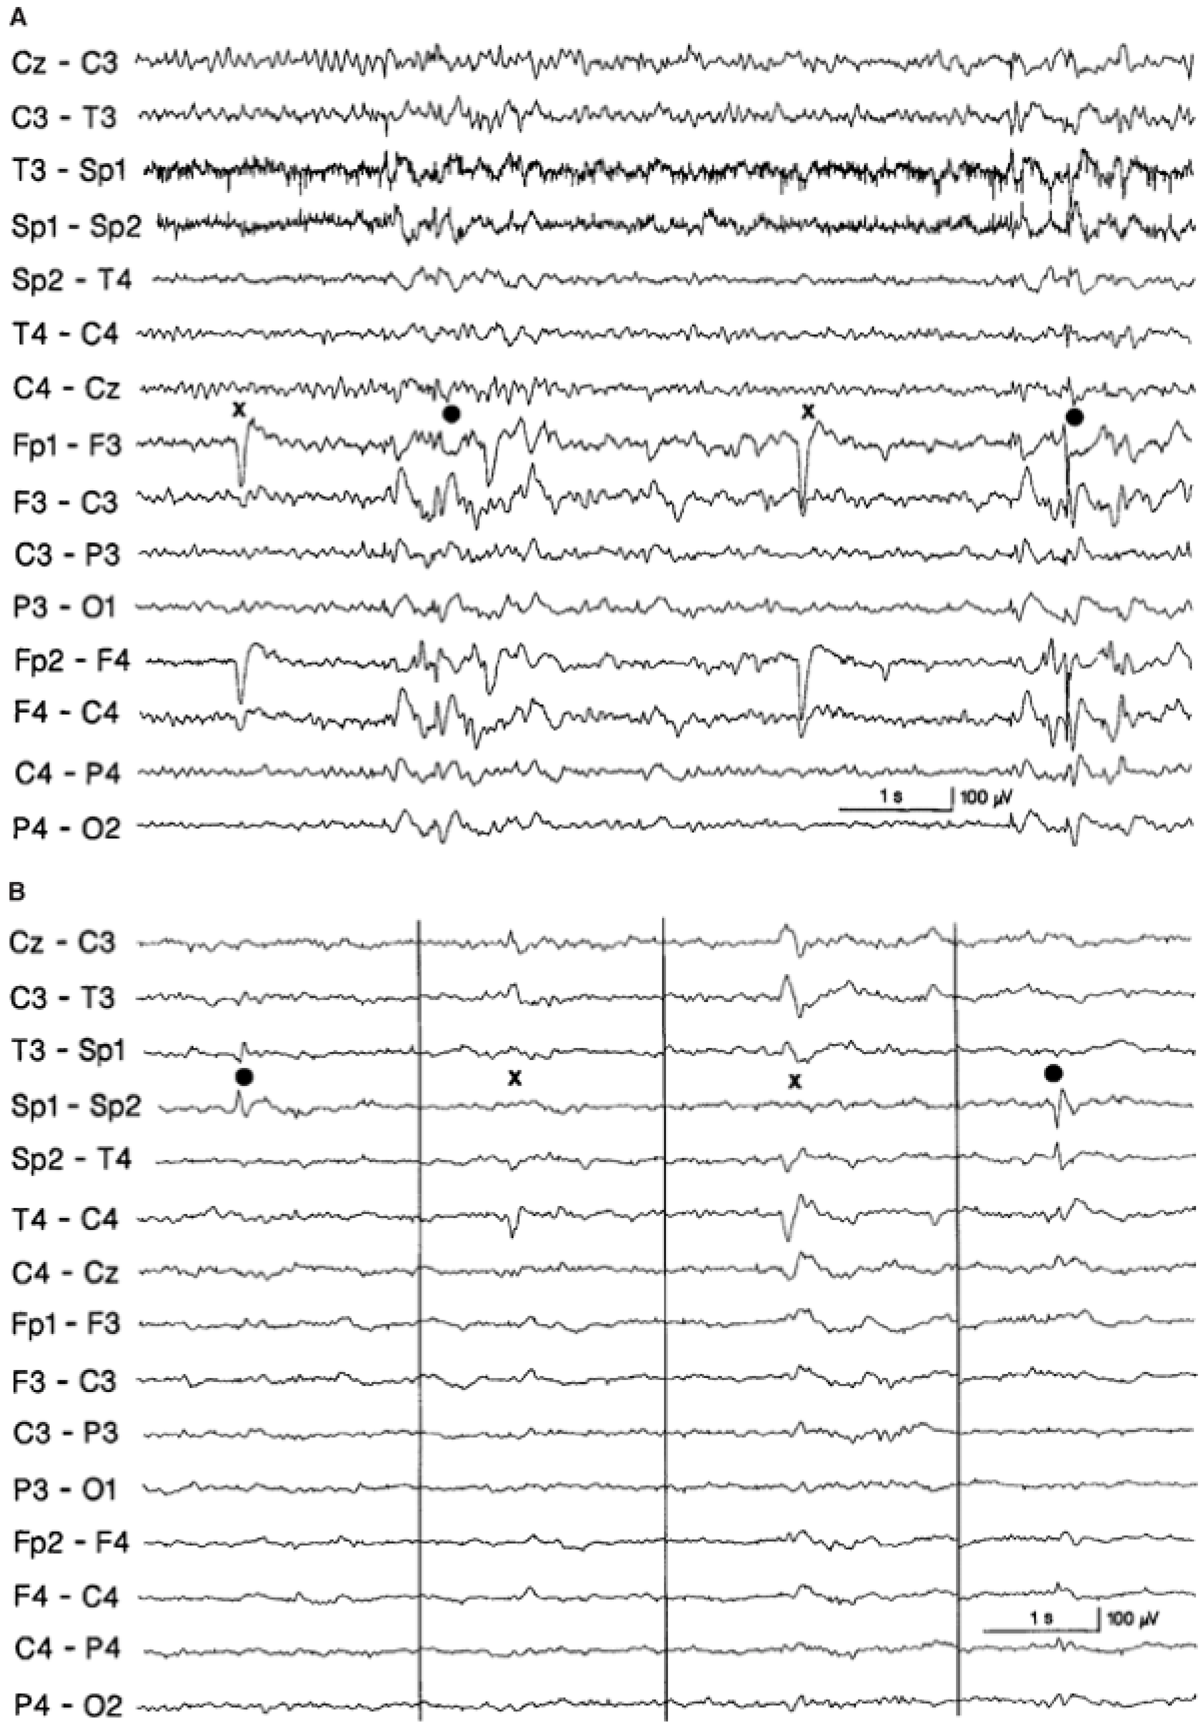

FIGURE 3. Use of spatial and temporal context in spike detection. Nonepileptiform transients are selectively

rejected (rejected events marked with **x**). **A:** During active wakefulness, as determined by automatic state classification, waves having the morphology and distribution of eye blinks are eliminated. **B:** During phasic sleep, sharp waves having a maximum at the vertex are eliminated. (From Gotman J, Wang LY. State dependent spike detection: validation. *Electroencephalogr Clin Neurophysiol.* 1992;83(1):12â€“18, with permission.)

Outpatient Monitoring

Portable devices are available with sufficient memory to allow 24-hour continuous recording of 20 channels of EEG. The recorded data can then be transferred to a standard computer for further analysis and archiving. Data analysis can include all the methods of automatic spike and seizure detection described previously, which can usually process a 24-hour recording in

<1 hour. Outpatient monitoring does not appear to change the spontaneous frequency of the patient's events, as hospitalization sometimes does; the yield of outpatient monitoring is therefore often higher than that of inpatient monitoring. The efficacy of this method was formally evaluated in 344 patients by Morris et al.[92] They concluded that combined pushbutton and automatic detection resulted in useful information being obtained in 74% of patients. Because equipment, methodology, and EEG quality are the same for inpatient and outpatient monitoring, patients can be shifted easily from one environment to the other according to the clinical situation.

Patients need to be selected carefully because outpatient monitoring is not always appropriate. If video is not essential and patients have frequent enough events, then outpatient monitoring is appropriate. When it is necessary to reduce antiepileptic medication to provoke seizure occurrence or when patients have a confusing type of event, then inpatient monitoring with video is recommended.

Display and Analysis After Detection

The benefits derived from computers relate not only to detecting epileptiform events during long-term monitoring, but also to displaying, manipulating, and analyzing the EEG. Some of the possibilities for display and analysis are outlined next.

Computer Review of the Electroencephalogram

A system that presents the EEG on the screen at 10 to 20 times the recording speed is easily implemented on a personal computer. When this is combined with data reduction, it is possible to review the most important information of a 24-hour recording in only a few minutes. This does not include the time required to interpret the EEG, particularly seizures, but rather indicates how long it takes to scan the recording. Seizures can be examined on a high-resolution computer screen displaying a large number of channels; 32 channels are commonly used, and even 128 channels can be viewed simultaneously, greatly facilitating the interpretation of EEGs from multiple intracerebral electrodes or the large subdural arrays sometimes used in presurgical evaluations. Furthermore, simple manipulations, such as changing gains or filters, reformatting the montage, or topographic mapping, can be performed interactively by the person interpreting the EEG at the time this information is required.

Analysis of Seizure Activity

It is possible to go beyond visual interpretation and analyze seizures to extract information of diagnostic or scientific interest. The graphic representation of seizures and quantitative measurements of their features can improve EEG interpretation.[3,5,15,22,45,52] Computerized signal processing tools can also be used to remove artifacts that may obscure ictal activity. For instance, digital filters are commonly used to remove high-frequency electromyographic (EMG) activity that frequently accompanies seizures recorded from the scalp.[49] However, muscle artifacts are known to contain significant power at frequencies below 30 Hz,[96] where seizure activity is also known to occur.[49] There is thus an overlap between the frequency spectra of EEG and EMG. Although aggressive filters could remove the entire EMG artifact, this would also inappropriately attenuate the EEG activity. Moreover, it might become difficult to differentiate between brain activity and the filtered EMG. Therefore, digital filters can only partially eliminate muscle artifact from the EEG.

Recently, methods based on independent component analysis (ICA)[20] have been applied to remove a wide variety of artifacts from the EEG signal. ICA is a blind source separation technique that can be used to decompose linear mixtures of signals. A classical application of ICA occurs in the so-called cocktail party problem, which stipulates that microphones placed at various locations in a crowded room will typically record several voices speaking simultaneously. ICA can then be used to process the recorded signals and extract each individual voice. In general, ICA can extract the sources, or components, contained in recorded mixtures, as long as these sources are statistically independent. This can be accomplished using any of the various algorithms designed for that purpose.[10,16,60]

The EEG signal originates from several independent sources of electrical activityâ€"brain generators, electrical fields due to ocular movements, scalp muscle activity, and so on. These electrical fields are known to propagate to the scalp by volume conduction, so that the signals recorded by scalp electrodes are sums of the activities from each source. EEG signals are thus well suited for processing by ICA. Based solely on the mixtures recorded by each electrode, ICA can automatically extract the original components. In particular, the sources of artifactual activity can be isolated and subtracted from EEG ictal recordings, thus improving the quality of the signal and facilitating seizure interpretation. Urrestarazu et al.[117] successfully applied this method to 10-second EEG segments containing the onset of seizures from patients with focal epilepsy. ICA was applied to these segments, thus automatically decomposing the EEG into several independent sources. The artifactual sources were then visually identified and subtracted from the EEG recordings. Two independent experts reviewed the original and processed EEGs in a random and blind fashion, and they concluded that ICA methods improved the quality of ictal EEG recordings, making it easier to determine the time of onset and topography of the seizures. It was also shown that the improvement in quality was superior to that provided by digital filters alone.

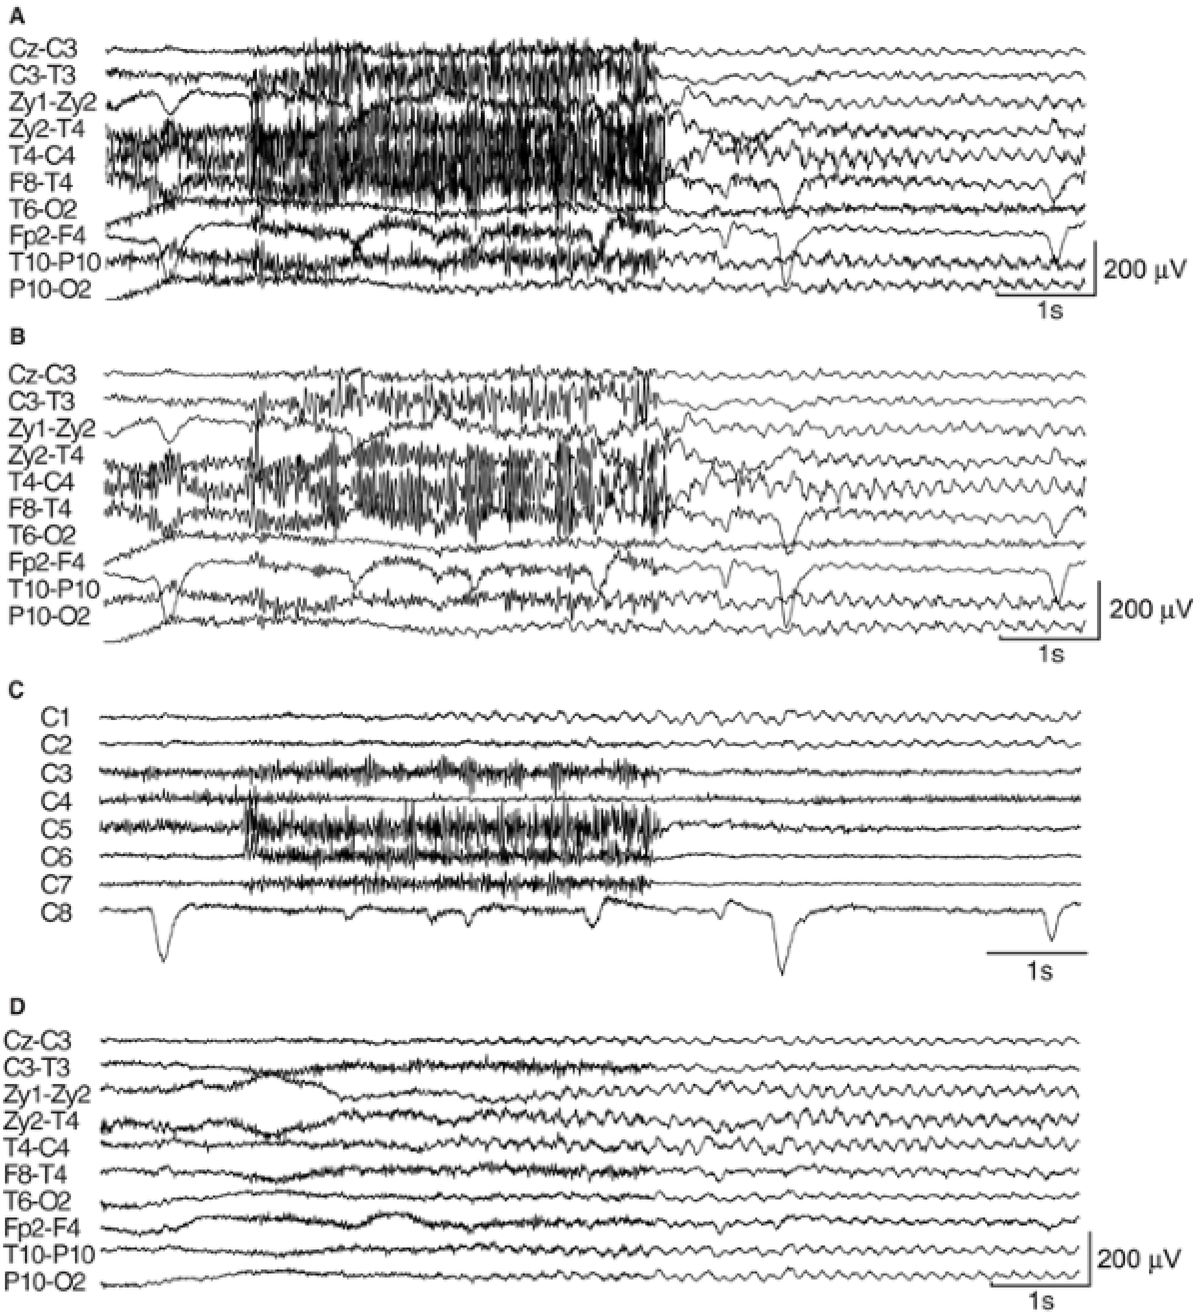

FIGURE 4. Application of independent component analysis (ICA) to automatically remove artifacts from seizure recordings using the system of LeVan et al.[82] **A:** Seizure heavily contaminated by electromyographic artifact, obscuring the onset. Eye blink artifacts are also clearly visible. **B:** Same seizure after the application of a low-pass 30-Hz filter. Muscle artifact is still clearly present at seizure onset. **C:** Time courses of the sources extracted by ICA applied to the seizure in panel A. The figure only shows a subset of the components. Components C1 and C2 correspond to seizure discharges, whereas components C3â€“C7 represent muscle activity. Component C8 corresponds to eye blinks. The amplitudes of the components are normalized because ICA can only extract sources up to a scaling factor. **D:** Electroencephalogram reconstructed after subtraction of automatically selected artifactual components. The eye blink artifacts have been eliminated, along with most of the muscle activity. The ictal discharges at seizure onset are now clearly visible.

There are some difficulties, however, with the application of ICA to remove artifacts from EEG recordings. ICA algorithms extract independent sources in an unpredictable order; this means that the sources must be visually inspected, and those corresponding to artifactual activity must be identified by the operator. This is a tedious process because the ICA decomposition of the EEG results in the extraction of a large number of sources. For example, there will be distinct components corresponding to the generators of epileptic activity and background activity, which might be numerous. In general, the application of ICA can potentially yield as many independent sources as there are recording channels. In a clinical setting, montages using 32 channels or more are common; it would thus be impractical to request that electroencephalographers manually identify the artifacts among the components extracted by ICA.

LeVan et al.[82] proposed a system for automatically classifying the sources extracted by ICA from ictal scalp EEGs. Their system is based on the use of spectral, statistical, and spatial features in a Bayesian classifier to identify artifactual sources extracted by ICA and subtract them from the recording. The system was evaluated using a data set of 23 unselected patients, resulting in the successful recognition of components of brain activity with 87.6% sensitivity while subtracting 70.2% of the artifactual components. A review of the results by an expert concluded that the automatic system could successfully remove a wide variety of artifacts from ictal scalp EEGs and facilitate the interpretation of the seizures without inadvertently subtracting cerebral activity from the recording. FIGURE 4A shows an example of a seizure that was heavily contaminated by EMG and ocular artifacts. The application of a low-pass digital filter

P.1109

at 30 Hz can reduce the EMG activity (Fig. 4B), but a portion of the artifact still obscures the seizure onset. Application of ICA on the seizure yields several components representing seizure activity and various artifacts (Fig. 4C). After identifying and subtracting the artifactual components using the automatic method, the resulting EEG activity becomes clearer (Fig. 4D). The EMG artifact has been greatly attenuated, and the eye blink artifacts have been eliminated. The onset of the ictal activity is now clearly visible. ICA, combined with the automatic classification of the extracted components, thus can be an effective method for removing artifacts from EEG recordings.

P.1110

In addition to artifact removal, computer methods can also be used to study seizure propagation. The study of interactions between brain regions during seizures was pioneered by Brazier,[14] who used the coherence function to measure the strength of interaction between seizure discharges in two locations and the phase spectrum to measure time differences of a few milliseconds. Thus, rapid propagation of seizures could be followed. The method was made more reliable by Gotman,[36,38] who included in the measurement a range of frequencies rather than a single frequency. Its validity was established in experimental and human epilepsy in cases in which the location of the focus was known. This method allowed the study of interhemispheric interactions during widespread spike-and-wave activity[36,74] and during temporal lobe seizures.[42,51,83]

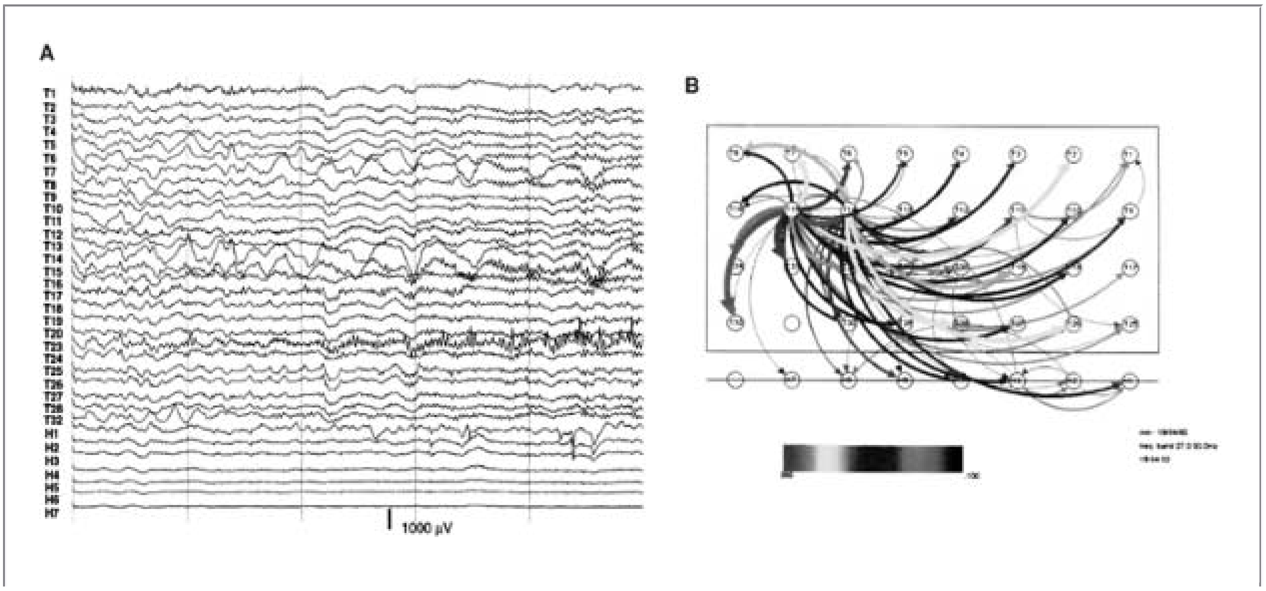

FIGURE 5. A: Intracranial electroencephalogram showing the onset of high-frequency activity in a patient with complex partial seizures. Subdural grid contacts are labeled T1â€"T32, and depth electrode contacts are labeled H1â€"H7. The depth electrode was placed through the grid, with H1 being the deepest contact, in the hippocampal structures. **B:** Plot of the integrated directed transfer function revealing the flow of activity for the 5-second interval illustrated in panel A. Each circle represents one electrode contact. The widths of the arrows are proportional to the value of the integrated directed transfer function for the respective contacts. (From Franaszczuk PJ, Bergey GK. Application of the directed transfer function method to mesial and lateral onset temporal lobe seizures. *Brain Topogr.* 1998;11(1):13â€"21, with permission.)

There are other methods for measuring interactions during seizures. The average amount of mutual information (AAMI) has a theoretical advantage over coherence because coherence can detect only linear (in the mathematical sense) relationships, whereas AAMI can also detect more complex relationships. Average amount of mutual information and other nonlinear methods are described by Lopes da Silva and Mars.[85] Fernandes de Lima et al.[26] compared a linear and a nonlinear regression coefficient in the study of interhemispheric interactions during hippocampal seizures in rats and found that the nonlinear measure was more robust than the linear one and could yield values of interaction when the linear one was at noise level. One important factor is not often discussed when these methods are compared: The size of the recording electrodes probably influences the type of relationship. Discharges recorded from very small electrodes, which can record multiple-unit activity, are more likely to have nonlinear relationships than discharges from macroelectrodes, which record from large populations of neurons. Nonlinear correlation coefficients were also used to investigate cortical and thalamic interactions during absence seizures in rats.[90] Le Van Quyen et al.[78] examined nonlinear interactions during temporal lobe seizures recorded with intracranial electrodes and found an increase in nonlinear interdependence in the early part of the ictal period. Franaszczuk et al.[28,29] presented another type of method, known as the directed transfer function, to study patterns of seizure propagation. This technique can be applied on several channels at once, detecting flows of propagation that cannot be identified visually. FIGURE 5A shows the onset of a seizure recorded in a patient with intracerebral electrodes. The seizure is characterized by high-frequency activity predominantly visible in contacts T14, T15, and T23. The flow of activity revealed by the integrated directed transfer function is illustrated by the arrows in FIGURE 5B. This suggests that the activity originates from contacts T14 and T15, with the largest flow (widest arrows) going from T15 to T23 and from T15 to T32.

Independent component analysis, which was described earlier as a method for separating artifactual sources from EEG sources, also can be useful for the analysis of seizure activity. McKeown et al.[89] applied ICA to spike-and-wave discharges in absence seizures. They found that the spike pattern and the wave pattern were separated into distinct components, with the spikes having a more focal spatial topography. Moreover, there were cases in which multiple components accounted for the wave pattern, with slightly different spatial topographies and a time delay between them. These multiple extracted sources could reflect the propagation of the wave pattern. Nam et al.[94] used ICA to study sources of ictal activity in medial temporal lobe seizures. They noted that the spatial topographies of the ictal sources extracted by ICA were dipolar in nature and could be used to successfully lateralize the seizures. Urrestarazu et al.[118] applied ICA to intracranial recordings of temporal lobe seizures. Among the extracted sources, they sometimes found components with a bilateral distribution even at times when visual inspection suggested that the seizure discharges were unilateral. This phenomenon was more frequent in seizures that subsequently clearly spread to both temporal lobes. The ICA method was thus able to reveal bilateral activity that occurred earlier than originally suspected by visual examination of the EEG.

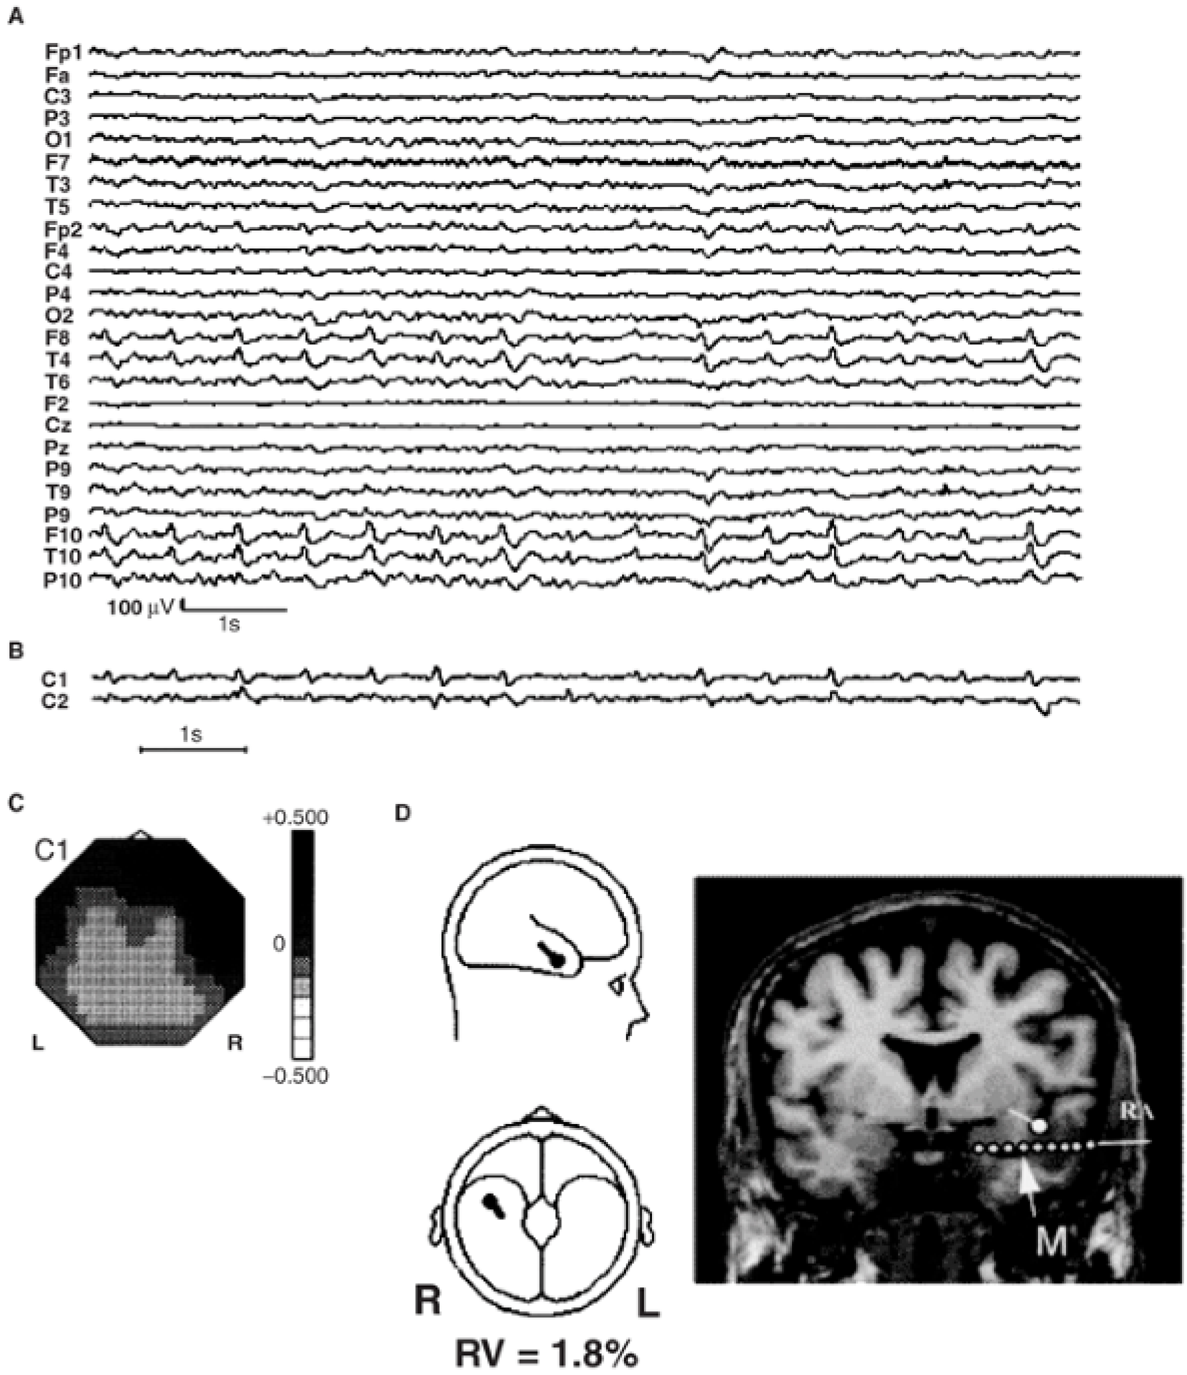

FIGURE 6. Application of independent component analysis (ICA) to the analysis of interictal spikes. **A:** Scalp electroencephalogram record formed by concatenating 15 spikes from one epileptic patient, along with some surrounding background activity. **B:** Two of the sources extracted by ICA include the interictal discharges, whereas the other components, not shown here, correspond to background activity. Component C1 has the clearest epileptic activity. **C:** Spatial map corresponding to component C1. The topography appears dipolar and right-sided. **D:** A single equivalent current dipole can be fitted to the spatial topography of component C1 with a residual variance (RV) of 1.8%. This dipole is then overlaid on a magnetic resonance image along with the locations of the contacts of depth electrode RA, which was part of an intracranial electrode investigation. This investigation revealed a maximal intracranial field M at a distance of 10.8 mm from the equivalent current dipole fitted to component C1. (From Kobayashi K, Merlet I, Gotman J. Separation of spikes from background by independent component analysis with dipole modeling and comparison to

intracranial recording. *Clin Neurophysiol.* 2001;112(3):405â€"413, with permission.)

Analysis of Interictal Activity

Automatic spike detection was described earlier in this chapter mainly in the context of data reduction, but it also offers the benefit of quantification. It is possible to edit interactively on the computer screen the false-spike detections so that only valid detections remain. They can be displayed along with their spatial and temporal distributions. Quantification of spike activity during several days of monitoring has proved to be invaluable in the study of factors that might affect the rate and localization of spikes. It was found that the rate of focal spiking does not change, by either increasing or decreasing, before seizures.[53,66,86] In contrast, there is a large increase in spiking in the days that follow most secondarily generalized seizures and many partial seizures; surprisingly, spiking rates appear unaffected by changes in AED levels.[50,53] These postictal increases in spiking and the absence of decrease in spiking with high AED levels were replicated in the kindling model of epilepsy.[34,39,81] Thus, quantification of spiking rates has established that spiking does not change as was intuitively thought (increasing before seizures and decreasing with high AED levels).

Spikes were also quantified during the different stages of sleep in patients evaluated for epilepsy surgery with noninvasive recordings. Results indicated that spiking is more focal during rapid eye movement (REM) sleep than during slow-wave sleep. The localization obtained from REM sleep spiking correlates better with other tests of localization (e.g., seizure onset, radiologic findings) than the localization obtained during slow-wave sleep or wakefulness.[110]

The question of seizure propagation was discussed previously. The question of whether spike activity propagates between brain regions has also been studied. Emerson et al.[24] used spike-triggered averaging to measure the propagation between temporal and frontopolar regions and concluded that it was possible to see relationships not apparent by visual inspection. Spatiotemporal dipolar modeling has also been used to see whether spikes could be represented by one or several dipoles, in an attempt to localize the source of spike activity.[9,23] The modeling of spike activity with dipole or distributed models is discussed extensively in Chapter 78.

Recently, Kobayashi et al.[72] studied epileptiform discharges by applying ICA on a data matrix formed by concatenating several EEG segments, each containing a spike and some surrounding background activity. The analysis revealed multiple extracted sources corresponding to the discharges, which were clearly separated from the background. The time delays and different spatial topographies of these multiple components could reflect the spatiotemporal evolution of the spikes. The validity of the sources extracted by ICA was later established by comparing the topographies of the spike components with the fields subsequently measured by intracranial electrodes.[73] It was observed that the number of intracranial peaks measured by depth electrodes generally matched the number of spike components extracted by ICA. A single equivalent current dipole was then fitted to the ICA source with the clearest epileptic activity. Despite the use of such a simple model, the distance between the dipole and the intracranial electrode contact with the maximal field was generally small, ranging from 4.7 to 31.9 mm.

An example of this is shown in FIGURE 6. After the application of ICA to the spikes of FIGURE 6A, epileptic activity was found in two of the resulting extracted components (Fig. 6B). The component having the clearest epileptic activity had a spatial topography that was dipolar (Fig. 6C). An equivalent current dipole fitted to that spatial map was 10.8 mm away from the maximal intracerebral field, as determined by a depth electrode investigation (Fig. 6D).

Promising results were also obtained when using the more sophisticated RAP-MUSIC algorithm for source localization; this algorithm was applied to the subspace formed by the epileptic components extracted by ICA.[70,71] ICA was thus used to subtract EEG sources of background activity or artifacts so that only epileptic sources remained. Applying RAP-MUSIC to this processed data set yielded more accurate results than those obtained by using averaged raw spikes. ICA can thus be an effective method for isolating the epileptic activity from the background. Jung et al.[65] analyzed generalized spike-and-wave discharges with ICA. The extracted components corresponding to the epileptic discharges were then modeled using dipole sources in a spherical head model. It was found that the position and orientation of the equivalent dipoles could be used to distinguish between patients with primary or secondary bilateral synchrony. Another recent study used ICA to distinguish between focal and multifocal spikes.[62] Spikes of different origins were generally separated into distinct components; each of these components thus tended to represent one focus of the spike activity.

Summary and Conclusions

Computers can play a variety of roles in assisting the recording and analysis of the EEG of epileptic patients. During long-term monitoring, computer assistance is almost indispensable for the detection of epileptic events. There is no single economical method that ensures the detection of all seizures in every patient; all available help must be used, including staff and patient reporting, and computer detection. In some patients, one method might prove to be more useful than others, but this is not known in advance of the monitoring sessions.

Spike and seizure detection are not simple tasks, as researchers in this area originally thought. The human who reads an EEG uses clues from a wide spatial and temporal context, clues that are difficult to encode in computer programs. Most methods analyze the EEG at a very local level (looking at 10 to 30 seconds of EEG at a time, often one channel at a time). It would therefore be naive to expect a high degree of reliability from such automatic methods. Nevertheless, they can be extremely useful if implemented in the context of human validation. In this case, methods can be designed to yield a sensitivity that is as high as possible, and false detections can be removed manually during a subsequent review of the detected events. On the other hand, automatic warning systems have much more stringent requirements: They must operate in real time, they must detect seizures as early as possible after their onset, and the false-detection rate should be minimized to avoid unnecessary disruptions. Nevertheless, some efficient systems have been designed to satisfy these constraints. Recently, improvements in the performance of detection methods have been achieved by incorporating knowledge of a wider context, such as the state-dependent spike detection method. Further developments in this area will in all likelihood result in much better performance, but it is unlikely that a stage will be reached in which human validation is not required.

Finally, computer analysis of seizures and spikes may provide information that is not readily available from traditional visual examination. This is primarily attributable to the possibility of quantifying the EEG and of making mathematical analyses that can be related to brain function. In particular, the method of independent component analysis is effective at separating the various sources of electrical activity present in the EEG signal. ICA can be used to remove artifactual sources contaminating the EEG signal and to analyze the patterns of propagation of ictal or interictal activity.

Chapter 96

Overview: General Approaches to Treatment

David W. Chadwick

Roger J. Porter

Emilio Perucca

John M. Pellock

Introduction

After making the correct diagnosis of a patient but before writing the prescription for a specific antiepileptic drug (see previous section), the physician must consider a number of additional issues. The full understanding of these issues is reviewed in this section and should permit the best outcome for the patient, regardless of the drug or other therapy that is chosen.

However, before entering into the complexities of treatment strategies, we need to provide a brief reminder about the accuracy of the patient's diagnosis. The correct diagnosis is, after all, the fundament on which all therapy is based. Inadequate or wrong diagnosis is likely to lead to inadequate and potentially harmful treatment. This a difficult area given that epilepsy is not a single disease but a heterogeneous array of syndromes with innumerable causes and a wide range of clinical expressions, the final one of which is the seizure itself. So how are we to make a correct diagnosis of the patient with the disorder? We can only do this by recognizing that multiple levels of diagnosis are present, and these must be identified in each patient.

Levels of Diagnosis

The meaningful levels of diagnosis in patients with epilepsy can conveniently be divided into three basic categories: (a) the etiologic diagnosis, (b) the seizure diagnosis, and, where possible, (c) the epilepsy syndrome diagnosis. The etiologic diagnosis requires identification of the cause of the epileptic seizures. The causes range from obvious structural abnormality of the brain to usually still obscure genetic abnormality. Every patient deserves a search for the etiologic diagnosis—and appropriate specific therapy for this etiology, when possible—even though, in a substantial proportion of patients, the effort will be unsuccessful. In most patients, the correct classification of seizure type(s) and, possibly, epilepsy syndrome permits the correct choice of therapy and, even more specifically, the correct choice of antiepileptic drug. Our ability to establish an accurate diagnosis has been greatly aided not only by a better overall understanding of the disorder, but also by technical advances such as brain imaging (for improved etiologic diagnosis) and intensive electroencephalographic (EEG)/video monitoring (for more precise seizure diagnosis). Although the seizure diagnosis alone can help with the choice of medication, the epilepsy syndrome diagnosis is more important for predicting the prognosis and, potentially, the duration of therapy. Recent improvements have been made in both the seizure classification and the classification of the epilepsies but, as noted in other chapters, considerable refinements are needed for better diagnosis at both of these levels.

Treatment Issues

Once the patient's diagnosis is secure, what are the treatment issues that must be considered to optimize the outcome for the individual? These treatment variables, discussed at length in the following three dozen chapters, have been divided into the following sections: (a) general aspects (indications for treatment, goals of treatment, need for a comprehensive treatment approach, assessment tools, and age considerations), (b) principles of drug treatment, (c) strategies for pharmacotherapy, (d) special therapeutic considerations, and (e) alternative and experimental approaches, although inevitably these areas will have considerable overlap and interaction.

Health-related quality of life (HRQoL) embraces the philosophy that treatment is much more than simply a knee-jerk drug prescription. Indeed, the physician's aim is to ensure that the patient derives the optimal overall value from the recommended therapeutic intervention by including measures of how the patient feels and functions so as to reduce both handicap and disability due to epilepsy and its diagnosis. Rarely does this assessment make inappropriate the primary choice of therapy (e.g., ethosuximide or valproate for absence seizures, or lobectomy for intractable temporal lobe epilepsy), but it does put into context the physician's impact on the whole patient rather than focus only on seizure control. Is the patient with multiple severe handicaps that include epilepsy at greater risk from increasing the antiepileptic drug load than from having a few more seizures every year? Is the patient who had a temporal lobe resection and is now seizure free but is increasingly clinically depressed better off at a time when his family expects him to exhibit greater independence and even to get a job? These highly focused examples are only a small taste of the issues addressed in the chapters on this topic, encouraging all of us to consider total patient care rather than merely seizure control.

The issue of patient autonomy is one of growing importance that needs to be considered and is of relevance to HRQoL. Patients and their caregivers expect adequate and appropriate information about treatments as well as active involvement in therapeutic choices. In many cases, the clinician has ceased to be the major provider of information because this is readily available from other sources that include package inserts and the Internet. He or she still has an important role to play, however, as an interpreter of information for the individual patient. It is axiomatic that the best therapeutic choice is one that is reached jointly by a well-informed patient (with or without caregiver involvement) and clinician. Indeed it can be argued that therapeutic decisions reached by other means are unlikely to be accompanied by adherence.

P.1118

Principles of Drug Treatment

The section on principles of drug treatment provides a fundamental perspective on how antiepileptic drugs work and how to use them optimally. Those who prescribe drugs must mentally separate the two basic issues of drug action—what the drug does to the body (pharmacodynamics) and what the body does to the drug (pharmacokinetics).

Seizure control and adverse drug effects are both pharmacodynamic measures of a drug's effect on the body, whereas the time needed for drug absorption, distribution, and elimination is a pharmacokinetic measure of the body's effect on the drug. Although a full understanding of both pharmacokinetics and pharmacodynamics is needed to prescribe antiepileptic drugs properly, chapters in this section concentrate on pharmacokinetics, therapeutic drug monitoring (e.g., the use of blood concentration data to improve patients' outcomes), and highly specific pharmacodynamic issues, such as differences in efficacy spectrum and adverse effects profiles between drugs, mechanisms of drug resistance, drug–drug interactions, and teratogenicity. These issues have important consequences for special groups of patients and raise questions concerning the degree to which therapeutic choices should be determined by, for example, gender and age in addition to seizure type and syndrome.

Strategies for Pharmacotherapy

If the previous section is essential for understanding how drugs function, the section on strategies for pharmacotherapy is devoted primarily to application of this knowledge to optimal clinical management. The questions answered here range from "When should one treat?" to "How should treatment be started?" to "How and when should treatment be discontinued?" In addition to these questions are chapters on how to maintain and alter therapy for maximal effectiveness. Although individual drugs are described in detail in the previous section, this section on strategies is the overview that permits the physician to put drug therapy in the best context for patient care.

Special Therapeutic Considerations

Nowhere is the heterogeneity of the epilepsies more evident than in the section on special therapeutic considerations. With emphasis on treatment, this section encompasses many of the vexing issues confronted by the health care provider. Should the first seizure be treated? Should one treat uncomplicated febrile seizures? What is the appropriate first medication for status epilepticus? These are only examples of the difficult questions addressed in this section. Although the section is entitled “Special,” by no means should the reader take this to mean *uncommon*, because some of the conditions considered here are among the most common in routine clinical practice.

Alternative Approaches

Many practitioners have recognized that standard drug therapy or surgical intervention is often suboptimal for the individual patient and that other approaches are worthy of consideration. The section on alternative and experimental approaches is designed to be a rather comprehensive view of therapeutic possibilities other than the usual drugs or standard surgery. These include some treatments that, while developed relatively recently, have already undergone rigorous testing in randomized, controlled trials (e.g., vagal nerve stimulation), treatments that we are just starting to understand although they have been around for almost a century (e.g., the ketogenic diet), and others that have not received much attention from the medical community, such as folk therapies. Although this discussion is small by comparison to the sections on more conventional treatments, interest in these approaches continues to increase for very good reasons—in some patients, some of these approaches are effective when the usual methods fail. No doubt we will be exposed to more experimental alternatives as we search for optimal patient care.

Summary and Conclusions

There are an increasing range of choices of treatments for patients with epilepsy. The best treatment will involve the use of high quality information, its interpretation by the clinician for the individual patient, and the involvement of the patient in the decision making process.

Chapter 97

Indications for Treatment

John M. Freeman

Timothy A. Pedley

Introduction

Epileptic seizures are among the most common symptoms of disturbed brain function. They result from many causes and can have widely varying manifestations. An *epileptic seizure* (a discrete event resulting from transient, hypersynchronous, abnormal neuronal behavior) should be distinguished from *epilepsy* (the condition of recurring epileptic seizures). Seizures are epileptic events and the indispensable characteristic of epilepsy, but not all seizures are manifestations of epilepsy. There are many different types of seizures, each producing a profile of characteristic behavioral changes and electrophysiologic disturbances. Some patients have seizures that are self-limited—that is, they occur only in the course of an acute medical or neurologic illness. Other people have one or two single seizures at some time in their life for which a cause is never determined. Such seizures are not epilepsy. Epilepsy, on the other hand, is a group of chronic disorders, the hallmark of which is recurrent, unprovoked seizures. Many patients with epilepsy have more than one seizure type, and many have other symptoms as well. Sometimes, additional electroencephalographic (EEG), clinical, familial, etiologic, and prognostic data are sufficiently similar among a group of patients with epilepsy that a more specific *epileptic syndrome* can be defined.

Given these considerations, it should not be surprising that the many seizure types and the various forms of epilepsy have different etiologies, different prognoses, and different consequences, each of which may have quite different implications for individual patients. Thus, indications for treatment also vary, and no formula or algorithm can be applied justifiably to all cases.

The nature and severity of the consequences of seizures depend on the type and timing of attacks, the age and condition of the affected individual, the patient's type of employment, the response of the patient's family, societal attitudes, and many other factors. Because the effects of seizure recurrence are so variable, each affected person must be considered uniquely during evaluation of the impact of further seizures in relation to the potential consequences—both beneficial and adverse—of treatment. Ultimately, the decision regarding whether to treat rests with the patient or, in the case of young children, the patient's family. This is as it should be because only the individual affected by seizures, and the family, can determine the extent to which further seizures will interfere with that individual's life. It is therefore the *patient's* perception of the consequences of further seizures that drives the decision to treat or not to treat.

Illustrative Cases

Case 1. Should a 2-year-old girl who has had a single convulsion lasting <2 minutes associated with a fever of 101°F be started on drug treatment? What if the seizure had lasted 20 minutes? What if the child had had a second brief seizure 24 hours after the first? Or another seizure 6 months later?

Case 2. Should a 14-year-old boy be started on drug treatment after a first unprovoked generalized tonic–clonic seizure? Would it make a difference if he were 17 years old and driving?

Case 3. Should antiepileptic drug therapy be recommended to a recently married woman whose husband first noted her early-morning "jumps" and then witnessed a generalized tonic–clonic seizure? Would the advice be different if she were eager to start a family?

Case 4. Should a 3-year-old girl with profound retardation who has been having two staring spells each week for the last several months be started on drug treatment? What if she were having drop attacks instead? Would the physician's advice depend on whether the child was ambulatory? At home or in a long-term care facility?

Case 5. How would a physician advise a factory worker who has had a first nocturnal generalized tonic–clonic seizure? Would the physician's advice be different if the patient expressed concern about failing the plant's required random drug screens and possible job loss after starting drug treatment? Would the physician's recommendations be influenced if the patient used heavy industrial power tools? Or drove a truck? Would the recommendations be the same for a housewife?

Each of these cases emphasizes situations that are unique to a particular patient and illustrates that both the consequences of further seizures and the consequences of treatment can be quite different, depending on individual circumstances. This chapter reviews the factors that physicians should consider in assisting patients and their families to reach informed, reasonable decisions about whether to initiate treatment.

Elements of the Decision-Making Process: Assessing Risks and Benefits

Type of Seizure

It is obvious that different seizure types have different consequences for patients. A generalized tonic–clonic seizure is likely to be far more hazardous and have more psychosocial impact than an absence seizure. A typical simple partial seizure of benign rolandic epilepsy, manifested only by speech arrest, salivation, and facial twitching, may be much less important to an individual than a complex partial seizure with unresponsiveness, prominent automatisms, and postictal confusion. An atonic seizure that causes a child to fall, with risk for injury, can be very debilitating, even though brief. Complex partial seizures that begin with a prolonged aura are usually less

P.1120

disabling than complex partial seizures that begin with abrupt loss of consciousness. Different epilepsy syndromes, with different seizure types and prognoses, are likely to affect patients in very different ways.

Timing of Seizures

Some persons have only nighttime seizures. Others have seizures only in the morning after awakening. Some women have seizures linked to phases of their menstrual cycles. Other patients have seizures only in certain circumstances (e.g., when deprived of sleep, when under great stress, or after drinking) or with specific triggers (reflex epilepsies). Many patients have seizures that are completely unpredictable. The temporal patterns of seizures clearly influence their impact on patients' lives.

Frequency of Seizures

Only about 30% of persons who have a single, unprovoked, generalized tonic–clonic seizure have a second, regardless of whether they are treated. Many children with benign epilepsy syndromes have only a few seizures. Patients with cryptogenic or symptomatic localization-related epilepsy usually have frequent seizures that may be drug resistant. Individuals with temporal lobe epilepsy typically have many complex partial seizures but relatively infrequent secondarily generalized seizures. Someone with frontal lobe epilepsy, however, may have mainly generalized seizures.

Frequent seizures of whatever type interfere with function, but the responses of individuals, even to daily or weekly seizures, vary widely. Some patients are greatly disabled; they are socially isolated, unemployed, and severely restricted in what they can do. Others with similar seizures are gainfully employed, well adjusted, and productive members of society. Children generally adapt better to a higher rate of seizures than do adults. Thus, although frequency of seizures is closely related to the consequences of epilepsy, the impact varies among individuals, even those with the same rate of seizures, depending on many factors—intrinsic and acquired; personal and societal—that affect a person's support mechanisms and ability to cope and adapt.

Effects of Age on Consequences of Seizures

The consequences of recurrent seizures are age dependent. Infants, whatever the seizure type, are unlikely to be physically injured during a seizure or even be aware, or remember, that a seizure has occurred. Toddlers, although usually in a supervised environment, are more likely to be affected by consequences related to the seizures, but these depend greatly on the type of seizure (e.g., head injury from an atonic seizure). In addition, children begin to feel the effects of overprotection resulting from the family's fear of recurrence. Adolescents, with their desire to conform, sensitivity to embarrassment, and growing desire for independence, are greatly affected by recurrent seizures. Common concerns include loss of control of bodily functions, especially incontinence; not being able to obtain a driver's license or, if they are already driving when seizures begin, loss of the license; social isolation; and conflicts about restrictions—both reasonable and unreasonable—imposed by parents, schools, and sports teams. Adults face restrictions on driving (which may, in some cases, directly affect livelihood); employment (keeping a job or having opportunities for career advancement); and social opportunities, including the ability to develop and maintain significant relationships. Adults are also concerned that they may be unable to meet their responsibilities as parents or providers, and they naturally fear embarrassment.

Environment

The consequences of seizure recurrence at each age may also vary according to whether the patient lives in a city, where medical facilities are generally close by and easily accessible via public transportation, or in a rural environment, where medical services and community resources are limited and often distant, close neighbors are few, and personal automobiles are the only means of transportation.

Consequences of seizures also depend on occupation. For any given seizure type or frequency, the consequences for office workers will likely be different than for persons operating machinery, and individuals who must work in exposed areas face different consequences than those who work in protected environments.

Consequences of Treatment

Consequences of treatment depend on the drug chosen and the number of drugs used. They also depend on whether side effects develop and whether seizures are completely or only partially controlled. All drugs have adverse effects, some more than others, and these range from minor to severe. Neurotoxicity can be subtle, especially in terms of effects on cognition and behavior. Children especially may inadvertently be overtreated, with adverse consequences for learning and psychological development.

Deciding Whether to Treat

The Issue

Although there can be little doubt that drug treatment is indicated and beneficial for most patients with epilepsy, there are certain circumstances in which antiepileptic drugs may reasonably be withheld or deferred or used for only a limited time. The common issues in such cases are those listed in the foregoing section and relate to (a) the probability of seizure recurrence, (b) the likelihood of substantial psychosocial, vocational, or physical consequences with further seizures, and (c) the question of whether the benefit to be derived from treatment substantially outweighs the chance of treatment-related side effects (Fig. 1).

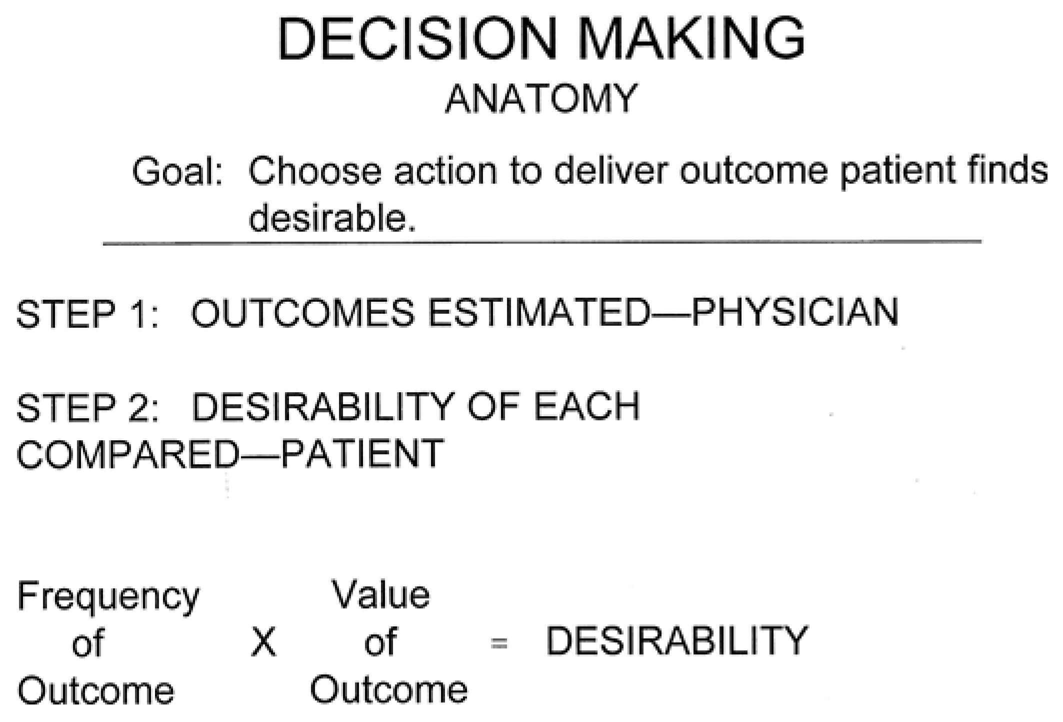

FIGURE 1. The key steps in the decision-making process regarding treatment. (Based on data from Eddy DM. Anatomy of a decision. *JAMA* 1990;263:441–443.)

Acute Symptomatic Seizures

Acute symptomatic seizures are those caused or provoked by an acute medical or neurologic illness. Febrile seizures in children are the most common example (see Chapter 57). Other frequently encountered causes include metabolic or toxic encephalopathies (uremia, hypoglycemia and hyperglycemia, hepatic failure, drug withdrawal) and acute brain infections (encephalitis, meningitis). To the extent that there is no underlying permanent brain damage, seizures occurring in these settings are usually self-limited. The primary therapeutic consideration in such patients should be identification and treatment of the underlying disorder. If antiepileptic drugs are used to suppress seizures acutely, they generally do not need to be continued after the patient has recovered from the primary illness. It is important to remember, however, that the presence of a precipitating medical illness does not necessarily exclude the

need to search for brain pathology; underlying brain lesions increase the risk for acute symptomatic seizures (as well as epilepsy) in appropriate settings.[7]

The issue of treating acute symptomatic seizures that occur in the setting of stroke, head injury, neurosurgical procedures, and alcohol use is more complicated. Each of these is a significant risk factor for both acute symptomatic seizures and epilepsy.[8] Although antiepileptic drugs are effective in treating seizures acutely, none has yet been shown to delay or reduce the development of later epilepsy. This has been best demonstrated for seizures occurring after a head injury (see Chapter 253). Phenytoin, for example, is highly effective in suppressing seizures in the first week after a head injury, but long-term prophylactic treatment is ineffective in preventing posttraumatic epilepsy.[22] The association between alcohol and seizures is also complicated. Whereas acute alcohol withdrawal can trigger self-limited seizures that do not require treatment, chronic alcoholism is a major risk factor for epilepsy.[14] Thus, over time, many alcoholics may have both acute symptomatic seizures (withdrawal seizures) and recurrent unprovoked seizures (epilepsy).[11,20] Given these considerations, we believe that the approach to patients who have acute symptomatic seizures as well as a substantially increased risk for later epilepsy should be based on the need to suppress active seizures, not on the hope that later epilepsy may be prevented.[17] This approach is supported not only by clinical experience and the results of a limited number of clinical trials, but also by results of animal experiments investigating the mechanisms of action of antiepileptic drugs now available. For the most part, current antiepileptic drugs, although effective as seizure suppressants, do not affect the development of epilepsy (epileptogenesis).[19]

Febrile seizures require special consideration. These are the most common and probably best-studied form of acute symptomatic seizure. They are almost always benign events in the sense that the potential neurologic and medical consequences of even multiple febrile seizures are vanishingly small (see Chapter 57). Furthermore, only about 30% of neurologically normal children with a single febrile seizure have further febrile seizures, and this risk is most clearly related to age.[3,12] Moreover, whereas the risk for later epilepsy is increased modestly in children with febrile seizures, to about six times that of the general population, this varies with the clinical features of the febrile seizures.[1,13,23] There are no data demonstrating that prophylactic treatment alters this risk. Although the possibility of recurrent febrile seizures understandably evokes fear and apprehension in parents, we believe that these concerns are best dealt with by education and reassurance rather than by treatment with antiepileptic drugs. Issues of treatment related to febrile seizures are discussed more fully in Chapter 124.

The Single Unprovoked Seizure

The majority of patients come to medical attention after having had more than one seizure. However, about 30% of patients with unprovoked seizures, virtually always generalized tonic–clonic convulsions, are seen by physicians after only a single attack. It is reasonable to consider whether treatment is indicated in this group of patients (see Chapter 122). The data of Hauser et al.[9] and Shinnar et al.[18] clearly establish low- and high-risk groups for recurrence after a single unprovoked seizure. The risk for epilepsy is greatly increased in the presence of an abnormal EEG, history of brain injury, and family history of epilepsy. Conversely, patients without any of these factors have a much lower risk for further seizures.

Although a large, multicenter, randomized study from Italy[6] demonstrated that antiepileptic drug therapy reduces the risk for relapse following a first unprovoked generalized tonic–clonic seizure, there is little evidence that the ultimate prognosis, especially regarding the development of epilepsy after 2 years or the chance of eventual remission following further seizures, is affected by early antiepileptic drug treatment.

Thus, although data demonstrating the positive effect of therapy on reducing relapse rates, even in patients at low risk for development of epilepsy, are available to justify treatment, we believe that treatment should not be automatic for this group of patients. Treatment decisions following a single unprovoked seizure should still involve a discussion and analysis of the benefits to be gained from treatment versus the potential risks or adverse effects of therapy. For example, in nearly one third of patients treated with antiepileptic drugs, side effects develop that are severe enough to require a change in treatment.[10,21] Furthermore, when there are particular concerns (as in children) about the effects of antiepileptic drugs on brain development, learning, and behavior,[5,16] we tend to

avoid or defer treatment, especially if the consequences of further seizures are judged to be insignificant.

Benign Epilepsy Syndromes

Several electroclinical syndromes have been identified that are characterized by seizure onset in childhood; absence of evidence of structural brain pathology, both clinically and on imaging studies; infrequent seizures; and a uniformly good prognosis for complete remission during middle to late adolescence. The most common and best-characterized of these syndromes is benign partial epilepsy of childhood with central-midtemporal sharp waves (see Chapter 236). Other similar syndromes include benign partial epilepsy with occipital spikes-and-waves (see Chapter 237), benign epilepsy with affective symptoms, and benign frontal epilepsy of childhood. When a child with seizures is evaluated and decisions about treatment are made, it is important to determine whether the clinical and EEG criteria fit one of these benign syndromes. Many children have only one or a few seizures, making treatment generally unnecessary. In selected cases, treatment may be viewed as desirable to prevent recurrences and help allay parental concerns. In such cases, drug treatment should be limited to 1 to 2 years. It is a mistake, in our view, to treat until the EEG normalizes, because interictal EEG abnormalities will persist, in the majority of such cases, long after seizures have remitted clinically.

Other Considerations

Is It a Seizure?

Not all paroxysmal events are epileptic seizures, and sometimes the diagnosis remains uncertain even after all relevant clinical and laboratory data have been considered. We generally advocate a period of "watchful waiting" and close follow-up in such circumstances rather than initiate treatment. Using the response to antiepileptic drug therapy as a diagnostic test is usually inadvisable because the placebo effect is high (about 20% to 30% in most clinical trials) and no antiepileptic drug has a therapeutic effect limited to epilepsy. Consider, for example, the widespread use of carbamazepine and valproate in the treatment of psychiatric disorders. In addition, there are unfortunately still adverse psychosocial and other consequences to the individual with epilepsy, and the diagnosis should not be made without reasonable certainty (see Chapter 68).

Factors Affecting Seizure Threshold

It is important to identify any environmental or physiologic factors that can lower an individual's seizure threshold and provoke seizures in certain circumstances (see Chapters 9 and 125). Sleep deprivation and irregular sleep habits are especially common triggers for seizures in some people, but other factors may be important in individual patients. Eliminating these can occasionally obviate the need for antiepileptic drug treatment or allow lower drug doses to be used.

Consideration of the Illustrative Cases

At the beginning of this chapter, several cases were described and questions asked regarding what effect the particular circumstances in each situation might have on treatment recommendations. With full recognition that there are no "right" or "wrong" answers and that treatment decisions are always a matter of judgment based on medical data modified by individual circumstances and patient preferences, we offer the following comments to give an indication of how the issues raised in the vignettes might be approached in the light of the foregoing discussion.

Case 1. Treatment of this child's febrile seizure, whether brief or prolonged, or whether a first seizure or one of several, is not recommended. Attempts should be made to inform the family about febrile seizures, give them literature to take home, and see them regularly for a while to provide continuing reassurance and education. In exceptional circumstances, when parents are unusually panicky and seem to be focusing unduly on preventing a recurrence, phenobarbital sufficient to produce a plasma concentration of 15 µg/mL might be prescribed for 6 months or so, with the drug being stopped if behavioral side effects develop. Diazepam administered rectally[2] or orally[15] at the time of fever is also effective in preventing recurrence of febrile seizures. The risk for recurrence of a first *afebrile* seizure and its consequences in this age group are very similar to those for a febrile seizure. The recommendations in this case, therefore, would be the same.

Case 2. Although the chance of a second generalized tonic–clonic seizure is the same in this 14-year-old boy as it was in the 2-year-old girl, the consequences for teenagers are far different. Foremost in most teenagers' minds is the effect another seizure will have on their independence, their ability to obtain a driver's license, and their relations with peers. The impact of another seizure in terms of these issues should be discussed forthrightly with teenagers while parents are out of the room, at least part of the time. Talking to siblings as well as parents is also helpful. In this age group, it is also important to explore the role of alcohol and other drugs, as well as other seizure precipitants (e.g., sleep deprivation). Although our bias in such discussions is against treatment, our ultimate recommendation is strongly influenced by the reaction of teenagers regarding what further seizures will mean to them. To the 14-year-old who will not drive for another 2 years, withholding treatment may be more acceptable than to the 17-year-old whose license is still new and a mark of pride. Physicians should also bear in mind that if drug treatment is recommended, most teenagers prefer to take drugs at home (i.e., once or twice daily), not "in public."

Case 3. This woman most likely has juvenile myoclonic epilepsy (see Chapter 244). It may have been unrecognized until her husband saw the morning "jumps" and then witnessed a generalized tonic–clonic seizure. This syndrome generally persists throughout life, and the probability of further generalized convulsive seizures is high. We would encourage her to start drug therapy, and we consider valproate to be the drug of choice. We also believe that a discussion of pregnancy-related issues and prescription of folic acid are mandatory for any woman of childbearing age, whether she plans a pregnancy in the near future or not. For a woman like this one, who is hoping to start a family soon, the various interactions between seizures and pregnancy should be discussed with her and her husband; it might be recommended that she remain off valproate during conception and for the first few months of pregnancy. Disabling myoclonic jerks can often be treated with small doses of diazepam or clonazepam taken as needed immediately after awakening. In the event of a second convulsive seizure occurring before conception or early in pregnancy, valproate could be started, with the patient followed closely in conjunction with a perinatologist. In new mothers with juvenile myoclonic epilepsy, the effects of unavoidably disrupted sleep and sleep deprivation may make treatment even more necessary.

P.1123

Case 4. Although she has profound retardation, this child warrants the same thoughtful consideration as the child with seizures who is otherwise normal. The impact of seizures, however, may be quite different. The following questions are always pertinent: "What effect are the seizures having on the child's daily routine and on the ability of the family or others to provide care?" and "How would this child's life be improved in real terms if seizures were controlled?" The answers to these questions depend very much on the type of seizure and also on the child's functional abilities, age, and care setting. Thus, atonic seizures are more disruptive and likely to lead to injury than absence seizures, especially in ambulatory patients. Older (bigger) children are generally more difficult to manage than younger (smaller) ones. Another consideration is the possible deleterious effect drug therapy may have on alertness and behavior. Sometimes, recognized seizures may be only the tip of the iceberg, and EEG recordings demonstrate that the child is having many more seizures that, untreated, are actually contributing to the severity of the encephalopathy. Treatment is virtually always indicated in children with epileptic encephalopathies, but outcome goals need to be defined realistically because complete seizure control is rarely obtained.

Case 5. If careful review of the history confirmed that this was, indeed, a first unprovoked seizure, and if the clinical and EEG data indicated that this person had a low probability of seizure recurrence, we would not recommend drug treatment. However, adults respond differently based on their individual perceptions of the consequences of another seizure (especially on driving and employment) and their view of drug treatment. If this factory worker is less concerned about driving than about an employer's mandatory drug testing policy, a recommendation to defer treatment would probably be acceptable. An important related issue is whether to inform the employer. This is generally the best policy, especially because there is a possibility that if another seizure occurs, it could happen while the patient is at work. However, physicians know, as do their patients, that employers still discriminate. What would happen to this person if results of the drug screen were positive and the employer had not been informed of a medical condition requiring treatment? There are many different combinations of decisions and consequences that can be imagined in this set of circumstances, and it is neither possible nor desirable for the physician to attempt to decide what is best for the patient. In situations like this, patients must make their own decisions and live with the consequences.

The responsibility of physicians is to ensure that patients and their families understand both the medical and psychosocial issues surrounding recurrent seizures, as best they can be defined, and the ramifications of treating or not treating given the various complexities of a particular set of circumstances. In discussions with patients, we have often found it helpful to pose the question, "What is the worst that could happen if…?" These worst-case scenarios help to keep risk-taking behavior in proper perspective. If patients understand and can accept the consequences of "the worst that could happen," then every other alternative is more acceptable.

Summary and Conclusions

Indications for treatment are based on assessing how seizures interfere with a patient's ability to function, quality of life, and health and well-being. Because seizures have diverse manifestations, because epilepsy is a group of conditions, not a homogeneous disorder, and because patients are unique individuals, each with a unique set of circumstances, it is not possible or even appropriate to formulate specific guidelines that specify when or how to treat and that are applicable to all settings. In fact, in many situations there is no single correct answer to the question, "Should this patient be treated?" What is right for one person may be wrong for another. Recommendations regarding treatment must be formulated individually for each patient and based on an interactive decision-making process that considers the consequences—both good and bad—of various courses of action. The physician's obligation is to ensure that patients and their families knowledgeably assess risks and benefits in light of factors that are germane to a given individual, and that the final decision, which must ultimately be the patient's responsibility, is as fully informed as possible.

Chapter 98

Goals of Therapy

Lawrence J. Hirsch

Timothy A. Pedley

Introduction

The goal of all medical therapy is to allow patients to live as normally as possible and to maximize quality of life, especially health-related quality of life. For patients with epilepsy, the desired goal is "no seizures, no side effects," as emphasized in a National Institutes of Health–sponsored consensus conference in 2000.[12] The availability of a number of newer antiepileptic drugs (AEDs) has helped us to reach this goal, particularly in terms of "no side effects." Unfortunately, there has not been a comparable benefit in the number of patients who become seizure free.[25]

General Aspects of Treatment

Having epilepsy commonly introduces several consequences that are relatively unique, including restrictions on driving, persistent stigma, and the small but real possibility of sudden death. There are also more subtle issues that affect the quality of a patient's life but can easily be overlooked, even in patients who are seizure free and who seem, on first glance, to be free of adverse effects as well. These include undesired chronic effects of AEDs on cognitive ability, mood, weight (both gain and loss), childbearing, and sexual function. Epilepsy can cause cultural and financial stress, and some AED regimens can be inconvenient and threaten compliance. Such issues are just as important, and can be as complex, in patients with mild epilepsy (or even a first seizure) as they are in those with intractable seizures. For these reasons, it is ideal for all patients who have seizures or epilepsy to be offered an opportunity to consult with an epilepsy specialist.

Successful management of patients with epilepsy requires treatment to be individualized. This can only be achieved if the physician, patient, and family cooperate in a productive partnership. It is useful early on to determine the relative importance the patient attaches to several possible outcomes and then to reevaluate these from time to time during the course of treatment. For a patient who has strong objections to taking medication, it is best to choose the simplest possible regimen with the least risk of side effects. Other reasonable considerations might include, as appropriate, reduction in dose or consideration of AED withdrawal, even if the chance of success is low. Another patient may view the possibility of an additional seizure as sufficiently devastating that he or she will not tolerate even a small risk of recurrence despite the potential benefit of lower doses or discontinuing medication altogether. The reasons may be psychological, professional, social, or practical (e.g., a compelling need to drive).

Although family members who accompany patients can be helpful in providing details and circumstances of ictal events, additional details of the family's history, and information about the patient's infancy and childhood, it is essential for the physician to meet privately with the patient at some point, even if this has not been specifically requested. Privacy encourages most patients to raise questions and express their concerns and also to discuss potentially sensitive issues such as alcohol, drugs, and sex. On rare occasions, patients may express unease about their caregivers, whose motives may not always be in a patient's best interest. For example, a caregiver in a group home might report that a patient's behavior has worsened and become problematic after a sedating medication has been stopped. In reality, the patient might be more alert and interactive but now also requires more attention.

Patients' reports of their seizures are notoriously unreliable. Blum et al.[5] determined seizure awareness prospectively in 31 patients admitted to an epilepsy monitoring unit (EMU). Twenty-three patients had epileptic seizures, but only 26% of them were aware of all of their seizures (regardless of seizure type), and 30% were not aware of any. Similarly, Eisenman et al.[11] found that self-reports of seizure frequency did not correlate with time to first recorded seizure in the EMU. Patients with infrequent seizures, averaging <2.2/month by history, and those who reported frequent seizures, averaging >24.1/month, both averaged 2 to 3 days to record the first seizure. Furthermore, even when patients recall their spells, details regarding impairment of consciousness are unreliable. Regularly obtaining collateral information from spouses, partners, or other close family members can add important information and improve historical accuracy. The foregoing data also suggest that having a low threshold for prolonged electroencephalogram (EEG) monitoring (either ambulatory or inpatient) is frequently necessary to resolve ambiguities or inconsistencies in the history and obtain a more accurate account of the patient's condition.

What do patients care about the most?

Previous work has shown that patients with epilepsy have many health-related quality of life concerns, and these frequently involve issues related to a desire for greater independence (especially in terms of driving, work, and social life), less stigmatization, improved mood and cognition, absence of drug-related adverse effects, and, of course, complete control of seizures.[9,15,39] Although seizure control without AED side effects is an important determinant of quality of life, other factors are also significant. Moreover, many of these may be amenable to educational or therapeutic interventions, resulting in improved quality of life even without a concomitant reduction in seizure frequency or severity.

There is convincing evidence that depression is a common comorbid condition in patients with epilepsy[14] and that the presence or absence of depressive symptoms might outweigh the impact of controlling seizures in determining the patient's perception of well-being[6,21](see also Chapter 205). Depression also influences how patients perceive their seizures. In a survey that assessed self-reported seizure severity and the burden of seizure components, respondents with moderate or severe depression reported significantly worse problems than did those

without depression in terms of overall seizure recovery, overall severity, and overall seizure burden (all p <.005). Cognitive, emotional, and physical aspects of seizure recovery were also rated worse among people with severe depression compared to those without depression (all p <.05).[7] (See Chapter 199 for an overview of psychiatric issues in epilepsy.)

Several studies have shown that individuals with frequent and more severe seizures have a significantly poorer quality of life than those with infrequent or no seizures.[3,4,20] Adverse events related to AEDs are also detrimental to quality of life. On the basis of a U.S. survey of >1,000 persons with epilepsy, Fisher et al.[13] concluded that "only 68% of respondents were very satisfied with their current seizure medications." Patients ranked seizure control, fewer side effects, convenient dosing regimens, and cost from most to least important. (See Chapters 100 and 220 for further discussion of quality-of-life and outcome scales.)

Driving

For most people, driving is a surrogate for independence, and freedom to drive is therefore a major contributor to quality of life.[15] Thus, it is not surprising that issues related to driving are among the most difficult routinely encountered in the care of patients, especially those with mild epilepsy. Recommendations must balance a physician's dual obligations—to the patient and also to society. Although advice must conform to applicable statutory requirements, it should, to the extent possible, be tailored to the circumstances of the individual patient.

Fortunately, fatal crashes due to seizures are rare. Between 1995 and 1997, only 0.2% of all driving fatalities in the United States were attributed to seizures in mortality reports. Although patients with epilepsy had a greater rate of fatal crashes than those with other medical conditions, occurrence of fatal seizure-related crashes was 2.6 times *lower* than in the general population.[36]

Many factors can influence a patient's risk for seizure recurrence and, therefore, the risk of seizure-related motor vehicle accidents. Seizure-free interval has been widely adopted by regulatory agencies as a practical measure of driving risk. A consensus statement from the American Academy of Neurology (AAN), the American Epilepsy Society (AES), and the Epilepsy Foundation of America (EFA) advocated a 3-month seizure-free interval, with allowance for modifiers that might extend or shorten the interval[1] (see Chapter 221 for more details). Drazkowski et al.[10] reported that in the state of Arizona, seizure-related crashes did not increase significantly when the seizure-free interval required before driving was allowed was reduced from 12 to 3 months. Krauss et al.[22] found that the following factors were associated with a significantly decreased risk of motor vehicle crashes due to seizures: (a) a seizure-free interval of >6 to 12 months (which is in contrast to the Drazkowski data); (b) the presence of reliable auras (although some patients still had crashes, possibly related to a later finding that some of the “auras” were actually complex partial seizures); (c) no or few prior accidents that were unrelated to seizures; and, unexpectedly, (d) switching or reducing AEDs. Given that 25% of patients with crashes had more than one seizure-related crash, patients with previous crashes due to seizures are likely to be at particularly high risk. Recommendations based on these findings are shown in Table 1.

In general, neither guidelines nor statutory regulations can substitute for clinical judgment. For instance, a patient who has had seizures regularly every 4 or more months for many years may well be seizure free for 3 consecutive months and therefore eligible for licensure in some states. However, such a patient warrants a longer seizure-free interval before driving can be considered acceptably safe.[1,22,23]

Sports, Exercise, Travel, and Alcohol

As with driving, it is hard to make generalizations regarding patients' involvement in sports and other activities. Recommendations have to be individualized, bearing in mind the frequency and type of seizures, presence of a reliable aura, the importance of sports to the patient, and the level of supervision required or available. Although physicians are appropriately concerned about their patients' safety, as are parents of children with epilepsy, it is also important that persons with epilepsy lead as normal lives as possible. Thus, individual decisions need to strike a balance between maximizing safety and minimizing the stigma that inevitably develops as a consequence of “being different” when activities are restricted (see Chapter 216). Nakken[28] reported that over half of 204 patients with epilepsy had never reported having a seizure during exercise. About 10% of the patients, predominantly those with symptomatic localization-related epilepsy, indicated that they often had seizures related to exercise. In general, sports and exercise are safe and healthy for persons with epilepsy, and they can generally be encouraged. Exceptions include such high-risk sports as scuba diving and sky diving, which should be avoided. Swimming must be supervised closely but can be permitted in most patients whose epilepsy is controlled. A “buddy system” works well for many patients. Travel and leisure activities rarely need to be restricted, but it is helpful to advise patients about minimizing sleep deprivation during travel, emphasize the importance of medication compliance, and discuss plans for emergency care while away, should that be necessary (including use of rectal, nasal, buccal, or oral benzodiazepines).

Similarly, many patients consider it important to have a glass of wine at a dinner party or celebration. This poses only a minimal risk if seizures are controlled. How much alcohol is too much should be discussed realistically in terms the patient can understand. In general, patients with epilepsy can tolerate alcohol in small amounts (e.g., one to two drinks per occasion or no more than three to six drinks per week). However, anyone with a history of alcohol or substance abuse, alcohol-related seizures, or noncompliance with AEDs should abstain completely. Adolescents and young adults, who often find it difficult to control the amount of alcohol they consume, should also probably abstain[18] but are not likely to do so. Patients who drink moderately (three to four drinks per occasion) or heavy amounts (four or more drinks per occasion) should be warned that they are at increased risk of having seizures, with the greatest risk occurring 7 to 48 hours after the last drink.[19,30] It follows that driving should be avoided the day or two after significant alcohol use. (See Chapter 268 for further discussion of alcohol and seizures.)

Table 1 Factors associated with reduced odds of seizure-related crashes and possible recommendations for patients with epilepsy who drive

Factor	Possible recommendations for epilepsy patients who drive
Factors associated with reduced odds of crashes	
Long seizure-free intervals	Comply with state or national mandated regulations and required seizure-free restrictions; maximize seizure therapy; consider long (6–12 mo) intervals to minimize risk further
"Reliable" auras[a]	Stop driving during auras; caution patients that auras do not guarantee that they will not crash while driving
Adjusting antiepileptic drugs (AEDs) to reduce seizures	Optimize AED therapy to control seizures; advise limiting driving during AED adjustments
No or few prior non-seizure-related motor vehicle crashes	Note importance of driving safety in general
Additional risk factors[b]	
First seizure while driving	Consider restricting driving for a period if at high risk for seizures (e.g., brain tumor or other structural lesions)
History of previous seizure-related traffic crashes	Caution patients about their increased risk for additional crashes, consider long (≥12 mo) seizure-free periods before driving
Missed AED doses	Reinforce the importance of AED compliance and advise patients not to drive after missing AED doses

[a] Auras "always" precede seizures; consider video/ EEG documentation of retained awareness during auras because patients may not be aware of their impaired consciousness.
[b] Not evident in the case–control analysis but directly linked to crashes.

Pregnancy

The vast majority of women with epilepsy can have healthy children and breast-feed if they so desire. A full discussion is provided in Chapter 198.

Sudden Unexplained Death in Epilepsy and Life Expectancy

A review of sudden unexplained death in epilepsy (SUDEP) is provided in Chapter 189, and mortality is discussed in

P.1127

Chapter 10. Although estimates vary, sudden unexplained death occurs in approximately 1 of 1,000 patients with epilepsy each year; rates are higher in selected subgroups. SUDEP is most common in young adults who have had uncontrolled epilepsy with frequent seizures for many years and are on polytherapy. At present there is no way to prevent SUDEP, although aggressive seizure control and emphasis on compliance are logical recommendations. In a case–control study, Nilsson et al. identified frequent changes in AED regimen as a risk factor for SUDEP.[32] Most SUDEP cases occur during sleep. One retrospective, nonrandomized study found that patients who sleep with someone else in the room or have nocturnal monitoring devices are less likely to be SUDEP victims.[24] It might also be reasonable to avoid AEDs that are known to affect the cardiac conduction system in patients judged to be at increased risk of SUDEP.

There are differences of opinion about if and when SUDEP should be discussed with patients. Although all patients and families should be aware of the dangers of seizures and the importance of medication compliance, we recommend concentrating on discussion of seizure-related injuries and deaths that are clearly preventable, such as those associated with driving, swimming or bathing alone, bicycling on busy roads, working at heights, or other risky behaviors. An extended discussion of SUDEP with every patient does not seem reasonable or warranted, given that SUDEP is not common, and that only a subgroup of epilepsy patients are at relatively high risk. A sense of proportion is required, and the potential of adverse psychological and other effects as a consequence of overemphasizing SUDEP, especially in children and young adults, from increased supervision and limitation of activities should be borne in mind. One approach is to provide all patients with comprehensive information on epilepsy and its consequences, including SUDEP but to discuss it directly only if asked, if patients are noncompliant, if there is a family history of sudden death, or as part of the decision-making process regarding epilepsy surgery. Although there is evidence that successful epilepsy surgery is associated with a lower risk of SUDEP and longer life expectancy,[35,37] some studies have shown little difference between preoperative and postoperative mortality.[31,38] If only seizure-free patients are considered, mortality does appear to be decreased postoperatively.[31,35] It is also possible that differences in survival between operated and nonoperated groups of patients with intractable epilepsy could be due, at least in part, to preoperative biologic differences between cured and noncured patients. For example, autonomic dysfunction appears to be more common in patients who fail surgery,[33] and it has been hypothesized that insular involvement could explain both surgical failure and a predisposition to SUDEP.[34]

Screening for medication side effects

After reviewing the importance of adverse effects of AEDs on health-related quality of life, the Commission on Outcome Measurement of the International League Against Epilepsy (ILAE) recommended the inclusion of reliable and valid screening instruments in clinical trials to assess more accurately subjective adverse effect rates and severity, which would positively affect quality of clinical care.[2] Trials that included systematic recording of adverse effects have consistently shown higher rates compared with spontaneous reporting.[9] For instance, the Veterans Administration Cooperative studies,[26,27] which included a standardized questionnaire for systematic assessment of adverse medication effects, found that such effects contributed to trial exit in 40% to 60% of participants. Gilliam et al.[17] showed that routine use of the Adverse Events Profile (AEP), a simple screening form filled out by patients, was associated with a 2.8-fold increase (95% confidence interval [CI] of 1.7 to 4.8) in AED modifications and significantly reduced adverse effects.

Routine screening for depression is also useful, and several rapid screening questionnaires, such as the Center for

P.1128

Epidemiologic Studies Depression Scale, exist for this purpose (see Chapters 100 and 205). Gilliam et al.

recently developed the Neurological Disorders Depression Inventory for Epilepsy (NDDI-E), a screening instrument that uses a brief set of symptoms to recognize major depression and differentiate it from common adverse effects of AEDs.[16]

Setting Realistic Goals

For some patients, such as those with Lennox-Gastaut syndrome, becoming free of seizures is not a realistic goal. Once this conclusion has been reached, it is important to minimize ineffective medications in order to maximize interictal cognitive, psychological, and motor function by reducing or eliminating adverse effects. In patients with refractory seizures on polytherapy, AEDs should be decreased or stopped at least as often as they are added or increased. In patients with refractory drop attacks due to seizures, vagus nerve stimulation and corpus callosotomy should be considered when it is clear that further drug changes are unlikely to improve seizure control without side effects. Both of these procedures, although rarely curative, can be effective in reducing seizure-related falls and injuries.[29,37] Callosotomy is probably somewhat more effective, but it also carries a greater risk, although most complications are transient.[29]

Summary and Conclusions

Successful treatment requires therapeutic management plans that are individualized for each patient. The goal is to provide each patient with maximal control of seizures without significant adverse effects. Undesirable effects from AEDs and psychiatric comorbidity, especially depression, profoundly affect quality of life. Systematic screening for these factors will assist in guiding clinical management and optimizing care with minimal additional physician time. For a patient with epilepsy, independence, driving, employment, safety, and social stigma are very real and serious concerns. Although "no seizures, no side effects" should be the primary goal in management, they should not be the only measures of a successful outcome. All aspects of a patient's health-related quality of life should be given due consideration and treated accordingly. In the end, it must be remembered that physicians treat individual persons, not a disease—or, as attributed to Hippocrates, "It is more important to know what sort of person has a disease than to know what sort of disease a person has."

Broader Aspects of Treatment

David C. Taylor

> This human ritual of suppliant and provider of balm is deeply rooted; extending back thousands of years.
>
> —W. Pickering[20]

Introduction

This chapter is about treating people who are sick. The book is concerned with people who have epilepsy, or who appear to have epilepsy, but these remarks also have broader applications in medicine. They do not concern the details of medical, psychological, or surgical treatments of epilepsy. They pose questions and suggest some attitudes about treating people based on the fact that all treatment takes place in some sort of psychological climate and that the better that climate is, the better everybody will feel. Nor is this entirely a plea for "evidence-based medicine"[11] because it is sometimes the evidence that, on reflection, has changed since it was raised.[24]

The general aim is to encourage careful consideration of a range of sense data that are available to therapists for monitoring their therapies. For example, it almost seems to follow necessarily that convulsions (epileptic seizures) should be treated by anticonvulsants or antiepileptic drugs (as they are rather quaintly called). A glimpse at practice tends to confirm this. The logic is similar to the treatment of infections by antibiotics and of depression by antidepressants. That logic, however, soon breaks down. We find we are obliged to consider the duration, scale, type, and origin of the illness and the age, size, resources, and situation of the patient[5,11,25] and any basis the convulsions have in nameable disease. Even then, seizures may continue, and other problems persist. In making a diagnosis for a sick person, naming the illness is not enough. "Diagnosis" requires a larger consideration. It derives from a root word meaning to perceive, to distinguish, to discern, to have knowledge. Diagnosis requires us to know about the sick person. What disease might underlie this illness? What is the situation, the predicament, of this person?[23] Who is this sick person, what life is the patient leading, and what is the patient's agenda, here and now, with me, today?[3,13]

The idea that a sick person with an illness creates a social problem that connects back to the medical problem is usually seen only in the sociological literature.[7,16] The examination of the treatment of epilepsy from such a perspective can be illuminating. There is nothing trivial or metaphorical about epilepsy.[22] Seizures, convulsions, fits, and bad turns all have metaphorical meanings, however, as well as meanings in the language of everyday life, most of them negative. To be diagnosed and treated for epilepsy is something of an ordeal in itself.

Diagnosis and Treatment

Making a diagnosis is an essential prerequisite to being able to help a sick person, but "the diagnosis" is an abstraction. The reality is the treatment that follows, whether reassurance, regimen, manipulation, medication, or surgery. Diagnosis, the knowledge and revelation of the problems that are agreed to exist, may not have been arrived at easily for the patient with epilepsy. The patient may have been pleading the case for his or her sickness to be recognized for a long time before a diagnosis was finally awarded. There could be anger at previous failure and time wasted. That could explain a negative or guarded attitude even toward the team that eventually made the diagnosis. On the other hand, even if the physicians exercised their utmost skill, patience, and technology to achieve the diagnosis, it might not be what the patient wanted because it demands ownership of the sickness with all its perils and stigmata or contradicts the patient's firmly held view of it. “Please doctor,” the father of one patient pleaded, “take away this diagnosis, it will ruin my son's life.” Thus, subsequent treatment might be resisted. Sometimes a diagnosis of epilepsy is ascribed on scant evidence, inadequate information, faulty logic, or with casual indifference. Thus, an illness is foisted on a patient. Occasionally the diagnosis and treatment for epilepsy might suit the patient in some ways, so the patient cleaves to it, and subsequently even a great authority might not succeed in changing the patient's view even though it is wrong and irrational.

These different ways of coming to the diagnosis affect the attitudes of patients and caregivers to the treatment. Treatment confirms the reality of the patient's diagnosis, whether accurate or wanted or not. Some examples of these processes can be given: The infantile spasms were brief and few and not distinctly described, but they were eventually seen by the physician, captured on electroencephalogram (EEG), and investigated to show the tuberous sclerosis of which the previously entirely healthy father proves to be the carrier. He now bears a “responsibility” for his son's condition. The onset of the brief nocturnal disturbances in this young woman was soon diagnosed as epilepsy, but this precluded her from driving and ruined the career that depended on that. The onset of focal motor seizures with some subjective feelings was treated successfully for several years with medication before breakthrough seizures led to investigations that revealed the cerebral tumor. In each case there is a negative side to the “good news” of achieving a diagnosis. Diagnosis and treatments, on one hand, bring relief and hope of cure, but, on the other hand, they convey the reality of what exists, confirm the worst fears, or require the sick person to submit to the ordeal of treatment, which may be a significant burden. At times, the procedures providing the relief of the sickness or the prospect of relief prove to be so hazardous to the patient that the patient feels the need to undermine them. That would be one reason for a therapist to feel frustrated by a patient.

The Treatment Process

Much of the process of medicine is unseen by practitioners, who take for granted the bizarre environment in which they

P.1130

work, which can be terrifying to patients. Diagnosis is achieved through a series of rituals. Some are verbal, such as asking a whole series of unlikely questions (called taking a history); others require apparatus, sometimes of gargantuan dimensions, for which purification and special clothing are required (called routine investigations). The modest EEG by which “they took the electricity from my head, doctor” is nowadays lodged in a bank of computers, TV screens, analog devices, and so on. In such a situation the patient must perform appropriately in order to “qualify” for a diagnosis. Days and days of anxious waiting might be required to capture even a single seizure.[26] Failure to achieve the wanted diagnosis leads to the limbo of unknowing and disqualifies the patient from treatments available to those who do qualify. That is, for them, another kind of failure. An escape with dignity has to be incorporated in our programs of investigation, which are, to patients, not so much diagnostic as a determination of whether they *qualify* for a treatment.

The ordeal of being passaged through our medical temples, at times without a priestly guide, reaches its zenith in neurosurgical treatment. Consider the special rooms, the ritual shaving of the head, the masks and gowns, the apparatus, the lying-in in recovery. What we require of patients generally is that they endure situations that are awesome, interventions that are perilous, and ministrations that are distasteful. The fact that they are tolerated with surprising equanimity for the most part allows us to overlook their impact. The unspoken bargain for the patient is that it is all done in the hope of benefit. It is about a *bargain*. Sometimes it is not a very good bargain.

Most treatment acts breach the ordinary protective taboos about inviolacy of the body. Treatment is intrusive, whether it includes medications being put into the body or rays shone on it or wires attached to it or hands manipulating it or minds analyzing it or holes made in it. The ritualistic aspects of treatment can be elaborated as a way of dealing with these protective taboos. The perpetrators of the intrusions, though granted a limited permit, tend to defend themselves from their violations by a process called “clinical detachment” or “denial” or callousness, depending on one's viewpoint. Within these necessary procedures and wanted effects lies the opportunity for negative effects. These include inciting dependency and amplifying dependency needs, which are necessarily increased at the point of diagnosis and treatment. The danger, once the taboos have been set aside, is that there is scope for degradation. Degradation can follow simply as a psychological outcome of the ordeal of therapy, or it may more explicitly occur as an effect of surgical treatment or, much more regularly, of the medical treatment of epilepsy. The negative effects of treatment are rarely phrased in terms of degradations—“side effects of the drug” or “unwanted outcome of the procedure” are the much-preferred designations. But consider the case of an adolescent girl given a new medication and an appointment in 3 months' time who is unable to deal with the offensive body odor it causes.

The history of medicine reminds us that severe and intractable sickness leads both doctors and patients toward desperate measures in search of a cure. However, the price to be paid by the patient in being rendered obese or bald or plethoric or losing a hemifield of vision or partial loss of verbal memory or experiencing a bout of madness[10,17] has to be balanced against the desired effects of the proposed therapy. That bargain cannot be struck while the negative effects are downplayed with medical euphemisms. It is thus that we forget the lessons of the therapeutics of epilepsy from the past. Korczyn et al.[14] recalled, for example, the monstrous era of colectomy along with purgations and enemas in desperate acts of purification applied to epilepsy. “Evidence” had suggested the presence of a “*Bacillus epilepticus*,” a “fact” several times confirmed. That epoch followed on the one in which the sexual parts were surgically assaulted with similar purifying zeal.[21] Now, of course, we are all much more rational, and we hope that this is how we will all appear in retrospect.

There are people who seek therapies because their degrading and self-punitive possibilities meet some of their needs.[18] Such people look for therapists who are likely to satisfy them. In the event of those people also having a chronic illness such as epilepsy, the stage is set for heroics on either side of the treatment bargain.

Outcome

There are many medical and surgical treatments whose outcome is envisaged as a permanent solution. Epileptic seizures, even when considered as just one aspect of the cerebral dysfunction of a person with epilepsy, can be a chronic, even lifelong problem for which there is no “outcome” in the ordinary sense, and the treatment requires close and repeated, endless attention. It is extremely difficult to bear this in mind when we are trying to restore the patient's enthusiasm for yet more tries at new treatments. The aim of each treatment, that is, the *specific* purpose, should be closely considered and noted and referred to at the next appointment. Only in that way can the effect on that aim be reasonably assessed. As things stand, antiepileptic drugs (AEDs) may prove to be rather less specific than has been thought in the control of particular syndromes. It might then be argued that about 50% of patients with epilepsy will respond to any anticonvulsant, and about 50% will not be comfortably controlled by any anticonvulsant.[4]

Over time, the aim of treatment might shift from giving great attention to one aspect of the sickness, say the seizures, to another, for example, the specific learning problem or the behavioral syndrome. These different aims should be made clear to the patient and his or her caregivers. Each treatment offers a prospect of relief, but each treatment also brings the dread of failure or further failure. Even apparent success, such as reducing weekly seizures to annual seizures, may not provide what was hoped for. The wait for the next confirmation that no cure has been effected is simply increased. So is the disappointment unless the patient has understood the palliative nature of the therapy. The restrictions imposed by “being epileptic” may persist. It is recognized that even after a radical cure provided by surgery, the effective outcome may be less than was hoped for. Against the patient's desperate wish for a cure there exists a real concern about losing the identity that was provided as a “sick person” and that is threatened by becoming well for the first time ever, or for the first time in many years.

Thus, ambivalence is all pervasive in the therapeutics of chronic sicknesses. To consider this only in terms of compliance and attribute it to the careless indifference of the patient is an error and a foolish trivialization of the psychology of chronic sickness. All treatments are about striking a deal between the worth of the life that is being lived, as opposed to that which might be lived, and the effort, ordeal, and constraints of the treatment. Many physicians feel obliged to persist with complex therapies despite the fact that they do not achieve their apparent aims. Their unspoken aim may be to guard against fatal accidents or sudden death. It is quite uncertain whether those are realistic.

Conclusions for Action

People who treat other people would do well to consider a series of propositions. They are relevant to every treatment, but they can be (and are) ignored in most treatment encounters because those encounters are trivial and brief. Their outcome is, in any event, only marginally contingent on the therapy. In the treatment of a potentially chronic illness with potentially highly

toxic agents or highly intrusive procedures, these propositions become increasingly important.

How Is the Treatment Offer Made? How Is It Understood?

Is the patient demanding a treatment rather than seeking advice? Can the patient retain some personal control in the therapy? Does the patient understand that all treatments are experimental from the individual viewpoint? Has the patient understood what "palliative" means? Has the patient understood the connection between what he or she complains of (or what is complained of about them) and the treatment? How, for example, will the learning problem (caused, say, by status of minor epilepsy) be addressed by taking certain tablets? Is there any scope for negotiation about this treatment offer? Is there a pause to consider it?

What Does the Treatment Provide, and What Does It Demand?

Is it likely to be worth it? Certain complex regimens may be very convincing and comforting to some people but leave others confused and desolate, not daring to question the procedures, potions, and pills that threaten to overwhelm them. Patients and their families might risk more than they can afford, financially or psychologically, in a demanding treatment sequence.

What Does the Treatment Ambience Provide?

If the treatment is in a hospital or a clinic, do the ambience and the milieu there promote and inspire confidence or do they detract from it or conspire against success? Should patients become aware of plights worse than theirs or more progressed stages of the condition from which they are suffering? Should admission for treatment require that patients associate with more disabled and deteriorated patients? There is a balance to be struck between becoming aware of certain realities (the condition of someone else just after the operation that has just been proposed) and being overwhelmed by them without discussion.

Who Are the Treaters?

The broad gamut of therapists and caregivers encountered by patients might each address some aspect of care. The caregivers are not confined to "the team" that knows the whole patient well. It deserves to be remembered that patients will scout for the opinions that most comfort them and that most conform to their own. Therapists (especially doctors) should be aware of what a small part of the sickness they address and respect the contributions of other therapists.

Consider the Outcome of This Treatment

Whatever it is, the treatment in hand will have its own outcome, and that outcome will be separable from the outcome of the sickness, which might be interminable. Each AED—the first, the next, and so on—will have to have some criterion of success. When cure is not possible or uncertain, how will some lesser degree of success be recognized and explained? How will failure be dealt with and a prophylactic be set up against a disastrous sense of failure? Having treatment hypotheses that are tested over and over is a way of guarding against random prescribing. The same holds for all sorts of managements—social, psychological, or surgical.

Why Are "Alternative Therapies" Attractive?

There are reports of a range of therapies for epilepsy that seem to have in common that they empower the patient to take some personal control of the sickness rather than to be under the control of the therapist or the therapy.[1,19] These include such activities as yoga.[19] Without making any sort of judgment about any of these treatments, it does seem that certain aspects of alternative treatments can be included in a medical treatment package with advantage. They are already evident in the work of some comprehensive multidisciplinary care centers[15] and specific self-management regimes.[6] Some good general principles of care are sustained in many "alternative therapies." First, a personal and individual relationship that is sustained through the therapy creates a good therapeutic bond, whereas chronically sick people tend to see a large number of different doctors. Second, those therapeutic relationships that involve touching, even physical examination, or closeness that comes from sharing the biography and attempting to personalize the relationship help to create a therapeutic effect. Moving from doctor to doctor will undermine this.

Self-selection of the alternative treatment seems to induce credibility, especially when this is allied to personal, emotional, or financial commitment. The notion of offering a real choice of therapies, even when they exist, is not a consistent part of many physicians' repertoires. Antiepileptic drugs are the most expensive part of the treatment of epilepsy,[2] and so they should be used skillfully, thoughtfully, and judiciously.

Summary and Conclusions

Experiencing a treatment is a significant life event. For a chronic illness such as epilepsy the treatment is a large and significant part of a person's life. The psychological dynamics of the treatment process can have negative effects or a positive influence on the sickness and on the quality of life. What, for the therapist, is a routine procedure can be a life-changing ordeal for the patient. Alternative medicine has won many adherents[8] and has aspects that can be used to advantage in routine medical practice. We can make a good start by recognizing that the scale of the sickness can extend beyond the symptom.

Quantitative Measures of Assessment

Gus A. Baker

Orrin Devinsky

Joanne Taylor

Joyce A. Cramer

Introduction

Quality of life refers to an individual's overall well-being and daily functioning. *Health-related quality of life* (*HRQOL*) can be divided into three principal components: (a) physical health (e.g., general health, daily functioning, symptoms such as pain and seizures and side effects of drugs, strength, ability to walk); (b) mental health (e.g., mood, self-esteem, perception of well-being, perceived stigma); and (c) social health (e.g., social activities and relationships). Economic and environmental factors, encompassed by overall quality of life, are not usually included within health-related quality of life. Epilepsy and other disorders have a significant effect on economic and environmental aspects of life, but these areas are beyond the scope of HRQOL.

Quality-of-life issues are most relevant in chronic disorders such as epilepsy, in which mental and social problems extend well outside the usual range of symptoms of disease.[22] Unfortunately, there is often a poor correlation between a doctor's and a patient's assessment of the patient's quality of life, despite the expectation that such perspectives would be very similar. Thus, when used to evaluate the effects of epilepsy and its treatment, HRQOL measures can provide important and complementary information to traditional assessments focusing on seizure control and adverse effects of antiepileptic drugs. Interest in the effects of disease on the patient's HRQOL began in the late 1940s with Karnovsky's rating scale for cancer patients and has grown exponentially during the past decade. Quality-of-life measurement has been increasingly reported in clinical trials, nonexperimental outcome studies, cost-utility analyses, and studies of quality of care.[37,71]

Although the concept of HRQOL is attractive and important, its quantification remains a challenge. Items included in HRQOL scales are often derived mainly from “medical experts,” whereas the patient's opinion of what is important should be given higher priority.[37] Other limitations in HRQOL research include lack of definition of HRQOL or targeted domains, failure to distinguish overall quality of life from HRQOL, and validation. Validation of HRQOL instruments is especially challenging because no gold standards are available. Validation is often based on medical outcomes, which is what HRQOL is intended to avoid.

Assessments of HRQOL may be generic or targeted toward a specific disease or disorder. Generic instruments assess a range of issues of functioning and well-being and can evaluate diverse patient populations. Commonly used generic HRQOL instruments include the RAND 36-Item Health Survey,[42] the Sickness Impact Profile,[12] and the McMaster Health Index Questionnaire.[67] Generic measurements permit comparisons among patients with different diseases, but they often lack sensitivity to change or responsiveness to intervention. For example, if a generic instrument does not assess HRQOL areas relevant to a certain patient group, positive or negative changes in these areas will not be detected when an intervention is made during a longitudinal study.

Disease-specific instruments use information about the ways in which a particular disease affects HRQOL. Such knowledge may be derived from patient interviews, medical and lay literature, expert opinion, or a combination of these sources.[37] Disease-specific instruments assess HRQOL domains that are most relevant to these patients, but they include areas that are less important and omit areas that are more important to patients with other disorders. Disadvantages of disease-specific HRQOL instruments include the time and monetary expenses in their development and the limitations on making comparisons among groups with different disorders. A generic core can be combined with a disease-specific supplement to provide the benefits of both.

Epilepsy: A Chronic Disorder with Special Issues

Epilepsy is often a chronic illness. Chronically ill patients strive not only to minimize their symptoms and survive, but also to lead normal lives despite the problems associated with their illness and its treatment. For most people with epilepsy, the first of these objectives can be realized. However, particularly for those patients with epilepsy that is difficult to control, the restrictions imposed on daily living often make the second objective difficult or impossible to attain.

Special Problems

Outcome measures for epilepsy patients traditionally include seizure frequency, severity, morbidity (e.g., seizure-related trauma), and drug side effects such as sedation, nausea, and tremor. The traditional medical factors—seizures and antiepileptic drugs—are viewed quite differently by patients and physicians. “Occasional” or “mild” seizures and “infrequent” and “tolerable” side effects are often considered as acceptable by physicians. For patients, such seizures and adverse effects can be very troublesome and are not “acceptable.” In many cases, patients have difficulty expressing their feelings to doctors, or doctors may be insensitive to complaints that do not fit their conventional wisdom (e.g., disabling lethargy or confusion associated with subtherapeutic or low therapeutic doses of a “cognitively benign” antiepileptic drug). In either case, the physicians remain unaware of the problems.

People with epilepsy have higher rates of psychosocial problems and psychopathology. Once a person has had two seizures and received the diagnosis of epilepsy, the disorder may cause the greatest HRQOL problems during the seizure-free intervals. The duration of medical therapy is often long, drugs often need to be taken several times a day and can cause side effects that

P.1134

affect a person's daily life, and the psychological and social consequences of epilepsy are often enormous. People with epilepsy may be limited in social, educational, and employment opportunities and modes of transportation—restrictions that may be either real or perceived. There are often parental and societal attitudes that foster low self-esteem and dependence, stigma, discrimination, and restrictions. In considering epilepsy as a chronic burden, one must carefully examine the neglected social, psychological, and behavioral problems as well as physical problems.

Physical Issues

Seizures increase the risk for bruises, lacerations, bone fractures and dislocations, burns, and drowning, as well as unexplained death.[41] Daily drugs reduce the seizure threshold but can cause adverse physical effects (e.g., gingival hyperplasia, sedation, nausea, double vision, tremor, hirsutism) and mental effects (e.g., memory impairment), some of which are subtle but chronic.[54] Quality-of-life measures show impairments in people who have systemic or neurologic adverse effects.[32]

Psychological Consequences

Patients with epilepsy have higher rates of certain behavioral disorders, such as depression and anxiety, and cognitive problems, such as impaired short-term memory and naming. Anxiety about the occurrence of seizures is a common concern, not only because of the suddenness of events, but also because of the possibility of negative sequelae. This loss of control over one's life can underlie many psychological problems. Fear of public exposure or injury can underlie self-imposed social and vocational restrictions. The actual or perceived sense of dependency can be fostered by parents of children with epilepsy and by spouses and families of adult patients. Children with epilepsy had twice as many referrals for mental health services (12%

vs. 23%) as the local population of children.[17]

Because anxiety and depression are the most frequent behavioral problem in adults with epilepsy, HRQOL instruments should be used as screening tools to help clinicians measure a patient's mood status.[26] This is especially important, given that Cramer et al.,[29] in a survey of a community sample of people with epilepsy, found clinical depression to be significantly associated with poorer HRQOL.

Social Consequences

The social label of epilepsy can be paralyzing. Both children and adults with epilepsy may feel and actually become removed from their social group and activities. People with epilepsy may be made to feel "different" by the need to go to the school nurse for medication at lunchtime, being restricted from driving or recreational activities, worries that antiepileptic drugs will be identified during urine tests administered by employers or prospective employers, and fears of rejection by peers if a seizure should occur in public. Epilepsy differs from most other medical and neurologic disorders because of these associated legal restrictions and requirements. Other patients fear dating, marriage (seizures during sex, possible decreased fertility), pregnancy (increased rate of pregnancy complications and birth defects), and parenthood (dangers of a seizure occurring while holding a baby or giving the baby a bath). Employment opportunities are restricted for many people with epilepsy, with unemployment and underemployment prevalent among adults with epilepsy. Employment problems limit financial and health insurance resources.

Multiple etiologies may contribute to the behavioral problems and psychopathology in epilepsy, including social, biologic, and drug-related factors. For example, a social withdrawal syndrome with low rates of employment and marriage may result from a combination of low educational attainment and self-esteem, legislative restrictions, perceived stigma and actual discrimination, and cognitive and behavioral deficits (impaired memory, hyposexuality).[45] Biologic (e.g., cognitive impairment) and drug-related factors (e.g., lethargy, tremor) can further complicate this syndrome. Some of these concerns can be related to incomplete compliance with medication as an aspect of quality of life for individuals.[21]

The selection of which scale to include in a quality-of-life questionnaire is governed by the clinical question being addressed. Measures applied to assessing the effect of treatment in patients with newly diagnosed epilepsy may be different from those assessing therapy for patients with chronic epilepsy or undergoing epilepsy surgery. This approach to individual clinical questions has also incorporated contributions from patients in assessments of their therapy and management. Cramer[23,25] and Leone and colleagues[52] have reviewed the types of measures available and under development for assessment of people with epilepsy.

Early Initiatives in Measuring Psychosocial Outcome in Epilepsy

Recognizing the cognitive and behavioral problems that can accompany epilepsy, many studies have used neuropsychologic testing to define functional brain deficits and the Minnesota Multiphasic Personality Inventory (MMPI) to assess personality issues. More recently, other psychiatric rating scales have been used to assess specific behavioral problems, such as anxiety or depression.

The Washington Psychosocial Seizure Inventory (WPSI)[36] was the first epilepsy-specific psychosocial measure. This 132-item inventory is a self-report measure consisting of eight psychosocial scales (Family Background; Emotional, Interpersonal, and Vocational Adjustment; Financial Status; Adjustment to the Diagnosis of Seizures and Epilepsy; Satisfaction with Medical Management; Overall Psychosocial Functioning) and three validity scales. The WPSI has been widely used in assessing psychosocial outcome among epilepsy patients and in assessing changes in psychosocial functioning before and after a specific intervention, such as epilepsy surgery or a new antiepileptic drug.[35]

The Well-being Scale was developed by Collings.[20] This scale of overall well-being includes six subscales: Self-esteem, Life Fulfillment, Social Difficulty, Physical Symptoms, Worries, and Affect Balance. Testing in 392 patients with active epilepsy showed lower well-being on all scales than in nonepilepsy control groups. The visibility of severe seizures and frequency of seizures were directly related to well-being. Self-image (perception of self) and epilepsy were most predictive of overall well-being. Other important variables included few seizures, mild seizures, recent diagnosis, confidence in the diagnosis, and employment.

The Social Effects scale was developed by Chaplin and colleagues as a postal questionnaire to investigate social aspects of epilepsy in a wide range of epilepsy patients. The Social Effects scale was designed following extensive patient interviews. Initially, 21 areas of concern were identified, but only 14 were included in the final version. Scale reliability, assessed by the test–retest method, was only moderate. Validity was established through a comparison of patient responses and their behavior as observed by medical staff criticism. Further evaluation of the scale is necessary, although the authors have applied the scale successfully in the National General Practice Survey of Epilepsy.[18,19]

Current Measures of Outcome in Adults

Epilepsy Surgery Inventory-55

Vickrey et al.[75] developed a new inventory to assess HRQOL in epilepsy, the Epilepsy Surgery Inventory-55 (ESI-55). Using the RAND 36-Item Health Survey[78] as the generic core, they added 19 items, the majority of which are epilepsy specific. Fifty-four items, shown in Table 1, make up 11 unique scales tapping into distinct dimensions of HRQOL; another item assesses change in health during the preceding year.

The ESI-55 was developed to assess HRQOL outcome after epilepsy surgery. Patients who continued to have seizures after surgery had lower ESI-55 scores (i.e., worse HRQOL) than those who were completely seizure free on all 11 scales ($p < .05$). The ESI-55 was developed to assess HRQOL in a group of postsurgical patients, a small and skewed group of patients with epilepsy. In addition, some aspects of HRQOL were underrepresented in the ESI-55, particularly in regard to social health, for which there is only a two-item Social-Functioning scale.

Liverpool Quality-of-Life Battery

The Liverpool battery began as a way to assess the psychosocial outcomes after a decision to withdraw or not withdraw from antiepileptic drugs.[50] Since then, this group has applied quality-of-life measures to several critical epilepsy issues, including the assessment of a novel antiepileptic drug in patients with refractory epilepsy,[70] quality of life and quality of services for a community-based population, efficacy of a novel antiepileptic drug in children with epilepsy and learning disabilities, and psychosocial outcomes of immediate versus delayed treatment in single seizures and early epilepsy.

[b]Added to later versions. From Baker et al.[10] Additional information can be obtained from Prof. Baker at the Department of Neurosciences, Walton Center for Neurology and Neurosurgery, Lower Lane, Liverpool L9 7LJ, UK.

This group has used a developmental model encompassing measures of physical functioning (Seizure Severity,[9] Seizure Frequency, Activities of Daily Living,[15] Social Functioning, Life Fulfillment,[8] Stigma,[48] Impact of Epilepsy[49]) and of psychological functioning (Affect and Balance scale,[13] Hospital Anxiety and Depression scale,[80] Self-esteem,[65] Mastery scale[61]) as shown in Table 2. Some of these scales were developed to assess the effects of epilepsy and its treatment; others were designed to assess other disorders but were successfully validated in people with epilepsy. Evidence of the psychometric validity has been reported.[8,10,48]

Repertory Grid Assessments

Kendrick and Trimble[51] hypothesized that HRQOL could be improved by increasing actual abilities or decreasing expectations, and that people judge their current quality of life in relation to past experiences and other people. In extensive interviews, patients identified specific issues important to their lives regarding physical functioning, cognition, emotion, social functioning, and financial and work status. A repertory grid technique was used with a Construct Importance scale in which patients identified issues important to themselves and rated the problems during follow-up. Analyses by gender showed that women and men with epilepsy had similar perceptions about their HRQOL.[56] Women were more concerned about friendship and being free of worries and anxiety than men. Men were more concerned than women about controlling their temper and being married. The profiles showed differences between actual (NOW) and desired (LIKE) status. This labor-intensive interview method is not feasible for large populations, but it can be applied in hospital or research settings in which extended interviews are possible, such as during evaluation for epilepsy surgery. The Quality of Life Assessment Schedule (QUOLAS) developed from this method has been modified and streamlined for use by Selai and Trimble[69] and has been used in research settings.[68]

[a]The QOLIE-89 contains 17 scales with 87 field-tested questions.

[b]The shorter QOLIE-31 includes items from the seven scales marked with an asterisk. The QOLIE-10 contains one or more questions from each of the seven QOLIE-31 scales.

[c]Two additional items were added after validation studies. U.S. English versions of the QOLIE instruments are available at http://professionals.epilepsy.com/page/qoltools.html. Permission to use the U.S. English versions of the QOLIE-89 and QOLIE-31 and scoring manuals can be obtained by writing to RAND, 1700 Main Street, P.O. Box 2138, Santa Monica, CA 90407-2138 (Attention: Contracts and Grant Services) or from RAND—Health@rand.org. Permission to use the QOLIE-10 can be obtained from Professional Postgraduate Services, 400 Plaza Drive, Secauscus, NJ 07094. Availability of and permission to use translations of the QOLIE-10, -31, -31-P, or -89 or QOLIE-AD-48 should be requested from Joyce.Cramer@Yale.Edu.

Quality of Life in Epilepsy Instruments

The Quality of Life in Epilepsy (QOLIE) Development Group expanded the ESI-55 to create a broad-based instrument for cases of epilepsy encompassing a wider range of severity. The

QOLIE test instrument included the RAND 36-Item Health Survey as a generic core, with eight additional multi-item scales. The epilepsy-targeted segment consisted of 48 items derived from patient interviews, literature review, and expert opinion. An open-ended question encouraged patients to report additional items that affected their quality of life. The resulting instruments, shown in Table 3, include the QOLIE-89 (17 scales, 89 items), the QOLIE-31 (7 scales, 31 items), and the QOLIE-10 screening questionnaire (10 items selected from the 7 scales in QOLIE-31). The QOLIE-89 and QOLIE-31 showed good reliability and construct validity. The QOLIE-10 and the QOLIE-31 have been compared by Cramer et al.[27] in a clinical trial of levetiracetam and were found to be highly correlated; both were able to detect change over time and both were able to detect differences among treatments and between groups of responders and non- responders.

Factor analysis of the 17 scales of the QOLIE-89 suggested four dimensions: (a) epilepsy-targeted, (b) cognitive, (c) mental health, and (d) physical health factors. Health care utilization was negatively correlated, whereas education and employment were positively correlated with better QOLIE scores. The mood factor showed high correlation and was a strong predictor of total HRQOL scores, with psychomotor slowing also showing significant relationships.[62] Patients with less severe epilepsy generally had higher HRQOL scores than patients with more severe epilepsy.[33] The epilepsy-targeted factor and the Seizure Worry, Health Discouragement, and Work, Driving, and Social Function scales best discriminated among groups of patients with epilepsy of different levels of severity. Negative correlations were found for all four HRQOL factors and overall scores for neurotoxicity and systemic toxicity. Employment also correlated well with the overall score and cognitive and physical health factors. These findings demonstrate the sensitivity of the instrument to differences among groups based on seizure frequency, demographic characteristics, and adverse effects.

Side Effect and Life Satisfaction Inventory

The Side Effect and Life Satisfaction (SEALS) inventory was initially developed by Brown and Tomlinson[15] as a measure of patient satisfaction with antiepileptic drug (AED) therapy. Originally a 51-item questionnaire, it was modified by Gillham et al.,[38] who reduced it to 38 items, consisting of five subscales (Worry, Temper, Cognition, Dysphoria, and Tiredness). The scale was validated in 307 patients with epilepsy against the Hospital Anxiety and Depression Scale, the Profile of Mood Scale, and the Medical Outcomes Study-Cognitive Functioning.[39] Responsiveness has been assessed in drug trials comparing lamotrigine with phenytoin, carbamazepine, and valproate.[14,16,73]

General Health-Related Quality-of-Life Assessment by the RAND 36-Item Health Survey

Wagner et al.[77] evaluated general HRQOL in 148 people with epilepsy using the RAND 36-Item Health Survey. Scores were compared with the Medical Outcomes Study population matched for social and demographic factors. Epilepsy patients had significantly lower scores in six of eight domains (all but physical functioning and bodily pain). Patients who had at least one seizure during the week before the assessment (31%) had significantly lower scores than patients who were seizure free for >1 year (27%).

Vickrey et al.[76] compared scores for a pictorial item and the eight scales of the RAND 36-Item Health Survey from patients undergoing epilepsy surgery and patients with other medical disorders. After resective surgery, seizure-free patients had generally better scores on all scales, and those with continuing simple partial seizures had HRQOL scores similar to those of patients with hypertension, heart disease, and diabetes. Patients who continued to have complex partial or tonic–clonic seizures after surgery had poorer emotional well-being and overall HRQOL than all other patient groups except those with depression.

Assessments in Adolescents and Children

Instruments for measuring HRQOL must be revised or created to address issues specific to the age group; for example, adolescents with epilepsy have special concerns about the feasibility of driving and dating that differ from those of adults. Therefore, to assess an adolescent's HRQOL, Cramer et al.[30] developed the Quality of Life in Epilepsy Inventory for Adolescents (QOLIE-AD-48). The 48-item questionnaire, which takes about 15 to 20 minutes to complete, provides information about eight different domains (impact of epilepsy, memory and concentration, attitudes toward epilepsy, physical

P.1137

functioning, stigma, social support, school behavior, and health perceptions). Initially tested on 197 adolescents with epilepsy aged 11 to 17 years, the scale was found to have satisfactory reliability and good content and construct validity.

Devinsky et al.[34] used this measure to examine the risk factors for poor HRQOL in 197 adolescents with epilepsy. Based on the QOLIE-AD-48 and data obtained from interviews, medical reports, and health records, they found that older adolescents (age between 11 and 17 years), those with more severe epilepsy and more symptoms of neurotoxicity, and those from lower-socioeconomic-status families were more at risk of reporting poor HRQOL.

Similar results were reported by Heimlich et al.[43] using the Child Attitude Toward Illness Scale. Attitudes toward epilepsy were examined in 197 adolescents, and it was found that adolescent girls had significantly more negative attitudes than adolescent boys, as did older adolescents (age 16 to 17 years) and those with more severe epilepsy.

Baker et al.[11] also found that adolescents with epilepsy in the United Kingdom report higher levels of depression, anhedonia, and social anxiety and a higher number of obsessive symptoms than adolescents without epilepsy. However, this can be mediated by access to appropriate information, seizure frequency and type, social support, and gender.[11,64]

The verbal and intellectual skills of adolescents allow one to assess HRQOL through direct patient reporting. In contrast, assessment of children must often use an interview with the parent or caregiver, and the responses might not reflect what is important to the child. Children with epilepsy often confront issues of self-esteem and dependency. These issues are probably most important in families with overly protective parents. Thus, having parents rate the HRQOL of children with epilepsy can provide a biased perspective.

Sabaz et al.[66] developed a parent-rated HRQOL scale for children of age between 4 and 18 years (the Quality of Life in Childhood Epilepsy questionnaire [QOLCE]). The final Australian version consisted of 76 items with 16 subscales consisting of five domains (physical function, social function, cognition, and emotional and behavioral well-being). The QOLCE has been adapted for use in an American population and evaluated for reliability and validity. The scale has also been used retrospectively to test sensitivity to postoperative outcome in a sample of children who had undergone epilepsy surgery.[66]

Miller et al.,[57] also using parent-rated measures, found diminished HRQOL in 41 children with epilepsy compared to an age-matched control group. Presence of comorbid neurologic impairments such as ataxia, developmental delay, and hemiparesis and number of antiepileptic medications correlated with lowered HRQOL.

A mixture of parent- and child-rated measures was used by van Empelen et al.[74] They assessed HRQOL and self-perceived competence in 21 children and adolescents who had undergone epilepsy surgery 2 years previously. Postoperative improvements were seen in HRQOL, with most improvements falling within the first 6 months.

Studying 127 children (8 to 12 years of age) and their mothers with self-report questionnaires, interviews, and medical records, Austin et al.[2] identified five variables that related to behavior problems: (a) female gender, (b) family stress, (c) family mastery, (d) extended-family social support, and (e) seizure frequency. Comparing children (8 to 12 years of age) with epilepsy versus children with asthma, Austin et al.[3] found more compromises in psychological, social, and school domains in the epilepsy group. The magnitude of differences between the two types of illness and other findings suggests that some other factor is related to poor quality of life in children with epilepsy.

The European DISABKIDS group developed condition-specific modules of the European DISABKIDS HRQOL instrument for children with asthma, juvenile idiopathic arthritis, atopic dermatitis, cerebral palsy, cystic fibrosis, diabetes, and epilepsy for use in seven European countries. These modules, which are to be used alongside a chronic generic module, have been evaluated in 360 children and their families. Further testing of reliability and validity for each country is being carried out.[4]

Heath-Related Quality of Life in the Elderly

Studying the elderly population with epilepsy can also be problematic.[31] There has been little empirical study of quality of life in the elderly,[53] and randomized clinical trials that have been undertaken have failed to use HRQOL measures.[53]

Any quality-of-life measures that have been used have been tested on adults <65 years of age. However, the elderly population differs from both young and middle-aged adults in terms of their epilepsy (etiology, clinical presentation, treatment) and lifestyle.[31]

Baker et al.[6] carried out a large cross-sectional study of epilepsy in the U.K. community. Using the Liverpool QOL battery, it was found that the elderly population diagnosed later in life can suffer from more anxiety and depression and report more negative quality of life than younger adults.

Therefore, given that epilepsy is the third-most-common neurologic condition among those of older age, research and development on quality of life in this group is vital for clinical management and targeting of appropriate psychosocial interventions.

Measures of Heath-Related Quality of Life in Epilepsy Studies

Although several groups have developed approaches to measuring HRQOL for people with epilepsy, few data are available demonstrating their sensitivity to changes in various interventions (e.g., change from two to one antiepileptic drug, change from a sedating to a nonsedating antiepileptic drug).[23] However, the QOLIE-89 has been used to assess improvements in QOL following a 2-year nurse-led structured intervention program. Following group education and extended counseling and teaching, the intervention group demonstrated significant improvements in overall QOL compared to controls.[44]

Furthermore, Privitera and Ficker[63] designed a large, community-based 3-month trial looking at changes in adverse events and HRQOL when switching from immediate-release to extended-release carbamazepine. Adult patients will be asked to complete the Adverse Events Profile (AEP) and the QOLIE-31, whereas adolescents with epilepsy will complete the Hague Seizure Severity Scale and the QOLIE-AD-48. Changes in efficacy of treatment are not expected because only medication formulation will be changed. They hope to detect differences in tolerability and QOL.

Drug Trials

The typical clinical trial of an investigational antiepileptic drug added to a standard antiepileptic drug does not usually produce dramatic clinical changes. Thus, large changes in HRQOL endpoints should not be expected. Most trials are relatively brief (3 to 6 months of blinded follow-up), further reducing the likelihood of finding major changes. Furthermore, Baker et al.[5] concluded that often there is a failure to apply QOL and behavioral measures in a systematic way in randomized,

controlled trials. Cramer[25] discussed the importance of carrying out HRQOL measurements in clinical trials and recommended principles for using them in such investigations. Cramer et al.[28] were the first to use the QOLIE-31 as part of a randomized, placebo-controlled, double-blind trial of the efficacy and tolerability of levetiracetam as an adjunctive therapy. Data from 246 patients randomized on levetiracetam 1,000 mg, levetiracetam 3,000 mg, or placebo were analyzed for significant changes in HRQOL at 18-week follow-up. Levetiracetam, especially 3,000 mg, seemed to provide significant positive improvements in HRQOL, particularly for those who were classified as responders (i.e., reduction in seizures of ≥50%). This study highlights the usefulness of the abbreviated QOLIE instrument in interventional studies. However, patients taking long-term open-label medication often have expectations, other changes in therapy, or significant life events that complicate the process of identifying the effect of a drug.

Jacoby et al.[50] used several scales to compare the effect of continuing versus withdrawing medication in patients who were seizure free for 2 years. Patients who relapsed while taking antiepileptic drugs did less well than patients who relapsed after discontinuation of medication, which likely reflects the fear that those relapsing on medications might not remain seizure free or would need to endure higher doses of antiepileptic drugs. These investigators concluded that continuing to take drugs implies persistence of epilepsy, whether or not seizures are controlled. Patients whose drugs were discontinued and who remained seizure free were better able to shed the stigma of the diagnosis.

Surgical Trials

The effect of epilepsy surgery, which can be curative for some patients, is another area beckoning HRQOL assessments. From Horsley's first operation in 1886[46] to cure posttraumatic epilepsy through Penfield's pioneering use of anterior temporal lobectomy in patients without gross lesions,[60] improving HRQOL has been an important implicit motivation for epilepsy surgery. Surgical treatment has often been undertaken to improve the social situation of patients with chronic epilepsy. Recently, the literature has focused on the effects of surgical treatment on other outcome measures relevant to quality of life, such as memory, cognition, and emotional and behavioral adjustment.[58]

Early evaluation of HRQOL before the special attention and stresses of the presurgical evaluation is important to define the patient in a "usual" state. Follow-up assessment should not be attempted too soon after surgery, but might profitably be repeated during several years postoperatively to evaluate changes over time.

Selai et al.[68] assessed the HRQOL of patients pre- and postsurgery using the QOLAS, the ESI-5, and the EQ-5D, which is used in economic analyses. Of the 145 patients evaluated for surgery, 22 underwent the procedure and achieved a 75% seizure reduction. Patients reported significant improvements on two of the three composite scores of the ESI-55 at mean 1-year follow up. They also reported significant improvements in all domains of the QOLAS.

Surgical success does not always equate with psychological or social recovery. Augustine et al.[1] found that most patients who did not work before surgery did not work after successful surgery. Many patients who worked before surgery despite frequent seizures resumed work. Seizure control was only one of many factors related to occupational adjustment.

Changes in HRQOL were also assessed by Cramer after vagal nerve stimulation (VNS).[24] The QOLIE-10 was administered to 136 intractable epilepsy patients before and after 3 months of stimulation. Patients reported improved overall HRQOL and improvements in energy, downheartedness, memory difficulties, work and social limitations, and fear of seizures. However, there were no differences in overall HRQOL or subdomain scores, except for energy level, between those classified as responders and nonresponders to VNS.

Cross-Cultural Adaptation and Translation

There is an increasing interest in conducting multicenter trials in different countries in Europe and the United States. This has meant that measures developed in one country need to undergo translation and retesting for use in another. However, the process is not a simple one. The technical issues are well documented.[40,47] Adaptations require emphasis on making the instrument sensitive to HRQOL concerns of individuals in each culture, with less emphasis on perfecting translation of terms. Various measures have been successfully translated and validated into other languages, including Greek,[59] German,[55] Serbian,[72] and Chinese.[79]

Baker et al.[7] conducted the largest study to date of the effect of epilepsy and treatment on the quality of life of people living in Iran, the Gulf States, and the Near East. The battery of questionnaires was translated forward and backward from English into Greek and Fufha (the official written Arabic language) and given to 3,847 people with epilepsy. Epilepsy was perceived to affect many different aspects of their daily lives and largely confirmed previous findings of the effect of epilepsy on people living in European and other countries.

Summary and Conclusions

Quality-of-life measures are critical for reaching a better understanding of the effect of epilepsy and its treatment. Medical outcomes—seizures and side effects of drugs—define only a small portion of the areas that affect the life of a person who has epilepsy. Furthermore, doctors' and patients' perspectives on how seizures and side effects affect the patient's life can be quite different. Quality-of-life questionnaires can be useful in epilepsy clinical trials and medical practice, allowing patients to express their concerns about a variety of issues affected by the diagnosis, psychosocial impact, seizures, and medication. Thus, the patient's perspective can provide new information about not only the critical psychological and social issues, but also the medical outcomes (seizures, adverse effects of drugs) that are often viewed solely from the physician's perspective.

Chapter 101

Age-Related Considerations

Ann Jacoby

Gus A. Baker

Introduction

The goals of therapy for people with epilepsy were discussed in an earlier chapter. They can be seen as being broadly concerned with reducing the impact of the condition on daily functioning and overall quality of life (QoL) by reducing seizure frequency and severity, minimizing the side effects associated with prescribed treatment regimes, and providing the necessary information and support to enable patients to manage their condition successfully. In considering what constitutes appropriate therapy for any individual patient, it is important to recognize that the impact of epilepsy and its treatment will vary across a number of patient characteristics, of which age is an important one. The quality of people's lives overall reflects the level of their functioning within a number of different spheres, and this may be enhanced or reduced by their condition and its treatment. However, the importance attached to optimal functioning within particular spheres varies at different stages of the life cycle, and as a result so does the extent to which the condition and its treatment are seen to impinge on quality of life.

This chapter considers the differential impact on quality of life of epilepsy and treatment for epilepsy at different stages of the life cycle—childhood, adolescence, and the earlier and later years of adulthood. Although the effects of epilepsy and its treatment on the quality of life may differ according to a person's age group, there are nonetheless implications common to all age groups, and these are discussed first.

A chronic illness such as epilepsy is associated with several concomitant problems, regardless of the point in the life cycle at which it develops. Conrad[31] identified among these the problem of managing the uncertainty that accompanies the onset of chronic illness; the impact that chronic illness can have on a person's sense of self; the issue of stigma, which is more problematic in some conditions than others; the impact of chronic illness not only on the patient, but also on the patient's family members; and the problem of managing treatment regimes. These are discussed in greater detail in the following paragraphs:

1. The problem of managing uncertainty in chronic illness. A defining quality of most chronic conditions, including epilepsy, is uncertainty, which relates not only to the interpretation of symptoms and the diagnosis, but also to the projected clinical course. Radley[100] argued that uncertainty is endemic to the situation of people who are chronically ill and "is not limited to one period of time or one situation." A person with epilepsy can face uncertainty regarding whether and when seizures will recur, the nature of seizures and how they can best be controlled, and whether the illness will ultimately go into remission. The unpredictability of the nature and course of epilepsy can thus be a key factor in the problems it engenders, whatever the age of the person affected.

2. The impact of chronic illness on sense of self. A number of authors have considered the impact that a chronic illness has on a person's self-concept.[21,22,27,140] The restrictions imposed by chronic illness, the inability to fulfill former tasks and roles, the consequent social isolation, and the increased dependency on others combine to make chronic illness what Charmaz[27] described as a fundamental form of suffering because those who become ill have to contend with "a crumbling away of their former self-images, without simultaneous development of equally valued new ones." This is clearly the case for people with epilepsy,

who may face various statutory and nonstatutory restrictions as a result of their illness, find themselves unable or unwilling to pursue particular activities, either because of their fears of precipitating seizures or as a result of the attitudes of others toward them, and consequently become increasingly socially isolated. The impact on self-concept may be felt equally acutely by the child with epilepsy excluded from sporting activities at school and the elderly person with epilepsy who is no longer regarded as capable of caring for a grandchild.

3. The issue of stigma. It has been argued that all chronic illnesses are stigmatizing to a greater or lesser degree by virtue of their representing a deviation from a state of health,[95] but epilepsy has, historically, been a stigmatizing condition par excellence.[126] For this reason, people with epilepsy often appear to regard their condition as a "new moral weight" that they have to carry,[114] and some see it as having an extremely negative impact on the quality of their lives. A number of authors have shown how the parents of children with epilepsy can act as what Goffman[56] referred to as "stigma coaches," inculcating in their offspring a sense of shame about their condition and counseling them not to disclose it to others.[114,139] Scambler[110] contended that because having epilepsy has more salience for people in some roles and situations than in others (and so, potentially, a greater effect at some periods of the life cycle than at others), the degree to which a person feels stigmatized by epilepsy will vary.
4. Impact of chronic illness on family members. Coping with chronic illness takes a toll not only on the person affected, but also on the patient's family members, so that their quality of life too can be diminished.[4,5,134] Venters[134] listed among the range of familial consequences of chronic illness increased communication difficulties, accentuation of preexisting marital problems, and increased social isolation and disorganization of family routines; although Venters was concerned with a specific condition, cystic fibrosis, it seems likely that these outcomes are common to all chronic conditions, epilepsy included. Confronted with the problem of chronic illness, many families become dysfunctional. Scambler and Hopkins[112]

examined the way epilepsy is accommodated in families and concluded that to survive intact the family must reestablish the equilibrium lost at the onset of chronic illness in one of its members.

5. Managing treatment regimes. Managing a treatment regime is part of the "work" of a chronic illness,[119] and people who are chronically ill often have to become experts in their own treatment, considering the associated costs and benefits and adhering to or adapting their prescribed regimes accordingly. Pinder[97,98] illustrated clearly how people who are chronically ill are constantly involved in maintaining a balance between minimizing the symptoms of their illness and incurring the side effects of medication. The problems of managing a drug regime are nowhere more apparent than in the sociological literature on epilepsy. Schneider and Conrad[114] and Scambler[109] found that adults with epilepsy frequently self-regulated their antiepileptic drugs, missing, raising, or reducing doses at particular times and in particular circumstances. West,[139] considering children with the condition, reported that their parents often decided to contravene the medication rules specified by the child's physician out of anxiety about the effectiveness of antiepileptic drugs and their possible side effects.

Age-Related Impact of Epilepsy

Although all people with epilepsy have to contend to some degree with the problems just outlined, the precise extent to which their impact is felt by any one individual is determined by a number of factors relating to their personal and social situation, of which age is one. This section gives more detailed consideration to the way in which such problems are manifested in childhood, adolescence, adulthood, and older age.

Impact of Epilepsy in Childhood and Adolescence

Epilepsy is the most common chronic neurologic problem of childhood, its incidence being highest in the first decade of life.[60] It is now known that a number of the childhood epilepsies are benign and will either remit or be easily controlled by appropriate treatment, whereas others have a much poorer prognosis and are often accompanied by significant brain dysfunction and developmental delay.[41] The epilepsies of early childhood tend to carry the worst prognosis because they are commonly associated with congenital disorders or birth and perinatal trauma.[99] At least 70% of childhood epilepsies, particularly the benign partial epilepsies, are known to remit at or before adolescence[1]; some, including severe myoclonic epilepsies and the Lennox-Gastaut syndrome, persist through adolescence and into adulthood; a third group, including juvenile absence and juvenile myoclonic epilepsy, begin in adolescence.[39]

Main Quality-of-Life Effects in Childhood

Compared with parallel work in adults, research into the impact of chronic illness on quality of life in children and adolescents has been hampered by a number of difficulties concerning measurement. These relate to the rapid physical, cognitive, and emotional changes that occur through this period,[43] which necessitate the development of scales focusing on narrow age ranges and developmental levels. Although efforts have been made recently to develop appropriate methodologies for obtaining information regarding quality of life from children and adolescents themselves,[28,47] studies of the impact of chronic illness on quality of life in childhood have generally rested on the assessments of parents, for reasons that are self-evident: Very young children are unable to express themselves verbally, and school-age children may have difficulty filling in forms or schedules or may be intimidated when asked questions by an unfamiliar researcher.

Despite such difficulties, an important finding from the work that has been done is that children and adolescents with epilepsy appear to have a relatively more compromised quality of life than children and adolescents with other chronic conditions or their healthy peers.[12,50,90] Identified risk factors for poor quality of life include epilepsy severity, antiepileptic drug (AED) side effects, and lower socioeconomic status.[36] Miller et al.[90] compared quality of life in children with epilepsy and healthy controls, using a generic measure, the Child Health Questionnaire, and showed that the former had more limited life quality in terms of physical function, emotional well-being, self-esteem, parental impact, and family activity; predictors for impaired quality of life were number of AEDs and presence of comorbid neurologic impairments. Räty et al.[101] found that even uncomplicated epilepsy exerted a negative impact, especially in the areas of competence. Both they and others[36,91] reported that patients in late adolescence are at greater risk of compromised quality of life than are those at earlier developmental stages, and as discussed later in this chapter, it appears that such effects sometimes persist into adulthood.

In a recent review of quality-of-life issues affecting children and adolescents with chronic illness,[135] self-esteem and school functioning were identified as being among the most significant. The relevance of both these issues for children with epilepsy is demonstrated in the work of a number of authors. Long and Moore[83] collected information from children with epilepsy about the effects of being “different” from other children and found that they had significantly lower levels of self-esteem than their healthy siblings. Poor self-concept among children with epilepsy has also been reported by Matthews et al.,[87] Hoare,[64] and Austin et al.[12] Matthews and Barabas[86] studied 45 children between the ages of 7 and 12 years, 15 with epilepsy, 15 with diabetes, and 15 in good health. Compared with the rest, the children with epilepsy had poorer esteem in relation to their intellectual and academic functioning and were also more likely to see themselves as unpopular with their peers.

Role of Important Others in Mediating Childhood Quality-of-Life Effects

Matthews and Barabas hypothesized that children's self-concept is threatened by a sense of lack of control, experienced as a result of the unpredictability of their seizures—an element of epilepsy that can, of course, be as much a problem for the families of children with epilepsy as for the children themselves.[7] The “vulnerable child syndrome,”[58] in which the fear and anxiety of both child and parent inhibit normal development, is not an uncommon phenomenon in families with children with a chronic illness such as epilepsy. Overprotectiveness on the part of parents may leave them reluctant to grant the child autonomy, so that his or her sense of competency and self-worth is threatened.[144] Williams et al.[141] documented the role of parental anxiety in compromising the quality of life of children with epilepsy and concluded that targeted interventions and support may be critically important.

Table 1 An ecological framework for understanding the role of family factors in child psychopathology

Proximal factors	Distal factors	Context factors
• Quality of parent–child relationship, e.g., rejection/acceptance, parental attachment • Parenting, e.g., level of parental support and control	• Parent characteristics, e.g., maternal depression, parental beliefs concerning their competence in parenting, ineffective coping strategies • Parental congnitions, e.g., perceptions concerning epilepsy, parental expectations for the child	• Marital conflict • Family adaptation • Family conflict/cohesion • Family stress • Social support

Adapted from Rodenburg et al.[104]

Matthews and Barabas also suggested that children's sense of self is the outcome of the feedback they receive from important others, and that such feedback may be fundamentally different for them than for children without epilepsy. There is evidence for this in the studies of interaction in families of children with epilepsy.[49,57,102] In a recent review, Rodenburg et al.[104]

P.1143

attempted to address the question of whether the families of children with epilepsy differ from others on *distinct* family factors and whether these factors are linked to psychopathology in the affected child. The theoretical framework for their analysis distinguished among proximal, distal, and context factors (Table 1).

Summarizing results from 35 studies involving 1,400 children aged 5 to 25 years, these authors reported that, compared to controls, parents of children with epilepsy appear to be less supportive and competent and more inconsistent and authoritative, with fathers being overnurturing and mothers exhibiting higher levels of emotional overinvolvement. Families of children with epilepsy tend to be more rigid and less close and more stressed and to have fewer social resources and support. With regard to the role of these family factors, maternal warmth and encouragement are shown to reduce psychopathology in children with epilepsy, as are parental support, satisfaction with family relationships, and family social support, whereas maternal criticism, depression and worry about epilepsy, parental overcontrol, perceived limitations and stigma, and family stress and conflict increase it. The authors made some important observations about these findings: Emotional overinvolvement can generate positive, as well as negative, effects for the affected child's adjustment; epilepsy is a stressor for parents as well as their affected child, but parental attitudes can become more positive over time; and lack of knowledge may induce negative parental perceptions of epilepsy but increasing knowledge can decrease parenting problems. They argued that future research should aim to determine the unique contributions made by family factors relative to neurologic and medication factors and to identify strategies to help families cope better with the challenges epilepsy in childhood can present.

Their conclusions are supported by the work of Oostrom et al.[93] who investigated factors associated with cognitive-behavioral function in children with newly diagnosed epilepsy attending mainstream school. Their analysis showed that in "epilepsy-only" children, context-related rather than epilepsy-related factors were important in predicting cognitive and behavioral disadvantages over time; children with persistent deficits were more likely to have shown behavior problems prediagnosis and to come from families with increased dysfunction and where the parents reported discontinuity in parenting style following the onset of epilepsy in their child. Similarly, Fastenau et al.[46] showed that in children with chronic epilepsy, neuropsychologic deficits had a smaller impact on their academic achievement if they were living in supportive and well-organized homes. These authors concluded that interventions that increase family structure, stability, and support can reduce the risk of adverse academic outcomes for such children and, it is hoped, their overall quality of life.

Quality-of-Life Effects for Family Members of Children With Epilepsy

The sometimes considerable effects of chronic illness on other family members, as noted in a number of sociological studies, are evidenced in epilepsy also. Perhaps as a result of parental preoccupation with and overprotectiveness of the affected child, families of children with epilepsy appear often emotionally skewed,[57] so that psychiatric morbidity is increased not only in children with the condition, but also in their siblings.[50,65,66] The effect on their other children was one of the main anxieties expressed by parents in the study by Ward and Bower,[137] who reported that siblings were often upset by the limitations imposed on the family as a whole as a result of the onset of epilepsy, jealous of their parents' preoccupation with the affected child, and resentful at the increased responsibilities assigned to them in helping to care for the child. The negative impact on parents is apparent from the reported higher rates of psychological difficulties[105] and of separation and divorce among the parents of children with epilepsy than in the general population.[115]

Impact of Antiepileptic Drugs on Quality of Life of Children

That the adverse effects of AEDs can reduce the quality of life for children and adolescents with epilepsy is well recognized. Besag[18] noted that although some antiepileptic drugs are notorious for causing gross overactivity and behavioral disturbance in children, others are known to have a marked sedative effect, particularly if used in combination. Aldencamp[2] reviewed findings from more than 300 studies (although not all in children) on the cognitive effects of antiepileptic drugs; these indicate associated impairments in memory, concentration, and mental and motor speed. The adverse effects of AEDS, particularly on cognition,[131] have provided one of the major arguments for their withdrawal in children[25]; it is interesting, however, that Aldencamp et al.[3] studied drug withdrawal in 100 children who were seizure free for at least 1 year and found a significant improvement in their scores on only one of a large battery of cognitive tests. Whether this was because, as the authors suggested, the impact of antiepileptic drugs on cognitive function in children is limited, or because, as Dreifuss[40] argued, it is less likely to be reversible for children than for adults is not clear. Whatever the results of such studies, it is clear from investigating the issue of patient adherence with drug regimes[138] that parents

P.1144

worry about the adverse effects of antiepileptic drugs on their children and so may decide to discontinue them; one study of the management of childhood epilepsy produced a figure for noncompliance of 60%.[35] With or without parental complicity, nonadherence to medication regimes appears to be a more common feature of adolescence than earlier childhood, a fact that Thornton[129] attributed both to a misunderstanding of the need for medication and an attempt to deny the “predicament” of having epilepsy. Wide fluctuations in blood levels of AEDs among adolescents have been reported by Takaki et al.,[123] indicating that erratic compliance was commonplace.

Reflecting concerns about further undesired effects of antiepileptic drugs on the developing brain, considerable emphasis has been given in studies of quality of life in children with epilepsy to emotional/behavioral issues[10,64,118,128] and the effect of epilepsy on school performance.[67,118,130] Berg et al.[17] assessed longitudinally the influence of epilepsy etiology and syndrome and seizure control for adaptive behavior in children; they concluded that in the majority of cases, it is in the normal range and shows no evidence of decline over time. The exception was for children with what these authors characterized as “epileptic encephalopathies” (including West syndrome and Lennox-Gastaut syndrome), who demonstrate impaired adaptation at the time of diagnosis and continue to experience further decrements. Austin and her colleagues examined academic achievement in children with both recent-onset and chronic epilepsy.[9,89] In a group of children diagnosed 12 months previously, they showed that mean academic achievement was in the average range. The same was true for children with established but low-severity or inactive epilepsy, although not for those with high-severity epilepsy, in whom scores were significantly lower. In both recent-onset children and children with established epilepsy, academic performance was significantly associated with adaptive competency (i.e., working hard, behaving appropriately, and being happy). An unexpected finding from the work reported is that there were no changes in academic achievement over the course of the 4 years during which the latter group were followed, that is, children with high-severity epilepsy did not get any worse in terms of academic achievement, but neither did children whose epilepsy was reduced in severity get any better. These findings highlight the need to ensure that the focus on medical management of epilepsy does not lead to problems with academic performance being overlooked.

The Role of Stigma

To understand fully why children with epilepsy and their families appear to fare worse in terms of quality of life than children with other chronic conditions and their families, it may be helpful to return to another of the common themes highlighted by Conrad,[31] namely, the issue of stigma. As noted earlier, epilepsy has long been a stigmatized condition—in the words of Schneider and Conrad,[113] a “closet illness”—and therefore it may have a particular significance for those in whom it is diagnosed and their relatives.[22] Although lay attitudes toward epilepsy appear to have become increasingly enlightened,[24,73,74] the theories about the nature and causes of epilepsy held by people, including the parents of children with the condition, may have important psychosocial implications. For example, West[139] found that many of the parents in his study held a view of epilepsy that was “predominantly stereotyped” and negative, and so experienced a sense of shame from having children with epilepsy. Thompson[128] commented that such negative attitudes on the part of parents are “easily internalized by the child, with negative consequences for the development of self-identity and self-esteem.”

Bagley[14] reported that teachers too often share in such commonly held stereotypes and prejudices, and as a result they are more likely to consider their epileptic pupils as having academic and behavior problems. The authors of one study reported that children who had seizures at school were significantly more likely to suffer from depressive illness than those whose seizures always occurred outside school hours; they attributed this finding to the rejection such children suffered from their peers as a result of their witnessed seizures.[96] When questioned about their main fears and concerns in relation to their seizures,[8] children with newly diagnosed seizures often said they were worried that their peers might tease or make fun of them. Oostrum et al.[92] reported that both children with epilepsy and their healthy peers attribute more shame to epilepsy than to other disorders. Such fears can be quite realistic, given the findings of Austin et al.[11] that among a general population of adolescents surveyed in the United States, about three fourths agreed that a young person with epilepsy would be more likely to be bullied or picked on, and less than one third would be willing to date someone with epilepsy. These negative attitudes were matched by gaps in U.S. adolescents' knowledge about epilepsy, with only half of them confident that epilepsy is not contagious and only one fourth that it is not a form of mental illness. Thompson[128] cited findings from a survey of schoolteachers' knowledge about epilepsy that showed that as many as 70% considered themselves ill informed about the condition; this has important implications for the quality of life of children with epilepsy because through such ignorance, children can be excluded from particular activities and denied valuable educational opportunities.

The problem of the stigma of epilepsy can be felt particularly acutely by adolescents, whose self-image is fragile and whose concern about the way others see them can be a cause of significant distress. Adolescence is the period during which people with epilepsy first have to confront the legal and statutory restrictions associated with their diagnosis—they may be unable to drive or to pursue certain career options—as well as the informal ones, such as the need to avoid excessive alcohol intake and sleep deprivation. Unable to establish themselves as “normal” in relation to their peer group, adolescents with epilepsy can become socially withdrawn and isolated. The struggle to develop independence, although faced by all adolescents, is thus further complicated for them, and their psychological development, social integration, and future independence may thus be at risk.[39] Kim[77] commented that identity formation can be a particularly difficult task for adolescents with epilepsy who “have not been able to build up competencies in the earlier developmental stages.” The need to consider the particular psychosocial difficulties faced by adolescents with epilepsy in addition to the traditional medical ones has been highlighted,[129] and it can best be served by providing special clinics for this age group.

Impact of Epilepsy on Quality of Life of Younger Adults

Efforts to assess the impact of epilepsy and its treatment on younger adults are somewhat further advanced than those for children, and there is a considerable literature on which to draw. The incidence of epilepsy is at its lowest from ages 20 to 60 years, and seizures are well controlled in the majority of adults in this age group. Despite the fact that the physical aspects of their condition may be of less significance for younger adults, the psychosocial ones may be of greater significance as they face the full weight of the formal legal restrictions on driving and employment that currently apply to people with epilepsy, as well as potential informal stigma

and discrimination. Although the social meaning of epilepsy has clearly shifted with time, in the words of Conrad and Schneider,[32] from "badness to sickness," many people continue to regard having *epilepsy* as worse than having *seizures* because of their fear that they might be stigmatized by the label.[109]

The Role of Stigma and Discrimination

The evidence from research on the extent of informal stigma and discrimination in the lay community is somewhat contradictory, as is evidence of the degree to which people with epilepsy perceive it. Information about the attitudes of those without epilepsy toward those with it suggest that, historically, these have been less than favorable[13,59,62,107]; however, recent research suggests that attitudes are improving.[23,24,63,72,73,74] It has been argued that many people with epilepsy are unconvinced by this apparent new enlightenment, believing that their condition is one against which a particular prejudice persists, even when they personally have had no experience of such prejudice.[20,109] Scambler[108] reported that almost all the adults in his study of epilepsy admitted to suffering from what he terms "felt" stigma, even if only sporadically; feelings of stigma were less readily expressed among the subjects studied by Ryan et al.,[106] Chaplin et al.,[26] and Jacoby.[69] However, like Scambler, Jacoby found that felt stigma was significantly more prevalent than was clearly supported by any actual incidences of enacted discrimination, suggesting that people with epilepsy are still aware of the potential stigma of their condition and the ways in which they *could* be marginalized by it. These findings reinforce the need for clinicians who care for people with epilepsy to give greater attention to the "demythologizing and destigmatizing of epilepsy"[111] and to help them to negotiate any statutory restrictions.

Dilorio et al.[37] documented associations of perceived stigma in 320 men and women with epilepsy recruited through three epilepsy centers. Participants ranged in age from 19 to 75 years, the mean age being 43 years. Those reporting higher levels of perceived stigma also reported reduced self-efficacy, more-negative expectations of the outcome of treatment, poorer medication management and adherence, and reduced satisfaction with health care. Factors predicting greatest risk of feeling stigmatized included having a first seizure before age 50 years, not being married or cohabiting, not being in paid employment, and living on a limited income.

Main Quality-of-Life Effects in Adulthood

Thompson[127] pointed out that failure to address the psychosocial problems of epilepsy emerging in childhood and adolescence can result in psychosocial problems in adulthood that are "a greater handicap than the seizures and more intractable to intervention." Two important longitudinal studies provide evidence for her argument.[116,136] The first of these involved 155 individuals in a single Japanese prefecture[136] diagnosed with epilepsy before age 16 years and followed for 20 years. The findings indicate that for the majority of individuals with childhood-onset epilepsy, the long-term medical, educational, and social prognoses are favorable: by the time of follow-up, 148 individuals survived, in whom prevalence of psychiatric complications was low, educational achievement for those of normal intelligence paralleled that of controls, and levels of employment were high. Although the overall rate of marriage was lower, this applied only among the younger age groups. A less optimistic message emerges from the second study, which involved a population-based cohort of 245 individuals in Finland[116] diagnosed as having epilepsy in childhood and then followed prospectively for >30 years. Here, persistent effects were noted when epilepsy continued into adult life, a critical factor being AED medication. For example, those whose epilepsy was in remission and were off medication reported less perceived impact of their condition than did either those in remission but still on AEDs or those with continuing active epilepsy. The role of medication also was evident in relation to objective measures of outcome; for example, few subjects on medication, whether in remission or not, were in employment, and reduced socioeconomic status was noted in these groups, despite the finding that there was no difference in educational achievement.

The conclusion drawn by its authors in the study is that AED medication has a major effect on QOL, regardless of seizure status, and although the cognitive effects may be less marked, adults with epilepsy, like children with epilepsy, have to contend with the unwanted side effects of medication and the possible disruptions they bring to normal day-to-day functioning. Dodrill[38] showed that patients experiencing the cognitive impairments associated with antiepileptic drugs also tended to have more psychosocial problems. Although their reasons may be different, adults can be as likely to not adhere to prescribed drug regimes as adolescents, and it is incumbent on clinicians to consider why this should be so. Many studies of nonadherence have been concerned with documenting its level[52,81,88] and considering ways in which it might be reduced,[33,44,143] but they have paid little attention to understanding the reasons why patients choose not to follow prescribed regimes. The sociological literature makes a valuable contribution to this latter topic, highlighting that for patients, taking medication is only one aspect of managing a chronic illness such as epilepsy, and managing the illness in turn comprises only one of a number of competing daily demands.[42] Stockwell Morris and Schulz[117] commented that whereas clinicians assume that the value of adherence will be self-evident to patients, inasmuch as it will be associated with a positive health outcome, patients determine its value using a variety of criteria and might place greater value on other personal and nonclinical outcomes. This difference between patients' and clinicians' perspectives regarding the place of medication in the management of epilepsy is clearly reflected in the fact that until fairly recently, clinical trials of novel antiepileptic drugs incorporated only purely clinical measures of outcome. However, this is now changing, and the importance of other “quality-of-life” outcome measures is increasingly accepted.

A considerable body of quantitative research has demonstrated that adults with epilepsy have poorer psychosocial functioning than the general population.[80] In particular, they appear to be more socially isolated,[6,78] less likely to marry and have children,[34,82,120] and more likely to be underemployed or unemployed[45,51,60,120] and to be at increased risk for physical[120] and psychological morbidity,[48,60,120] including anxiety,[6,30] depression,[61,103] and poor self-esteem.[29,30,122] There are methodologic problems attached to such findings because many of the studies from which they are derived drew their samples from special epilepsy centers or epilepsy support groups and so tend to overrepresent adults with difficult-to-manage seizures, who may therefore be at increased risk for experiencing psychosocial difficulties. In two recent studies of people with well-controlled epilepsy, the majority of whom were seizure free,[68,70,132] levels of psychosocial distress appeared to be low and subjects emerged as having few problems associated with their condition. The term *epilepsy* represents a variety of disorders with a wide range of severity, and it is not surprising that adults with well-controlled epilepsy, as a group, do better than those with poorly controlled epilepsy.[15,71,79] Nonetheless, those involved in their treatment do a disservice to people with epilepsy if they assume that the relationship between severity of epilepsy and level of psychosocial function is necessarily a linear one. Although seizure frequency emerges clearly as a key factor among potential clinical contributors to reduced quality of life, there is increasing evidence of the

P.1146

important role of other, nonclinical factors, including medication effects and psychological status.[53,55,75,121,142]

Table 2 Factors that contribute to or detract from quality of life

Factors that contribute	Factors that detract
Family support/relationships	Psychological distress
Social support/relationships	Transport limitations

Religion/spirituality	Stigma/perceived stigma
Leisure activities	Restrictions on freedom
Security	Seizures
Positive self-concept	Cognitive limitations
Employment	Seizure worry
Health	General health
Independence/autonomy	Employment restrictions
Seizure control	Medication effects
Helping others	Heath care problems
	Social isolation
	Poor family relationships

Adapted from Gilliam et al.[54]

Expressed Concerns of Adults with Epilepsy

Recently, qualitative research has provided valuable insights into the domains of QOL that adults with epilepsy perceive as impaired.[19,54] Gilliam et al.[54] identified 24 distinct domains, including driving, independence, social embarrassment, personal safety, medication side effects, and seizure unpredictability. In the study by Bishop and Allen,[19] epilepsy was seen as exerting direct and indirect effects on quality of life at intrapersonal, interpersonal, and extrapersonal levels. This included effects on autonomy and independence, self-concept and mental health, family and social support, and work and productivity. Table 2 shows factors that contribute to and detract from QOL, as identified by those participating in the study.

Understanding the way in which epilepsy affects quality of life (not only in younger adults, but across the life span) is facilitated by considering factors that contribute to and detract from it and the extent to which they balance one another. Explanatory models such as that proposed by Ormel et al.,[94] which proposes that high QOL can be maintained, or at least restored, in individuals facing the onset of a chronic illness such as epilepsy if they can replace QOL losses with equivalent gains, can be helpful for encouraging QOL investigations beyond the purely descriptive.

Impact of Epilepsy and Treatment on Older People

Although it is now known that the incidence and prevalence of epilepsy begin to rise again after the age of 60 years, Tallis[124] commented that epilepsy was long thought to be uncommon and unimportant in this age group, and as a result older people have tended to be excluded from studies both of specific treatment effects and of the broader impact of epilepsy. In reality, epilepsy is the third-most-common neurologic condition of older age, after cardiovascular accident and dementia, and thus represents a significant health problem. Tallis[125] noted that in terms of its impact on older people's quality of life, epilepsy can represent a watershed, with both immediate and less immediate deleterious consequences. In older people, uncertainty over the diagnosis of epilepsy may be prolonged because seizures sometimes are manifested differently in older people and more extensive investigations are required to eliminate the greater number of potential causes for attacks that are suspected of being epileptic in nature; the aftereffects of seizures may be more prolonged, and they may more often lead to injuries, which, because of the aging process, may also be more serious. Tallis cites among the less immediate consequences of epilepsy in older people both social and psychological effects. Older people, like younger ones, suffer a loss of confidence because of the uncertainty of their condition and the unpredictability of its course; in older people, however, this may be accompanied by a much more marked loss of functional independence. Although the majority of older people are no longer in the work force and therefore do not have to contend with problems regarding employment, they may face the loss of other equally valued roles and of the ability to drive, which, because of their increasing physical frailty, may make them more liable to social isolation. They are more likely to live alone and so to have limited social support in coping with their condition, and if they are living with someone else, they may be more likely to be acting as an informal caregiver. Tallis described the social effects of the onset of epilepsy in older age as embodying a process of “marginalization and disempowerment,” which in turn can profoundly undermine the concept of self.

Effect of Antiepileptic Drugs on Quality of Life of Older People

The problems of side effects of antiepileptic drugs may be exacerbated in older people as in children, even though the causes for this differ.[133] Decreases in cognitive functioning associated with the aging processes may be intensified by the effects of antiepileptic drugs, and there may be other, more marked, nonneurologic side effects. Older people are more likely than younger ones to be taking other medications, and so are at increased risk for drug interactions; for the same reason, they may also be less likely to adhere to AED regimes.[76] Jones[76] also points out that recognition of the adverse effects of antiepileptic drugs may be delayed in older people because of prejudice among their doctors, who attribute cognitive impairments more readily to age than to drugs. Given the particular circumstances and physical considerations, Tallis[124] concludes that although the principles of management of epilepsy are the same in older as in younger people, the uncertainties—regarding when to start and stop treatment, which treatment to use and in what dose—are greater.

Quality-of-Life Concerns of Older People

Recently, Martin et al.[85] have documented the concerns older people themselves have about living with epilepsy. Their request to over 300 people over the age 60 living in the US, all of whom were being treated for intractable partial epilepsy, to list their concerns about their condition elicited 28 different areas of concern, the most frequently cited being driving and transportation and medication side effects (each cited by 64%). These were followed by personal safety (cited by 39%), AED costs (by 29%), employment (by 26%), social embarrassment and memory loss (each by 21%). In the United Kingdom (UK), Baker et al.[16] compared the self-reported quality of life of 155 men and women with epilepsy post-retirement age (65 years for men and 60 years for women at the time of the survey) with that of 514 men and women of working age, as part of a large community-based survey. Compared to their younger counterparts, these older people were no more likely to be an-xious or depressed and were less likely to consider that epilepsy impacted significantly on their social relationships and overall health, or to report feeling stigmatized by it. This last difference likely reflects the fact that for older people, discriminatory

P.1147

attitudes toward epilepsy have less significance than for younger people who may have to confront them in potential employers, and so supports Scambler's[110] suggestion that a person's epilepsy will commonly have more salience for them in some roles and situations than in others. There was, however, evidence of differences among older people themselves, depending on the time at which their epilepsy was diagnosed; with older people diagnosed post-retirement experiencing greater impact on their psychological well-being and overall life quality. Both sets of authors[16,84,85] highlight the need for further empirical exploration of the impact of epilepsy in this age group and a clearer understanding of their preferences and goals for treatment of their condition.

Summary and Conclusions

Examining the impact of chronic conditions such as epilepsy on a person's quality of life has long been the concern of social scientists, who have sought to understand the coping strategies adopted and the process of adjustment to changed life circumstances. Recently, clinicians too have become increasingly interested in disease impact, quantifying it to make more meaningful and comprehensive assessments of the outcomes of particular treatments. Understanding and quantifying the impact of chronic illness and the outcome of treatment are important, given that the aim of health care is to reduce the severity of such impact and its burden to patients, hence improving the quality of their lives. The impact of chronic illness is mediated by a number of factors, of which the age of the affected person is one. In this chapter, an attempt has been made to draw attention to some ways in which illness impact is common across all age groups, and some in which it varies.

In considering the impact of epilepsy, it is important to recognize that the underlying causes of epilepsy may be different in different age groups; its symptoms may be differently manifested; the impact and outcome of treatment may be variable because of physical, developmental, and aging processes; the life circumstances, and therefore the particular aspects of functioning affected, may vary. As a result, affected individuals may have different health care requirements, not only in relation to clinical management, but also in relation to informational needs and need for counseling and support. In conclusion, age-related issues in the quality of life of people with epilepsy should be taken into account, both in the development of measures of the outcome of specific treatment modalities and in the implementation of broader health care interventions.

Chapter 102
Pharmacokinetics

Emilio Perucca

Introduction

Pharmacokinetics is the study of changes in the concentration of drugs or drug metabolites within the body as a function of time. Its clinical importance stems from the fact that the concentration of the active principle at the site of action is generally the primary determinant of therapeutic and toxic effects. Therefore, pharmacokinetic principles play a critical role in determining the time of onset, magnitude, and duration of drug action.

For some drugs (e.g., carbamazepine), there seems to be a direct relationship between drug concentration in blood and the intensity of pharmacologic effect.[84] In other cases, the relationship between kinetics and effects may be more complex. The duration of action of vigabatrin, for example, may outlast significantly the presence of the drug in the body owing to the fact that the effect is mediated by irreversible inhibition of the enzyme γ-aminobutyric acid (GABA) transaminase.[23] Although in such cases a direct relationship between plasma (or brain) concentration and pharmacologic effect is not anticipated, it is still true that the effects ultimately depend on an adequate amount of drug reaching its site of action in the brain.

Drug kinetics result from a complex interplay among three basic processes: (a) absorption, (b) distribution, and (c) elimination. Characterization of these processes has proved to be invaluable for the rational use of antiepileptic drugs. Therapeutic advances related to an understanding of kinetics include recognition of the need to individualize dose to compensate for interpatient differences in drug disposition, selection of rational dosing schedules and dosing intervals, development of innovative drug formulations, identification of clinically relevant pharmacokinetic interactions, and use of plasma drug level monitoring as a guide to adjustments in dose.[17,69,83]

Absorption

The term *absorption* is used to describe the processes involved in the transfer of the drug from the site of administration to the bloodstream. The most important factors affecting absorption are the route of administration, the physical-chemical properties of the drug, the formulation used, and the pathophysiologic conditions of the patient.

The term *bioavailability* has been introduced to define how much of a drug reaches the systemic circulation after extravascular administration and the rate at which this takes place. Bioavailability primarily depends on the rate and extent of absorption, but it is also influenced by biotransformation or degradation, which may occur before the drug reaches the systemic circulation. For example, a compound may be fully absorbed from the gastrointestinal tract and yet be incompletely bioavailable if a significant fraction of the dose is metabolized during its first passage through the liver (the so-called first-pass effect).

Antiepileptic drugs are normally administered orally, but in particular situations the intravenous, intramuscular, and rectal routes are used alternatively. Other routes are used far less commonly; for midazolam, in particular, a number of studies have suggested that intranasal[47] or buccal[38] administration may result in rapid achievement of serum drug levels sufficient for anticonvulsant activity.

Gastrointestinal Absorption

Several processes must take place before an orally administered drug reaches the systemic circulation. These include (a) disintegration of the pharmaceutical preparation or release from the formulation (in the case of solid dose forms), (b) dissolution into the gastrointestinal fluids, (c) transfer across the gastrointestinal mucosa to the local bloodstream (a process that for some drugs may be affected by the activity of transporter systems located on the intestinal epithelium), and (d) possible presystemic degradation (or biotransformation) in the gastrointestinal tract or in the liver.[66]

Although some drugs can be partially absorbed from the stomach (especially acidic compounds, which are nonionized and lipophilic at low pH values), absorption takes place mostly in the gut and therefore may be slowed when gastric emptying is delayed. In general, absorption is faster after ingestion of syrups or solutions than after intake of solid forms. Formulations produced by different manufacturers may differ in rate or extent of absorption, resulting in potentially important differences in bioavailability. For example, intoxication or loss of seizure control has occurred following the substitution of one formulation for another that was subsequently found to have a different bioavailability. Such problems have been reported with many antiepileptic drugs, including phenytoin,[56] carbamazepine,[21] and primidone.[103] Regulations for the licensing of new formulations, including generics, recently have been tightened in several countries. Therefore, problems resulting from bioinequivalence are less likely to occur when a brand product is substituted with a generic product intended to ensure a comparable absorption profile.[82]

At times, formulations are especially designed to modify advantageously the release of the active principle into gastrointestinal contents. For example, drugs such as carbamazepine and valproic acid, which are absorbed and eliminated rapidly, are also available as sustained-release dose forms; these may be useful for attenuating excessive fluctuations in plasma drug levels and allowing less frequent dosing.[9] Sodium valproate may also be prescribed in the form of enteric-coated tablets, which are designed to avoid disintegration in the stomach and so prevent gastric irritation. Enteric-coated tablets do not behave as sustained-release forms because after dissolution of the coating, absorption proceeds very rapidly. Enteric coating, however, does modify absorption characteristics significantly. In fact, although small particles (<2 mm in diameter) can pass through the pylorus irrespective of the degree of

P.1152

gastric filling, the motility pattern of fasting is needed for larger particles to leave the stomach.[92] Ingestion of enteric-coated preparations after a meal may result in a long delay (sometimes up to 10 hours or even longer) before the tablet leaves the stomach and reaches the duodenum, where the coating dissolves and absorption occurs rapidly. This phenomenon explains the long latency that may occur before valproic acid is absorbed from enteric-coated tablets taken with or after a meal (Fig. 1).[42]

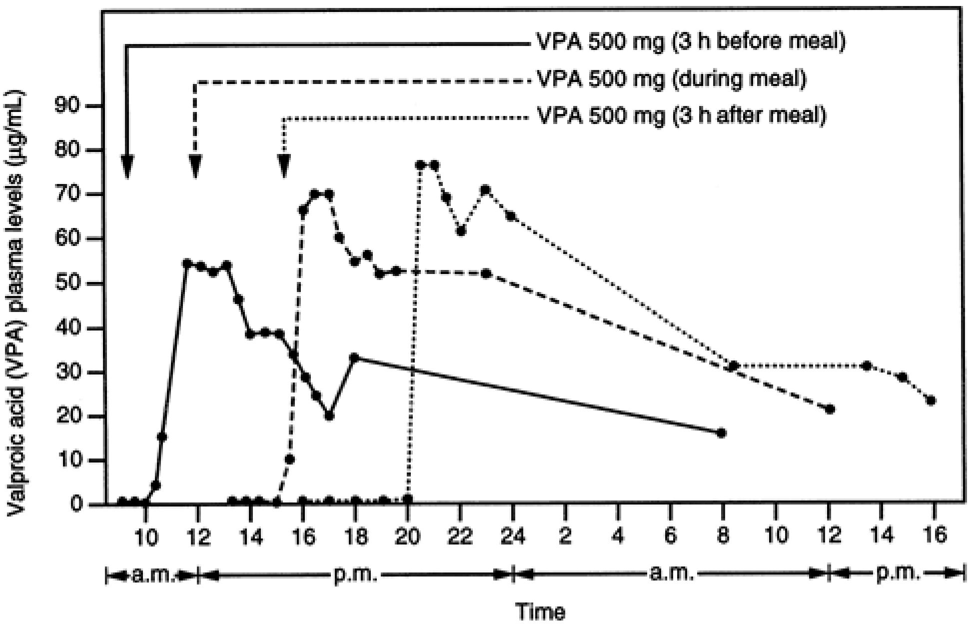

FIGURE 1. Effect of a meal on the absorption of valproic acid (VPA) from enteric-coated tablets in a representative individual. The same dose (one 500-mg tablet) was taken before a meal, during a meal, and 3 hours after a meal. Arrows indicate the time of drug intake. Note the long latency between drug intake and initiation of absorption when the drug was taken during or after a meal. (From Levy RH, Cenraud B, Loiseau P, et al. Meal-dependent absorption of enteric-coated sodium valproate. *Epilepsia*. 1980;21:273–280, with permission.)

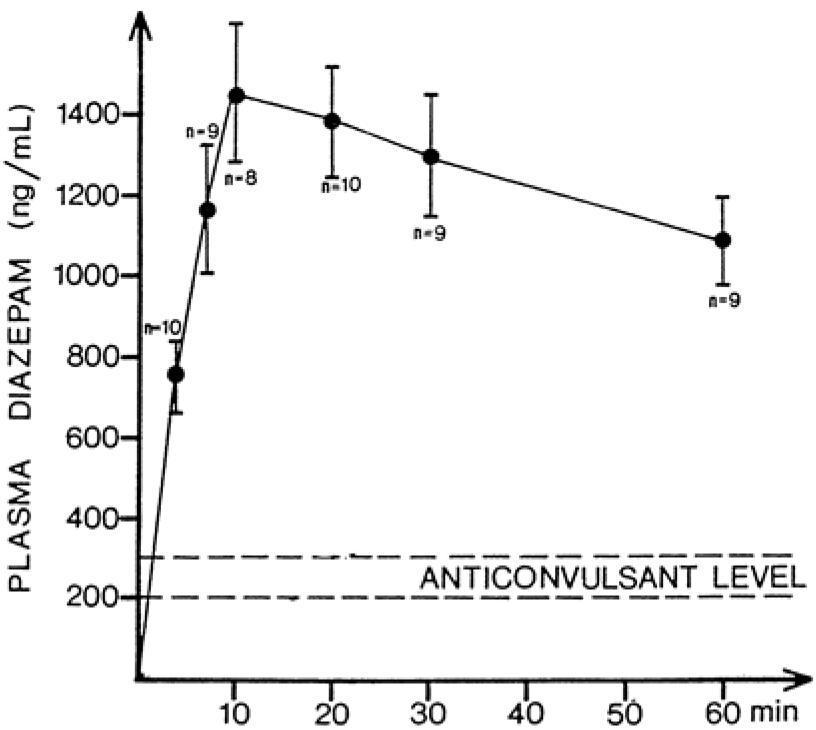

FIGURE 2. Rapid absorption of diazepam from a commercial solution (0.7 mg/µg) after rectal instillation in infants. Anticonvulsant activity is considered to develop when plasma concentration reaches the range of 200 to 300 ng/mL. (Modified from Knudsen FU. Plasma diazepam in infants after rectal administration in solution and by suppository. *Acta Paediatr Scand.* 1977;66:563–567.)

Irrespective of the formulation used, concurrent intake of food may have a profound influence on drug absorption. For some drugs (e.g., azithromycin, albendazole, griseofulvin), the rate and extent of absorption can be enhanced by food intake, whereas for others (e.g., clodronate, etidronate, tetracycline), bioavailability may be reduced drastically when they are taken after a meal.[87] Absorption may also be affected by drug interactions in the gastrointestinal tract, including interactions affecting the activity of transporter systems such as P-glycoprotein (see Chapter 110).

Rectal Absorption

The rectal route may provide a useful alternative when oral administration is not feasible because of, for example, palat-ability problems, nausea and vomiting, or a patient's inability to cooperate during ongoing seizures. For drugs that show a prominent first-pass effect in the liver, rectal administration may enhance bioavailability because only the superior hemorrhoidal vein drains into the portal system.

The efficiency of rectal absorption is influenced primarily by the physical-chemical properties of the drug (lipophilic compounds are usually well absorbed) and by the type of pharmaceutical formulation.[96] Suppositories may be associated with lower rates and extent of absorption, whereas absorption from rectal solutions or rectal capsules can be quite efficient. In the case of diazepam, anticonvulsant concentrations can be achieved within minutes of rectal instillation of the commercial solution (Fig. 2). The rapid absorption of rectally administered diazepam can be exploited when, for example, prolonged

seizures must be managed by nonmedical personnel or intermittent prophylaxis is needed against the recurrence of febrile convulsions.[36]

Intramuscular Absorption

The rate of absorption following intramuscular injection is determined by the solubility properties of the drug, the pharmaceutical characteristics of the formulation, and the degree of local blood perfusion. The latter, in turn, varies with site of injection (blood flow and absorption rate are greater in the deltoid region than in the buttock), hemodynamic state (absorption may be inadequate in hypotensive patients), and injection technique (massaging the muscle after the injection, e.g., may hasten absorption).

With some drugs, such as diazepam, intramuscular absorption may be slow and erratic.[32] For this reason, diazepam should not be given intramuscularly for the treatment of status epilepticus. Midazolam, a hydrophilic benzodiazepine, is absorbed from the muscle at a much faster rate than diazepam, and intramuscular midazolam is a viable option for the treatment of acute seizures.[80]

The slow and prolonged absorption of some drugs from muscle should be taken into account when the route of drug administration is temporarily switched from oral to intramuscular to provide therapeutic cover when a patient is transiently unable to take medications orally. For example, if phenytoin needs to be given intramuscularly for a few days, a dose 50% higher than the oral maintenance dose may be needed to compensate for inadequate intramuscular absorption. On resumption of oral therapy, half of the original oral dose should then be given for a period of time equal to the period of intramuscular administration so that toxicity resulting from delayed absorption from muscle stores is prevented.[99] Whenever possible, however, intramuscular administration of phenytoin should be avoided because it may cause local pain and muscle damage. If the patient cannot take phenytoin orally, the intravenous route is a preferable alternative. Another alternative is to switch temporarily to fosphenytoin, which, unlike phenyt-oin, is efficiently absorbed after intramuscular injection (see Chapter 154).

Distribution

After reaching the circulation, a drug undergoes distribution within blood components and body tissues. The rate and extent of penetration into individual tissues depend on a number of factors, such as the physical-chemical properties of the drug, the degree of drug binding to plasma and tissue components, the degree of tissue perfusion (blood flow), the presence of biologic barriers to tissue penetration (e.g., the blood–brain barrier), and the activity of transporter systems that may limit drug access to certain tissues and/or certain cellular or subcellular compartments. Compared with highly water-soluble drugs, lipophilic compounds generally exhibit more extensive tissue penetration, particularly in organs with a high lipid content, such as the brain. Distribution primarily occurs by passive diffusion, although in some cases drug transfer may be regulated by active transport mechanisms.

Table 1 Plasma protein binding of major antiepileptic drugs

Drug	Percentage (%) bound
Carbamazepine	70
Clobazam	90
Clonazepam	85
Diazepam	98
Ethosuximide	0
Felbamate	30
Gabapentin	0
Lamotrigine	55
Levetiracetam	0
Oxcarbazepine[a]	40
Phenobarbital	50
Phenytoin	90

Pregabalin	0
Primidone	30
Tiagabine	96
Topiramate	15
Valproic acid[b]	90
Vigabatrin	0
Zonisamide	45

[a]Binding refers to active metabolite 10-hydroxy-carbazepine.
[b]Binding is concentration dependent.

One estimate of the extent of drug penetration into tissues is provided by the *volume of distribution*. This parameter, which is usually normalized for body weight, can be defined as the virtual volume in which the total amount of drug present in the organism after completion of distribution processes needs to be dissolved to yield a concentration identical to that found in plasma. A volume of distribution of about 1 L/kg indicates that the drug is found in tissues at an average concentration equivalent to that in plasma. A volume of distribution <1 L/kg indicates that the tissue concentration is on average lower than the plasma concentration. Conversely, a volume of distribution in >1 L/kg indicates a high tissue concentration relative to the concentration in plasma. Most antiepileptic drugs have volumes of distribution between 0.6 and 1.2 L/kg, indicating that *on average* their tissue concentration is 60% to 120% of their plasma concentration.[67,68] There are exceptions to this rule, however, the most notable example being valproic acid; the small volume of distribution of this drug (about 0.15 L/kg) indicates its relatively poor tissue penetration.[73] An important concept is that the volume of distribution does not provide any information about drug concentration at specific sites; in fact, any given average tissue concentration may result from drug accumulation at extremely high levels in some organs, with other tissues receiving little or no drug exposure. More specifically, the volume of distribution does not provide any indication about drug concentration in the brain: Some drugs have a high volume of distribution and yet fail to reach the central nervous system because of inability to cross the blood–brain barrier.

Binding to Plasma Proteins

Many drugs are significantly bound to plasma proteins (Table 1). Although the binding is generally of a loose and reversible type, the drug–protein complex is too large to move freely across biologic membranes, and therefore it is only the unbound moiety that creates the diffusion gradient driving drug molecules from the blood into the tissues. Albumin is the most important protein available for the transport of acidic drugs, such as phenytoin and valproic acid, whereas α_1-acid glycoprotein is primarily involved in the transport of basic compounds, such as chlorpromazine and lidocaine. Some drugs (e.g., carbamazepine), bind to a significant extent to both albumin and α_1-acid glycoprotein.[2]

P.1154

Binding to plasma proteins may have a significant influence on drug kinetics. First, the protein-bound drug represents a reservoir within the bloodstream that tends to increase the concentration in plasma relative to the concentration in tissues. Second, drug binding to proteins may affect the rate of drug elimination. In the case of low-clearance drugs, only the unbound drug can be cleared, and therefore protein binding tends to restrict the efficiency of the elimination process. Conversely, in the case of high-clearance drugs, both the unbound and the protein-bound drug can be cleared; under these circumstances, protein binding enhances elimination by increasing the amount of drug delivered to the eliminating organ.[77,101]

The binding of drugs to plasma proteins may vary considerably among patients because of differences in protein concentrations or the presence of endogenous and exogenous substances competing at protein-binding sites. Because only the unbound drug is in equilibrium with drug molecules at receptor sites, pharmacologic effects usually correlate better with concentration of unbound drug than with total plasma concentration. Therefore, any condition leading to a change in unbound fraction will alter the relationship between plasma drug concentration and therapeutic effect, and this needs to be taken into account when drug levels are interpreted in clinical practice.[74] For example, a reduced binding of phenytoin to plasma proteins is observed in neonates; the elderly; women in late pregnancy; patients with other hypoalbuminemic conditions, hyperbilirubinemia, or uremia; and patients undergoing concomitant treatment with displacing drugs, such as valproic acid.[63] Under these circumstances, total plasma phenytoin levels underrepresent the concentration of unbound, pharmacologically active drug.

Tissue Binding

Some drugs are found in certain tissues at concentrations much higher than concentrations in plasma. To some extent, this may be a consequence of partitioning related to the physical-chemical properties of the drug; a highly lipophilic compound, for example, accumulates in lipidic tissues in a manner roughly proportional to its partition coefficient between oil and water. In some cases, drugs may be “sequestered” in tissues as a result of binding with proteins and other macromolecules. Because the bound drug is not available to interact with receptor sites, the total drug concentration in a given tissue might not provide a reliable estimate of the drug concentration at sites of action within the same tissue.

Tissue Blood Flow and Drug Distribution

After drug administration, distribution phenomena may take a long time to be completed. Initially, distribution tends to be confined primarily to highly perfused organs, such as the heart, liver, kidneys, and brain, which receive a large fraction of cardiac output. Subsequently, the drug redistributes gradually throughout the organism, and distribution can be considered complete only when the plasma-to-tissue concentration ratio has reached equilibrium in all tissues.

A good example of the clinical implications of redistribution phenomena is provided by thiopental, a compound sometimes used in the management of refractory status epilepticus. After a single injection of thiopental, the drug is transferred largely to the brain, where it penetrates rapidly because of its high lipophilicity. Other lipid-rich tissues (e.g., adipose tissue) initially receive little exposure to the drug because their perfusion is low compared with that of the brain. During the subsequent minutes, however, thiopental is redistributed gradually out of the brain into less perfused tissues, which tend to accumulate it at high concentrations.[19] Redistribution is mainly responsible for termination of action after a single dose, and it explains the apparent discrepancy between the short duration of thiopental-induced anesthesia (20–30 minutes) and the relatively long elimination half-life of the drug (about 9 hours). The situation is completely different when thiopental is administered by continuous infusion over several days. Under these circumstances, drug stores in poorly perfused tissues become gradually saturated. When treatment is discontinued, redistribution no longer occurs, and the termination of drug action is then determined by hepatic elimination, which explains the long delay before consciousness is recovered.

Blood–Brain Barrier

The anatomic configuration of the cerebral circulation represents a barrier to the entry of certain drugs into the brain and cerebrospinal fluid. As a general rule, the ability of a compound to diffuse across the blood–brain barrier is directly proportional to its lipid solubility. A number of poorly lipid-soluble drugs, however, may be transported in or out of the brain by selective uptake mechanisms. For example, l-dopa is transported into the central nervous system by a carrier-mediated process, whereas penicillin and salicylic acid are transported out of the brain by a different system of carriers. When carriers are involved, there is possibility of competition by other substrates at the site of transport; some amino acids, for example, compete with l-dopa for entry into the brain, whereas probenecid may block the uptake of penicillin from the cerebrospinal fluid by a similar mechanism.

The kinetics of penetration of antiepileptic drugs across the blood–brain barrier has been investigated in the anesthetized dog.[44] The fastest rates of entry were recorded for clonazepam, *N*-desmethyldiazepam, diazepam, and ethosuximide, whereas valproic acid, phenytoin, phenobarbitone, carbamazepine, and particularly primidone crossed the blood–brain barrier at a much slower rate (Table 2). Ionization did not appear to be a rate-limiting factor in brain penetration because all drugs except for valproic acid are mostly nonionized at physiologic pH. Furthermore, no correlation was found between rate of brain penetration and plasma protein binding, but for most drugs the ratio of cerebrospinal fluid to total plasma concentration at equilibrium was almost equal to the unbound fraction in plasma. Rate of entry into the cerebrospinal fluid correlated with lipid solubility as assessed by the benzene/buffer distribution ratio. Valproic acid showed unique features because it crossed the blood–brain barrier relatively rapidly despite its very low lipid solubility. These data suggest that the brain penetration of valproic acid may be regulated by an active transport process. There is also evidence that valproic acid may be transported out of the cerebrospinal fluid by an active uptake system localized in the choroid plexus, an observation that may explain the very low concentrations of the drug (relative to plasma concentrations) in the brains of patients receiving chronic treatment.[89]

In recent years, the mechanisms affecting access of drugs to the brain have been extensively investigated. Evidence has accumulated that, for many drugs, access to brain is influenced by the expression of efflux transporters, including P-glycoprotein, located in the cerebral capillary endothelial cells and in other cells, for example, astrocytes.[45] These transporters play a key role in reducing the penetration of substrates across barriers where they are expressed, including the blood–brain barrier, the blood cerebrospinal fluid (CSF)–barrier, and the blood–inner ear barrier.[39] Studies have suggested that several anticonvulsants, including phenytoin, phenobarbital, carbamazepine,

P.1155

lamotrigine, gabapentin, topiramate, and felbamate, are substrates of P-glycoprotein and other transporters, although evidence is not univocal for all drugs.[39] It has also been suggested that overexpression of these transporters may be a cause of drug resistance by limiting access of drugs to their site of action in neurons.[39,86]

Table 2 Rates of penetration of different antiepileptic drugs from plasma into cerebrospinal fluid in anesthetized dogs[a]

Drug	Nonionized[b] (%)	Unbound in plasma (%)	Partition factor[c]	Mean half-time to equilibrium (min)
Carbamazepine	100	28	48	18
Carbamazepine-10, 11-epoxide	100	54	1.2	46

Clonazepam	>99	18	38	3.2
Diazepam	>99	5	84	3.2
Ethosuximide	99	95	0.5	4.6
N-Desmethyldiazepam	>99	4	24	7.2
Phenobarbital	51	55	0.3	16
Phenytoin	89	22	6	17
Primidone	100	80	0.1	43
Valproic acid	0.16	22	0.1	12

[a]Rates expressed as half-times to equilibrium between unbound concentration in plasma and concentrations in cerebrospinal fluid. Each drug was studied in from 2 to 13 animals, except for phenobarbital, which was assessed in one animal.

[b] Percentage of drug nonionized at pH 7.4.

[c] Benzene/buffer (pH 7.4) distribution ratio.

Source: From Loscher W, Frey HH. Kinetics of penetration of common antiepileptic drugs into cerebrospinal fluid. Epilepsia. 1984;25:346–352.

The permeability of the blood–brain barrier is influenced by physiologic and pathologic factors. The increased sensitivity of neonates to some centrally acting drugs may be related, at least in part, to enhanced permeability of the blood–brain barrier during early stages of development. Many diseases can affect the integrity of the barrier. Disruption of the blood–brain barrier, resulting in increased brain exposure to valproic acid, may explain the occurrence of severe valproate encephalopathy within days of supratentorial surgery in some patients.[40]

Selective Drug Delivery to the Brain

The existence of the blood–brain barrier can be exploited by developing chemical systems designed to ensure preferential drug delivery to the brain. The best known of these systems is based on the dihydropyridinepyridinium salt–type redox molecular carrier.[79] In brief, the drug is conjugated with a 1,4-dihydropyridine moiety, resulting in a lipophilic complex that readily penetrates all tissues, including the brain. Thereafter, the complex undergoes quick oxidation to a highly polar quaternary pyridinium salt that is rapidly eliminated from the periphery but remains "locked" in the brain because of the impermeability of the blood–brain barrier. Over time, the active drug is released from the oxidized complex by enzymatic hydrolysis and becomes available to exert its pharmacologic action. The small, polar targeter released by the process of hydrolysis is readily expelled from the brain through an active transport mechanism. Because the system allows selective drug delivery to the brain, peripheral toxic effects can be minimized. Central tolerability may also be improved because of the slow and sustained delivery of the active principle at the site of action.

Experimental delivery systems based on the dihydropyridinepyridinium salt–type redox molecular carrier have been developed for a variety of antiepileptic drugs, including phe-nytoin, valproic acid, and stiripentol. Although at present the practical applicability of these systems is limited by the instability of dihydropyridine moiety in gastric fluids, innovative formulations for clinical use may become available in the future.

Placental Barrier

The use of the term *barrier* to indicate the anatomic structures regulating drug exchanges between mother and fetus is improper. Unlike the blood–brain barrier, generally the placenta does not provide an efficient obstacle to drug penetration. Although lipophilic drugs may enter the fetal circulation more readily than water-soluble compounds, from a practical point of view the fetus can be considered as subject to exposure to all drugs taken by the mother. For gabapentin, drug concentrations have been reported to be almost twice as high in the fetal circulation than in the mother, possibly due to existence of an active transplacental transport.[57]

Distribution Into Breast Milk

The distribution of drugs into breast milk is determined by a number of variables, the most important being the nonionized fraction of the drug in plasma and milk, lipid solubility, and the binding of the drug to plasma and milk proteins.[102] Drug exposure in the breast-fed infant, however, depends not only on the concentration of the drug in milk and the amount of milk ingested, but also on the infant's ability to absorb and clear efficiently the ingested drug.

All anticonvulsants pass into breast milk and the average milk-to-plasma concentration ratio ranges from about 0.7 to 1.4 for gabapentin and levetiracetam to 0.01 to 0.1 for valproic acid, which is hydrophilic and highly protein bound.[30,57,60] As a general rule, the presence of antiepileptic drugs in breast milk is not considered to be a contraindication to breast-feeding, although for some medications, particularly lamotrigine, primidone, phenobarbital, ethosuximide, and, to a lesser extent, carbamazepine and benzodiazepines, intake through breast milk may result in appreciable drug concentrations in the infant and the need to monitor for possible side effects. Because felbamate-induced hematological toxicity may be dose independent, use of this drug during breast-feeding has been discouraged.

Elimination

The most important routes of drug elimination involve direct excretion, mostly into urine, and biotransformation with subsequent excretion of breakdown products in urine and/or bile. The extensive interindividual variability of these processes is largely responsible for the wide differences in plasma drug levels observed in patients receiving the same dose. Therefore, a correct understanding of the factors that may affect drug elimination is crucial for rational prescribing.

Pharmacokinetic Concepts

Drug Clearance

The pharmacokinetic parameter that best describes the efficiency of elimination processes is the *clearance*, defined as the virtual volume of blood (or plasma) from which the drug is entirely removed per unit of time.[101] When a drug is eliminated exclusively by the kidneys in unchanged form, blood clearance equals *renal clearance*. When metabolism contributes to elimination, blood clearance is equal to the sum of renal clearance and *metabolic clearance*. Within any organ involved in drug elimination, the efficiency of the elimination process can be defined according to the formula

$$CL_1 = Q \cdot E \qquad (1)$$

where CL_1 is the contribution of that organ to the total clearance (e.g., in the case of the kidney, CL_1 equals renal clearance), Q is the blood flow through the organ, and E is the extraction ratio (i.e., the fraction of drug passing through the organ that is removed as a result of the elimination process). If a drug is totally removed during a single passage, E is equal to 1 and CL_1 becomes a direct measure of the blood flow through the organ.

From inspection of Equation (1), it is clear that drug clearance is influenced not only by the capacity of the organ to remove the drug efficiently from the bloodstream, but also by the rate of drug delivery to the site of elimination. In this respect, it is useful to differentiate between low- and high-clearance drugs.

In the case of low-clearance drugs, the efficiency of the elimination processes is relatively low, and protein-bound drug cannot be removed by the eliminating organ. The clearance of these drugs is restricted by the degree of binding to plasma proteins; a reduction in plasma protein binding, by increasing the availability of unbound molecules available for removal, will result in a corresponding increase in clearance. Conversely, the clearance of these drugs will not be affected by blood flow because any increase in rate of delivery of the drug to the eliminating organ due to increased blood flow will be offset by the organ's inability to maintain the efficiency of drug removal (i.e., an increase in blood flow will be accompanied by a corresponding decrease in extraction ratio, and clearance will remain unchanged). For these reasons, low-clearance drugs are said to exhibit *restrictive, flow-independent* elimination.[101]

The situation is reversed in the case of high-clearance drugs. These compounds are removed from the circulation so efficiently that protein-bound drug can also be eliminated during a single passage through the organ. The clearance of these drugs is *nonrestrictive* because plasma protein binding does not restrict the removal process but may actually facilitate it by increasing the delivery of the drug to the site of elimination. The clearance of these drugs is also *flow dependent*. In fact, in this case the eliminating organ can cope with an increase in blood flow without losing its extraction capacity, resulting in a direct relationship between blood flow and drug clearance. When the organ responsible for drug removal is the intestine or the liver, a third characteristic of high-clearance drugs is a prominent first-pass effect after oral administration. This is explained by the fact that the efficient elimination (i.e., a high extraction ratio) leads to removal of a significant fraction of the dose before the drug reaches the systemic circulation.

Elimination Half-life

An additional pharmacokinetic parameter used to describe drug elimination is the *terminal half-life* (or, more simply, half-life), which can be defined as the time taken for the plasma concentration to fall by one half during the terminal (postdistributive) elimination phase. The half-life is a useful parameter because it provides a direct measure of the rate of decline of drug concentration in plasma after discontinuation of therapy. In pharmacokinetic terms, however, the half-life is a hybrid parameter, determined not only by the efficiency of the elimination processes (i.e., drug clearance), but also by the volume of distribution. This can be understood easily by considering that after removal of any given amount of drug per unit of time, the percentage of reduction in plasma drug concentration primarily depends on the total drug stores in the body. If body stores are large (i.e., volume of distribution is large), the fall in concentration resulting from the removal will be minor. Conversely, if body stores are small, removal of the same amount of drug will have a much greater impact on plasma concentration.

Based on the foregoing considerations, it is clear that a change in half-life does not always reflect a change in the efficiency of the elimination process (i.e., drug clearance) but may be secondary to an alteration in volume of distribution. For example, the marked prolongation in the half-life of diazepam in the elderly is determined largely, although not exclusively, by an increase in volume of distribution.[35] The differentiation between clearance and half-life has important practical implications. In fact, mean plasma drug concentrations at steady state during long-term dosing are determined exclusively by bioavailability and clearance and are unaffected by half-life. Conversely, the half-life determines the time required to reach steady state (about four to five half-lives) as well as the degree of fluctuation in plasma levels during a dosing interval.

Biotransformation

Most drugs are too lipid soluble to be excreted efficiently by the kidneys, and after being filtered by the renal glomeruli, they are almost completely reabsorbed by diffusion from the tubular epithelium.[77] Elimination of these compounds depends primarily on their conversion to polar and water-soluble metabolites that can be excreted more rapidly in urine. In general, biotransformation products are inactive or less active than the parent drug, although there are numerous examples of metabolites retaining pharmacologic activity and contributing significantly to the production of therapeutic or toxic effects. Among antiepileptic drugs, those converted at least in part to active metabolites include clobazam, diazepam, carbamazepine, primidone, fosphenytoin, and oxcarbazepine (Table 3). Fosphenytoin and oxcarbazepine can be regarded as prodrugs because their effects are mediated virtually entirely by their active metabolites—phenytoin in the case of fosphenytoin, and 10-hydroxycarbazepine in the case of oxcarbazepine.

Almost invariably, the reactions involved in drug meta-bolism are catalyzed by enzyme systems and often exhibit a considerable degree of stereoselectivity. The most important enzyme systems are located in the smooth endoplasmic reticulum (microsomes) of hepatic cells, but significant levels of drug-metabolizing activity can be detected in the microsomes and the cytosol of other tissues, including the gastrointestinal mucosa, kidney, lung, blood, and brain.

The main metabolic pathways involved in drug metabolism include oxidation, reduction, hydrolysis, and conjugation. The first three are collectively known as *phase I reactions*, whereas conjugations are generally referred to as *phase II reactions*. In phase I reactions, functional groups such as —OH, —COOH, and $—NH_2$ are introduced into the drug molecule. In phase II reactions, functional groups already present in the molecule or introduced in the previous step are conjugated with an endogenous substrate, such as glucuronic acid, acetic acid, or inorganic sulfate, resulting in the generation of water-soluble metabolites that are readily excreted in urine.

Table 3 Main routes of elimination of antiepileptic drugs

Drug	Main route of elimination	Active metabolities
Carbamazepine	Oxidation	10,11-Epoxide[a]
Clobazam	Oxidation	*N*-Desmethylclobazam
Diazepam	Oxidation	*N*-Desmethyldiazepam
Ethosuximide	Oxidation	No
Felbamate	Oxidation[b] + renal excretion	No[a]
Gabapentin	Renal excretion	No
Lamotrigine	Glucuronide conjugation	No[a]
Levetiracetam	Renal excretion + hydrolysis	No
Nitrazepam	Reduction[b]	No
Oxcarbazepine	Reduction	10-Hydroxycarbazepine[a,c,d]

Phenytoin	Oxidation	No[a]
Phenobarbital	Oxidation + renal excretion	No[a]
Pregabalin	Renal excretion	No
Primidone	Renal excretion + oxidation	Phenobarbital[a,c]
Tiagabine	Oxidation	No
Topiramate	Renal excretion + oxidation	No
Valproic acid	Oxidation + conjugation	No[a]
Vigabatrin	Renal excretion	No
Zonisamide	Oxidation + Conjugation[b] + renal excretion	No

[a]Reactive intermediates may contribute to toxic effects.
[b]Other metabolic pathways may be important.
[c]Metabolite is primarily responsible for pharmacologic effects.
[d]Metabolite is eliminated primarily by glucuronide conjugation.

Oxidation

Oxidation is by far the most important among phase I reactions. Although occasionally the enzymes involved may be located outside the endoplasmic reticulum, a large majority of oxidative reactions are catalyzed by a group of closely related microsomal isozymes that utilize a specific cytochrome known as *cytochrome P450* because its complex with carbon monoxide exhibits an absorption peak at 450 nm. In addition to drugs and other xenobiotics, cytochrome P450 isozymes play an important role in the metabolism of endogenous substances such as free fatty acids, leukotrienes, prostaglandins, steroid hormones, and vitamins.[14,77]

Based on the degree of analogy between amino acid sequences in the enzymatic protein, cytochrome P450 (CYP) isozymes can be classified into different families and subfamilies,[54] and preferential substrates for each isozyme have been identified. Because each isozyme system is regulated in a different way by endogenous and exogenous factors, knowledge of the specific enzyme system responsible for the metabolism of a given drug is essential to predict situations associated with clinically significant alterations in the biotransformation of that drug. For example, the metabolism of the antiepileptic drugs mephobarbital (methylphenobarbital) and mephenytoin is catalyzed by an isozyme system that is subject to genetic polymorphism.[58] About 2% to 5% of white patients and 18% to 25% of Japanese and Chinese patients show a genetically determined deficiency of this enzyme and metabolize mephobarbital and mephenytoin at an abnormally slow rate, resulting in increased vulnerability to the toxic effects of these drugs. Because many inhibitors (or inducers) of drug metabolism selectively affect specific CYP isozymes, knowledge of the enzyme system or systems responsible for the metabolism of a given drug can also be used to predict drug interactions (Chapter 110).

A list of major cytochrome P450 isozymes and representative compounds metabolized by each of them is provided in Table 4. Although biotransformation products are usually pharmacologically inert, it is not uncommon for oxidation to result in the formation of active metabolites. At times, drug oxidation generates reactive toxic intermediates that are rapidly detoxified through hydrogenation or conjugation with glutathione or other substrates. When these detoxification processes are not fully efficient, the reactive intermediate can interact with endogenous macromolecules and produce serious toxicity, resulting in immune-mediated drug reactions, hepatic necrosis, mutagenesis, and carcinogenesis.[25] A toxic intermediate, probably the arene oxide, may play an important role in phenytoin teratogenicity, hepatotoxicity, and bone marrow toxicity.[77]

Table 4 Some important cytochrome P450 isozymes and examples of respective substrates

Enzyme	Substrate
CYP1A1	Benzo(*a*)pyrene and other polycyclic hydrocarbons
CYP1A2	Caffeine, theophylline, phenacetin, acetaminophen, imipramine
CYP2A6	Coumarin, losigamone
CYP2C8	Carbamazepine
CYP2C9	Phenytoin, phenobarbital, tolbutamide, *S*-Warfarin
CYP2C10	Tolbutamide
CYP2C19	*S*-Mephenytoin, mephobarbital, nirvanol, phenobarbital, phenytoin, diazepam, *N*-desmethyldiazepam, omeprazole, proguanil
CYP2D6	Amitryptiline, chlomipramine, desipramine, imipramine, nortriptyline, fluoxetine, paroxetine, clozapine, haloperidol, perphenazine, thioridazine, codeine, dextromethorphan, phenformin, alprenolol, metoprolol, debrisoquine, encainide, flecainide, indoramin, propafenone
CYP2E1	Felbamate, phenobarbital, chlorzoxazone, enflurane, halothane, ethanol, acetaminophen
CYP2E2	Benzene, styrene, acrylonitrile, vinyl chloride
CYP3A3/4	Carbamazepine, ethosuximide, felbamate, tiagabine, zonisamide, midazolam, triazolam, nicardipine, nifedipine, nimodipine, nisoldipine, felodipine, cyclosporine, ethinylestradiol, lidocaine, astemizole, terfenadine, lovastatin

Closely related isozymes may participate in the same reaction (e.g., CYP2C8, CYP2C9, and CYP2C10 may all catalyze tolbutamide methyl-hydroxylation).

Assessment of liver metabolic function. Clinical implications. *Clin Pharmacokinet*. 1994;27:216–248.

Reduction

Reductive reactions take place predominantly in the hepatic microsomes but also occur to an important extent at other sites. The reduction of certain compounds containing azo and nitro groups, for example, is catalyzed by bacteria found in the gut, not by mammalian enzymes.[53] The most important example of a reductive reaction implicated in the biotransformation of antiepileptic drugs is probably the conversion of oxcarbazepine to the active metabolite 10-hydroxycarbazepine.[49] The conversion of nitrazepam to the corresponding amine and the conversion of chloral hydrate to trichloroethanol provide additional examples of reductive pathways.

Hydrolysis

Hydrolytic reactions take place in many tissues, including blood. Cholinesterases and arylesterases play a role in phase I metabolism of drugs containing ester groups such as succinylcholine and many local anesthetics. Among antiepileptic drugs, hydrolytic enzymes mediate the conversion of fosphenytoin to phenytoin and the conversion of levetiracetam to the inactive metabolite L057.

Epoxide hydrolases represent a separate class of hydrolytic enzymes. An epoxide hydrolase is responsible for the conversion of carbamazepine-10,11-epoxide to its inactive diol derivative. Other hydrolases may be important in the detoxification of reactive epoxide intermediates, and it has been suggested that a relative deficiency of these enzymes may play a role in the pathogenesis of some hypersensitivity reactions to antiepileptic drugs.[78]

Conjugation

In conjugation reactions, a drug or its phase I metabolite is linked covalently with an endogenous molecule or another functional group, resulting in the formation of more polar, water-soluble metabolites suitable for renal excretion.[15] The most common conjugation pathways include acetylation, glucuronidation, glucose conjugation, sulfate conjugation, methylation, cyanide detoxification, glutathione conjugation, and amino acid conjugation. Most of these reactions are catalyzed by families of specific transferases and require high-energy nucleotide intermediates. Some conjugates formed in this way are excreted in the bile and may undergo hydrolysis in the gastrointestinal tract. This results in regeneration of the parent compound, which can then be reabsorbed, giving rise to what is known as the *enterohepatic circulation*.

Like phase I enzymes, conjugative enzymes are subject to modulation by genetic, developmental, and environmental factors. In general, conjugated metabolites are pharmacologically inactive, but there are several exceptions to this rule. Examples of pharmacologically active conjugated metabolites include the 6-glucuronide of morphine and the acetylated derivatives of sulfanilamide, procainamide, and acebutolol.

Most phase I metabolites of antiepileptic drugs are excreted in urine in conjugated form, usually as glucuronides. Lamotri-gine and lorazepam are examples of drugs eliminated primarily by conjugation in the absence of phase I metabolism.

Factors Affecting Drug Metabolism

The large interindividual differences that can be observed in rates of biotransformation are caused by a variety of factors.

Genetic Factors.

Because specific genes code for drug-metabolizing enzymes, it is not surprising that genetic factors play an important role in determining the differences in drug metabolism that are found among species, genders, and individuals. Although the metabolism of all drugs is subject to the influence of genetic factors, the importance of such factors becomes overwhelming in the case of the genetically determined polymorphisms.[20,58,100]

With respect to the cytochrome P450–catalyzed reactions, several important polymorphisms have been described.[20] The CYP2D6 polymorphism, which is transmitted as an autosomal-recessive trait associated with a gene located on chromosome 22, results in a bimodal distribution in the ability to eliminate several drugs metabolized by the CYP2D6 isozyme (Table 4). About 5% of whites (and <1% of Japanese or Chinese individuals) metabolize many of these drugs at a particularly slow rate, with important clinical implications.[58] A second major genetic polymorphism involves the CYP2C19 isozyme responsible for the stereoselective oxidation of the *S*-enantiomer of mephenytoin.[58] In approximately 2% to 5% of whites and about 20% of Chinese and Japanese, an impaired capacity to hydroxylate *S*-mephenytoin and nirvanol, the active metabolite of mephenytoin, results in the accumulation of these compounds at potentially toxic concentrations.[20] This genetically transmitted autosomal-recessive trait affects

not only the metabolism of mephenytoin, but also that of other agents metabolized by the same isozyme, including mephobarbital, hexobarbital, diazepam, *N*-desmethyldiazepam, omeprazole, and proguanil. Defective hydroxylators show an impaired ability to eliminate these drugs, although with some compounds, such as diazepam, the existence of alternative metabolic pathways may limit the extent of drug accumulation.[8] In general, slow hydroxylators also show an increased vulnerability to the toxic effects of drugs metabolized by the isozyme. In the case of drugs such as proguanil, however, which are converted to an active metabolite, an impaired rate of metabolism may result in reduced effectiveness.

Although phenytoin may also be metabolized by CYP2C19, the major enzyme responsible for phenytoin metabolism appears to be CYP2C9, which is also subject to genetic polymorphism. Subjects carrying defective alleles for the *CYP2C9* gene eliminate phenytoin at a slower rate, and the importance of this for endpoints of clinical responsiveness has been demonstrated.[13,20] Evidence for the importance of the *CYP2C9* genotype in affecting phenytoin response was reinforced by a recent pharmacogenomic study that demonstrated a significant association between the presence of the *CYP2C9*3* allele and reduced phenytoin dose requirements in 281 patients with epilepsy.[95]

Genetically determined defects in drug metabolism are not confined to cytochrome P450–catalyzed reactions, and polymorphisms affecting many other drug-metabolizing enzymes have been described.[77] The acetylator phenotype is probably the best-known example of genetic polymorphism affecting phase II metabolism.[97] This polymorphism is related to a defect in *N*-acetyltransferase type 2 activity, which is inherited as an autosomal recessive trait. Approximately 50% of whites (and variable proportions in other ethnic groups) show a reduced capacity to metabolize substrates of the affected enzyme, such as isoniazid, sulfonamides, hydralazine, amrinone, dapsone, prizidilol, and aminoglutethimide. In general, these individuals are at a higher risk for adverse effects, although the reverse may be the case when acetylation results in the formation of potentially toxic metabolites.

An interesting observation is that sometimes genetic polymorphisms in drug metabolism have been associated with changes in susceptibility to a variety of diseases. For example, slow acetylators may show an increased risk for bladder cancer but a lower risk for colorectal cancer. These differences may be related to the role exerted by drug-metabolizing enzymes in the activation or inactivation of certain carcinogens.

Developmental Factors.

The biotransformation of most drugs proceeds at a slower rate in neonates (especially those born prematurely) than in adults.[33,65] The drug-metabolizing capacity of newborns, however, is not limited to the same degree for all drugs, and some metabolic pathways (e.g., glucuronidation) appear to be more affected than others (e.g., sulfate conjugation). Qualitative differences in drug metabolism can also be observed between newborns and adults; for example, newborns may be unable to demethylate theophylline to 3-methylxanthine (the normal metabolic pathway in infants, children, and adults), but they can N-methylate the drug to caffeine, a reaction that does not occur in infants and adults.[11] These findings can be explained by the observation that some forms of enzymes are expressed only in fetal liver and disappear rapidly after birth. The production of drug-metabolizing enzymes can also be affected by exposure to chemicals and drugs during pregnancy; for example, newborns of mothers treated with phenytoin, carbamazepine, or barbiturates during pregnancy may show a surprisingly efficient oxidizing capacity because of the stimulating effect that the same drugs exert on the microsomal enzymes of fetal liver.[65]

Biotransformation rates increase gradually over a period of several weeks to several years to peak rates that are often, although not invariably, higher than those observed in adults. For some drugs, the increased metabolic activity is most evident during the period between 2 to 3 months and 2 to 3 years of age, and after that time the rate of metabolism tends to decline slowly, reaching adult values after puberty. For other drugs, peak metabolic rates occur at a later stage.[65] An increased rate of metabolism in children compared with adults has been described for most antiepileptic drugs, including diazepam, carbamazepine, ethosuximide, phenobarbital, phenytoin, valproic acid, lamotrigine, oxcarbazepine, topiramate, tiagabine, felbamate, and zonisamide.[4,5,70] These findings provide an explanation for the observation that the average dose requirements of most of these drugs (on a milligram-per-kilogram basis) are greater in children than in adults.

Significant alterations in drug metabolism are also observed in the elderly.[26,51] A reduced rate of elimination in elderly patients has been reported for a large number of compounds, including carbamazepine, phenytoin, phenobarbital, valproic acid, oxcarbazepine, lamotrigine, topiramate, felbamate, diazepam, desmethyldiazepam, and clobazam.[7,70,72] In the case of some benzodiazepine drugs, the reduction in metabolic clearance is more pronounced in elderly men than women.[24] Because old age may be associated with reduced drug binding to plasma proteins, the elevated drug concentrations that result from reduced metabolic clearance may not be immediately apparent when total rather than unbound drug concentrations are measured. For example, total plasma concentrations of valproic acid may be similar in the elderly and in the young, but the elderly show an increased concentration of non–protein-bound, pharmacologically active drug.[75] Although the efficiency of glucuronidation pathways may be less susceptible to aging-associated decline, a decrease in clearance in old age is also observed for some agents that are eliminated primarily by conjugation, such as lamotrigine and 10-hydroxycarbaze-pine.[70]

Pregnancy.

Drug biotransformation in pregnancy may be affected by several factors, including hormonal changes, the contribution of the fetoplacental unit to drug metabolism, alterations in binding to plasma proteins, and hemodynamic changes.[43] Although the metabolism of some compounds, notably caffeine and theophylline, is impaired during pregnancy, evidence indicates that the metabolic clearance of most drugs increases during pregnancy, usually reaching a peak in the second or third trimester.[65] The frequently observed decrease in the plasma concentration of carbamazepine, phenytoin, phenobarbital, primidone, valproic acid, and lamotrigine during pregnancy is likely to be related at least in part to faster metabolism, although for some of these drugs, most notably valproic acid and phenytoin, a decrease in plasma protein binding may also play an important role.[60,65,105] The increase in metabolic clearance is especially marked for lamotrigine,[61] and preliminary observations suggest that a marked change may also be observed for 10-hydroxycarbazepine, the active metabolite of oxcarbazepine.[50] Because both lamotrigine and 10-hydroxycarbazepine are primarily cleared by glucuronide conjugation, these observations suggest that the activity of glucuronidation pathways may be particularly susceptible to stimulation by the physiologic changes occurring during pregnancy.

In the case of primidone and phenobarbital, an increase in renal clearance may also contribute to the decrease in plasma drug levels during pregnancy. Of interest, there is evidence that in some pregnant patients, conversion of primidone to phenobarbital may be impaired.[3]

Diet.

Certain constituents of the diet may exert inhibitory or stimulatory effects on the drug-metabolizing enzymes.

One interesting example is the inhibition of CYP3A4, CYP1A2, and other CYP isozymes by ingredients (probably

bioflavonoids) contained in grapefruit juice. Inhibition of cytochrome CYP3A4 results in reduced first-pass metabolism and increased serum concentration of several drugs, including various dihydropyridine calcium antagonists, terfenadine, cyclosporine, and midazolam; for example, concurrent intake of grapefruit juice may increase the peak plasma concentration of felodipine by 56% to 546%.[1] A similar interaction may occur with Seville orange juice, but not with most other types of orange or tangerine juice.[27] Many other dietary components, including some herbal products, influence drug metabolism to a significant extent and may contribute to explain the interindividual variation in the pharmacokinetics of a wide range of drugs.[27]

Enzyme Induction.

The term *enzyme induction* is used to indicate the phenomenon in which certain chemicals stimulate ("induce") the synthesis and/or the activity of drug-metabolizing enzymes in the liver or other organs. This stimulatory action affects predominantly a subset of cytochrome P450 enzymes, although induction of other enzyme systems (e.g., epoxide hydrolase or glucuronyl transferase) has also been documented.[55] The term "induction" is also used more broadly to indicate a stimulatory action of some chemicals on other systems, for example, efflux transporters such as P-glycoprotein.[34] In fact, there is a strong overlap in substrate specificity between CYP3A4/5, a major CYP enzyme, and P-glycoprotein; moreover, inducers and inhibitors of CYP3A4/5 may also induce and inhibit P-glycoprotein and other transporters.[34] Therefore, it is probable that some interactions resulting in decreased blood concentrations of certain substrates are mediated by stimulation of transporter-mediated efflux in the gastrointestinal tract (resulting in reduced oral bioavailability), liver (resulting in enhanced biliary elimination), or kidney (resulting in increased renal excretion) rather than enhanced drug metabolism in the liver and other tissues.

Unlike enzyme inhibition, which may become manifest rapidly after the introduction of the interacting agent, enzyme induction requires several days or weeks to develop fully. Different inducers stimulate specific CYP isozymes or other systems, and therefore they may have different effects on the metabolism of various substrates. The two best-known prototypes of CYP inducers are polycyclic aromatic hydrocarbons and phenobarbital. Polycyclic aromatic hydrocarbons interact with a specific cytosolic receptor, known as the *Ah receptor*, and trigger a sequence of events that results in induction of CYP1A isozymes.[55,104] Because many reactions catalyzed by these isozymes generate carcinogenic intermediates, induction may alter individual susceptibility to the action of environmental procarcinogens. Although polycyclic aromatic hydrocarbons are among the constituents of cigarette smoke, it is likely that other compounds present in smoke contribute to the stimulating effects of smoking on CYP1A activity. Both CYP1A1 and CYP1A2 enzymes are induced by cigarette smoke; in humans, cigarette smoke has been reported to accelerate the oxidation of diazepam, desmethyldiazepam, phenacetin, nicotine, theophylline, propranolol, imipramine, and pentazocine but not the oxidation of meperidine, nortriptyline, ethanol, phenytoin, phenobarbital, and carbamazepine.[31,64] It is interesting that the inducing effect of cigarette smoke is much more prominent at extrahepatic sites, such as the placenta, than in the liver.[59]

Enzyme induction caused by phenobarbital differs from that caused by polycyclic aromatic hydrocarbons.[59,104] Phenobarbital appears to induce hepatic enzymes preferentially to placental enzymes. The most important enzyme system induced by phenobarbital is the CYP3A family, which is responsible for the clearance of the majority of therapeutic CYP-metabolized drugs. Apart from barbiturates, examples of CYP3A inducers include carbamazepine, phenytoin, rifampicin, rifabutin, some glucocorticoids, and St. John's wort. With respect specifically to barbiturates, the spectrum of enzymes stimulated includes not only CYP3A but also CYP1A2, CYP2C9, CYP2C19, and possibly other CYP isoforms, in addition to enzymes involved in glucuronidation and some other conjugation reactions, as well as some efflux transporter systems. Induction of these enzyme systems by barbiturates and/other drugs involve an interaction with specific receptors, such as the constitutive androstane receptor (CAR) and the pregnane X receptor (PXR).[104]

Apart from barbiturates, other antiepileptic drugs that have been shown to act as broad-spectrum inducers of CYP3A and other drug-metabolizing enzymes include phenyt-oin and carbamazepine. Although therapeutic doses of these antiepileptic drugs increase antipyrine clearance (a nonspecific marker of drug-metabolizing capacity) to a similar extent,[76] evidence has been provided that some isozymes induced by carbamazepine and phenytoin may be different from those induced by barbiturates.[85] Topiramate, oxcarbazepine, and felbamate also exhibit some enzyme-inducing activity, but this appears to more restricted than that caused by phenobarbital, phenytoin, and carbamazepine, and is probably limited to fewer CYP3A enzyme isoforms, with special reference to those involved in the metabolism of steroid oral contraceptives and few other drugs.[71] In the case of topiramate, induction of the metabolism of steroid oral contraceptives is seen at doses >200 mg/d and does not occur at doses <200 mg/d, whereas evidence for an interaction at 200 mg/d is equivocal.[10] This observation highlights the important concept that enzyme induction is a dose-dependent phenomenon.[76] Lamotrigine 300 mg/d has also been found to increase the clearance of levonorgestrel, but whether this is due to enzyme induction is unclear.[90] Antiepileptic drugs that are devoid of enzyme-inducing properties at therapeutic doses include benzodiazepines, valproic acid, tiagabine, gabapentin, pregabalin, zonisamide, vigabatrin, and, probably, ethosuximide.

Induction of microsomal enzymes by antiepileptic drugs has important implications.[64,94] In the case of carbamazepine, autoinduction (i.e., induction of its own metabolism) is responsible for the progressive decline of the plasma concentration of the drug a few weeks after initiation of treatment, as well as for the nonlinear relationship between plasma concentration of carbamazepine and dose. The isozymes stimulated by enzyme-inducing antiepileptic drugs also metabolize a large number of endogenous compounds, such as cortisol, testosterone, vitamin D_3, and bilirubin. Induction of the metabolism of vitamins and hormones may play a role in the pathogenesis of anticonvulsant-induced rickets and osteomalacia, folate deficiency, and altered metabolism of steroid and thyroid hormones. Other conditions that might be related to enzyme induction include elevated plasma levels of α_1-acid glycoprotein, sex hormone–binding globulin, γ-glutamyltransferase, and alkaline phosphatase; the precipitation of attacks in patients with acute intermittent porphyria; and an increase in the levels of high-density-lipoprotein (HDL) cholesterol. Finally, induction of the metabolism of concurrently administered drugs is responsible for a large number of interactions (see Chapter 110).

Enzyme Inhibition.

Inhibition of drug-metabolizing enzymes can be caused by endogenous compounds (e.g., certain hormones), food constituents (e.g., grapefruit juice), environmental contaminants, and concurrently administered drugs. The mechanisms involved can include reversible competition by alternative substrates or noncompetitive inhibition caused by irreversible cytochrome P450 inactivation.[55]

Like inducers, inhibitors tend to affect only a limited number of isozymes and therefore can be used as tools to discriminate among the effects of different isozymes. Knowledge of the isozyme metabolizing a given drug also allows drug interactions involving inhibition of that isozyme to be predicted. A detailed discussion of these interactions is given in Chapter 110.

P.1161

Plasma Protein Binding and Blood Flow.

Plasma protein binding and blood flow influence drug metabolism by determining the availability or the delivery of drug molecules to the site of biotransformation. The relationship between these variables and elimination processes has been considered in the discussion of clearance concepts.

Disease.

Because of the role of the liver in biotransformation, hepatic disease may be associated with significant alterations in drug metabolism. Factors that may affect metabolic elimination in liver disease include a reduction in cell mass, a change in cellular enzyme content or activity, a decrease in plasma protein binding, a decrease in blood perfusion resulting from reduced portal blood flow and extrahepatic and intrahepatic shunting, a reduced exchange across the endothelial lining, and impaired diffusion within Disse spaces.[52] The pharmacokinetic implications vary depending on type and severity of hepatic disease, degree of hypoalbuminemia, age of the patient, and route of administration and intrinsic characteristics of the drug. Oxidative drug metabolism is generally impaired in liver disease (most notably in cirrhosis), whereas conjugation pathways are usually less severely affected.[28]

Disease states affecting organs other than the liver may also affect the rate of drug metabolism,[53] but a detailed discussion of these is beyond the purpose of this chapter.

Renal Excretion

The mechanisms regulating the excretion of drugs or their metabolites in urine include glomerular filtration, active tubular transport, and passive tubular reabsorption.[62] Filtration is determined primarily by the glomerular filtration rate and plasma protein binding, with only unbound drug being able to pass through the glomerular filter.

A number of drugs may be actively transported in the proximal tubules. A major transporter system involves P-glycoprotein and multidrug resistance–associated protein type 2 (MRP2), which are located in the apical brush border membrane and mediate the secretion of amphipathic anions and conjugated metabolites, respectively.[62] Separate transporter systems also exist that are more selective for organic bases such as choline and tetraethylammonium. Other transporters located mainly in the distal tubuli are responsible for active reabsorption of drugs from the tubular lumen back into the circulation. Most of the reabsorption, however, takes place by passive diffusion.

Because of reabsorption of water and electrolytes, a concentration gradient is created within the renal tubules that facilitate extensive backdiffusion of lipophilic drugs into the circulation. Therefore, only water-soluble compounds can be excreted efficiently in urine. In the case of ionic drugs, the degree of passive reabsorption is determined by the proportion of molecules that are in nonionized (lipid-soluble) form. Acidic compounds are excreted more efficiently when urine is alkaline (which results in a higher proportion of ionized molecules), whereas basic drugs are excreted better when urine is acidic. The influence of changes in pH on drug excretion is more profound for those drugs having a pKa within the range of urinary pH (5–8). In some cases, urinary pH can be manipulated deliberately to enhance drug elimination; one example is the use of urine alkalinization to hasten the excretion of phenobarbital in cases of overdose.[48]

Competition for the carrier systems by other drugs or endogenous substrates may lead to inhibition of transport. For example, cimetidine may impair the elimination of many drugs by competitively inhibiting the carrier system responsible for the secretion of organic bases.[91]

In general, urinary excretion is subject to less extensive interindividual variability than is metabolic elimination. A significant impairment in renal elimination is expected whenever the glomerular filtration rate is reduced, as in the newborn, in the presence of acute or chronic renal failure, and in the elderly.[16,70] In some of these conditions, concomitant alterations in active transport mechanisms may contribute to the impairment of elimination processes.

The dose of drugs that are eliminated predominantly unchanged in urine may need to be adjusted in patients with reduced renal function; examples of such drugs include primidone, levetiracetam, gabapentin, pregabalin, and vigabatrin.

Single-Dose Pharmacokinetics

Although pharmacokinetics may be concerned with changes in drug concentrations in any body fluid or tissue, in the clinical setting, kinetic data are usually derived from the most accessible tissue—plasma (or serum) or blood. The rationale for measuring drug concentrations in these fluids is that under most circumstances these are related to the concentration at the site of action. This section provides a simplified description of drug kinetics after single intravenous or oral doses.

Intravenous Administration

The kinetic pattern observed after intravenous injection of a single dose of a drug varies in relation to the distribution and elimination characteristics of the individual compound.[6] In simple terms, drugs can be classified into two categories. The first includes compounds that diffuse almost instantaneously into tissues. In this case, the body can be considered as a single compartment from which the drug is eliminated. The second group of drugs comprises compounds that require some time before distribution can be completed. In this case, the body can be considered as an arrangement of two (or more) compartments, one representing the plasma (or blood) and highly perfused tissues, and the other representing tissues into which the drug distributes more slowly.

One-Compartment Model

When distribution takes place extremely rapidly, drug kinetics can be described according to the one-compartment model (Fig. 3A). In this model, the input is represented by entry of the drug into the circulation (which is virtually instantaneous in the case of a bolus injection), whereas output is dictated by the elimination processes.[6] Unless particular conditions apply (see section Nonlinear Pharmacokinetics), elimination typically follows a first-order process, that is, the amount of drug cleared per unit of time represents a constant fraction of the drug that is present in the body at that time. Under these conditions, the decline in drug concentration over time is described by a monoexponential equation:

$$C = C_0 e^{-kt} \qquad (2)$$

where C is the plasma concentration at time t, C_0 is the concentration at zero time (time of injection), e is the base of the natural logarithms, and k is a rate constant that reflects the efficiency of the elimination process. A semilogarithmic ($\log_{10}$) plot of plasma drug concentrations versus time yields a straight line with an intercept equal to C_0 and a slope equal to $k/2.3$ (Fig. 4A). When $C = ½C_0$, t is by definition equal to the half-life $t_{1/2}$, and Equation (2) can be solved as follows:

$$t_{1/2} = (\ln 2)/k = 0.693/k \qquad (3)$$

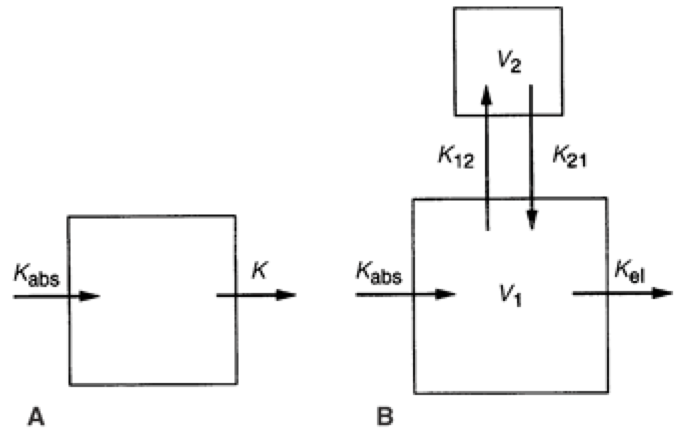

FIGURE 3. Schematic representation of two widely used compartmental models applied to pharmacokinetic analysis. **A:** One-compartment open model. In this model, the body is assimilated to a single compartment. Arrows indicate transfer processes for drug entry and removal. K_{abs} refers to a first-order rate constant of drug absorption, and K refers to a first-order rate constant of drug elimination. Absorption does not apply in the case of instantaneous intravenous injection. **B:** Two-compartment open model. In this model, the bloodstream and tissues undergoing rapid distribution are assimilated to a central compartment (V_1), whereas a peripheral compartment (V_2) is used to represent tissues into which distribution occurs more slowly. Arrows refer to processes of absorption, transfer, and removal. K_{abs} refers to a first-order rate constant of drug absorption, and K_{el} refers to a first-order rate constant of drug elimination; these are assumed to take place in the central compartment. [K_{el} does not correspond to the hybrid rate constant of terminal elimination β as defined in Equation (8).] K_{12} and K_{21} refer to the transfer rate from the central to the peripheral compartment and vice versa.

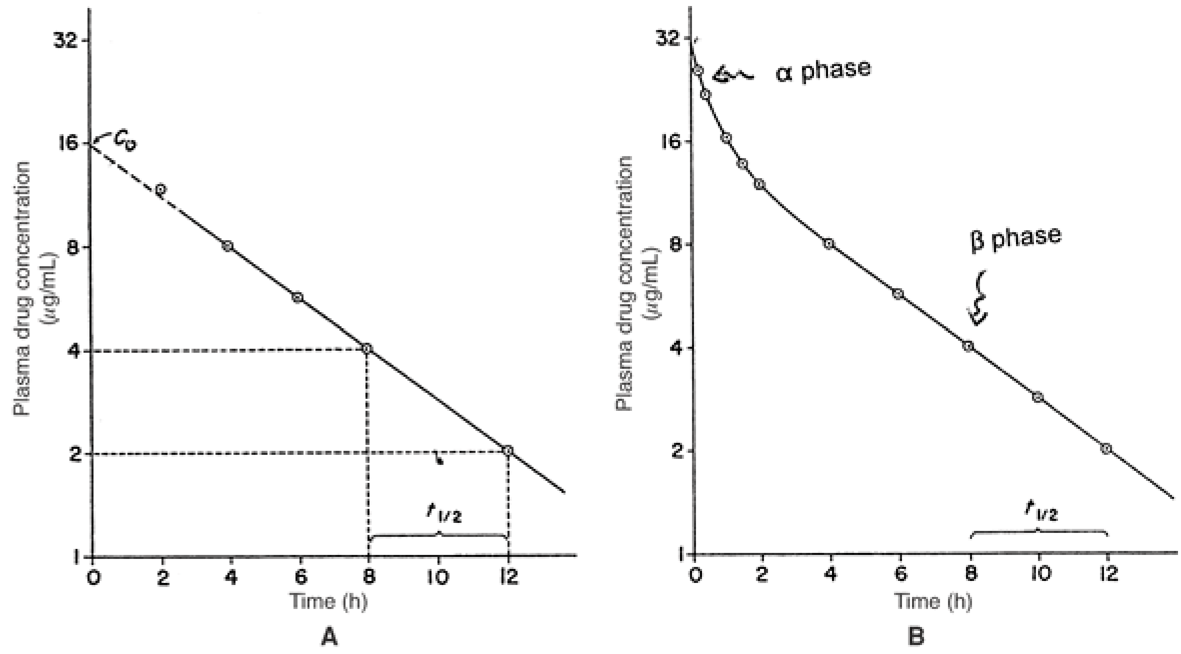

FIGURE 4. Decline in plasma drug concentration following a single intravenous bolus injection. **A:** Concentration declines monoexponentially according to a one-compartment open model. C_0 indicates the concentration at zero time, and $t_{1/2}$ is the half-life of the drug. **B:** Concentration declines biexponentially according to a two-compartment open model. The distributive (α) phase, the elimination phase (β), and the terminal half-life are also shown. (Modified from Buxton ILO. Pharmacokinetics: the dynamics of drug absorption, distribution, action, and elimination. In: Brunton LL, Lazo JS, Parker KL, eds. *Goodman and Gilman's The Pharmacological Basis of Therapeutics.* New York: McGraw-Hill; 2005:1–39, with permission.)

In the one-compartment model, apparent volume of distribution V_d can be calculated as follows:

$$V_d = \text{Dose}/C_0 \qquad (4)$$

which corresponds to the definition of V_d as the virtual volume in which the amount of drug present in the body (which at zero time equals the injected dose) must be dissolved to obtain a concentration equal to that found in plasma (C_0).

The elimination rate *k* is related directly to clearance *CL* and inversely to volume of distribution V_d as follows:

$$k = CL/V_d \qquad (5)$$

Hence, the relationship between clearance and half-life is as follows:

$$CL = 0.693\frac{V_d}{t_{1/2}} \qquad (6)$$

Multicompartment Models

In these models, the drug is administered into a central compartment (which simulates the bloodstream and other tissues into which the drug is distributed almost instantaneously) and diffuses thereafter into peripheral compartments. The latter are intended to represent less-perfused tissues into which the drug is distributed relatively slowly. Drug transfer from the central to the peripheral compartments (and vice versa) is determined by first-order rate constants, and elimination is assumed to take place only from the central compartment. The simplest of these models includes two compartments (Fig. 3B) and is adequate for describing the kinetics of most drugs.

In the two-compartment model, the decline in plasma drug concentration following intravenous administration is initially

rapid, resulting from a combination of two processes: (a) Elimination and (b) distribution into tissues (peripheral compartment). With time, the concentration in the peripheral compartment increases progressively until equilibrium with the central compartment is achieved; at that point, distribution is complete. The decline in plasma concentration then depends exclusively on drug elimination, and it therefore occurs more slowly (Fig. 4B). Although a precise characterization of drug kinetics according to the two-compartment model involves calculation of all rate constants depicted in FIGURE 3B, from a practical point of view the two most informative parameters are the hybrid decay constants α and β, which characterize the distribution phase (α phase) and the terminal or elimination phase (β phase). Determination of these constants allows calculation of the distribution half-life $t_{1/2\alpha}$ and terminal half-life $t_{1/2\beta}$:

$$t_{1/2\alpha} = 0.693/\alpha \qquad (7)$$
$$t_{1/2\beta} = 0.693/\beta \qquad (8)$$

The distribution half-life provides an estimate of the rate at which a drug is distributed into tissues (α phase in Fig. 4B), whereas the terminal half-life reflects the rate of drug elimination. In general, the terminal half-life is a more important parameter because it determines the time to reach steady state (see section Pharmacokinetics During Continuous or Multiple Dosing) and, in most cases, it also indicates the duration of drug action. As discussed in the section on drug distribution, however, there are situations in which the time course of effect is related more to distribution half-life than to terminal half-life.

Model-independent Calculation of Kinetic Parameters

At times, the mathematical models described previously may not be fully adequate for describing the pharmacokinetic pattern observed experimentally, or there may be too few data points to allow a meaningful selection of the most appropriate model. To circumvent these problems, procedures have been developed that allow a model-independent calculation of kinetic parameters. The rationale for this calculation is based on the fact that after intravenous administration, the area under the curve (*AUC*) of plasma concentration versus time from time zero to infinity is related directly to the administered dose and inversely to total plasma clearance. Therefore, this relationship can be used for the calculation of clearance according to:

$$CL = \text{Dose}/AUC \qquad (9)$$

The volume of distribution V_d can be calculated by exploiting its known relationship to clearance and terminal half-life:

$$V_d = CL\frac{t_{1/2}}{0.693} = \frac{\text{Dose} \cdot t_{1/2}}{0.693 \cdot AUC} \qquad (10)$$

Of course, these calculations require reliable characterization of the terminal elimination phase. No pharmacokinetic analysis can provide meaningful information when experimental data are inadequate.

Oral Administration

The kinetic pattern observed after oral administration is similar to that described after intravenous dosing, except that drug entry into the bloodstream occurs more slowly and might be incomplete. Under most circumstances, absorption is a first-order process and can be described in terms of a rate constant k_{abs} that can be incorporated into pharmacokinetic models as an input function representing the rate of drug entry into a single (Fig. 3A) or a central (Fig. 3B) compartment.

During the initial part of the absorption phase, the amount of drug that enters the systemic circulation per unit of time exceeds the amount that leaves the bloodstream as a result of distribution and elimination processes. Under these conditions, the plasma concentration increases gradually. As absorption proceeds, the proportion of drug remaining in the gastrointestinal tract and available for absorption decreases progressively, until a time is reached at which the amount entering the circulation equals the amount that is eliminated. This time corresponds to the peak, or plateau, of plasma drug concentration. After that time, elimination proceeds at a faster rate than absorption, and plasma drug concentration decreases at a rate that eventually equals the terminal elimination rate. Even for drugs with kinetics that are best described by a two-compartment model, a distribution phase during the decline of plasma concentrations may not be detected because of the masking effect of ongoing absorption.

The oral bioavailability (*F*), defined as the fraction of the oral dose that reaches the systemic circulation, can be calculated by comparing the areas under the plasma concentration curves from zero to infinity following oral (AUC_{po}) and intravenous (AUC_{iv}) administration of the same dose:

$$F = \frac{AUC_{po}}{AUC_{iv}} \qquad (11)$$

If different doses are used, a correction factor must be introduced based on the assumption, which is correct in the case of linear kinetics, of a direct relationship between *AUC* and dose. A value for *F* that is <1 indicates incomplete absorption and/or presystemic elimination by first-pass metabolism in the gastrointestinal tract or the liver.

It should be emphasized that the definition of bioavailability given in Equation (11) is overly restrictive. In fact, the term *bioavailability* is generally used to define not only the fraction of the dose that reaches the systemic circulation, but also the *rate* at which absorption occurs. The clinical relevance of this concept is illustrated in FIGURE 5, which depicts plasma drug concentration profiles after administration of the same dose intravenously (Fig. 5A) and orally in two different formulations (Fig. 5B, C). Despite the fact that *AUC* is the same for both oral formulations (indicating no difference in the fraction of the dose reaching the systemic circulation), only formulation B ensures a rate of absorption sufficiently rapid to produce a pharmacologic effect. Formulations B and C can be differentiated pharmacokinetically by also calculating the peak concentration (Cmax) and the time of peak (Tmax).

Pharmacokinetics During Continuous or Multiple Dosing

Continuous Dosing

The most common situation in which continuous dosing is used is in the management of status epilepticus, when drugs may be given by intravenous infusion. If the infusion is given at a constant rate (zero-order input), drug concentration in plasma will increase progressively over time. Because elimination is generally a first-order process, the amount of drug eliminated from the body will increase with increasing plasma concentration up to a point at which the amount eliminated per unit of time will equal the amount administered through the infusion pump. When the rate of drug entry into the system equals the rate of drug removal, the plasma concentration will remain stable at a constant value, and steady-state conditions are said to exist (Fig. 6).

P.1164

P.1165

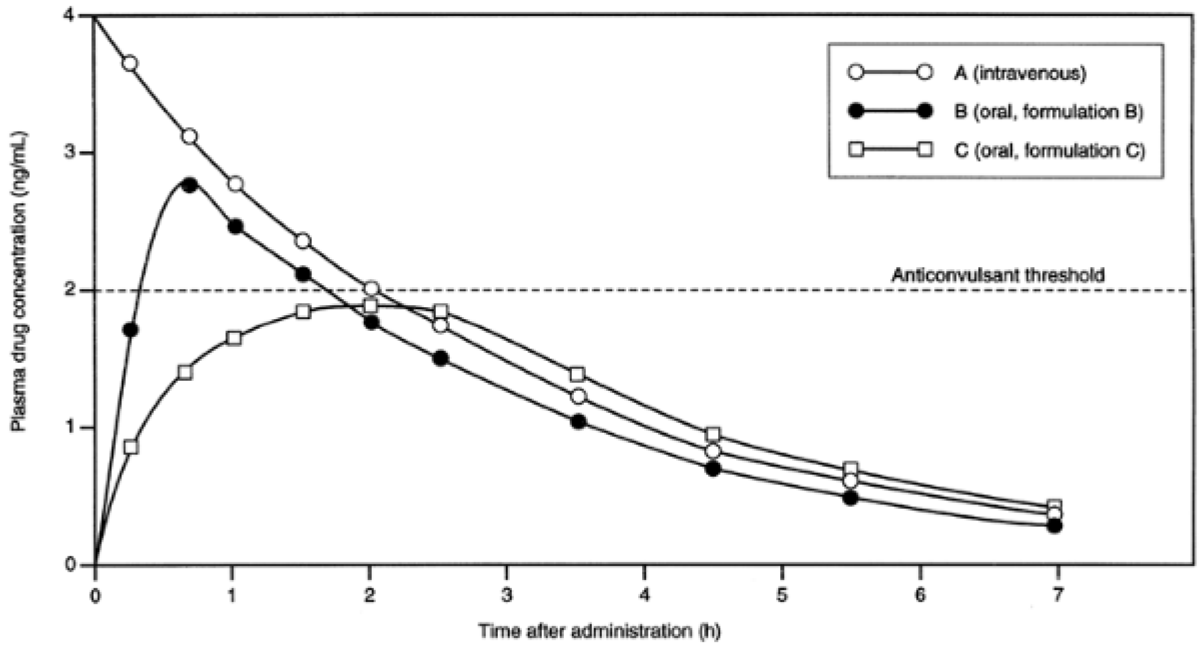

FIGURE 5. Plasma drug concentration profiles following intravenous **(A)** and oral **(B, C)** administration of the same dose. Two different pharmaceutical formulations are represented by B and C. The area under the curve (*AUC*) after intake of formulations B and C is approximately 80% of that observed after intravenous injection, indicating that the bioavailability of the two oral formulations is about 80%. Despite equal values for *AUC*, the two oral formulations differ in absorption rate, and only formulation B allows plasma concentrations to be achieved above the threshold required for anticonvulsant effect.

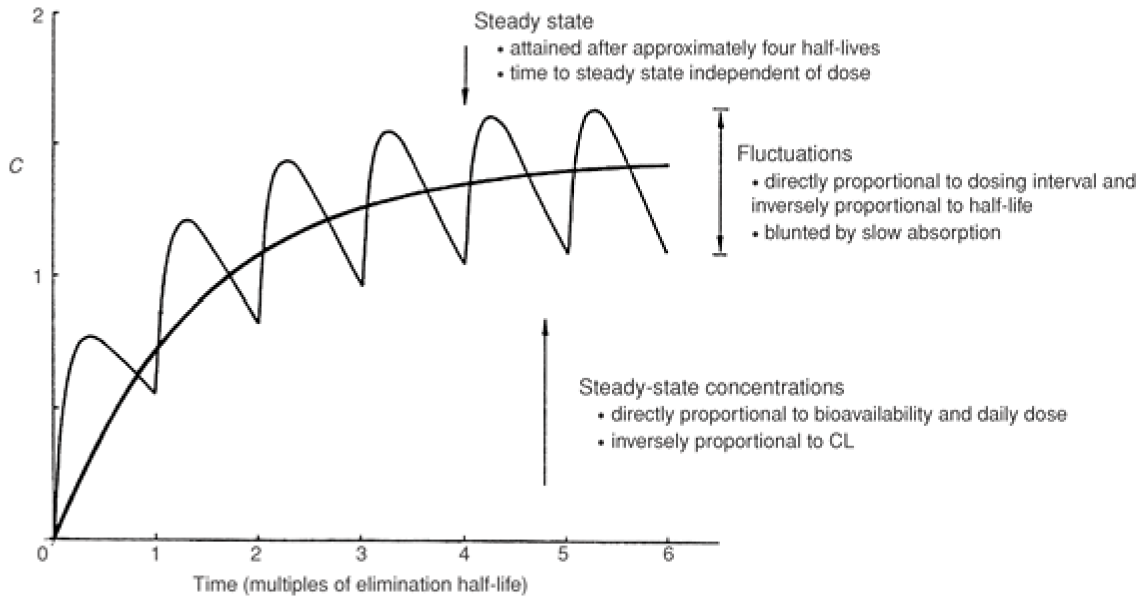

FIGURE 6. Plasma drug concentration (*C*) profiles after initiation of treatment by constant-rate intravenous infusion (*smooth curve*) and by multiple oral doses given at intervals of one half-life (*oscillating curve*). Steady-state conditions are reached after about four to five half-lives. Steady-state

concentration is directly related to bioavailability F and dosing rate and is inversely related to clearance CL. (Modified from Buxton ILO. Pharmacokinetics: the dynamics of drug absorption, distribution, action, and elimination. In: *Goodman and Gilman's the Pharmacological Basis of Therapeutics*. New York: McGraw-Hill;2005;1–39, with permission.)

The concentration at which steady state is achieved C_{ss} is determined exclusively by intravenous dosing rate and plasma clearance:

$$C_{ss} = \text{Dosing rate}/CL \qquad (12)$$

The drug concentration C at any time t following initiation of drug infusion is related to C_{ss} as follows:

$$C = C_{ss}(1 - e^{-kt}) \qquad (13)$$

where k is the rate constant of the terminal phase, which is related to terminal half-life by the relationship expressed in Equation (3). By substituting in Equation (13) values of t that are multiples of the half-life, we can show that after two half-lives, C equals 75% of C_{ss}, and that after four and five half-lives, C equals 94% and 97%, respectively, of C_{ss}. This underscores the important principle that the time required to reach steady state depends exclusively on terminal half-life. From a practical point of view, steady state can be considered complete when four to five half-lives have elapsed after initiation of treatment.

In the case of drugs that are eliminated slowly (e.g., phenobarbital, with a half-life that may range from 50–150 hours), the time required to reach steady state may be several weeks. When it is desired to obtain steady state in a shorter time (e.g., when phenobarbital is infused intravenously to control neonatal convulsions), an adequate loading dose (mg/kg) may be given initially at an appropriate rate. A rough approximation of the intravenous loading dose may be obtained by multiplying the desired steady-state concentration (mg/L) by the volume of distribution of the drug (L/kg). In practice, however, choice of the loading dose and choice of its optimal rate of administration are dictated primarily by clinical information because in some situations too rapid attainment of high plasma concentrations may lead to serious toxicity.

Multiple Doses

Mean plasma drug concentrations during multiple dosing are roughly equivalent to those achieved during continuous dosing, except that fluctuations will be observed during the dosing interval as a result of the discontinuous mode of administration (Fig. 6). During oral therapy, the mean steady-state plasma concentration C_{ss} is related to administered dose D, bioavailability F, plasma clearance CL, and dosing interval t according to the following relationship:

$$\text{Mean } C_{ss} = \frac{FD}{CL \cdot t} \qquad (14)$$

As discussed previously for continuous administration, four to five half-lives must elapse before C_{ss} is reached after initiation of treatment or a change of dose. The degree of fluctuation of drug levels around the mean is determined by absorption rate, dosing interval, and elimination half-life. In the case of reversibly acting drugs with short half-lives, multiple daily doses may be needed to avoid excessive swings in plasma concentration during the dosing interval.

Nonlinear Pharmacokinetics

Most of the pharmacokinetic concepts described previously are valid only when the kinetics is linear, that is, the rate constants describing absorption, distribution, and elimination are first order and do not change over time. When this is the case, steady-state plasma concentrations are linearly related to daily dose (Fig. 7A). When rate constants change with dose or duration of treatment, nonlinear kinetics is said to apply. Nonlinearity is common when drugs are taken in overdose, but occasionally it may occur even at therapeutic dosages with particular drugs. Antiepileptic drugs provide good examples of different mechanisms that may cause nonlinearity.

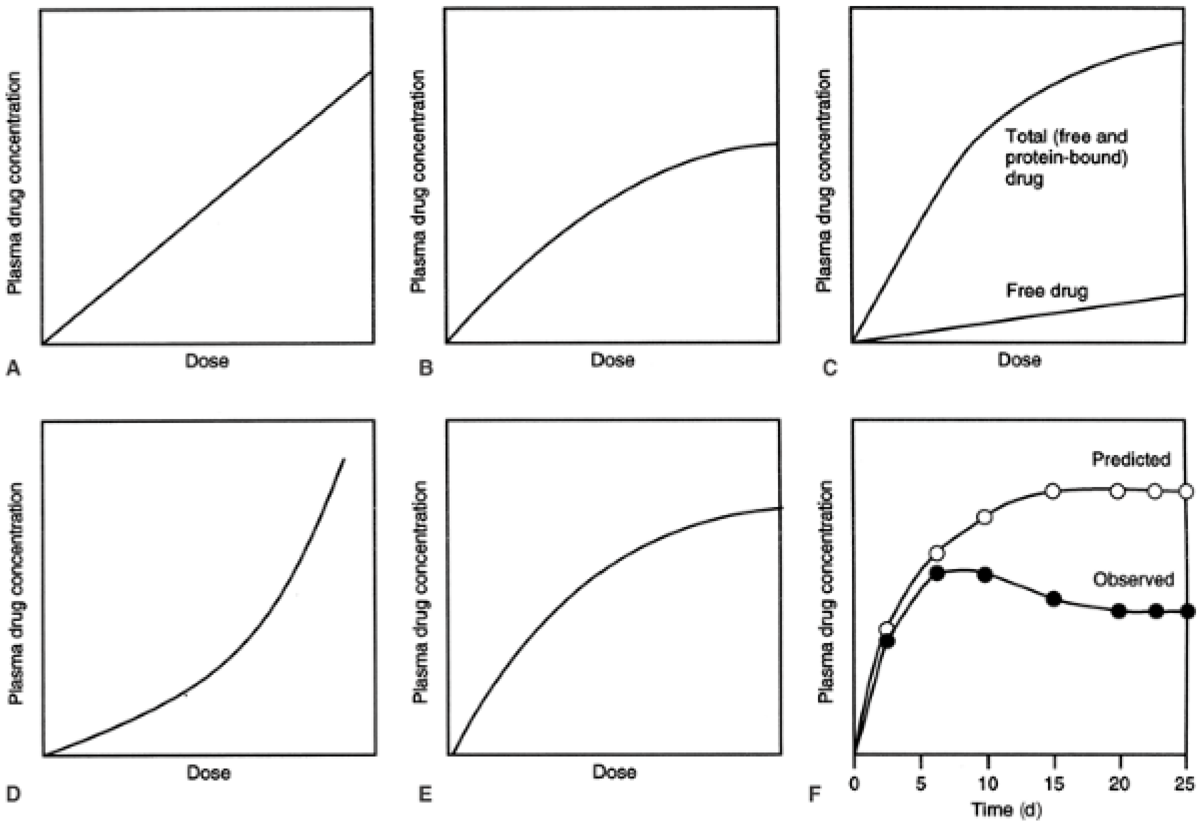

FIGURE 7. A comparison of linear and nonlinear pharmacokinetics. Panels A to E show the relationship between steady-state plasma concentrations and daily dose for drugs exhibiting linear and nonlinear (dose-dependent) pharmacokinetics. Panel F shows an example of time-dependent kinetics. **A:** Linear pharmacokinetics. Plasma concentration is linearly related to dose. **B:** Dose-dependent absorption. Saturation of active transport system in the gut, as documented for gabapentin, causes bioavailability to decrease with increasing dose. **C:** Dose-dependent protein binding. Saturation of plasma protein-binding sites results in increased unbound fraction at higher doses. For drugs exhibiting restrictive elimination, such as valproic acid, this causes an increase in total plasma clearance. However, unbound drug concentration, which is responsible for pharmacologic effect, remains linearly related to dose. **D:** Enzyme saturation. Saturation of the drug-metabolizing enzymes, as seen with phenytoin, causes clearance to decrease with increasing dose. As a result, small dose increments can result in disproportionate increases in drug concentration. **E:** Dose-dependent autoinduction. Enhanced stimulation of its own metabolism causes the clearance of carbamazepine to increase with increasing dose. This results in a flattened dose–concentration relationship. **F:** Time-dependent kinetics. Development of autoinduction of metabolism causes serum carbamazepine concentration to decrease slightly after about 1 week of treatment and to stabilize at a steady-state level lower than predicted from single-dose pharmacokinetic data.

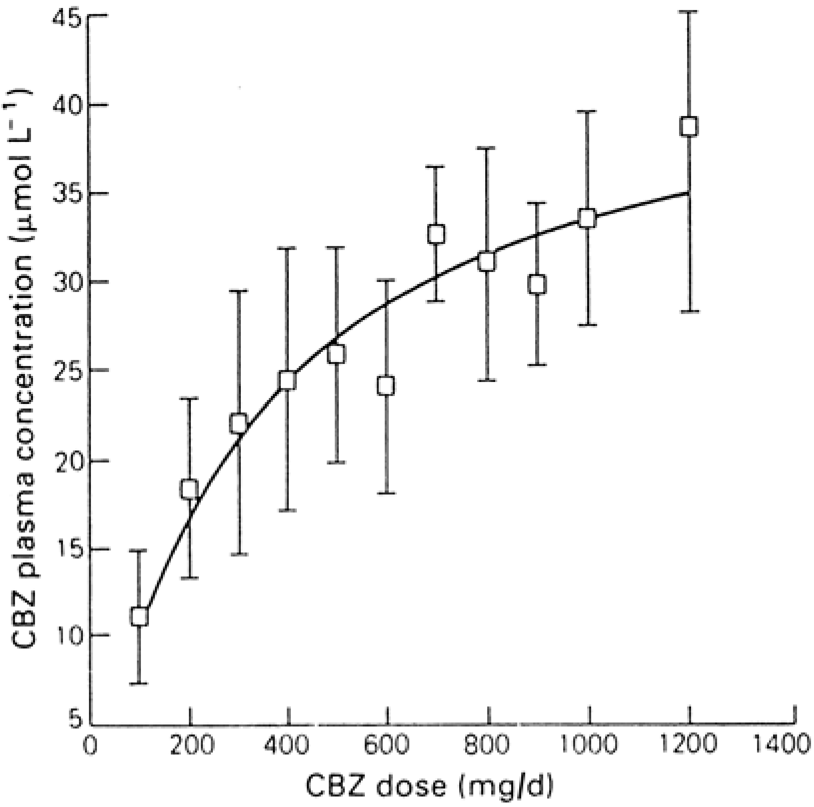

FIGURE 8. Relationship between daily dose and steady-state plasma concentration of carbamazepine in patients with affective disorders. Results are expressed as means ± standard deviation (n = 7–16 at each point). (From Kudriakova TB, Sirota LA, Rozova GI, et al. Autoinduction and steady-state pharmacokinetics of carbamazepine and its major metabolites. *Br J Clin Pharmacol.* 1992;33:611–615, with permission.)

Dose-dependent Kinetics

Kinetics is dose dependent when the rate constants describing the processes of absorption, distribution, or elimination depend on drug concentration.

Dose-dependent Absorption

Some drugs are absorbed by active transport systems that become saturated when a given concentration is exceeded. If this is the case, oral bioavailability may decrease with increasing dose (Fig. 7B). A saturable transport mechanism in the intestinal absorption of gabapentin appears to be responsible for the lack of proportionality between dose and plasma levels of this drug.[93]

Dose-dependent Protein Binding

Plasma protein-binding sites may become saturated within the range of drug concentrations that occur clinically. A situation of this kind is observed with valproic acid; the unbound fraction of this drug in plasma increases with increasing plasma concentration. Because valproic acid shows restrictive, flow-independent elimination, the increase in unbound fraction leads to increased plasma clearance and to a curvilinear relationship between plasma concentration and dose (Fig. 7C).[22] Because of the decrease in plasma protein binding at higher concentrations, however, the curvilinear relationship does not apply to the levels of unbound drug. In fact, unbound valproic acid concentrations are linearly related to dose or, in some cases, may show increments that are even greater than the increment in dose.[12] Under these circumstances, total plasma levels underrepresent the amount of pharmacologically active drug and may lead to incorrect adjustments in dose.[41]

Dose-dependent Metabolism: Enzyme Saturation

The enzymes responsible for the metabolism of a number of drugs may become saturated within the range of doses used clinically. When this is the case, first-order kinetics no longer applies, and the fraction of the drug cleared by the eliminating organ decreases with increasing drug concentration.

In the case of drugs that undergo extensive first-pass metabolism, the high drug concentrations found in the portal blood during the absorption phase may easily saturate the metabolizing enzymes, leading to decreased hepatic extraction and consequently increased oral bioavailability with increasing dose.

Saturation kinetics during the postabsorptive phase is observed more rarely, with phenytoin providing the best example.[81] Because of gradual saturation of the metabolizing enzymes, the rate of elimination of phenytoin decreases progressively with increasing dose and plasma concentrations, resulting in a nonlinear relationship between steady-state plasma level and dose (Fig. 7D). This has clinical significance because small increments in phenytoin dose can easily raise the plasma concentration to toxic levels. Another implication of saturation kinetics is that after discontinuation of treatment, the elimination phase is not log-linear because the rate of elimination increases with decreasing concentrations as the enzymes become desaturated. Under these conditions, a true half-life cannot be calculated, and drug elimination can be described by using the Michaelis-Menten equation:

$$V = \frac{V_{\max} C}{K_m + C} \qquad (15)$$

P.1166

where *V* is the rate of metabolism, V_{max} is the maximum velocity of the metabolic reaction, K_m is the Michaelis constant, and *C* is the plasma concentration. Various methods have been proposed to predict the adjustment in phenytoin dose required to produce a desired plasma concentration based on rearrangements of Equation (15).[98]

Dose-dependent Metabolism: Enzyme Induction

The ability of carbamazepine to induce its own metabolism is dose dependent, that is, metabolic clearance of carbamazepine increases with increasing dose.[37] This results in a curvilinear relationship between dose and steady-state plasma concentration opposite to that observed in the case of phenytoin (Figs. 7E and 8). Because of the dose-dependent induction of carbamazepine metabolism, the ratio between the concentrations in plasma of the active metabolite carbamazepine-10,11-epoxide and the parent drug increases within certain limits, with increasing dose. This implies that at higher doses, the plasma levels of parent drug may underrepresent the amount of active moieties at the site of action.

Time-dependent Kinetics

The kinetics of certain drugs may change over time as a result of circadian variation in absorption and disposition. In other cases, pharmacokinetic changes may be related to duration of treatment. One example is provided again by carbamazepine (Fig. 7F). Because autoinduction requires some

P.1167

time to develop, the clearance of carbamazepine increases progressively following initiation of treatment, leading to a decrease in plasma concentrations after 1 to 2 weeks of therapy. Eventually, a new steady-steady concentration is reached that is lower than that predicted from single-dose pharmacokinetics.[18]

Population Pharmacokinetics

Because pharmacokinetic properties represent an important determinant of variation in pharmacologic response, it would be useful to obtain an estimate of mean pharmacokinetic parameters in a given population and to quantitate the effects of different variables on the same parameters. The information acquired in this process could then be used to predict the dose required to produce a desired plasma concentration of the drug in an individual patient.

Estimates of population pharmacokinetic parameters can be obtained by different methods.[29] In the *two-stage* method, individual parameters are obtained by intensive sampling in a group of subjects who are considered representative of the population of interest. The mean, standard deviation, and distribution of these parameters can then be calculated and used as estimates for the population values. Refinements of this method by means of iterative approaches and further data processing allow estimation of covariances and correlations between parameters. The *nonlinear mixed effects model* (NONMEM) differs from the two-stage method because it allows use of even a single plasma concentration point per subject.[88] Essentially, the NONMEM model uses individual data points collected at random times from a large number of patients to estimate by means of a computer program the means, standard deviations, and covariances of population parameters. In addition to allowing use of sparse and more easily collected data, this approach usually provides more reliable estimates of population parameters compared with the two-stage approach. A third method of estimation is based on the *nonparametric maximum likelihood* (NPML) approach described by Mallet.[46] This method estimates the entire collection of points and the joint probability density function of the parameters; there is no need to make any traditional (parametric) assumptions about the shape of the distribution assessed. The NPML method permits explicit discovery of previously unsuspected clusters of outliers, such as slow metabolizers of a drug. Refinements of this method have also been described.

Reliable population parameters are essential for the use of Bayesian forecasting in predicting individual dose requirements. In Bayesian forecasting, a computer program uses population pharmacokinetic parameters and their covariances to provide individualized, patient-specific models of drug behavior based on dose and other relevant variables, such as age, gender, body weight, and creatinine clearance. When plasma concentration values for an individual patient are available, the Bayesian approach moves away from the population estimates and uses the data obtained from the patient to refine the estimate of individual pharmacokinetic behavior. Bayesian methods are much more precise than linear regression on logarithms of plasma levels in predicting individual dose requirements.

An extensive discussion of the use of population phar-macokinetics, Bayesian fitting, and pharmacokinetic-phar-macodynamic modeling in dose prediction can be found in the excellent review by Jelliffe et al.[29] These methods can provide valuable information for individualization of dose, but in no case should pharmacokinetic predictions be used without thorough consideration of clinical data and careful assessment of the patient's response.

Summary and Conclusions

The onset and duration of pharmacologic effect is a function of the time course of the concentration of the drug at the site action, which, in turn, is related to the drug concentration in plasma. Therefore, a full understanding of pharmacokinetic principles is essential for a rational use of drugs in clinical

practice. Pharmacokinetic parameters that are especially important in therapeutics include (a) bioavailability, which determines the rate and extent at which a drug enters the systemic circulation; (b) volume of distribution, which provides an indication of the amount of drug in the body relative to its concentration in plasma; (c) clearance, a measure of the efficiency of the elimination processes and a major determinant of the plasma drug concentration at steady state; and (d) half-life, which determines the time required to reach steady state and the fluctuation in plasma drug concentrations during a dosing interval. Although under most circumstances pharmacokinetic processes are linear, that is, independent of dose and duration of administration, there are important exceptions to this rule. Examples of drugs whose kinetics may deviate significantly from linearity at therapeutic doses include phenytoin, carbamazepine, valproic acid, and gabapentin. With most drugs, the rates of absorption, distribution, biotransformation, and excretion exhibit wide interindividual differences under the influence of constitutional and environmental factors, such as genetic background, age, associated disease, and exposure to dietary constituents, voluptuary substances, industrial contaminants, and concurrent drug therapy. The resulting variation in pharmacokinetic parameters has important clinical consequences, and it contributes to the requirement to tailor drug doses to individual needs. Although under selected circumstances clinical benefits can be achieved through pharmacokinetic optimization of the dose based on serum drug level monitoring, knowledge of pharmacokinetic characteristics of the prescribed drugs is always essential if dosing schedules are to be implemented correctly, and this is true also for drugs whose dose is individualized on purely clinical grounds.

Therapeutic Drug Monitoring

Svein I. Johannessen

Philip N. Patsalos

Torbjörn Tomson

Emilio Perucca

Introduction

Therapeutic drug monitoring (TDM) can be defined as "the measurement and the clinical use of drug concentrations (levels) in body fluids (usually serum or plasma) to adjust each patient's individual drug dosage and schedule to each patient's individual therapeutic requirement." In practice it is the patient who is treated and not the concentration, so that the dose of a drug is adjusted, using the drug concentration as a guide, to optimize its efficacy, avoid, minimize, or identify toxicity, and detect or confirm poor compliance. It is therefore important to appreciate that TDM begins before a drug concentration is measured and that the measurement itself is only part of the overall process of planning, monitoring, and optimally adjusting the dosage regimen.

Many pharmacologic properties of antiepileptic drugs (AEDs) support suitability for TDM, and during the last 40 years therapeutic monitoring of AEDs has had an undeniable impact on the management of patients with epilepsy.[13] Major contributing factors are our enhanced understanding of AED pharmacokinetics and its relevance to drug therapeutics and the development of robust, reliable, and specific analytical methodologies underpinned by appropriate quality assurance schemes.[102,106] Assay results should be available quickly, preferably within 24 hours of sampling, because the most important use of blood concentrations are for making dosage adjustments and diagnosing toxicity when rapid decisions need to be made. Indeed, on-site, near-patient AED monitoring has been shown to have an immediate impact on clinical decision making and to enhance patient management.[18,49,64]

The criteria for valid TDM are the availability of accurate pharmacokinetic data; a poor correlation between dose and blood concentrations (i.e., substantial pharmacokinetic variability); good correlation between blood concentration and therapeutic effect, toxicity, or both, at least within individuals; a narrow therapeutic index (i.e., the therapeutic dose is close to the dose associated with toxicity); and the availability of simple, accurate, reproducible, and inexpensive analytical assays. However, some AEDs are more suitable candidates for monitoring than others. Phenytoin best fulfills these criteria because its saturable pharmacokinetics makes it very difficult to prescribe the optimum dose without measuring blood levels.

The goal of AED treatment is seizure freedom without side effects. However, even with the introduction of nine new AEDs, a significant number of people with epilepsy are still not achieving this goal. TDM can help to improve seizure control in numerous ways including the following:

- Identification of therapeutic failure due to underdosage.
- Detection of noncompliance with prescribed therapy, which may be responsible for avoidable therapeutic failure.
- Identification of the uncommon situation in which overdosage causes increased seizures.
- Detection of pharmacokinetic interactions that may compromise the adequacy of the therapy.

The following section provides a concise description of the current issues relating to the use of TDM for AEDs.

Principles of Therapeutic Drug Monitoring

Interest in the use of TDM as an aid to optimizing epilepsy treatment stems from the realization that serum AED concentrations may vary severalfold among patients who are prescribed the same dosage.[28] There are multiple reasons for such variability. To start with, the dose prescribed may differ from the dose actually taken, mainly due to variation in the degree of compliance. Even when drugs are taken as directed, serum concentrations may vary dramatically as a result of inter- and intraindividual differences in pharmacokinetics. Although most AEDs are absorbed efficiently from the gastrointestinal tract, the extent of absorption may be variably affected by factors such as age, interactions with foods or other medications, and characteristics of the pharmaceutical formulation used.[22] More important, the metabolic and renal clearance of AEDs is subject to prominent variability, both within and between subjects, under the influence of the genetic background (e.g., variation in genes controlling drug metabolism and drug transport), physiologic factors (e.g., changes in drug-metabolizing-enzyme activity and renal function during development, pregnancy, and aging), drug interactions, and disease states, with special reference to disorders affecting the function of the liver and the kidney.

Because the concentration of AEDs in serum is in equilibrium with the drug concentration at the site(s) of action in the brain, it is not surprising that differences in serum drug concentrations represent an important source of variability in dose requirements. Based on this background, knowledge of serum drug concentrations provides a more direct estimate, compared with prescribed daily dose, of the amount of drug that is available to produce pharmacologic effects. In fact, it is reasonable to assume (and this assumption can be verified in the clinic under many circumstances) that therapeutic and toxic effects correlate better with the concentration of a drug in the serum than with the prescribed daily dose.[21] In other words, under appropriate circumstances, the serum concentration of an AED can be used as a surrogate marker in assessing whether the patient is receiving an adequate amount of the prescribed drug.

Obviously, serum drug concentration measurements are superfluous when tools are available to measure drug effects directly. For example, we do not need to measure the serum concentrations of an antihypertensive drug or an oral anticoagulant because we can measure directly arterial blood pressure

P.1172

or International Normalized Ratio (INR) ratio and individualize dosage directly based on therapeutic response. In the case of AEDs, however, direct measurement of pharmacologic response can be elusive. In a newly diagnosed patient with infrequent seizures, for example, it may take months to determine whether the dosage initially prescribed is sufficient to prevent seizure recurrence. Measuring the serum AED concentration in that patient and comparing it with the concentration range that in previous studies has been found to maximize the probability of seizure control helps in predicting the effectiveness of the administered treatment and in determining whether a dosage adjustment would be appropriate.

Factors Affecting Response to a Given Antiepileptic Drug Concentration

If all patients achieved the best response at the same AED concentration, optimizing treatment would be easy. We would simply need to administer an initial dose, measure the serum drug concentration, and adjust the dose accordingly until the "therapeutic" concentration is achieved. Unfortunately, in real life things are much more complicated because the serum concentration of any given AED required to produce an optimal response varies more than tenfold across individuals and can also change substantially over time within the same individual.[21,75,94] This is due to a combination of factors, all of which may confound the relationship between serum drug concentration and pharmacologic effects, as follows.

Characteristics of the Seizure Disorder

There is evidence that the concentration of an AED required to produce seizure control differs in relation to the type and severity of the seizure disorder. Schmidt and Haenel[89] compared serum AED concentrations associated with complete seizure control in 84 patients stabilized on monotherapy with phenyt-oin, carbamazepine, or phenobarbital. In 26 of the 40 patients (65%) with generalized tonic–clonic seizures only, seizure control was achieved at concentrations of <60 µmol/L (<15 µg/mL) for phenytoin, <108 µmol/L (<25 µg/mL) for phenobarbital, and <25 µmol/L (<6 µg/mL) for carbamazepine. Conversely, only 3 of 32 well-controlled patients (9%) with complex partial seizures achieved remission at these relatively low drug concentrations. The AED concentration associated with seizure control also varied in relation to number of seizures in the first year of epilepsy. The 50 patients who were controlled at concentrations in the low range had suffered a median of 5 seizures (range 1 to 18) in the first year, whereas those who were controlled at higher concentrations had 61 seizures (range 0 to 300) over the same period. Recent studies also suggest that, within a given syndrome, responsiveness to AED treatment also depends on underlying etiology: For example, among patients with localization-related epilepsy, those showing underlying cortical atrophy or cerebrovascular disease may respond more favorably to AEDs than the remainder of the symptomatic group.[54]

Age

Because the distribution of epilepsy syndromes and underlying etiologies vary across age groups, we would expect the optimal concentration of an AED to be influenced by age. Evidence has been provided, in particular, that many elderly patients achieve seizure control at lower serum AED concentrations than younger subjects, although they also tend to develop adverse effects such as impairment of gait and tremor at lower concentrations.[27,39]

Duration of Treatment

For many AEDs, the response to a given drug concentration may change over time, most notably due to gradual development of tolerance to adverse effects. Patients with a prolonged exposure to phenobarbital or benzodiazepines, for example, might tolerate without major untoward effects serum drug concentrations that can cause extreme sedation and even coma in acutely exposed subjects.[14,30] A gradual improvement in central nervous system (CNS) tolerability with slowly rising serum drug concentrations during the initial up-titration phase is also observed with topiramate, tiagabine, pregabalin, and many other AEDs.[73]

Conditions Associated With Altered Drug Binding to Serum Proteins

Although routine methods for measuring AEDs in body fluids do not discriminate between drug molecules that are present in free (unbound) form and those that are bound to plasma proteins, only the free drug is available to move across the endothelium and to equilibrate with the concentration in the interstitial space in the brain. If the free fraction increases, the total drug concentration in serum will underestimate the amount of free, pharmacologically active drug, and under these circumstances therapeutic and toxic effects will be observed at total drug concentrations that are lower than usual.[68] Among AEDs that are commonly monitored, those that are most extensively bound to serum proteins are phenytoin and valproic acid. Impairment in the protein binding of these drugs may be caused by hypoalbuminemia (as observed during pregnancy, old age, liver disease, and many other pathologic conditions), accumulation of endogenous displacing agents (most notably in patients with renal insufficiency), and administration of other medications that compete for plasma protein–binding sites.[2,68] In these conditions, interpretation of serum drug concentration requires special skills: For example, in a patient in late pregnancy, the change in unbound fraction of phenytoin can be predicted by measuring the serum albumin concentration.[75] Techniques are also available for the direct measurement of unbound drug concentrations. These techniques are not used routinely because measuring unbound drug concentrations is more expensive and more cumbersome than measuring total drug concentrations. Moreover, in most situations, the intersubject variability in unbound fraction is relatively small, and measurement of total concentrations is more than adequate for clinical purposes. However, if a major change in unbound fraction is expected (or suspected), measuring unbound drug concentrations might be justified.

Comorbidities

Several diseases, particularly those affecting the liver and the kidney, are associated with changes in the binding of AEDs to serum proteins, and by this mechanism they alter the relationship between total serum concentration of highly protein-bound drugs and clinical effects.[74] Associated disorders may also modify the response observed at any given serum AED concentration at the pharmacodynamic level. For example, it has been elegantly shown that the threshold serum carbamazepine concentration that induces ataxia is significantly lower in patients with magnetic resonance imaging (MRI) evidence

P.1173

of preexisting cerebellar atrophy than in patients without atrophy.[93]

Drug Interactions

As discussed previously, concomitant drugs may affect concentration–response relationships by displacing highly bound AEDs from plasma protein–binding sites. Valproic acid, in particular, causes a marked displacement of protein-bound phenytoin, and in valproic acid–treated patients, therapeutic and toxic effects of phenytoin are observed at total serum phenytoin concentrations lower than usual.[47,68] Concomitant drugs can also affect concentration–response relationships through pharmacodynamic interactions: For example, the tolerability associated with any given concentration of carbamazepine is reduced in the presence of adverse pharmacodynamic interactions caused by oxcarbazepine[1] or lamotrigine.[12]

Confounding Effects of Active Metabolites

At times, effects apparently unrelated to the drug concentration in serum can be explained by the presence of active metabolites. One example is the precipitation of carbamazepine toxicity following addition of valpromide, a valproic acid derivative: The toxic reaction is caused by a prominent increase in the concentration of the active metabolite carbamazepine-10,11-epoxide, whereas serum carbamazepine concentration is unaffected.[77]

The Concept of Therapeutic Range

In the light of the variability discussed earlier, "therapeutic" ranges of serum AED concentrations reported in the literature (Table 1) must be interpreted flexibly. These ranges have merely a probabilistic value, that is, they represent the concentration interval at which the *majority* of patients are expected to show an optimal response. Indeed, some patients may do best at concentrations above and below the range, and there is no justification for modifying dosage in these patients if their seizures are well controlled and no adverse effects have emerged.[38,107]

The validity of therapeutic ranges quoted in the literature depends on the population and methodology that led to their definition. In particular, the pivotal study that led to the widespread acceptance of a 40- to 80-µmol/L (10- to 20-µg/mL) therapeutic range for phenytoin[44] was conducted in a small and preselected population of patients with heterogeneous epileptic disorders who had not responded to phenyt-oin. Thus, it is likely that the study excluded patients who had become seizure free at concentrations <40 µmol/L (10 µg/mL). In fact, in different studies, the proportion of patients achieving complete seizure control at phenytoin concentration <40 µmol/L (10 µg/mL) has been on the order of 22%,[86] 35%,[88] and 73%.[23] Similar observations have been made with other AEDs, leading to the suggestion that the lower limit of the therapeutic range should be disregarded altogether, and that any measurable concentration up to the level at which toxicity is likely to occur should be regarded as potentially therapeutic.[75]

In the light of these considerations, it is clear that therapeutic ranges must be interpreted flexibly, by taking into account all information that is available for the individual patient, and that no dosing changes should be made without careful evaluation of clinical response. Still, knowledge of the probability that a given concentration can be associated with seizure control or toxicity can be useful in specific situations. For example, in a patient with newly diagnosed epilepsy and infrequent seizures who is concerned about potential adverse drug effects and would not be excessively disturbed by the risk of having another seizure, it would make sense to adjust the dosage to achieve a relatively low target concentration. Conversely, a target concentration in the higher range would be appropriate whenever the patient's social, professional, or psychological condition makes it imperative to reduce to the very minimum the risk of seizure recurrence.

The Individual Reference Concentration

The existence of a wide variability in the concentration at which different patients respond justifies an alternative (or complementary) approach to TDM, based on the identification of the so-called *individual reference concentration*.[69] In this approach, treatment is adjusted based on the individual's clinical response (assisted, if appropriate, by monitoring serum concentrations) until a dose is identified that controls optimally the seizures without undue adverse effects. The serum concentration that is associated with that dose represents, for that patient, the *individual reference concentration* and can be helpful during subsequent management in ascertaining potential causes for a change in clinical status or in determining the need for dose adjustment. For example, if the patient will need an additional medication that is likely to increase or decrease the serum concentration of the AED, knowledge of the baseline (reference) AED concentration will allow adjusting the dose of the latter to compensate for the effect of the drug interaction. Likewise, knowledge of the *individual reference concentration* can be invaluable in clarifying the mechanisms responsible for the sudden onset of toxicity or for an unexpected recurrence of previously controlled seizures. An example is provided by a recent study that assessed serum AED concentrations in 52 patients shortly after the occurrence of a breakthrough seizure: In 44% of the cases, the serum concentration measured after the seizure was less than one-half the *individual reference concentration* that had been previously found to be associated with a good response in the same individual.[92] In most cases, this was ascribed to poor compliance. Because the *individual reference concentration* is specific for each patient, it can be used in the absence of information on the serum concentration–response relationships in a population and when such a relationship is very variable across patients. There is, however, an important caveat: At times, concentration–response relationships can change within patients, as when drug responsiveness changes as a function of brain maturation in a child, or when a medication is added that causes displacement of the monitored drug from its serum protein–binding sites.

Assessment of the Impact of Therapeutic Drug Monitoring on Clinical Outcome

Although TDM has been established as a routine aid in the effort to individualize the dosing of AEDs since the 1960s, the impact of using TDM on the outcome of drug treatment of epilepsy has rarely been assessed in a systematic manner. Open uncontrolled studies have demonstrated that the introduction of a TDM service can result in a larger proportion of patients being treated with AED serum concentrations within the recommended ranges.[34,41,49] However, studies on the effect of TDM on outcome in terms of seizure control are scarce. In fact, there are only two published randomized studies comparing the outcome of pharmacologic treatment with or

P.1174

P.1175

P.1176

without the use of TDM.[25,35] In the first, 127 chronic epilepsy patients, most on polytherapy, were randomly assigned to treatment with or without the support of TDM.[25] Blood samples for determination of drug concentrations were drawn from all patients, but for one of the two groups the treating physician was not informed about the results. Of the randomized patients, 105 completed the 1-year follow-up. The therapeutic results of the two groups were not significantly different. However, a substantial proportion of patients, similar in both groups, had AED concentrations that fell outside of the therapeutic range. This observation suggests that the physicians responsible for the treatment did not use the information provided by the TDM service, which may have affected the negative outcome of the study. Such interpretation is in line with the observations made in a retrospective analysis of 164 patients with epilepsy.[6] Seizure control one year before the introduction of TDM was compared to results one year after the service was made available. Seizure control was improved only when the physicians, according to the investigators, appropriately used information from the serum concentrations.

Table 1. Pharmacokinetic parameters of antiepileptic drugs in adults[9,71]

Drug	Oral bioavailability	Time to peak concentration	Time to steady state	Half-life monotherapy	Half-life AED+ enzyme inducers	Serum protein binding	Main route of elimination	Tentative therapeutic range[a]	Conversion factor F µmol/L = F × µg/mL)	Documentation of/ comment on usefulness of serum drug concentration monitoring
	(%)	(h)	(d)	(h)	(h)	(%)		(µmol/L)		
					Older AEDs					
Carbamazepine	~85	4–8[b]	4–7	8–20	5–12	75	Oxidation	15–45	4.23	Useful
Clobazam	~100	1–5	4–7	15–50	<30	85	Oxidation	0.1–1.0	3.32	Limited value
Clonazepam	~100	1–3	5–10	20–60	12–46	82	Oxidation	60–220[c]	3.17	Limited value
Ethosuximide	~100	3–7	5–10	40–60	20–30	0	Oxidation	300–600	7.08	Useful
Phenobarbital	~100	2–8	10–35	50–160	50–160	50	Oxidation, *N*-glucoside conjugation, and renal excretion	50–130	4.31	Useful
Phenytoin	~100	2–8	4–8	7–60[d]	7–60[d]	90	Oxidation	40–80	3.96	Very useful
Primidone	~100	2–5	1–3	4–12	4–12	0	Cleavage of the pyrimidine ring, oxidation to phenobarbital, and renal excretion	30–60	4.58	Monitor serum phenobarbital
Valproic acid	~100	3–6[e]	2–4	11–20	6–12	78–94[d]	Oxidation and glucuronide conjugation	300–600	7.08	Useful
					Newer AEDs					
Felbamate	~100	1–4	3–5	14–22	10–20	30	Oxidation and renal excretion	125–250	4.20	Potentially of value
Gabapentin	Up to 60, decreases with increasing dose	2–3	2	5–7	5–7	0	Renal excretion	70–120	5.83	Potentially of value
Lamotrigine	~100	1–3	3–15	15–30 + VPA 30–90	8–20 + VPA 15–30	55	Glucuronide conjugation	10–60	3.90	Useful
Levetiracetam	~100	1	2	6–8	5–8	0	Renal excretion and hydrolysis	35–120	5.88	Probably of limited value
Oxcarbazepine[f]	Prodrug of MDH	4–6	2–3	8–15	7–12	40	Ketoreduction, then glucuronide conjugation of MHD	50–140	3.96	Serum MHD potentially of value

Table 2 Some general indications for therapeutic drug monitoring

1. After initiation of treatment (to provide a baseline steady-state concentration)
2. After change in drug dose, in particular when nonlinear kinetics applies (to confirm new drug concentration)
3. At therapeutic failure (to confirm or exclude a pharmacokinetic explanation for uncontrolled seizures or adverse effects
4. To identify or control for drug–drug interactions
5. After a change in drug formulation
6. When pharmacokinetic alterations due to physiologic or pathologic changes are anticipated (e.g., pregnancy, hepatic disease, renal disease, gastrointestinal conditions potentially affecting drug absorption)
7. When poor compliance is suspected
8. Routine sampling annually of phenytoin because of saturation kinetics

The second and most recent randomized, controlled trial on the impact of TDM included 180 newly diagnosed, previously untreated patients with epilepsy who were about to start treatment with an older-generation AED.[35] The majority of the included patients were prescribed carbamazepine, and only a small fraction were on phenytoin. Patients were randomized to either treatment with dosage adjusted on clinical grounds alone or treatment with dosage adjusted to achieve serum concentrations within predefined target ranges. Both groups were followed for 24 months. There were no significant differences between the two groups with respect to patients achieving 12-month remission, patients remaining seizure free since initiation of treatment, time to first seizure or to 12-month remission, or frequency of adverse effects. Hence, this study could not demonstrate an effect of routine use of TDM on the clinical outcome of early treatment of epilepsy. In contrast, a small retrospective study from Mumbai, India, indicated that TDM can improve outcome in patients with established "generalized tonic–clonic epilepsy."[79] The proportion of patients with seizure control was higher and the frequency of adverse reactions lower among 25 epilepsy patients who had undergone TDM at least twice a year compared with 25 matched epilepsy patients from the same epilepsy clinic who had not. Unfortunately, there is no information on the type of AEDs prescribed in this study. Although the retrospective design calls for caution in interpretation, the results suggest that TDM can have an impact on outcome in special situations and settings despite the negative findings from randomized studies.

The cost-effectiveness of TDM has recently been assessed in a systematic review.[96] Based on a low level of evidence (level 3), the review concluded that TDM of older-generation AEDs can lead to better control of patients with fewer side effects and be cost-effective. Furthermore, TDM of the new AEDs was considered useful in titrating patients whose epilepsy is difficult to control and in case of questionable compliance and drug–drug interactions.[97]

Thus, there is an obvious need for studies assessing the impact of TDM on the outcome of treatment. Although the two available randomized studies did not provide evidence for the usefulness of routine monitoring of AEDs in general, this does not exclude the value of TDM in special situations.

Table 3 Enzyme-inducing properties of antiepileptic drugs (AEDs)

Non-enzyme-inducing AEDs	Broad-spectrum enzyme-inducing AEDs
Ethosuximide	Carbamaxepine, phenytoin, phenobarbital, primidone
Gabapentin	
Levetiracetam	Narrow-spectrum enzyme-inducing AEDs,[a]
Pregabalin	Felbamate, lamotrigine, oxcarbazepine, topiramate
Tiagabine	
Valproic acid	
Vigabatrin	
Zonisamide	

[a]Felbamate, lamotrigine, topiramate (at doses >200 mg/d), and oxcarbazepine may reduce the serum concentrations of steroid oral contraceptives. Felbamate and oxcarbazepine may reduce the serum concentrations of some other cytochrome P450 substrates; both felbamate and oxcarbazepine may also act as enzyme inhibitors as well as enzyme inducers.

Use of Therapeutic Drug Monitoring in Various Clinical Settings

TDM is of particular value in situations in which clinical effects are difficult to assess and when there is intra- or interindividual variability in drug concentrations that may account for differences in treatment outcome. Examples are discussed in this section; some general indications for TDM are summarized in Table 2.

Settings in Which Clinical Assessment of Effects Is Particularly Difficult

The optimal dose of any AED for a patient with newly diagnosed epilepsy can only be defined clinically after considerable follow-up of the effects of the prescribed treatment. Evidently, most patients would prefer to get the optimal dose from onset rather than having it titrated against toxic effects or continued seizures. Although evidence for the effectiveness of the procedure is lacking, it is therefore advisable to measure the serum concentration of a newly initiated AED once steady-state concentration has been achieved. The value of such concentrations is higher for drugs with reasonably established concentration–effect relationships and is particularly high for a drug such as phenytoin with complicated pharmacokinetics. Although strict adherence to therapeutic ranges is unjustified, the measured concentration could be used for consideration of dose adjustments based on the individual patient's treatment priorities. Even if such an initial steady-state serum concentration does not prompt a dose adjustment, it can be of value as a reference to facilitate interpretation of future drug concentrations associated with toxicity or therapeutic failure.

Some adverse effects of AEDs, not least those affecting cognition, are difficult to identify in certain patient groups with limited abilities to communicate. This includes young children, people with learning disabilities, and elderly patients with dementia. Wide indications for TDM on suspicion of concentration-related adverse effects are therefore justified in these patient groups.

There are also situations in which toxic symptoms and signs might be difficult to distinguish from those of undertreatment. Many AEDs may have a paradoxical seizure-aggravating effect as one manifestation of overdosing.[70] Nonconvulsive status epilepticus, other subtle seizures, and effects of subclinical ictal discharges, on the other hand, can be misinterpreted as a sign of AED toxicity. A drug concentration obtained in situations of seizure aggravation, impaired consciousness, or sedation can help to resolve the issue.

Settings With Alterations in Pharmacokinetics

Pharmacokinetics can change due to physiologic factors, pathologic states, and drug–drug interactions, all of which can potentially result in modified effects. Correctly applied, TDM can identify such alterations and facilitate dose adjustments to maintain efficacy. For example, unless the dosage is adjusted, serum concentrations will change as children grow, partly because of increased body weight, but also due to changes in clearance and other pharmacokinetic parameters.[29] It thus might be justified to monitor AED concentrations at regular intervals in children during their growth, more frequently in children with unstable seizure control, and at longer intervals among those with mild epilepsy.

Age-related alterations in pharmacokinetics occur also at the other end of the age spectrum. Decreased binding to serum proteins, increased volume of distribution, and reduced metabolic and renal capacity can all be seen to a variable degree among the elderly. This complicates prediction of the pharmacokinetics of AEDs in elderly patients[72] and justifies the use of TDM. However, elderly patients seem to obtain seizure control and experience adverse effects at lower serum concentrations than do patients in other age groups,[77] which has to be taken into account in the interpretation of drug concentrations. In addition, an age-related decrease in binding to serum proteins can result in total serum concentrations underestimating the effects of highly bound AEDs, such as valproic acid and phenytoin. Measuring unbound concentrations of these AEDs might thus be preferable in the elderly.

Pregnancy is another physiologic condition that affects the pharmacokinetics of AEDs to an extent that may require dose adjustments.[66,95] The effect of pregnancy on drug disposition varies with different AEDs, and the extent of the effect on a specific AED will also vary among patients.[95] Serum concentrations of most older-generation AEDs tend to decrease during pregnancy.[96] For valproic acid, and to some extent phenytoin, the decline in total concentration is due to a decrease in protein binding, a mechanism that might not imply major changes in the unbound concentration of the drug. A fall in the serum concentrations of other AEDs is mainly related to enhanced metabolism.[95] The most pronounced effects of pregnancy have been reported with lamotrigine, with average concentrations in late pregnancy of only approximately 30% of pre-pregnancy concentrations.[19,56,66,98] Preliminary observations suggest that the serum concentration of the active monohydroxy derivative (MHD) of oxcarbazepine may also decrease markedly during pregnancy.[48] The effect of pregnancy on the pharmacokinetics of other new-generation AEDs has not been adequately explored. In general, because of the possibility of pharmacokinetic changes, monitoring drug concentrations is recommended during pregnancy. Unbound drug concentrations should ideally be measured for highly protein-bound AEDs. The timing and frequency of drug concentration monitoring during pregnancy need to be individualized based on the type of AED used and on patient characteristics. A schedule of once in each trimester is often recommended and is probably sufficient in most cases. More frequent sampling is advisable in patients with complicated epilepsy and in patients under treatment with lamotri-gine. The need for monitoring in the postpartum period depends on the clinical situation and whether dose changes were made during pregnancy.

Pathologic states such as hepatic or renal disease can also affect the pharmacokinetics of AEDs and its predictability.[73] Hepatic disorders can be associated with a reduced capacity to eliminate the many AEDs that undergo extensive metabolism. In addition, binding capacity to serum proteins can be reduced. Serum concentration monitoring is indicated to control for such pharmacokinetic alterations for AEDs that are metabolized or highly bound to serum proteins. Renal failure is also associated with reduced binding of AEDs to plasma proteins. It will also affect the elimination of AEDs that are excreted unchanged through the kidneys. Although the latter correlates with creatinine clearance, measuring serum concentrations of AEDs and, when appropriate, unbound serum drug concentrations is a more direct method for assessing the pharmacokinetic consequences of renal failure.

Pharmacokinetic interactions between AEDs and between AEDs and other drugs are common.[62,63] Interactions involving displacement from plasma proteins will generally not alter the effects of treatment, but they can lead to misinterpretation of the total drug concentrations. Drugs that induce or inhibit the metabolism of an AED, however, can modify the effect of treatment. These interactions are frequent, and the resulting changes in serum AED concentrations are often difficult to predict. Monitoring AED concentrations is therefore recommended whenever a pharmacokinetic interaction can be expected. Ideally, a baseline serum concentration should be obtained before adding the interacting drug and when the effects of combination treatment are stabilized. Because drug interactions are frequent and not always known beforehand, monitoring drug concentrations should be considered whenever addition of a new drug is followed by an unexpected change in clinical state. This will help to distinguish pharmacokinetic from pharmacodynamic interactions, facilitate dosage adjustments, and identify previously unknown interactions.

A change in drug formulation, for example, from brand name to generic or between generics, is another situation in which TDM can be indicated to control for differences in pharmacokinetics. This is particularly important for a drug like phenytoin that has dose-dependent kinetics. Because of these characteristics, any dose adjustment of phenytoin should also be monitored by TDM.

Settings With Unexpected Clinical Response

TDM can be useful in assessing the reasons for an unexpected drug response, clarifying whether this has a pharmacokinetic explanation. A serum concentration should be obtained whenever seizures persist despite a reasonable dose of an appropriate AED. This will help in the recognition of patients who need higher doses because of unusually efficient drug elimination and also those that fail to take the drug as prescribed. A pronounced variation in repeated drug concentrations can indicate noncompliance.[42] Measuring drug concentrations in conjunction with breakthrough seizures has been suggested as another method. Postictal drug concentrations considerably lower than a baseline value for the same patient are likely to imply poor compliance.[92] TDM also facilitates the interpretation of suspected dose/concentration-related adverse effects of AEDs. Trough concentrations obtained before the morning dose should be the routine, but sampling at the time of adverse effects is rational if symptoms are intermittent and suspected to be related to fluctuations in serum concentrations.

Time of Sampling

TDM can be rendered ineffective by random sampling. It is important to ensure that sampling occurs at steady state, which occurs at four to five half-lives after starting treatment or a dose change. For drugs with a short half-life, such as carbamazepine, valproic acid, gabapentin, levetiracetam, pregabalin, tiagabine, vigabatrin, and, in enzyme-induced patients, lamotrigine and topiramate, it is important to standardize the sampling time in relation to dose. Patient noncompliance within a period of three to four half-lives before the blood sample is drawn can

significantly affect the blood level and cause misinterpretation of the result. The ideal blood sampling time for all AEDs is immediately before the next oral dose (trough), but if this is not possible, it is desirable to note the sampling time and the time medication was last ingested. In some cases, two blood samples, for example, one taken at the time of trough and a second taken at the expected time of peak (or in conjunction with the appearance of symptoms suggestive of transient concentration-related toxicity), could be valuable for optimizing the dosing schedule.

If blood sampling is undertaken before steady state, serum concentrations for a given dose will be underestimated. Consequently, if a dose increase is undertaken, this will eventually result in unnecessary toxicity for the patient. In the case of carbamazepine, sampling before autoinduction is complete will result in overestimation of the steady-state concentration. This can result in a dose that is subtherapeutic, and patients may continue to have unnecessary seizures. A meticulous dosage history is therefore required. During overdose, sampling should be undertaken as soon as the patient presents at casualty.

Biologic Matrixes

The matrix of choice for TDM is usually serum or plasma, which can be used interchangeably, although it is preferable to use one or the other consistently. Other biologic matrixes that have been investigated include whole blood, saliva, tears, and hair.

Interest in saliva began in the 1980s when it was suggested that saliva could be used as an alternative to serum. Several recent developments in sample collection and analytical techniques and the growing interest in unbound drug monitoring have provided a renewed interest in saliva monitoring of AEDs.[43] Its value relative to blood sampling can vary in different clinical settings. Collection of saliva is simple and noninvasive; does not require expertise in drawing blood, so that sampling can be undertaken by patients; can be especially useful in patients with disabilities; and is preferred by children and their parents. In addition, for some drugs, measured concentrations reflect the unbound (pharmacologically relevant) concentration in blood. Drawbacks of saliva include the difficulty of measuring concentrations that might be lower than total serum concentrations, the unacceptability of this matrix for some patients, and the possibility of unreliable results due to the presence of drug residues in the mouth or leakage of drug-rich exudate, particularly in patients with gingivitis. There are substantial data suggesting useful correlations between saliva concentrations and free (unbound) serum concentrations for many AEDs.[31,51,52,87] This is not the case for valproic acid, and there is some controversy for phenobarbital.

Analysis of AEDs in scalp hair can provide another useful approach because content has been shown to reflect the mean blood level profile over a prolonged period prior to sampling,[104] and in addition hair sampling is noninvasive (assuming that hair is not at a premium). Because hair acts as a "tape recorder," drug concentration in different hair segments can reflect a history of drug ingestion over a period of months or years (depending on the length of hair), thereby providing data on patient long-term compliance in different periods.[45,103,105]

Analytical techniques

Commercial reagents used in conjunction with a variety of analyzers form the basis for the analysis of the established AEDs (carbamazepine, phenytoin, phenobarbital, primidone, ethosuximide, and valproic acid). For the benzodiazepine drugs (clobazam, clonazepam, and diazepam) and AED metabolites that are pharmacologically active (e.g., carbamazepine-10,11-epoxide and *N*-desmethylclobazam) analysis can only be undertaken by use of chromatographic techniques[85,88] that require specialized equipment and advanced know-how.

Commercial immunoassays are available for topiramate and zonisamide, and those for others, including lamotrigine, are under development.[11] Other new AEDs can only be measured by high-performance liquid chromatography using primarily ultraviolet (UV) detection, but some AEDs require more difficult detection techniques such as fluorescence (e.g., vigabatrin, gabapentin, and pregabalin) and electrochemical (e.g., tiagabine) techniques. Because of the relative ease of use of UV detection, numerous chromatographic techniques have been described for lamotrigine, oxcarbazepine, levetiracetam, felbamate, and zonisamide,[7,26,80] and to increase assay efficiency in terms of both cost and turnaround times, methodologies have been developed whereby these new AEDs are simultaneously measured along with old-generation AEDs.[17,46,57,84]

Various chromatographic fluorescence detection techniques have been described for vigabatrin, gabapentin, and pregabalin, and techniques that involve simultaneous analysis of two or three of these AEDs may be preferable.[81,100] The most difficult AED to analyze is tiagabine, partly because its clinically occurring concentrations in serum are in the nanomolar range (in contrast to micromolar range for all other AEDs) and also because electrochemical detection is more difficult.[32]

Direct Measurement of Unbound Drug Concentrations

The techniques used most commonly involve ultrafiltration of the serum sample to separate a protein-free fluid containing the unbound drug. Important considerations are that unbound concentration values can vary depending on the technique used (e.g., ultrafiltration vs. dialysis) and are temperature dependent (they vary inversely with the temperature at which the separation of unbound drug is accomplished), and therefore results obtained with different techniques are not interchangeable.

Table 4 Pharmacologic factors of importance for the therapeutic drug management of antiepileptic drugs

Mechanism of action	Reversible, except for vigabatrin
Active metabolites	Carbamazepine, clobazam, oxcarbazepine, and primidone
Interindividual variability in pharmacokinetics	Pronounced for clobazam, clonazepam, carbamazepine, felbamate, gabapentin, lamotrigine, phenytoin, tiagabine, topiramate, valproic acid, and zonisamide
	Moderate for ethosuximide, oxcarbazepine, phenobarbital, and primidone
	Slight for levetiracetam, pregabalin, and vigabatrin
Linearity in pharmacokinetics	At therapeutic doses, no major deviations from linearity for clobazam, clonazepam, ethosuximide, felbamate, lamotrigine, oxcarbazepine, phenobarbital, pregabalin, primidone, tiagabine, topiramate, and zonisamide
	Phenytoin shows Michaelis-Menten kinetics; gabapentin, dose-dependent bioavailability; carbamazepine, dose-dependent autoinduction; valproic acid, concentration-dependent plasma protein binding

Relevance and Application of Therapeutic Drug Monitoring in Relation to Individual Antiepileptic Drugs

The value and applicability of TDM are influenced by the pharmacologic properties of the drug to be monitored. The properties of importance for TDM are summarized in Tables 1, 3, and 4 and are referred to in the text for the individual drugs.

Therapeutic ranges of serum concentrations have been proposed for most of the older AEDs, particularly phenytoin, phenobarbital, carbamazepine, ethosuximide, and valproic acid. The usefulness of TDM for clonazepam, clobazam, and primidone is limited because of the poor correlation between their serum concentration and effects and because this relationship can change with time. More work is needed to assess the value of TDM for the newer AEDs, although at least for lamotri-gine and topiramate there is increasing experience that measuring drug concentration can be of considerable help for clinical management.

In the following, both older and newer AEDs are discussed in order of importance in terms of need for and usefulness of TDM.

P.1179

Older Antiepileptic Drugs

Phenytoin metabolism follows Michaelis-Menten rather than first-order kinetics. The hepatic enzymes responsible for phe-nytoin metabolism become saturated within the clinically occurring serum concentration range, and therefore the time needed to attain steady state increases with increasing serum concentration. Because phenytoin follows nonlinear kinetics, even a slight inhibition of metabolism can lead to a considerable increase in its serum concentration and pharmacologic effect. Its high protein binding with consequent variability in the fraction of unbound, pharmacologically active drug can also be important. The main interactions between phenytoin and other drugs are probably those that lead to an inhibition of phe-nytoin metabolism. Due to the special pharmacokinetic features of phenytoin, use of this drug is difficult without serum concentration monitoring. For most patients the optimal serum concentration is within a range of 40 to 80 μmol/L (10 to 20 μg/mL).[5,8,55,71]

Carbamazepine metabolism can vary considerably, resulting in a poor correlation between dose and serum concentration. The half-life during long-term treatment is considerably shorter than following a single dose, because of autoinduction. The main metabolite of carbamazepine, carbamazepine-10,11-epoxide, contributes to the pharmacologic effect, and its measurement can be useful in special cases (e.g., when the metabolite is suspected to be contributing to toxicity). A number of drugs can influence the pharmacokinetics of carbamazepine. Optimal responses are usually achieved at serum carbamazepine concentrations in the range of 15 to 45 μmol/L (4 to 12 μg/mL).[5,8,55,71]

Phenobarbital metabolism is particularly slow (although the half-life is shorter in children than in adults), and diurnal variations in steady-state drug concentration are therefore small within individuals taking a constant dose. Some drugs, particularly valproic acid, can increase the serum concentration of phenobarbital. The relationship between the serum concentration of phenobarbital and adverse central nervous system effects varies with the development of tolerance. For phenobarbital most patients are optimally treated with serum concentrations between 50 and 130 μmol/L (10 to 30 μg/mL).[4,8,55,71]

Valproic acid disposition is influenced by several factors. Due to interindividual differences in metabolism, there is a poor correlation between the dose and the serum concentration. As with other AEDs, children need higher doses in terms of milligrams per kilogram of body weight than do adults. Enzyme-inducing AEDs lower serum valproic acid concentrations (Table 3). Valproic acid is highly protein bound, and the binding is concentration dependent, especially at serum concentrations in the high range. Most patients are optimally treated with serum valproic acid concentrations between 300 and 600 μmol/L (50 to 100 μg/mL).[4,8,55,71]

Ethosuximide elimination is slow, and its serum concentration is relatively stable even if the drug is given once a day. The half-life in children, however, is considerably shorter than in adults. Due to interindividual differences in ethosuximide pharmacokinetics, it is not possible to predict the serum concentration following a certain dose. In most patients, therapeutic effects are observed at serum concentrations in the range of 300 to 600 μmol/L (40 to 80 μg/mL).[4.55,63,71]

Clonazepam serum concentrations are linearly correlated with dose. The half-life is shorter in children than in adults, and serum concentrations are lowered by concomitant use of enzyme-inducing AEDs. In general, a clear relationship between serum concentration and effect has not been established. In patients treated with therapeutic doses of clonazepam, serum concentrations on the order of 60 to 220 nmol/L (20 to 70 ng/mL) have been reported.[20,40,55]

Clobazam is mainly metabolized to its desmethyl metabolite, which is also pharmacologically active. The metabolite has a much longer half-life than clobazam, and its steady-state serum concentrations are at least eight times higher than those of the parent compound. In general, clinically significant pharmacokinetic interactions between clobazam and other major AEDs are uncommon, although clobazam metabolism is inducible. Because of the active metabolite and development of tolerance to the adverse and, at times, therapeutic effects, no clear correlation exists between serum clobazam concentrations and effect. In patients treated with therapeutic doses of clobazam, serum concentrations on the order of 0.1 to 1.0 μmol/L (30 to 300 ng/mL) for the parent drug and 1 to 10 μmol/L (300 to 3,000 ng/mL for the metabolite desmethylclobazam have been reported.[8,55,83]

Primidone is rapidly metabolized to two active metabolites, phenobarbital and phenyl-ethyl-malonamide (PEMA), and both compounds accumulate during long-term treatment. Primidone probably also has an anticonvulsant effect of its own. There is a great individual variability in the relationship between primidone dose and the concentration of the drug and its metabolites. Because primidone is metabolized to phenobarbital, most often the phenobarbital concentration is used as a guide to therapy. Primidone serum concentrations per se are usually in the range of 30 to 60 μmol/L (5 to 10 μg/mL).[4,90]

Newer Antiepileptic Drugs

Lamotrigine has several pharmacokinetic characteristics that suggest that its use can be optimized by applying TDM. Its

serum half-life is shortened by enzyme-inducing AEDs, is considerably prolonged by valproic acid, and is intermediate in patients treated with both enzyme-inducing AEDs and valproic acid. Lamotrigine clearance is higher in children and somewhat reduced in elderly patients. There are large interindividual variations in serum concentrations in patients on monotherapy, and the kinetics is also influenced by interacting AEDs, pregnancy, and oral contraceptives.[5,55,71] In most studies there is an overlap in serum lamotrigine concentrations between responders and nonresponders and also between patients with or without side effects. However, the risk of toxicity increases considerably with concentrations >60 μmol/L (15 μg/mL), although such concentrations seem to be tolerated in many patients. In patients treated with therapeutic doses, serum lamotrigine concentrations on the order of 10 to 60 μmol/L (2.5 to 15 μg/mL) have been reported.[36,37]

Topiramate shows a wide scatter of serum concentrations among patients taking the same dose and wide variation in the relationship between its concentration and therapeutic or toxic effects. Children require a higher dosage in terms of milligrams per kilograms of body weight than do adults to obtain similar serum concentrations. Serum concentrations of topiramate are lowered by enzyme-inducing AEDs.[3,71] In patients treated with therapeutic doses, serum topiramate concentrations on the order of 15 to 60 μmol/L (5 to 20 μg/mL) have been reported, even though most patients will probably have concentrations in the low to mid range with the dose regimens used today.[15,36,37,101,108]

Felbamate disposition is variable. The half-life is shorter in patients on enzyme-inducing AEDs, somewhat prolonged by valproic acid, and longer in renally impaired patients. Clearance is higher in children and lower in the elderly. Monitoring felbamate concentrations can be useful because serum concentrations are not easily predicted from administered doses, especially in patients on polytherapy.[3,33,55,71] In patients treated with therapeutic doses, serum felbamate concentrations on the order of 125 to 250 μmol/L (30 to 60 μg/mL) have been reported.[36,37]

Oxcarbazepine, the 10-keto analog of carbamazepine, is rapidly metabolized to the pharmacologically active MHD (10-hydroxycarbazepine). Elimination is faster in children 2 to 6 years of age than in older children and adults. Conversely, MHD clearance is reduced in the elderly. The metabolism of MHD is enhanced by enzyme-inducing AEDs, which decrease the MHD concentration/dose ratio.[5,55,71] Retrospective analysis of a large number of patients showed a mean serum MHD concentration of 20 μmol/L (5 μg/ml) (range: 12 to 160 μmol/L [3 to 53 μg/mL]), but no detailed correlations with response were presented.[24] In a small study of seizure-free patients the mean MHD concentration was 64 μmol/L (16 μg/mL) (12 to 128 μmol/L [3 to 32 μg/mL]), which was similar to that observed in nonresponders.[99] Somewhat higher concentrations have been reported in children in whom side effects were more frequent at serum concentrations of 140 (35 μg/mL) to 160 μmol/L (40 μg/mL). In patients treated with therapeutic doses of oxcarbazepine, serum concentrations of MDH are on the order of 50 to 140 μmol/L (12 to 35 μg/mL).[36,37]

Zonisamide pharmacokinetics does not appear to show major deviations from linearity at daily doses up to 10 to 15 mg/kg. Its half-life is considerably shortened by enzyme-inducing AEDs, and children require higher doses in terms of milligrams per kilogram body weight than do adults to achieve any given serum concentration. A considerable overlap of serum concentrations between seizure-free patients and non-responders, or between patients with and without adverse effects, has been observed.[53,55,71] No clear relationship between zonisamide serum concentrations and clinical response has been established, but a range of 45 to 180 μmol/L (10 to 38 mg/mL) has been reported in patients treated with therapeutic doses.[36,37]

Levetiracetam excretion is primarily renal. Its half-life is shorter in children and somewhat prolonged in elderly patients. Children seem to need higher doses of levetiracetam in terms of milligrams per kilogram of body weight than do adults to achieve a given drug concentration. Enzyme-inducing AEDs can moderately lower serum levetiracetam concentrations.[16,55,58,71] The role of TDM for levetiracetam has not been established, but there might be useful applications in addition to ascertaining compliance. In patients treated with therapeutic doses, serum levetiracetam concentrations on the order of 35 to 120 μmol/L (8 to 26 μg/mL) have been reported.[36,37]

Gabapentin pharmacokinetics can be very variable, possibly because the absorption mechanism from the gut becomes saturated. The drug is excreted renally, and a decrease in dose may be necessary in elderly patients. Gabapentin has a low drug interaction potential. Cimetidine can reduce the renal clearance, however, and antacids can reduce the absorption of gabapentin.[49,55,71] A wide range of serum concentrations associated with seizure control has been observed. In patients treated with therapeutic doses, serum gabapentin concentrations are on the order of 70 to 120 μmol/L (12 to 20 μg/mL).[36,37]

Tiagabine is extensively metabolized and has a short half-life (5 to 8 hours). Clearance is higher in children than in adults, and its metabolism is inducible. There are large intraindividual and interindividual variations in serum concentration. Due to the short half-life, there are also large tiagabine interdose fluctuations in serum concentration. The high protein binding with consequent variability in the fraction of unbound, pharmacologically active drug might also be important.[55,71] Information on concentration–effect relations with tiagabine is scarce, and difficulties with measuring its low serum concentrations have resulted in poor analytical reliability in some laboratories.[102] In one study, trough concentrations >96 μmol/L (40 μg/mL) were reported to be associated with the greatest reduction in seizure frequency.[86] In patients treated with therapeutic doses, serum tiagabine concentrations are on the order of 50 to 250 nmol/L (20 to 100 μg/mL).[36,37]

Pregabalin is excreted renally in unchanged form, and pharmacokinetic drug–drug interactions involving pregabalin are therefore unlikely. Dose adjustment, however, might be necessary in patients with renal insufficiency.[8] Data on TDM for pregabalin are scarce. Berry and Millington[10] reported on concentration measurements in predose samples from a group of patients escalated up to a maximum of 600 mg daily and found a range of 18 to 52 μmol/L (2.8 to 8.2 μg/mL) at steady state.

Vigabatrin is not metabolized and is mainly excreted unchanged in urine. A dose reduction is required in patients with impaired renal function. The half-life of vigabatrin is very short (6 to 8 hours), and drug–drug interactions are minimal.[55,71] Monitoring the serum concentrations of vigabatrin may not be of great value as a guide to therapy due to its irreversible mechanism of action. Because of long-lasting inhibition of gamma-aminobutyric acid transaminase, the antiepileptic effect of vigabatrin outlasts its presence in serum. However, it might be useful to employ serum vigabatrin concentrations as a check on recent compliance.[36,37]

Summary and Conclusions

The use of TDM, which entails that AED concentrations are always interpreted in conjunction with the clinical status of the patient, can provide important information in making therapeutic decisions (Table 4). Because clinical effects can be more closely related to drug concentrations than to dose, drug concentrations can be used as surrogate for both therapeutic and adverse effects. Interpretation of drug concentrations

requires an understanding of both the pharmacokinetics and pharmacodynamics of the drugs and is made easier if simple dosage regimens are used in conjunction with optimum timing of blood sampling. For highly protein-bound AEDs (e.g., phenytoin and valproic acid), altered plasma protein binding is an important cause of misinterpretation of serum drug concentrations, and in certain clinical settings (e.g., pregnancy and postsurgery) patient management may be best guided by monitoring free (non–protein-bound) concentrations. The indications for monitoring the new AEDs are the same as for older-generation AEDs, although for newer AEDs the optimal ranges of serum concentrations have not been extensively investigated. In any case, for all AEDs the therapeutic range be considered should not as a concentration interval appropriate for all patients, but instead as an expression of the probability of beneficial effects with an acceptable risk of toxicity in a population. Indeed, because the optimal concentration varies among patients, the concept of an *individual reference concentration* is advocated. Furthermore, it is increasingly being recognized that the lower limit of the therapeutic range is of little value because many patients do well with lower serum concentrations.

Chapter 104

Efficacy of Antiepileptic Drugs

W. Edwin Dodson

Martin J. Brodie

Introduction

Since 1962, when the Kefauver-Harris Drug Amendments were passed, proof of effectiveness and evidence of reasonable safety have been required to obtain regulatory approval from the Food and Drug Administration (FDA) before a drug can be marketed to the public in the United States. Previously, drugs could be marketed if they were safe and contained what the label indicated, but proof of efficacy was not required. Hence, the antiepileptic drugs that were available before 1962 came to market without scientific studies that established their efficacy in preventing seizures.

The efficacy of an antiepileptic drug is its ability to prevent or interrupt seizures. However, efficacy is only one of several components of a drug's actions that contribute to its clinical usefulness or clinical effectiveness. Whereas the information about efficacy as an isolated variable can be determined readily in experimental animals, actual measures of efficacy generally cannot be obtained in humans because assessment of seizure-suppressing activity is confounded by the occurrence of adverse side effects. As a result, in patients, the term *clinical efficacy* or *clinical effectiveness* is more appropriate even though the term *efficacy* is widely used colloquially.[46] This chapter addresses basic aspects of drug efficacy as well as the clinical effectiveness of antiepileptic drugs in clinical settings.

Basic Measures of Drug Efficacy

Efficacy has two key dimensions: (a) potency and (b) spectrum of activity against different types of seizures. Efficacy is quantified by the term *drug potency*, which refers to the amount of a drug that is needed to produce a defined action. The less of a drug required, the higher is the potency. In measuring antiepileptic action, drug potency can be expressed in several ways. One of the most common ways is to describe the dose of drug that prevents seizures in 50% of experiments, which is abbreviated as ED_{50}. Potency could also be expressed in other ways, such as the minimally effective dose or as the concentration of medication that produces the desired action.

In animal models used for screening antiepileptic drugs, seizures are induced by various techniques such as electroshock or chemoconvulsant administration. These models provide standardized systems in which progressively increasing doses of a drug can be evaluated (Fig. 1). However, due to concerns about drug-induced adverse effects that might occur when very high doses are administered to humans, a comprehensive assessment of efficacy per se cannot be obtained in people. Instead, what is measured and what is most important in patients is *clinical effectiveness*.

Drug toxicity can be quantified in animals using approaches similar to those used to determine efficacy except that the experimental endpoint is a toxic outcome. The rotorod test is a widely used measure of toxicity for antiepileptic drugs in animals. Although this test has little relevance to humans, we mention it here because it has a well-defined outcome and illustrates an idealized measure of drug toxicity. The experimental animal, usually a mouse, is placed on top of a slowly rotating rod. Normal mice can maintain their balance on the rod indefinitely; intoxicated mice fall off the rotating rod, thereby providing a clear experimental endpoint of drug intoxication. By administering progressively larger doses to groups of mice and then testing their ability to stay atop the rotating rod, one can find the dose that produces toxicity in 50% of the mice (TD_{50}). No such clear-cut test exists for evaluating antiepileptic drug toxicity in humans. Furthermore, adverse effects of medications in rodents generally provide little insight into the toxicities that occur in people.

Whereas side effects impose limits on the dose of a drug that can be given, to determine the usefulness of a drug, information is needed about both drug efficacy and drug toxicity. The parameter that combines these measurements is the therapeutic index (TI). The therapeutic index is the ratio of the dose that produces toxicity in half of animals to the dose that is effective in half ($TI = TD_{50} \div ED_{50}$). The larger the therapeutic index, the wider is the margin of safety for the drug and the more likely it is that it will be clinically useful. The wider the therapeutic index, the higher is the percentage of people who are likely to benefit without limiting adverse effects. FIGURE 1 was constructed for a drug with a relatively narrow therapeutic index of 1.5 and results in a clinical dose–response curve on which the best-tolerated dose would benefit only 60% of patients.

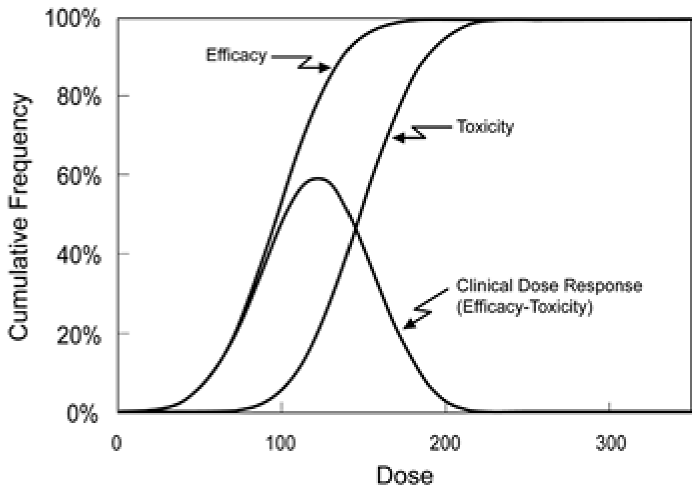

FIGURE 1. Idealized dose–response curves for efficacy and toxicity for a drug with an ED_{50} (dose of drug that prevents seizures in 50% of experiments) of 100 mg and a TD_{50} (dose that produces toxicity in 50% of subjects) of 150 mg, resulting in a therapeutic index of 1.5. The resulting clinical dose–response cure was obtained by subtracting the toxicity curve from the efficacy curve at various doses.

Table 1. Factors that influence antiepileptic drug effectiveness

Toxicity profile and therapeutic index
Commercial availability
Cost

The therapeutic index indicates the potential clinical effectiveness of a drug in patients. The limit of clinical usefulness of a drug is determined by its tolerability, where the term *tolerability* describes the collective toxicities of a drug that would lead to its being discontinued. In this chapter, the term *clinical effectiveness* is the clinical counterpart of the basic concept of the therapeutic index.

The critical contribution of toxicity to the clinical usefulness of a drug is illustrated by the drugs clonazepam and valproic acid. Among the available antiepileptic drugs, clonazepam is most potent, but it is among the least useful because of its toxicity profile and low tolerability. For practical purposes, clonazepam has an antiepileptic therapeutic index of approximately 1, which is to say that the dose that prevents seizures also causes adverse effects. On the other hand, compared to other antiepileptic drugs, valproic acid has low potency, but it is highly useful because of its even lower toxicity and better tolerability. This results in a larger therapeutic index than that of clonazepam and greater clinical usefulness. Thus, the relationship between efficacy and toxicity—the

therapeutic index—is a key determinant of a drug's effectiveness and practical value. Whereas individual people differ in their sensitivity to developing side effects to a given drug, from the perspective of an individual person, the clinical effectiveness of the drug is related to the risk-to-benefit ratio for that individual.[24,46,52]

Besides the efficacy and tolerability of an antiepileptic drug, several other factors help to determine the extent to which a drug is clinically useful (Table 1). These can be categorized as patient related, epilepsy related, and drug related. Epilepsy-related factors dictate the clinical conditions in which a drug might be used. Patient-related factors influence how a drug might be suited for use in various groups of patients. Drug-related factors, such as the pharmacokinetics of the drug, affect the drug's ease of administration and have a major impact on a drug's usefulness. Drug availability and cost put practical limits on drug usefulness as well.

Methods for Establishing Drug Effectiveness

Determining the effectiveness of an antiepileptic drug is a lengthy process that evolves over time. Preclinical studies that are done to satisfy regulatory requirements start with dose-ranging and other pilot studies that provide insight into how to design scientifically sound clinical trials that can document beneficial drug action. A minimum of two clinical trials must be done, but often several more are completed before a drug is approved for public use.

Drug approval requires randomized, controlled trials. These are conducted in groups of volunteer patients with defined clinical features that are selected to minimize subject-to-subject variation and to conform to ethical human studies guidelines. Experimental controls are essential in new drug evaluation because in even the most severe forms of epilepsy, seizure frequencies fluctuate over time, resulting in appreciable placebo effects. For example, cinromide, a drug investigated in the 1970s and 1980s, appeared promising in pilot studies in preventing frequent seizures associated with the Lennox-Gastaut syndrome.[65] A randomized trial, however, disclosed that cinromide's effect was no different than placebo, and hence it was shown to be ineffective.[16]

A wide array of research designs has been used to establish antiepileptic effectiveness in humans (Table 2). Different

research designs require different endpoints depending on considerations such as the duration of epilepsy among patients (chronic vs. new onset), seizure frequency, seizure severity, and characteristics of the group selected for study. For both practical and ethical reasons, during the initial phases of new drug evaluation, studies are conducted in patients with severe epilepsy whose seizures have not been controlled with available medications.

Time to *n*th seizures

Duration of therapy (life-table analysis)

Study Designs and Experimental Endpoints

Drug testing starts in patients who have epilepsy with uncontrolled seizures. Whereas these patients have the most to gain by participation in drug trials, the refractory nature of their seizures to medication makes them a challenging group in whom to show effectiveness of a new drug. The most common research design is adjunctive (also called add-on) parallel-group design in which a group of patients with uncontrolled epilepsy are randomly assigned to treatment with the investigational agent or with an inactive placebo. Later in the drug development process, the drug may be evaluated as monotherapy depending on the promise of the drug in terms of its clinical effectiveness and the manufacturer's priorities and resources. As discussed later, despite extensive preclinical testing, information about how to use new drugs in the population at large is patchy and incomplete at the time when drugs are first approved for marketing.[22]

Traditional measures of antiepileptic drug effectiveness in adjunctive studies include percentage seizure reduction from the baseline period, percentage of patients rendered seizure free, and responder rate. Change in seizure frequency is the most widely used outcome measure and is usually expressed as mean or median percentage reduction. This measure compares the seizure frequency during the treatment period to the seizure frequency during the baseline period before the investigational drug is administered. In add-on trials of new drugs, so few patients become seizure free that cessation of seizures is rarely a useful outcome measure.[15]

The responder rate is a widely used outcome when change in seizure frequency is the primary outcome measure.[1,3,45] This is the proportion of subjects whose seizure frequency decreases by various percentages from the baseline period. The proportion that is most often reported is the 50% responder rate. The 50% responder rate is the percentage of patients who experience a 50% or greater reduction in seizure frequency while taking the investigational compound as compared to their baseline seizure frequency. Other levels of response such as the 75% responder rate can be used as well,[8,19,35,48] but the 50% rate appears most often because higher responder rates are uncommon in new antiepileptic drug trials. Representative 50% responder rates during clinical trials of newer antiepileptic drugs introduced since 1992 are in the range of 20% to 50%.

Seizure severity outcomes depend on the use of rating scales or seizure scores. A number of scales have been developed to evaluate seizure severity, adverse drug effects, and overall quality of life, but there is no consensus regarding which scales are most useful. Overall, however, the cessation of seizures has the greatest beneficial impact as measured by quality-of-life scales.[13] On most scales, frequent and generalized convulsive seizures are scored as being more severe than infrequent seizures and nonconvulsive partial or absence seizures.[7,14,46,63] Note that scales for quantifying adverse effects can be better predictors of a person's completing a study than seizure counts. For example, quality-of-life measurements using the Side Effect and

Life Satisfaction (SEALS) Inventory correlated better with study completion than seizure counts in a double-blind comparison of lamotrigine and carbamazepine.[29]

The response ratio has been used infrequently as an investigational endpoint, mainly for gabapentin trials. It is the difference in seizure frequencies during the treatment period minus the frequency during baseline, which is then divided by the sum of the seizure frequencies during both periods.[26,27] The response ratio has no dimensions, and results expressed in this way are intuitively difficult to use.

The outcome of time to the *n*th seizure has also been used in presurgical monotherapy trials.[21,46,51,53,54] This endpoint is versatile, and it offers a measure of protection for patients by limiting the number of seizures that they need to experience before exiting the study and moving on to another treatment. Whereas the time to *n*th seizure outcome is useful in establishing drug effectiveness, it has not been used widely because allowing patients to have seizures while receiving only placebo or a suboptimal therapy, albeit under watchful supervision, introduces risk and raises ethical concerns.

Besides ethical concerns, there are methodologic pitfalls to the time-to-*n*th-seizure endpoint. Whereas time to *n*th seizure can rapidly detect antiepileptic effects in patients with high seizure frequencies, it is not useful for comparing the effectiveness of different drugs. Moreover, applying this endpoint can also be tricky, and if it is not used properly, a beneficial drug action can be missed. For example, if the *n*th-seizure criterion is set at, say, the second or third seizure and if the investigational drug is more effective than expected, the number of seizures that occurs in the study may be insufficient to permit the detection of a difference between treatment groups. This outcome occurred with a monotherapy trial of topiramate in which the time of the second seizure was chosen as the primary outcome variable but the patients had insufficient numbers of seizures during the study.[31] When the study was repeated with the endpoint set to time of the first seizure, the effectiveness of the drug was documented.[4]

Monotherapy Trials

Some drugs that show promise in polytherapy or adjunctive trials are subsequently tested in monotherapy. Whereas add-on study designs actually compare various drug combinations, they do not scientifically establish the effectiveness of drugs used alone in monotherapy. Establishing a drug's effectiveness in monotherapy requires randomized, controlled trials of the drug given alone. Monotherapy can be approached by eliminating other drugs from multidrug regimens or can be evaluated de novo in patients who are untreated.

The optimal design of monotherapy trials is a matter of ongoing discussion. In the United States, the FDA requires that to show efficacy the investigational compound must be superior to a comparator compound. A demonstration of equivalence to an established drug is not sufficient. Even when an active comparator is used (usually a suboptimal dose of an established drug), the investigational agent must demonstrate superiority to establish its effectiveness in monotherapy. Hence monotherapy trials for regulatory purposes in the United States require the administration of either placebo or a suboptimal dose of an established drug. As a result, ethical concerns have been raised when patients are randomized to ineffective doses of drug or placebo and thereby put at risk to the adverse consequences of recurrent seizures.[5] Unlike control patients in add-on trials, who continue to take their baseline medications, control patients in monotherapy trials may have little or no antiepileptic protection during the study.

Evolution of Clinically Relevant Prescribing Information

Although the initial randomized clinical trials provide essential data to justify a new drug's being marketed, information about the effectiveness of new drugs is incomplete when they are introduced to market.[46] This occurs for several reasons. Relatively few people will have taken the medication before it comes to market. Those who took the drug will have had atypically severe epilepsy due to high-frequency seizures with seizures that were previously medication resistant. This situation favors the use of higher doses of medication than might be required by people with milder forms of epilepsy. Similarly, patients with long-standing epilepsy who have taken antiepileptic drugs for long periods of time are likely to tolerate adverse drug effects differently than individuals who are more pharmacologically naive.[30] Finally, the duration of exposure to investigational agents in clinical trials is relatively brief compared to long-term chronic therapy. Due to differences between the way drugs are administered in regulatory trials compared to how drugs are administered in clinical practice, there is a great deal to be learned about dose and administration schedules after a drug comes to market.[46]

As experience accumulates after a drug is marketed, the picture of a drug's clinical effectiveness in the general population evolves and becomes more complete. Gaps in knowledge regarding both the efficacy and tolerability begin to be filled in as more people are treated for longer periods of time. During the early months and years when experience is increasing, information about proper dose is refined and the incidence, severity, and demographics of the drug's tolerability become better known. The process unfolds over a period of years and, in some cases, decades, causing perceptions about the effectiveness of the drug to evolve and leading to refinements in recommendations for administration.

In regulatory trials, patients take predetermined, target doses that are achieved in uniform time periods according to the research protocol. In the clinic, the tried and true approach is to “start low and go slow,” starting with a below-average dose and then slowly escalating it until either seizures are controlled or the person develops intolerable adverse effects signaling that the drug is ineffective. A slow, stepwise escalation of dose has several advantages. It allows individual patients time to develop tolerance to side effects, thereby optimizing the drug's tolerability. It also lets the clinician individualize the dose as necessary due to pharmacokinetic variability and interpersonal variability in responsiveness to the drug's actions. The go slow approach to dose escalation helps to improve seizure control even among people with chronic, severe epilepsy.[34]

The extent to which dosing recommendations change after a drug comes to market can be dramatic. In the case of gabapentin, initially recommended doses of approximately 1,200 mg/d were generally too low as compared to current target doses of 3,600 mg/d. For topiramate, dosing guidelines initially were too high, approximately twice as high as currently recommended starting doses. Early investigations of topiramate evaluated doses of 1,000 mg/d,[58] and when topiramate first went to market, the recommended dose of 400 mg/d was twice as high as the current generally recommended initial target dose of 200 mg/d.[18,57] For lamotrigine, the recommended schedule for implementing therapy was slowed after recognition of the heightened risk of Stevens-Johnson syndrome when the dose was escalated more rapidly. Hence, after a drug comes to market, guidelines for administration nearly always change as experience identifies areas for needed refinements.

Drug tolerability is another area in which knowledge increases because so few people have taken drugs during premarketing drug evaluation.[22,62] Regulatory studies customarily require that the drugs be administered to a few thousand people, typically 2,000 to 5,000. If a drug causes an adverse effect at a frequency of <1 in 5,000, that adverse effect is likely to go undetected in preclinical drug trials. As a rule of thumb, adverse effects usually are not detected until at least three times as many people as the frequency of the side effect have been ex-posed. For example, for a side effect that occurs in 1 per 5,000 patient exposures, 15,000 or more people would need to be exposed to have a 95% probability of at least 1 patient developing such an effect. Furthermore, whether the side effect gets attributed to the medication is influenced by other factors, including its severity and the sensitivity of the surveillance system. Even when adverse effects are severe and dramatic, they can go unrecognized for surprisingly long periods of time. With the drug felbamate, which caused fatal adverse effects in 1:2,500 to 1:5,000 people, approximately 100,000 people were exposed in the first year after the drug went to market before the alarm was sounded. When a side effect such as osteopenia is subtle and slow to develop, extremely long periods of time elapse before the full picture is discerned. It took years before visual changes, endocrinologic disturbances, and reduced bone density were recognized as consequences of treatment with vigabatrin, valproic acid, and phenytoin, respectively.

Ultimately a drug's adverse effect profile—its tolerability—strongly shapes perceptions of its effectiveness and clinical usefulness.

Comparisons of Antiepileptic Drugs

Which drug is best for patients who have a specific seizure type or type of epilepsy? With newer drugs, the question is unresolved. The best way to answer this question is to compare different drugs in the same investigation, so-called head-to-head comparisons. For drugs that were introduced before 1990, the U.S.

Veterans Administration (VA) collaborative studies provided the gold standard for how to approach the question of drug superiority.[42]

The landmark studies sponsored by the VA compared the most commonly prescribed antiepileptic drugs in the 1980s administered in monotherapy by using life-table data analysis. Among all the methods for comparison of antiepileptic drugs, many feel that the duration of continuation of a drug during a trial expressed in a life table is the best measure that combines efficacy and toxicity in order to demonstrate clinical effectiveness.[46] Life-table analysis measures how long patients continue on an investigational agent and reflects the net consequences of beneficial and negative attributes of a drug. Results are expressed as the percentage of patients continuing treatment at periodic time points after the initiation of therapy.[40]

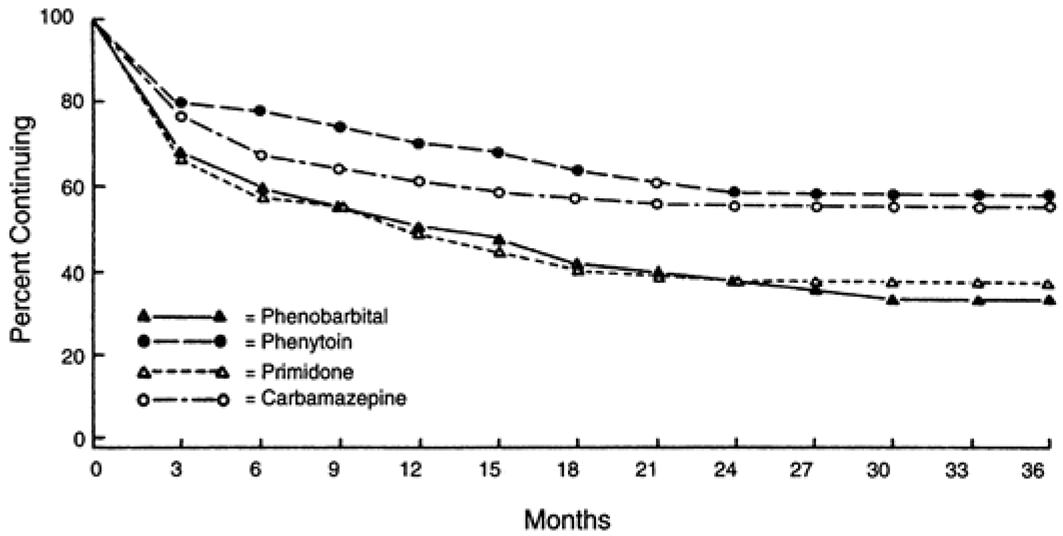

FIGURE 2. Veterans Administration randomized, controlled trial of carbamazepine, phenobarbital, phenytoin, and primidone in previously untreated or undertreated epilepsy. Cumulative percentage of patients with partial seizures that were treated with each drug during 36 months of follow-up. There were 105 patients at 12 months, 67 at 24 months, and 37 at 36 months. (From Mattson RH, Cramer JA, Collins JF, et al. Comparison of carbamazepine, phenobarbital, phenytoin, and primidone in partial and secondarily generalized tonic–clonic seizures. *N Engl J Med*. 1985;313(3):145–151; with permission.)

The first of the VA collaborative studies became available in 1985 (Fig. 2).[42] The investigators enrolled 622 adults, who were randomized to treatment with phenytoin, carbamazepine, phenobarbital, or primidone and then followed for up to 36 months. Although all four drugs prevented generalized tonic–clonic seizures equally well, carbamazepine and phenytoin were best at eradicating partial seizures (FIGURE 2). In this study as in others that followed subsequently, adverse effects that led to discontinuation of therapy were the principal factors that differentiated the four drugs.[61] Phenytoin and carbamazepine had superior tolerability as compared to phenobarbital and primidone, with approximately 60% of patients continuing treatment indefinitely with phenytoin or carbamazepine as compared to only 40% to 50% of subjects continuing with primidone or phenobarbital.[42]

P.1189

In the second VA collaborative study, a similar approach was used to compare valproate and carbamazepine among patients with partial and secondarily generalized seizures. As in the previous study, the drugs performed equally well in preventing secondarily generalized tonic–clonic seizures, but carbamazepine was superior against partial seizures on four of five outcome variables and had fewer chronic side effects.[41] Thus, valproate was documented to have a broad range of antiepileptic action but was less effective than carbamazepine at preventing partial seizures.

Direct Comparisons of Newer Antiepileptic Drugs

Although there have been comparisons of older versus newer drugs, there are few head-to-head studies comparing antiepileptic drugs introduced since 1992, and none has been as comprehensive as the earlier VA trials. In some head-to-head comparisons of different antiepileptics, no differences were found in either seizure prevention or tolerability. For example, when lamotrigine and gabapentin were administered to patients with new-onset epilepsy, each prevented seizures in >50% of subjects and each was well tolerated.[10] In other comparisons, oxcarbazepine had superior tolerability versus phenytoin in children; carbamazepine was better tolerated than vigabatrin and remacemide.[29] Although comprehensive expert reviews of data from multiple studies have not established any antiepileptic drug as being superior to others, many studies have identified differences in tolerability as indicated by different rates of discontinuation of the medication, patient preference, and results of psychological testing for adverse cognitive effects.

Studies have shown topiramate and tiagabine to have cognitive disadvantages in acute and chronic dosing as compared to lamotrigine, gabapentin, and valproic acid, although in some cases the doses of topiramate were higher than those currently recommended.[25,39] These types of studies also underscore the importance of target doses and dose escalation rates, with lower doses and slower dose escalation being associated with better tolerability. Nonetheless, in a comparison of lamotrigine and topiramate in which each was taken for 12 weeks, 70% of patients preferred lamotrigine.[64] Furthermore, normal volunteers who took 300 mg of lamotrigine and 300 mg of topiramate in a crossover design had superior scores on various cognitive tasks while taking lamotrigine.[44] Similarly, compared to the usual recommended dose of gabapentin of 3,600 mg/d, 400 mg/d of topiramate had a negative impact on cognitive test results.[60] In yet another trial, doses of 400 mg/d of topiramate were associated with worse performance on the Symbol Digit Modalities Test and the Controlled Oral Word Association Test as compared to valproic acid taken at 2,250 mg/d.[43] Similarly, more-negative scores were associated with topiramate 200 to 400 mg/d than with valproate 1,800 mg/d, but the differences were minimized by slow escalation of dose.[2] At lower daily doses of 100 to 200 mg, topiramate has been tolerated better.[2] When compared to carbamazepine 600 mg/d and to valproate 1,250 mg/d, topiramate 100 mg/d was equally effective and had fewest discontinua-tions.[57]

Differences in tolerability of antiepileptics have been found in other investigations. For example, lamotrigine was less likely to be withdrawn than carbamazepine.[28] Different adverse drug effects vary in the extent to which they abate over time due to the development of tolerance. Whereas some adverse effects can be minimized by slow escalation of drug doses, others, such as topiramate-associated paresthesias, are more likely to be persistent.[37]

In 2007, the first monotherapy trial to be published that followed the European regulatory guidelines recommending demonstration of noninferiority of the test product with an acknowledged standard at individually optimized dosages using clinically relevant endpoints compared levetiracetam with controlled-release carbamazepine.[11] Both treatments produced similar seizure freedom rates in adults with newly diagnosed epilepsy at optimal dosing in a setting mimicking clinical practice. This trial has confirmed in a randomized, double-blind setting the uncontrolled observations that most people with newly diagnosed epilepsy respond to their first antiepileptic drug at low dose.[47] The results also support the assertion that optimal doses of antiepileptic drugs identified from randomized adjunctive studies in refractory epilepsy are not applicable to monotherapy trials in a newly diagnosed population.[53]

Indirect Comparisons of Antiepileptic Drugs

Drug trials done for regulatory purposes are poorly suited for direct comparisons of antiepileptic drugs for the reasons noted previously, mainly because the patients in whom drugs are evaluated have severe epilepsy and are not representative of the population at large with epilepsy. In addition, innovations in study designs over the last two decades have facilitated more expedient documentation of antiepileptic efficacy by conducting drug studies in patients with high seizure frequencies such as presurgical patients and children with the Lennox-Gastaut syndrome, but the resulting information has little direct applicability to a majority of patients.[9,17] Nonetheless, in the absence of studies that directly compare various antiepileptic drugs, other approaches have been taken using available information from placebo-controlled trials for comparison using meta-analysis, systematic review, and guideline development in attempting to identify superiority among newer drugs. All of these approaches depend on comprehensive review and interpretation of existing studies by experts in the field.

These approaches start with convening a knowledgeable panel to review all of the evidence, including unpublished studies, grading the evidence as to its scientific rigor and freedom from bias, and then crafting recommendations based on published standards for guideline development. Meta-analysis provides a statistical method for combing results from several studies for purposes of comparing different therapeutic agents.[56] In this approach, a question is posed and then a systematic review of available research is conducted to glean the relevant information regarding a common endpoint such as the 50% responder rate. The studies are evaluated to determine whether they meet quality standards for inclusion, and then the results are expressed in a common format or scale such as the odds ratio or the number needed to treat.[66,67] Most antiepileptics developed since 1992 have been compared using this approach.[50]

Although meta-analytic comparisons have not revealed statistically significant overall superiority, sizeable differences have been noted and consistent trends in differential tolerability have been observed. For example, no statistically significant differences were found in comparisons of 50% responder rates from studies of gabapentin, lamotrigine, tiagabine, topiramate, vigabatrin, and zonisamide in either responder rates or indices of tolerability.[56] In other analyses, the differences point to substantial differences in tolerability. The least tolerable drug was fourfold as likely to be stopped as the best-tolerated drug.[12] For example, in one analysis, the most efficacious drug—topiramate—was twice as effective as the least efficacious—gabapentin—whereas the least tolerable drug—zonisamide—was fourfold as likely to have been discontinued during clinical trials as the most tolerable drug—lamotrigine.[12] Other comparisons of topiramate and lamotrigine versus phenobarbital reveal no differences in seizure control, but adverse effects differentiated the drugs, with phenobarbital faring worst.[36]

Systematic Reviews and Sponsored Guideline Development

Since the 1990s, there have been a number of systematic reviews of various trials of new antiepileptic drugs. The first group to undertake these comparisons was the Cochrane Collaboration (http://www.cochrane.org), which was founded in 1993. Other analyses have been sponsored by the American Academy of Neurology, the American Epilepsy Society, the Child Neurology Society, the National Institute for Clinical Excellence Committee in the United Kingdom, the Scottish Intercollegiate Guidelines Network, and the International League Against Epilepsy.[32] Each of these organizations maintains a website that should be consulted for up-to-date recommendations, reviews, and guidelines (Table 3). A recent search of the Cochrane Database for "epilepsy" resulted in 132 reports, whereas a Cochrane Database search for antiepileptic drugs found 39 citations. In balance, these reviews illustrate the paucity of comparable information in support of claims of overall superiority of any particular agent. Unfortunately, they have not provided a means for discerning the superiority of new agents.[38]

All of the newer antiepileptic drugs introduced since the VA-sponsored multicenter studies have been effective in partial and secondarily generalized seizures. Some drugs, such as lamotrigine, have broader spectra of activity against absence seizures as well. As with the older agents, however, the efficacy of the new compounds is curtailed by adverse effects. The new agents include vigabatrin, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, topiramate, tiagabine, and zonisamide. Among these, use of felbamate and vigabatrin has been so diminished by serious toxicity that they will not be mentioned further. Similarly, there is little to say about pregabalin because it was only recently brought to market. Finally, some guidelines do not consider drugs that are unavailable in some countries. These include vigabatrin, felbamate, sulthiame, and clobazam.

These labor-intensive reviews have resulted in guidelines for newer antiepileptic drugs introduced since 1992 in various types of epilepsy.[23,24] The guidelines that have been developed thus far have been less effective at differentiating new drugs than the direct head-to-head comparisons in the VA-sponsored trials. As a result, current guidelines are better able to summarize which drugs are effective than they are to identify a hierarchy of effectiveness. The clinical effectiveness of drugs varies according to patient characteristics, but there is little information that characterizes these differences. There are many reasons for this, but foremost is differential vulnerability of various groups to developing adverse effects. Many different groups can be identified with categories formulated by age, gender, comorbid disorders, and epileptic pathobiology. Among the elderly, drugs such as lamotrigine, gabapentin, and carbamazepine are no different in preventing seizures, but lamotrigine and gabapentin are better tolerated than carbamazepine.[59] In children, systematic reviews generally have not provided a basis for superiority claims. No differences could be documented for ethosuximide, valproate, or lamotrigine among children with absence seizures.[55] Among the drugs lamotrigine, topiramate, and felbamate, which have been shown

P.1191

to be effective adjuncts in Lennox-Gastaut syndrome, superiority could not be established, but felbamate-associated aplastic anemia and liver failure clearly are the most severe toxicities.[33]

The role of the pathobiology of seizures is rarely evident in influencing drug effectiveness but it is likely to be more important than is commonly appreciated. For example, in one consecutive series of 431 patients treated with topiramate, the presence of a left temporal lobe electroencephalographic (EEG) focus plus simple partial seizures increased risk of topiramate-associated word-finding problems more than fivefold.[49]

Based on the desire to consider more patient-related features in recommendations for drug utilization, an expanded approach has been to categorize patients according to additional features besides seizure type and type of epileptic syndrome.[6] The major additional feature used for the grouping devised by the National Institute for Clinical Excellence Committee in the United Kingdom is the duration of epilepsy, dividing patients into those with newly diagnosed partial seizures versus those with chronic, often refractory partial seizures. This is highly relevant clinically because new-onset seizures are much likelier to respond to any antiepileptic drug than are chronic seizure disorders that have proved resistant to previously administered drugs. Despite this laudable approach to refining the recommendations for drug utilization, the lack of supportive relevant information results in the recommendations from expert panels in the United States and the United Kingdom being quite similar.[6]

Summary and Conclusions

Although efficacy and toxicity of antiepileptic drugs are separable conceptually, in practice they are indivisible and jointly manifest as the therapeutic index or clinical effectiveness. Drug tolerability—the collective impression of a drug's adverse effects—is a major variable that limits the effectiveness of various drugs and distinguishes drugs from each other. The therapeutic index is the indicator of overall clinical usefulness of a drug. The best of the older antiepileptic drugs were clinically effective in only 60% of patients. Based on comparisons between older and newer drugs, newer drugs generally have improved tolerability, but direct head-to-head comparisons among newer drugs are lacking.

Effective doses of antiepileptics vary widely from one person to the next due to individual variability in seizure responsiveness to medication, vulnerability to adverse drug effects, and pharmacokinetics. Unfortunately, for individual patients, these characteristics often are unknown when therapeutic decisions must be made. As a result, doses of properly selected antiepileptics need to be individualized to achieve optimal effectiveness. Due to the inherently high failure rates of antiepileptic drugs, optimal treatment usually requires stepwise dose adjustment and careful follow-up.

Chapter 105

Dose-Related Side Effects

Dieter Schmidt

Steven C. Schachter

Introduction

Most antiepileptic drugs (AEDs) block seizure generation by altering membrane excitability, increasing postsynaptic inhibition, or modifying the synchronization of neuronal networks.[34] At therapeutic doses, this may also cause dysfunction of the central nervous system (CNS) and other organ systems, resulting in adverse effects that may be life threatening in rare cases.[2] Not surprisingly, adverse effects significantly impair health and well being, particularly in patients with refractory epilepsy.[16] Accordingly, the goal of treatment should be seizure freedom with no or a minimum of side effects. The patient should not suffer more from the side effects of treatment than from the epilepsy itself. Fortunately, most side effects of AEDs are predictable, dose dependent, and resolve with dose reduction. Furthermore, a number of unpredictable and idiosyncratic side effects of AEDs are also characterized by a dose–response relationship.[21] As a consequence, one major strategy to minimize dose-dependent side effects is to avoid overtreatment.[33,38] Overtreatment is broadly defined as unnecessary or excessive drug load in the management of epilepsy leading to a suboptimal risk-to-benefit balance.[40] The second major strategy is to recognize patients at increased risk for host-dependent side effects. In this chapter, we give an overview of dose-related side effects of drug treatment for epilepsy. Furthermore, we describe clinical scenarios that often lead to side effects and outline specific strategies to minimize or prevent dose-related side effects of AEDs.

The Scope of Dose-Related Side Effects

The scope of dose-related side effects ranges from rare serious and irreversible adverse events to common reversible side effects.[36] In a survey of >5,000 patients living in Europe, 88% of patients currently treated with AEDs reported at least one side effect, and 44% of respondents said they worried "a lot" or "some" about the possible side effects of their medication.[3] In different studies, the proportion of patients with side effects from AED therapy range from <10% to >70% depending on ascertainment procedures, definitions and measurements of side effects, characteristics of patients, AED dose, and duration of follow-up.[19,30] Important methodologic differences between studies hamper the comparison of side effects among AEDs.[12,19] Although no AED is free of adverse effects, some AEDs have fewer side effects than others, and there are clearly differences in the spectrum of adverse effects produced by specific agents (Table 1). These specific adverse effects influence drug selection in the individual patient. For example, AEDs causing weight gain may not be the best choice for overweight patients. On the other hand, agents that cause weight loss may not be ideal for an anorectic patient trying to gain weight. Finally, it has been suggested that some of the newer AEDs are better tolerated in clinical use than some of the older agents (Table 1).[16] When used appropriately, some of the newer AEDs undoubtedly offer relevant advantages in tolerability, in particular, less sedation and fewer metabolic changes, including fewer drug interactions.[19,38] However, when all newer AEDs were compared in a critical review of 80 randomized, controlled trials reporting adverse events of AEDs, there was no consistent or convincing evidence for better relative safety and tolerability of newer AEDs.[48] For full details of individual side effects and contraindications of each AED, see Summary of Product Characteristics of each AED and respective chapters of this and other books (e.g., Levy et al.[24]).

Irreversible Side Effects

Dose-related side effects may be irreversible and life threatening in some patients. Such cases include severe bradyarrhythmia after rapid intravenous phenytoin, pneumonia with nitrazepam treatment in young children, and respiratory arrest following high-dose intravenous benzodiazepines.[7] In addition, the serious Stevens-Johnson syndrome or the Lyell syndrome may be dose related. The highest incidence of Stevens-Johnson syndrome (1:50 to 1:300) is observed in association with use of lamotrigine in children, particularly when a high starting dose is used or valproate is given as comedication, which increases the serum concentration of lamotrigine by inhibition of its metabolism.[30] The incidence seems to be decreasing following introduction of a slower dose escalation and the wider use of lamotrigine monotherapy.[30] Further examples of irreversible side effects that may be dose related are malformations in the offspring following maternal exposure to AEDs, which is discussed in detail elsewhere in this book. For other irreversible and often severe side effects, a dose relationship is not well documented. This group, as shown in Table 1, includes concentric visual field defects following exposure to vigabatrin and cases of rare phenytoin-associated cerebellar degeneration or Dupuytren contracture and Ledderhose syndrome during chronic treatment with phenobarbital or primidone.[36]

Summary (all +)	9	8	10	8	7	3	5	5	4	14	13	7	10	10	12	9

The incidence of many early adverse events shown here may vary significantly from patient to patient, depending on individual susceptibility, development of tolerance, titration, and drug load. The list summarizes the adverse event potential of a given compound, in the authors' view. In our view, representing evidence class IV, (+) denotes minimally increased risk at effective dose in clinical use, + denotes a risk higher than for AEDs without a + sign, and ++ denotes the highest risk among AEDs. CBZ, carbamazepine; CLB, clobazam; FBM, felbamate; GBP, gabapentin; LEV, levetiracetam, LTG, lamotrigine; OXC, oxcarbazepine: PGB, pregabalin; PHB, phenobarbital; PHT, phenytoin; TGB, tiagabine; TPM, topiramate; VPA, valproate; VGB, vigabatrin; ZNS, zonisamide.

[a]Dose-related side effect.

[b]Dose relationship not proven or controversial.

Reversible Side Effects

A number of CNS side effects such as dizziness, ataxia, or somnolence emerging early in the course of treatment with AEDs are transient despite continued therapy.[24,25,36] The mechanism underlying the resolution of early CNS side effects without dose reduction is the rapid development of functional tolerance to adverse effects within weeks.[28] Functional tolerance to early side effects such as dizziness and gastrointestinal adverse effects was elegantly demonstrated for several first-generation AEDs in a well-controlled comparison of carbamazepine, phenytoin, phenobarbital, and primidone.[28] Although serum

P.1194

concentrations were similar at weeks 1 and 12, the proportion of patients with dizziness and gastrointestinal complaints was much lower at week 12.[28] For newer antiepileptic drugs such as gabapentin, lamotrigine, pregabalin, topiramate, vigabatrin, and zonisamide, resolution of early CNS side effects during continued therapy has also been noted in many patients.[24,25]

The vast majority of persisting side effects occur more often at higher doses and, fortunately, are reversible with dose reduction.[19] Contrary to intuitive belief, hypersensitivity reactions of the skin ranging from mild maculopapular rashes (affecting up to 15% of patients started on lamotrigine, phe-nytoin, and carbamazepine) to severe cutaneous adverse reactions such as Stevens-Johnson syndrome and Lyell syndrome (toxic epidermal necrolysis) occur more often in susceptible individuals with loading doses compared to slow titration. A notable example is skin rash associated with lamotrigine, the incidence of which can be minimized by starting with a low dose and titrating slowly, particularly in patients comedicated with valproate.[49] It is possible that slower titration reduces the risk of allergic reactions by gradual desensitization of the immune system. All antiepileptic drugs have dose-related CNS adverse effects, as noted previously, although some drugs may be more troublesome than others (Table 1). During chronic treatment, the most common side effects involve the CNS and include cerebellar-vestibular and oculomotor symptoms (ataxia, dysarthria, vertigo, tremor, diplopia, blurred vision, various forms of nystagmus, and gaze palsy), extrapyramidal symptoms (dyskinesia, parkinsonism, tics, and myoclonus), drowsiness, fatigue, impairment of cognitive function, and disorders of mood and behavior.[7,50] At high doses, paradoxical seizure aggravation as a manifestation of toxicity (paradoxical intoxication) has been reported with virtually all AEDs, although

P.1195

phenytoin, topiramate, and vigabatrin have been particularly implicated.[32] After massive overdose, virtually all AEDs can cause seizures, even in patients who do not have epilepsy.[32] Seizure aggravation may result, however, from selection of the wrong AED for the patient's seizure/epilepsy type, emphasizing the importance of accurate classification.[32] In addition, deterioration in seizure control may be caused by the development of tolerance to the effect of the drug or be simply related to a spontaneous increase in seizure frequency.[46] Whatever the reason, the treating physician should be aware of paradoxical seizure aggravation to avoid a dangerous vicious circle whereby the dose is increased further in an attempt to bring the epilepsy under control. Finally, seizure worsening after AED withdrawal, especially when abrupt, may also be seen as a reverse dose-related side effect, especially with felbamate and viga-batrin, and can also result in transient increase in seizures or even status epilepticus.[32]

In addition, a number of non-CNS side effects are dose related including gum hyperplasia with phenytoin and frozen shoulder syndrome with phenobarbital.[36] Weight gain has been found to be dose related for AEDs such as gabapentin, pregabalin, valproate, and vigabatrin.[19] For example, pregabalin was associated with weight gain (of at least 7% of initial body weight) in 14% of patients receiving 600 mg/d compared with 7% of those taking 150 mg/d and 2% of patients given placebo.[45] Topiramate weight loss is also dose related, with approximately 10% of patients showing body weight reductions at a dose of 100 to 200 mg/d.[45] Nephrolithiasis may occur with topiramate and zonisamide, and endocrine and metabolic disturbances are seen with a number of AEDs.[45]

Patient Groups With an Increased Risk for Dose-Related Side Effects

Some patients require unusually low doses to achieve optimal therapeutic response due to differences in genetic background, body weight, age, hormonal status, coexisting illness, and interactions with concomitant medications. Failure to take these host-related factors into account may easily lead to overtreatment. For example, the elderly generally require lower AED doses to achieve seizure control, and they may develop adverse effects at doses (and serum drug concentrations) that are usually well tolerated in younger individuals.[19]

For patients with renal impairment, doses of AEDs that are primarily excreted renally, for example, primidone, gabapentin, pregabalin, and levetiracetam, should be reduced. A recent report of increased incidence of gabapentin-induced myoclonus in patients with renal failure highlights the risk of overtreatment in this patient group.[51] Although these patients received gabapentin doses that could be regarded as relatively low in an individual with normal renal function, their use in renally impaired patients probably resulted in excessive accumulation. For patients with serious liver disease, AEDs that are primarily detoxified in the liver, such as barbiturates, phenytoin, suximides, carbamazepine, felbamate, lamotrigine, tiagabine, valproate, and benzodiazepines, may rise to toxic levels and may not be the first choice, or doses may require close monitoring. This reflects, in part, the pharmacokinetic changes and lower serum albumin in elderly adults. Liver volume, blood flow, and metabolism decrease with age.[19] Elderly adults or neurologically impaired patients of all age ranges also may be more susceptible to some dose-related adverse effects, such as dizziness, because of preexisting neurologic problems.

Some types of seizures (but not usually epileptic syndromes) in one age group may be made worse by the same AED that controls them in another age group. For example, vigabatrin reduces myoclonic seizures of infancy (infantile spasms), and yet worsens myoclonic seizures in older patients with other types of epilepsy.[32] Infants and young children, however, are at greater risk for other host-related adverse effects. The occurrence of Stevens-Johnson syndrome was higher in patients taking AEDs who were <18 years of age.[35] Other examples of host-related greater susceptibility for adverse effects are instances in which infants and children have a greater susceptibility to an AED adverse effect.

The influence of genetic variation on drug metabolism has long been recognized. Polymorphisms in the genes that code for drug-metabolizing enzymes, drug transporters, drug receptors, and ion channels can affect an individual's risk of having an adverse reaction.[29] Genetic polymorphism of the cytochrome P450 (CYP) enzymes, which metabolize a range of AEDs, affects their expression and may determine individual susceptibility to drug toxicity. Dosing with "standard" phenytoin regimens without prior knowledge of the genetic profile has been reported to lead to overtreatment and toxicity in isolated cases.[29] As the complexity of genetic influences on treatment responsiveness becomes better understood, pharmacogenetic profiling may become a practical tool for preventing overtreatment in high-risk patients.

In addition, the type and severity of the epilepsy may influence the optimal dose (or serum drug concentration) required. In the Glasgow study,[23] patients with symptomatic or cryptogenic epilepsy were more likely to withdraw from treatment due to side effects compared to those with idiopathic epilepsy, possibly because the latter required lower doses to achieve seizure control. In another study that explored the relationship between serum AED concentrations and clinical response, patients who had tonic–clonic seizures only in their history or a low pretreatment seizure frequency were found to become controlled at much lower AED concentrations compared with those who had partial seizures, multiple seizure types, or a high pretreatment seizure frequency.[42] These observations are important to be able to tailor the initial target maintenance dose to individual needs and avoid overtreatment in patients who are particularly likely to do well at relatively low doses or serum levels. In addition to increased host susceptibility, some treatment strategies may carry a higher risk for side effects than others.

Treatment Scenarios Resulting in an Increased Risk of Dose-Related Side Effects

Although some early CNS side effects improve or even resolve over time without a change in AED dose due to rapid development of tolerance as described previously,[28] dose-related adverse effects are more prominent in the first weeks of treatment. In addition, tolerance and adaptation to dose-related AED adverse effects vary widely among patients for many reasons.[19] Poor adherence to medication regimens may eliminate previously acquired tolerance and transiently worsen the tolerability of treatment. As discussed earlier, idiosyncratic reactions after the start of treatment, such as hypersensitivity reactions and hepatic adverse effects, are most likely to occur within 2 to 8 weeks.[19] Because many adverse effects occur most frequently at the start of treatment, clinicians should be most vigilant during this time.

Patients and their families should be alerted to look for adverse effects during the first weeks of a new AED treatment and should be asked to contact the physician quickly if they have concerns about an adverse effect so that the severity of these complications can be reduced. The patient should be urged to bring to the physician's attention any symptoms that the

patient believes could be side effects (the physician may need to encourage their patients to discuss symptoms related to sexual functioning). Once a patient raises possible side effects, the physician needs to determine whether they are AED related. Some side effects may not be AED related—for example, a contact dermatitis, fatigue secondary to a sleep disorder, and memory dysfunction or erectile dysfunction due to depression—and therefore should not lead to AED dose reduction, which could then lead to increased seizures. In addition, patients should be told not to decrease or stop their medications because of symptoms they believe could be side effects, but rather to contact their doctor and have a discussion (for the same reason as given previously).

When choosing the initial dose or making adjustments, consideration should be given to the dose–response relationship for the individual AED being used. The risk of side effects is particularly high with phenytoin, the pharmacokinetics of which changes from first to zero order across the therapeutic dose range, resulting in a disproportionately large elevation in serum concentration with a small dose increase.[24] Monitoring serum phenytoin levels is important in minimizing side effects with this drug. However, one of the commonest reasons for overtreatment is overreliance on serum drug concentration monitoring. A "therapeutic range" is often interpreted injudiciously to dictate dose adjustment without sensible clinical correlation.[20] Although "therapeutic" or "target" ranges are often quoted for established AEDs in standard textbooks, these should only be used as an aid in dose adjustment, and the clinician must realize that some patients will do well below the lower limit of the range, whereas others tolerate higher levels with benefit and without toxicity.[33] Increasing the dose in well-controlled patients simply because they have a low serum AED concentration will expose them to overtreatment.

Rapid titration, prescribing too-high doses, using too many antiepileptic drugs, and continuing treatment too long, which often cause unnecessary side effects, are discussed in the following paragraphs. In most therapeutic settings, initiation of treatment is best carried out by applying the well-known, but often ignored, "start low, go slow" principle.[43] Slow uptitration minimizes tolerability problems by allowing gradual development of adaptation, or tolerance, to CNS side effects as discussed in the previous section. This is particularly applicable to primidone, benzodiazepines, topiramate, tiagabine, zonisamide, and, to a lesser extent, carbamazepine, phenytoin, oxcarbazepine, and vigabatrin.[31] In a double-blind trial, gradual initiation of topiramate (reaching 400 mg/d in 8 weeks compared to 3 weeks) significantly lowered the incidence of dose-related side effects without delaying therapeutic response.[9] Unfortunately, different titration schedules tend to be poorly investigated in regulatory controlled trials, and optimal dose escalation rates are usually only defined through postmarketing clinical experience.[47] For instance, topiramate and viga-batrin have been found to be often optimally effective at doses that are substantially lower than those tested in early trials,[4] and the neurotoxicity of topiramate may be improved by slow titration.[9] Contrary to intuitive beliefs, the risk of idiosyncratic reactions may also be reduced by slower titration, as reviewed earlier.

Prescribing too-high doses is a well-known and yet still common cause of side effects. This is particularly relevant for AEDs, which have a narrow therapeutic ratio, that is, the dose required to control seizures is usually close to the dose that causes adverse effects.[30] There are at least two common clinical scenarios in which excessively and unnecessarily high dosages may be given. A recent observational study conducted in a large population of patients with newly diagnosed epilepsy in Glasgow provides particularly relevant information in this respect.[23] Among 470 patients who had never previously received AED treatment, 47% became and remained seizure- free on the first AED. Remarkably, around 80% of the seizure-free patients required relatively modest daily doses (600 mg or less of carbamazepine, 1,000 mg or less of sodium valproate, 200 mg or less of lamotrigine), with a sigmoid dose–response relationship.[23] Particularly for carbamazepine, these maintenance doses tend to be lower than those that, in the authors' experience, are initially prescribed by many practitioners, suggesting that overtreatment is not rare among apparently "well-managed" patients.

The second scenario concerns the rationale for excessive dose increments in patients not responding at average doses. There is in fact a paucity of studies that support the rationale for further increasing dose (or serum drug concentrations) beyond a certain limit. In the Glasgow study,[23] only 20% of patients who achieved seizure freedom on the first prescribed AED did so at more than a modest dose, suggesting that a surprisingly modest therapeutic gain can be achieved by increasing doses indiscriminately. In fact, the notion that seizure control increases proportionally with increasing dose is probably inappropriate. For example, in a recent controlled trial in patients with newly diagnosed epilepsy randomized to receive 25 or 200 mg/d to-piramate (or 50 and 500 mg/d in patients weighing 50 kg or more), seizure freedom rates were similar, while paraesthesia as one of the dose-related side effects of topiramate was more frequent (35% vs. 13%, p <.0001).[18] There is also evidence that excessively high doses can lead to paradoxical deterioration in seizure control as discussed earlier. These considerations suggest that increasing the dose above a certain level may result in seizure freedom in only relatively few patients, and many more will be overtreated and suffer the associated toxicity.

Finally, using too many antiepileptic drugs is well known to cause side effects. Dose-related CNS side effects, particularly ataxia, somnolence, and dizziness, are often more prominent in patients on multiple AEDs,[26] although it has been suggested that neurotoxicity is better related to total drug load (defined as the sum of defined daily doses for each drug) than to the actual number of AEDs taken.[13] The fact that many patients experience fewer side effects and at times even better seizure control after being converted from polytherapy to monotherapy was first demonstrated in the late 1970s to early 1980s and confirmed in subsequent reports.[41] The negative impact of overtreatment with polytherapy may result from both pharmacokinetic and pharmacodynamic drug interactions. Enzyme inhibition may lead to elevation in the plasma levels of the affected drug, as shown by the effect of valproate on phenobarbital and lamotrigine,[24] resulting in increased toxicity. The combination of valproate and lamotrigine appears to exacerbate the teratogenicity seen with either agent alone, as is discussed in detail elsewhere in this book. Knowledge of the effects of individual AEDs on the metabolizing enzymes of the affected agent will aid in making appropriate dose adjustments and avoiding the negative consequences of these interactions. There is some evidence that adverse pharmacodynamic interactions are more likely to occur when AEDs sharing a similar mechanism of action are combined. For instance, excessive neurotoxic side effects have been noted in patients given a combination of carbamazepine and lamotrigine[8] or carbamazepine and oxcarbazepine, both sodium channel blockers.[5] Recent interim results of the U.K. pregnancy registry, published in abstract form only, suggest that although only 64 cases could be included, the incidence of teratogenicity might be higher in women given a combination of valproate and lamotrigine (11.9%) compared with either drug alone (valproate, 7.2%; lamotrigine, 3%).[6] If this apparently adverse interaction is confirmed, it would be very unfortunate because valproate plus lamotrigine is a particularly useful combination in patients with difficult-to-treat epilepsies, as is discussed elsewhere in this book.

Furthermore, continuation of AED therapy when the risk-to-benefit ratio is in favor of drug withdrawal may be a less common example of overtreatment. At least for the self-remitting epilepsies, such as benign Rolandic epilepsy and childhood absence epilepsy, or rare seizures, AED therapy should not be unnecessarily prolonged after achieving an adequate period of complete seizure control. Another strong predictor for relapse is the duration of seizure freedom before drug withdrawal. It should be noted, however, that risks weigh against discontinuation of AEDs in a number of seizure-free patients.[44] These risks include (a) a seizure recurrence rate between 12% and 66% (mean 34%) and (b) complete and rapid seizure control cannot be guaranteed when AEDs are given for treatment of recurrence. In fact, in one half of the patients, it may take several years to reach control and, in one review, 23% of chronic uncontrolled epilepsy remained uncontrolled in a follow-up of up to 9 years.[44] Relatively little information is available to guide consideration of drug withdrawal after successful epilepsy surgery. According to a review, AED discontinuation is associated with a seizure recurrence in one in three patients rendered seizure-free by epilepsy surgery. Reinstitution of medical treatment after seizure recurrence in patients withdrawn from AED treatment proved effective in most cases. However, 9% of patients developed intractable epilepsy after AED discontinuation despite restarting AEDs. These results will be useful in counseling patients about discontinuing AED treatment after successful epilepsy surgery.[39]

Finally, overdose is a rare but serious cause of side effects of AEDs. With newer AEDs, —doses of up to 48.9 g of gabapentin and, separately, 4 g of lamotrigine—patients developed CNS symptoms including ataxia, confusional state, headache, and sedation but recovered without any sequelae. A patient who ingested between 4 and 5 g of lamotrigine was admitted to hospital in a coma lasting 8 to 12 hours, followed by recovery over the next 2 to 3 days. Another patient who ingested 5.6 g was found unconscious and, following treatment with charcoal, recovered after sleeping for 16 hours. Although no serious clinical consequences were reported in the these cases, in one patient with a lamotrigine overdose of 1.3 g, the electrocardiogram showed QRS width of 110 ms.[11] Vigabatrin overdoses, most commonly at doses between 7.5 and 30 g but up to 65 g, have been reported. Approximately half of these cases involved multiple drug ingestion, none resulting in death (for review see Mattson et al.[28]). Reviews of overdose with older AEDs are available.[36]

Management of Dose-Related Side Effects

The cornerstones of the effective management of a patient with side effects are improved recognition of side effects by systematic assessment and careful reduction of drug load without worsening seizure control. Foremost, prevention of side effects is often easier than correction of an existing side effect.

Table 2 Strategies for preventing side effects of antiepileptic drugs in patients with epilepsy

- Make all efforts to ensure accurate diagnosis and classification, and start treatment only after careful consideration of the risk-to-benefit ratio.
- Select the most appropriate drug for the individual patient based on consideration of the primary strength and weakness of the individual compound. The adverse event potential and specific side effects should influence drug selection in the individual patient.
- Use appropriately lowest dose titration and the lowest maintenance dose based on the epilepsy syndrome and characteristics of the patient.
- Monitor regularly clinical response, with special consideration of adverse drug effects and systematic screening for adverse effects. Increase awareness of toxicity by effective patient information.
- Adjust dose only when there is a clinical indication. Consider the dose–response relationship when making dose increments. If indicated, monitor serum drug concentrations.
- If seizures are uncontrolled and compliance problems are excluded, adjust treatment gradually up to the highest tolerated dose. Return to average dose, however, if the patient dose not benefit from the dose increment. Review diagnosis and classification.
- Most patients refractory to a single drug can do well on an alternative monotherapy. If combination therapy is indicated, consider the possibility of drug interactions and adjust dose accordingly.
- Consider the possibility of paradoxical intoxication whenever an increased drug load is associated with deterioration in seizure control.
- In drug-refractory patients, consider the feasibility of alternative treatments, e.g., epilepsy surgery, ketogenic diet, or neurostimulation.
- Reassess regularly the risk-to-benefit ratio of treatment and consider the possible benefits of reducing drug load.

Prevention

One way to avoid side effects is to carefully consider whether drug treatment is necessary at all. A number of clinical situations exist in which starting drug treatment needs to be individualized in consideration of the individual risk–benefit balance and the patient's preference. A firm diagnosis of an epileptic seizure or epilepsy is crucial to avoid treating nonepileptic seizures such as psychogenic seizure or syncope as outlined elsewhere in this book. Patients with a first epileptic seizure or patients with benign epilepsy syndromes or very rare seizures may neither wish nor need chronic AED treatment. Prophylactic treatment in high-risk patients who did not have a seizure and may never have one (even without treatment) has not been shown to be effective in preventing the development of epilepsy, as outlined elsewhere in this book. Once the decision to start treatment has been made, judicious selection of the most appropriate AED and dose is sensible. General guidelines for prevention of adverse effects of AEDs include a number of recommendations as shown in Table 2.

Identification of Side Effects

Strategies to improve epilepsy care should include systematic monitoring to identify side effects. Despite the apparent importance of medication problems on self-reported health as reviewed previously in this chapter, few investigations have been published on techniques for monitoring adverse effects. Trials that included monitoring of side effects have consistently shown higher rates compared with spontaneous reporting. For example, one benchmark study, which included a standardized questionnaire for systematic assessment of side effects of AEDs, found that such effects contributed to the exit from the trial

in 40% to 60% of participants.[27] This is substantially higher than was found in most studies that used only spontaneous self-reporting.[12] Use of a structured patient interview called the Adverse Event Profile (AEP) provided similar rates of important side effects such as sedation or fatigue with phenyt-oin and carbamazepine in a survey of >5,000 patients from 15 European countries.[3] The utility of the AEP was demonstrated in a randomized trial.[17] The 4-month study showed that care improved with the use of the AEP in an outpatient epilepsy clinic. With more frequent dose reduction in the AEP user group versus the group in which AEP was not available, AED toxicity was reduced and subjective health status improved, notably without seizure worsening.[17] Heightened awareness of side effects, with or without the use of AEP, allows reduction of drug load to lessen medication problems.

Reducing Overtreatment

Although treatment of epilepsy can easily evolve into a situation of overtreatment, reversing the process can be difficult and time consuming. There can be little doubt that decreasing the doses and/or number of AEDs will be associated with a decrease in side effects. This decrease in side effects involves a reduction in their severity, their number, or both. Several studies in the 1980s suggested that a reduction in the number of AEDs reduces the overall occurrence of side effects, in particular the sedative effects and the dose-related neurologic side effects in general.[1,37]

In addition to the dose-related central nervous system side effects of AEDs, there is no doubt that eliminating drugs from the regimen will eliminate the various individual and specific side effects of those drugs that are discontinued, such as excessive weight gain or tremor from valproate, behavioral problems from levetiracetam, or cognitive impairment from topiramate.[10] Additional benefits of reducing overtreatment may include a simplification in the medication regimen, improved compliance, and reduced costs. It is interesting that there was little or no increase in seizure frequency among the patients enrolled in these studies, and a reduction in seizures was actually not uncommon.[1] There are several possible explanations for this observation, including spontaneous fluctuation; removal of paradoxical intoxication and of seizure-aggravating drugs; elimination of enzyme-inducing agents, which may increase the serum concentration and consequently the efficacy of remaining AEDs; and possibly increased compliance with fewer drugs being taken. In addition, the dose of potentially effective drugs may be increased, which was not possible before because of side effects, and this may improve seizure control. However, dose increments may lead to more side effects. This may explain why in some studies there was no difference in tolerability following transfer from two-drug treatment to monotherapy.[37]

The risks include seizure exacerbation due to loss of protection, spontaneous fluctuation in seizure frequency, or withdrawal. At the onset of an increase in seizure frequency that occurs during medication reduction, it is initially virtually impossible to determine which one of these three mechanisms is involved. Loss of seizure protection is a real possibility. In any patient who has been taking several AEDs for a certain period of time, it becomes virtually impossible to determine which one of the drugs, if any, is exerting a protective effect against the seizures. Therefore, any drug that is being reduced or eliminated may actually have been exerting a protective effect whose loss manifests itself as a seizure aggravation. If this is the case, there is usually no change in the intensity or duration of the seizures, and the increase in seizure frequency will tend to persist, in contrast to withdrawal seizures and to seizure increase due to spontaneous fluctuation. In addition, seizure frequency will usually not decrease until the dose of the drug is increased again. A seizure increase due to spontaneous fluctuations may subside spontaneously, and, in an individual patient, it may be impossible to determine whether the exacerbation was due to a spontaneous fluctuation or to a withdrawal phenomenon. The literature provides some evidence suggesting that certain AEDs such as benzodiazepines, carbamazepine, and phenobarbital are more likely to be associated with withdrawal seizures (for review see Zaccara et al.[50]). Reversal of pharmacokinetic interactions may also lead to seizure aggravation or to drug toxicity as well as to some problems with other medication besides AEDs if their dose is not adjusted. When reducing overtreatment, there are three main challenges: (a) to select the drugs that should be eliminated, (b) to choose an appropriate rate of reduction, and (c) to anticipate reversible pharmacokinetic interactions that can have clinically significant consequences. This may seem theoretically relatively simple, but it can be practically more challenging. The answer to the question “Which drug first?” depends on the reason behind the decision to reduce what is perceived as being overtreatment. Accordingly, there will not be a single criterion. If side effects are the main reason, one may first target the drug that is considered to have the worst or strongest adverse effects. It is not always easy to identify that drug, especially when the side effects consist of nonspecific CNS-related symptoms, such as lethargy or mental slowing, which may actually result from cumulative toxicity. In other cases, the adverse effects may be easily attributed to a certain drug, such as excessive weight gain from valproate, excessive weight loss from topiramate, behavioral problems from gabapentin or levetiracetam, or oligohydrosis from zonisamide. Another reason to reduce overtreatment may be the evidence or the suspicion that one of the AEDs may potentially be aggravating the seizures. Obviously, if there is none of these specific reasons to reduce overtreatment, a logical target drug would be the one that is considered to be the least effective. This can sometimes be determined from careful compilation of the drug history and clinical responses. Often, however, it is not possible to determine which of the AEDs the patient is taking is currently effective, if any, especially if the drugs have been prescribed for a relatively long time. Certainly, a drug that was never at any time associated with a seizure reduction is very unlikely to be effective. However, a temporary improvement after the introduction of a given AED is often related by the patients or by the caregivers, in which case one is left with little evidence to go by. Whether tapering and discontinuing a given drug is likely to be associated with withdrawal seizures will only rarely influence the choice of the first drug to be discontinued. Nevertheless, drugs considered to be associated with withdrawal seizures are tapered at a slower rate, and one may choose accordingly to initiate the process relatively early. For slow tapering, the following rates of reduction have been recommended: phenobarbital or primidone, 20% to 25% per month; benzodiazepines, 20% to 25% per month; phe-nytoin, 20% to 25% per week; carbamazepine, 20% to 25% per 2 weeks; valproate, 25% per week; and ethosuximide, 50% per week. For other AEDs, 20% to 25% per 2 weeks may be appropriate.[10] Depending on the severity of the seizure exacerbation, one may chose to increase the dose of the drug back to the previous dose or simply delay the next scheduled dose reduction.

Finally, it is important to anticipate reversible pharmacokinetic interactions. If necessary, the doses of remaining drugs will have to be reduced or increased if it is important to maintain their levels. One should keep in mind that enzymatic inhibition is usually competitive and rapidly reversible. Induction, however, is based on enzyme synthesis and is more slowly reversible. The process of reversal of enzymatic induction may take 3 to 4 weeks to be completed. This reversal of pharmacokinetic interactions does not affect AEDs only. It is

important to remember that enzyme-inducing AEDs may lower the levels of certain anticoagulants, oral contraceptives and other steroids, and cyclosporine. When an enzyme-inducing AED is removed from the drug regimen, it is very important to notify the other specialists, such as the cardiologist, gynecologist, or transplant physician, who are prescribing these drugs, to avoid potentially grave consequences.[10] Overall, there is a lack of published data properly to support recommendations for implementing reduction of overtreatment. This is particularly the case in the pediatric population and for the newer antiepileptic drugs.[10]

Future Approaches

As discussed, most side effects of AEDs respond to dose reduction. To avoid side effects, increasing awareness of medication-induced toxicity and overtreatment and the development of even better-tolerated AEDs will improve the risk–benefit balance of future drug treatment of epilepsy. In addition, advances in pharmacogenetics may help to predict patients with increased risk of adverse effects.[29] Similarly, advances in neuroimaging, such as identification of pretreatment γ-aminobutyric acid (GABA) levels may indicate increased sensitivity to side effects of GABAergic drugs.[22]

Summary and Conclusions

In this chapter, we give an overview on dose-related side effects of drug treatment for epilepsy. Furthermore, we describe clinical scenarios that often lead to side effects and outline specific strategies to minimize or prevent dose-related side effects of AEDs. Most side effects of AEDs respond to dose reduction. To prevent side effects, treatment should be started at very low doses and dose escalation should be slow. Increased awareness of medication-induced toxicity, anticipating inhibitory drug interactions and avoiding overtreatment will reduce the incidence of side effects. The development of even better-tolerated AEDs will improve the risk–benefit balance of future drug treatment of epilepsy. In addition, advances in pharmacogenetics and neuroimaging may help to predict patients with increased risk of adverse effects.

Chapter 106

Idiosyncratic Adverse Reactions

Munir Pirmohamed

Santiago Arroyo

Introduction

A perusal of the product information sheets for all antiepileptic drugs (AEDs) reveals a long list of adverse effects. Fortunately, the majority of these adverse effects are mild and predictable from the known pharmacology of the AEDs. These types of adverse reactions are termed type A ("augmented") adverse reactions.[81] They typically tend to be dose dependent, usually improve with reduction in dose, and tend to be identified early during the course of the development of the drug.

AEDs can also cause type B ("bizarre") or idiosyncratic adverse reactions,[81] which are the focus of this chapter. These can be severe and sometimes fatal; they cannot be predicted from the known pharmacology of the drugs. Typically, there is no clear relationship between the occurrence of the reaction and the dose administered to the patient. Nevertheless, for some idiosyncratic adverse reactions, there is evidence of some relationship to dose and/or the speed of titration; for example, the risk of phenytoin-induced rashes seems to be greater if the starting dose is high.[16] Similarly, with lamotrigine, patients started on lower doses and slower titration schedule have a reduced risk of developing rashes.[110]

Idiosyncratic adverse reactions may be acute—occurring soon after the start of therapy—or chronic—occurring after prolonged therapy. They cannot be reproduced in animal models, and the only model in which they can be studied is the human.[71] Idiosyncratic adverse reactions, as the name implies, cannot be predicted and tend to affect a minority of patients taking the drug; the risk factors for individual susceptibility in most cases have not been identified, and genetic factors are thought to be important, although the supportive evidence only exists for a minority of the reactions. Due to their infrequent occurrence, many idiosyncratic adverse reactions are usually not detected during the premarketing phases of drug development and are only identified after licensing when there is high market exposure of the drug. Statistically, this is not surprising given that 30,000 patients have to be exposed to have a 95% probability of detecting 1 case of an adverse reaction occurring at a frequency of 1 in 10,000.[79]

Detection of idiosyncratic adverse reactions therefore largely, although not exclusively, depends on postmarketing surveillance strategies, in particular spontaneous reporting systems such as the MEDWATCH scheme in the United States and the Yellow Card scheme in the United Kingdom. There are limitations of spontaneous reporting systems, however, the most important being the degree of underreporting: Less than 10% of serious adverse reactions are reported.[89] This can lead to a substantial delay in detecting idiosyncratic adverse reactions after the drug is introduced onto the market. In some cases, certain idiosyncratic reactions, although frequent, might not be easily clinically demonstrable, leading to a substantial underreporting. For example, vigabatrin was introduced onto the U.K. market in 1989, but the first reports of visual field constriction appeared 8 years later in 1997,[29] despite the fact that we now know that the prevalence of vigabatrin-induced visual field constriction is between 30% and 40%.[22] In addition, data on adverse reactions submitted to the reporting systems are often incomplete and inadequate, being collected from different sources without expertise or standardization of terms and diagnostic criteria, making their evaluation more difficult.[53]

Idiosyncratic adverse reactions associated with AEDs can take many forms and can affect any body system (Table 1). In this chapter, we do not cover all of the reactions that have been reported with AEDs but focus on certain areas that we feel are perhaps the most important because of their prevalence, severity, or both.

Hypersensitivity Reactions

In this chapter, we use the term hypersensitivity to indicate a presumed allergic drug reaction, most commonly manifested as a maculopapular eruption. In some cases, the associated rash may be more severe, with the development of blisters and involvement of the mucous membranes, as in Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). In other cases, the reaction, with or without rash, may be associated with fever, eosinophilia, arthralgia, and internal organ involvement, a condition known as anticonvulsant hypersensitivity syndrome (AHS), also termed DRESS (drug rash with eosinophilia and systemic symptoms).

Maculopapular eruptions have been reported with most AEDs (Table 2).[5] Fortunately, with most of the drugs, such reactions are relatively mild and infrequent, but they do represent a problem particularly with the aromatic AEDs (phenytoin, carbamazepine, and phenobarbitone) and lamotrigine, in which case they may become more serious with the development of SJS or TEN, or AHS. Maculopapular eruptions are relatively common, occurring in 5% to 15% of patients receiving aromatic AEDs[16,88] and in 10% of patients on lamotrigine.[40] These figures probably represent overestimates, however, because the frequency of rashes is lower with more modern dosing strategies, which start at a low dose and increase the dose slowly.[63] AHS is less common; the risk within the first 60 days of a new prescription for either phenytoin or carbamazepine has been estimated to be 2.3 to 4.5 per 10,000 and 1 to 4.1 per 10,000, respectively.[101] The incidence of SJS and TEN is not known; these conditions are relatively rare, however, with a global population incidence of 1 case per million per year.[18] It is interesting to note that lamotrigine was associated with a higher risk of SJS, particularly in children (1 in 100 incidence), at the time of its introduction.[62]

Table 1 Idiosyncratic adverse reactions reported with antiepileptic drugs

System	Idiosyncratic adverse effect
Cardiac	Arrhythmias, eosinophilic myocarditis
Eyes	Visual field constriction (vigabatrin)
Gastrointestinal	Serum amylase elevation, acute pancreatitis, enterocolitis
Hematologic	Aplastic anemia, pure red cell aplasia Leucopenia, neutropenia, agranulocytosis Thrombocytopenia, platelet dysfunction, von Willebrand disease Macrocytosis, disseminated intravascular coagulation
Immunologic	Selective IgA immunoglobulin A deficiency, immunoglobulin deficiency, systemic lupus erythematosus, pseudo-lymphoma
Kidneys	Interstitial nephritis

Liver	Abnormal liver function tests, microvesicular steatosis, cholestasis, hepatitis, fulminant hepatic failure
Lungs	Pulmonary eosinophilia, acute pneumonitis
Metabolic	Weight gain, insulin resistance, dyslipidemia Folate deficiency, hyperhomocysteinemia Polycystic ovarian syndrome Thyroid dysfunction Osteoporosis, osteomalacia, bone fractures
Skin	Fixed drug eruption, urticaria, maculopapular eruption (and other erythematous generalized eruptions), hypersensitivity syndrome, Stevens-Johnson syndrome, toxic epidermal necrolysis

A wide range of adverse reactions are included here and are termed idiosyncratic; although we may have some knowledge of mechanisms, this list is partial, and in particular cannot explain individual susceptibility.

Table 2 Some Antiepileptic drugs reported to cause hypersensitivity reactions

Antiepileptic drug	Reference
Carbamazepine	96
Ethosuximide	20
Felbamate	13
Gabapentin	87
Lamotrigine	63
Levetiracetam	11
Oxcarbazepine	23

Phenobarbitone	96
Phenytoin	96
Tiagabine	2
Topiramate	93
Valproic acid	45
Vigabatrin	15
Zonisamide	57

This list of antiepileptic drugs causing hypersensitivity is not meant to be exhaustive. It is important to note that some antiepileptic drugs, for example, benzodiazepines, that have been reported to cause reactions that may have an immune basis have not been included. In addition, there have been isolated reports with some of the drugs mentioned here, but this does not necessarily imply causality.

Pathogenesis

Hypersensitivity reactions caused by AEDs have an immune pathogenesis. Initially this was an assumption based on

P.1202

clinical features (see later discussion) and the rapid recurrence of the reaction on rechallenge.[84] However, more recently, direct evidence indicating that drug-specific T cells are involved in the pathogenesis of hypersensitivity reactions associated with phenytoin,[59] carbamazepine,[59,66] and lamotrigine[67] has been provided. The exact antigens responsible for these reactions, however, remain elusive. Traditionally, it has been assumed that these drugs underwent bioactivation to toxic metabolites such as arene oxides, which then covalently bound to proteins and acted as haptens.[7] According to this hapten hypothesis, the drug–protein conjugate would be recognized as being foreign and an immune response would result. More recently, it has also been suggested that AEDs may be able to stimulate an immune response through direct interaction with the T cell receptors in the absence of any covalent binding or antigen processing.[78] However, such studies have been performed in vitro, and whether the same also occurs in vivo is unclear. It is of interest that it has also been suggested that activation of human herpesvirus 6 (HHV-6) may be responsible for propagating the severity of the hypersensitivity reaction.[69] However, this has largely been shown in Japanese patients, and given the high frequency of background infection with HHV-6 (almost 100% of patients have been exposed to it), it is not clear whether this represents an epiphenomenon or is causal.

Clinical Manifestations

The most common manifestation of a hypersensitivity reaction is a generalized maculopapular eruption (Fig. 1), which typically occurs within the first 3 months of therapy (with a peak in the first 6 weeks). These reactions are usually mild, are not accompanied by systemic symptoms, and resolve on drug discontinuation. Very occasionally, the rash may manifest as an urticarial reaction (FIGURE 1). The rash may be a prelude to the development of full-blown AHS. AHS is manifested by fever (100% of cases), rash (87%), eosinophilia (30%), and atypical lymphocytosis (6%). Internal organ involvement is also common, the liver being the most commonly affected (51%), followed by the hematologic system (23%), kidneys (11%), and lungs (9%).[96] Additional clinical findings may include periorbital or facial edema, exudative tonsillitis, oral ulcers, strawberry tongue, hepatosplenomegaly, flu-like symptoms, myopathy, disseminated intravascular coagulopathy, and pharyngitis.[94]

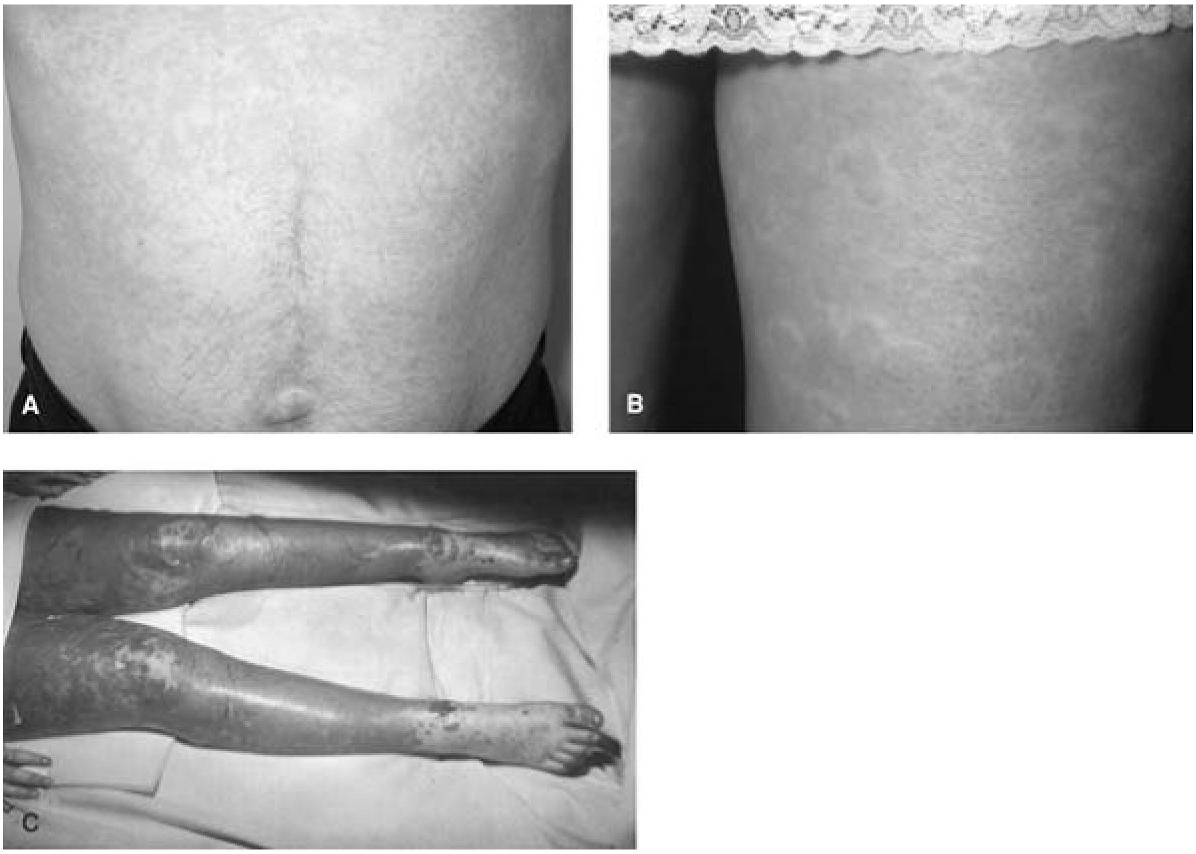

FIGURE 1. Cutaneous manifestations of antiepileptic drug hypersensitivity. **A:** Patient with phenytoin-induced maculopapular eruption. (Figure kindly provided by Dr. Gavin Wong, Liverpool, U.K.). **B.** Patient with carbamazepine-induced urticaria. (Figure kindly provided by Dr. Clodagh King, Liverpool, U.K.). **C.** Patient with carbamazepine-induced toxic epidermal necrolysis. (See the color insert.)

Very occasionally, an erythematous rash may progress to a more severe, blistering condition such as SJS or TEN (FIGURE 1). SJS is characterized by blistering affecting <10% of the body surface area; whereas in TEN, >30% of the body surface area is blistered. Blistering between 10% and 30% is termed the SJS-TEN overlap syndrome.[90] These conditions are characterized by the involvement of at least two mucous membranes, which is uncommon in AHS. Atypical target lesions may also be present in SJS but are absent in AHS. Lymphadenopathy is more common in AHS than in SJS.[39]

Predisposing Factors

The higher incidence of AHS reported in blacks may be a reflection of a higher incidence of epilepsy in this patient group.[94] Chinese seem to have a higher predisposition

P.1203

to develop SJS than whites. Consistent with this, a highly significant association of carbamazepine-induced SJS with *HLA-B*1502* has recently been reported in Han Chinese.[19] This does not seem to be relevant in whites, however, in whom AHS has been associated with major histocompatibility complex (MHC) polymorphisms residing in the ancestral haplotype 8.1.[80]

Management

The key to clinical management is the prompt recognition of the occurrence of the hypersensitivity and withdrawal of the offending drug. With mild maculopapular eruptions, this is often all that is needed, with the reaction improving within a few days. AHS is more severe and may require hospitalization. After withdrawal of the drug, patients may require symptomatic (e.g., antipyretics) and supportive therapy. Corticosteroids are often used, but there is no good randomized, controlled data on their effectiveness.[5] Severe involvement of the internal organs may require treatment by specialists in the field. This is also certainly true of patients with SJS or TEN, in whom treatment in a specialist unit is vital. Nursing care, often in intensive care settings, and adequate topical management reduce associated morbidity and allow a more rapid reepithelialization of skin lesions.[37] Many different therapies have been tried in patients with SJS/TEN, including corticosteroids, intravenous immunoglobulins, and plasmapheresis, but evidence of efficacy is either lacking or contradictory. This issue is beyond the scope of this chapter; see the article by Ghislain and Roujeau[37] for more details. Patients with AHS usually improve over 2 to 3 weeks, but some patients may experience a flare of symptoms a few weeks after the initial improvement. Mortality of AHS, especially if the liver is involved, can be as high as 20%.[94] Patients with SJS/TEN may take several weeks to improve; mortality is high at 5% for SJS and 30% for TEN.[37]

Prevention

Initiation of AED therapy at low doses and slow uptitration seems to be effective in reducing the incidence and severity of hypersensitivity with aromatic AEDs and with lamotrigine.[5] Prompt discontinuation of the offending drug has also been shown to reduce progression to a more severe form of the reaction.[35] There is a theoretical risk that sudden withdrawal of an AED may precipitate status epilepticus; however, this has not been borne out in clinical practice if the patient's treatment is continued with an alternative agent.[39] When the risk of withdrawal seizures is thought to be high, short-term benzodiazepines represent a suitable treatment option. In patients who have had a hypersensitivity reaction with an aromatic AED such as phenytoin, it is prudent to avoid another drug within the same class because of the risk of cross-sensitivity. In vitro, the risk has been estimated to be as high as 80%,[96] but clinically it is probably lower, around 20%.[83] Valproic acid is probably a safe alternative to aromatic AEDs in patients on monotherapy; lamotrigine, despite the fact that it does not demonstrate cross-reactivity with aromatic AEDs, is best avoided because rapid uptitration of the dose is contraindicated. In patients on polytherapy, other drugs such as levetiracetam and gabapentin may also be safe alternatives.

In terms of drug development, prevention of AED hypersensitivity has depended on the development of drugs that do not undergo hepatic metabolism such as levetiracetam, gabapentin, and vigabatrin. Hypersensitivity is not a recognized clinical problem with these drugs, although there have been occasional reports (Table 2). Oxcarbazepine, a keto analog of carbamazepine, is associated with a lower incidence

P.1204

of hypersensitivity, with cross-reactivity being seen in 30% of patients.[48]

Liver Toxicity

Liver injury has been observed with many AEDs; its severity varies and can range from mild asymptomatic elevation of the liver enzymes to acute liver failure, which may require liver transplantation. The hepatotoxicity may be part of the spectrum of AHS, particularly with the aromatic AEDs. However, it can occur in isolation, in which case the pathogenesis may be immune mediated, for example, aromatic anticonvulsants, or due to metabolic idiosyncrasy, for example, with valproic acid.

Aromatic Anticonvulsants

Enzyme induction by these drugs can lead to an increase in γ-glutamyltransferase (γ-GT) and, to a lesser extent, in alkaline phosphatase (ALP). For instance, 64% and 14% of patients on carbamazepine had elevations of γ-GT and ALP, respectively.[99] Phenytoin leads to asymptomatic elevation of γ-GT in almost 100% of recipients.[3] In general, it is not necessary to stop the drug.

Mild elevation of serum transaminases is also commonly seen (22% with carbamazepine[74]), and this sometimes normalizes despite continuation of therapy.[3] The relationship to more severe forms of liver dysfunction is unclear.

Clinically symptomatic hepatic injury is often part of AHS (see prior discussion), although the liver can be affected on its own.[74,96] The exact incidence is unknown; an analysis of all adverse reactions to carbamazepine reported to the Swedish Regulatory Agency showed that liver disorders accounted for 10% of all reactions.[7] The risk was estimated to be 16 cases per 100,000 treatment years. The time to onset of symptomatic hepatotoxicity is about 4 weeks with a range of 1 to 16 weeks.[107] Clinically, liver involvement may be characterized by right upper quadrant abdominal pain and jaundice, which is seen in nearly one half of the patients with hepatitis.[30] Biochemical abnormalities include an elevation of transaminases; however, about 30% of patients with carbamazepine-induced liver injury have a cholestatic pattern. Certainly, cholestasis seems to be more common with carbamazepine than with phenytoin. A prolonged rise in bilirubin levels similar to that seen in primary biliary cirrhosis is observed in patients with vanishing bile duct syndrome secondary to carbamazepine.[31] In patients with hepatocellular necrosis, the rise in bilirubin levels reflects the severity of damage[65] and may be accompanied by changes in clotting parameters. Histologically, granulomatous hepatitis is observed in up to three fourths of patients with carbamazepine-induced liver injury[107] but is less common with phenytoin, which is more commonly characterized by hepatocellular injury accompanied by a prominent inflammatory infiltrate.[64] Prognosis is worse in those with a predominantly hepatocellular pattern than in those with cholestatic injury.[107]

Valproic Acid

Dose-related elevations in hepatic transaminases occur in approximately 40% of patients without attendant symptoms of hepatic dysfunction.[100] These elevations are transient and generally abate with a reduction in dose.[26] Valproic acid also causes weight gain and insulin resistance, which may in some cases lead to the development of a nonalcoholic fatty liver.[55] Occurring less frequently but of greater clinical concern is the potential for fulminant hepatic failure that is irreversible in most cases. Severe hepatic damage initially manifests as nausea, vomiting, abdominal pain, increased seizure frequency, lethargy, and coma.[12,27,28] The onset of symptoms occurs within the first 6 months of therapy in 95% of affected individuals, generally within the first 2 to 3 months. Overall, fatal hepatotoxicity actually occurs in only a small number (<0.01%) of individuals treated with valproic acid, although high-risk groups have been identified (see later discussion). The prothrombin time provides more accurate assessment of residual hepatic function[26] than the elevated high serum transaminase and bilirubin levels. Elevated ammonia levels are also present. The histopathology of valproic acid hepatotoxicity differs substantially from that associated with the aromatic AEDs in that signs of immune involvement and eosinophilia are not present. In fatal cases, the most prominent findings consisted of microvesicular steatosis occurring primarily in periportal zone 1 together with zone 3 necrosis.[110]

The risk of fatal valproic acid hepatotoxicity is highest in children <2 years of age receiving concurrent AED therapy, in whom the incidence was estimated to be approximately 1/500.[27,28] This represents a 16-fold increase in risk relative to children of the same age on valproic acid monotherapy (1/8,000). Patients with inborn errors of metabolism or reduced hepatic mitochondrial activity also appear to be at increased risk for fatal hepatotoxicity associated with valproic acid.[92] Epidemiologic studies have failed to demonstrate a relationship between valproic acid dose and hepatotoxicity.[27,28]

Two general mechanistic hypotheses for valproic acid–associated hepatotoxicity have emerged over the last few years. In each, valproic acid biotransformation appears to be intimately involved in the process leading to hepatotoxicity, although the precise mechanism remains to be elucidated. The immune system is not involved, and this is a form of metabolic idiosyncrasy. The first hypothesis focuses on valproic acid interference with ß-oxidation of endogenous lipids.[9] The second hypothesis focuses on the hepatotoxic unsaturated valproic acid metabolite 4-ene-valproic acid, which is cytotoxic and able to inhibit enzymes in the ω-oxidation pathway.[8]

Felbamate

The risk of hepatic failure due to felbamate was initially estimated to be 1 per 26,000 to 34,000 exposures[76] but has been revised to be approximately 1 per 18,500 to 25,000 exposures.[75] Female individuals seem to be more susceptible, with a time to presentation of 25 to 181 days. Patients may present with nausea, vomiting, and lethargy, with evidence of hepatic dysfunction and eosinophilia. Histology reveals massive to submassive necrosis without significant fibrosis and moderate inflammatory infiltrate.

The mechanism of felbamate hepatotoxicity is unknown but is thought to be due to the formation of a chemically reactive aldehyde carbamate intermediate, which can either undergo detoxification or form the toxic atropaldehyde metabolite.[102] The mechanism by which atropaldehyde causes the liver (and bone marrow) toxicity is unknown. It has been shown that atropaldehyde is cytotoxic and depletes glutathione.[50] In addition, atropaldehyde can bind to glutathione transferases and inhibit their activity, which may in turn enhance its propensity to bind to other cellular proteins and interfere with their function.[25] However, a recent study has also suggested that the reactive metabolite of felbamate is a potent immunogen, suggesting that an immune pathogenesis may also be important.[85] No genetic predisposing factors have been identified.

Management

The essential step in the management of AED-associated hepatotoxicity is the early detection and the recognition that the

drug is responsible for the hepatic injury. Causality is determined as a diagnosis of exclusion by measurement of biochemical, immunologic, and virologic markers to exclude non–drug-induced diseases. In general, for patients that are prescribed a drug with known potential for severe hepatotoxicity, it is a sound practical measure to obtain baseline values for the liver enzymes so that a comparison is readily available. In patients with lower degrees of enzyme elevation (e.g., <3 times the upper limit of normal for transaminases), close monitoring should be instituted. If the drug is suspected and the elevations of hepatic enzymes are progressive or >5 times (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) or >2 times (bilirubin) the upper limit, discontinuation of the offending agent is important. Subsequently, the management of severe hepatic toxicity attributed to AED therapy is essentially supportive. There is little evidence to support the use of steroids in treatment, even when the hepatic injury is thought to be immune mediated.

As mentioned in the discussion of AHS, prevention is important. In the case of valproic acid, the drug should be used with great caution in children <3 years of age and those treated with cytochrome P450-inducing aromatic AEDs and avoided in children with metabolic disorders who are <2 years old. Similarly, extreme caution should be exercised if a family history of fatty acid oxidation defects or urea cycle defects is present. Clearly, any decision to use valproic acid in high-risk groups should be made after careful assessment of the known risks and benefits.

If there has been a hepatic reaction to one aromatic AED, given the possibility of cross-sensitivity, other aromatic AEDs should be avoided. There is no evidence of cross-reactivity between the aromatic AEDs and valproic acid, although it may be prudent to avoid valproic acid in a patient with manifestations of hepatotoxicity. If valproic acid is used, it should be introduced cautiously while liver function is still impaired. Routine monitoring of liver function tests is recommended in product information sheets; however, there is little evidence to support the predictive value of such monitoring.[82] The use of felbamate has been restricted in most countries because of its potential to cause aplastic anemia and hepatotoxicity. However, it may still be useful in certain patients; in such cases, it is important to follow the advice issued by the American Academy of Neurology.[32]

Hematologic Abnormalities

AEDs can induce a number of hematologic adverse reactions, in particular aplastic anemia, agranulocytosis, or thrombocytopenia. The overall rate of blood dyscrasias in a 29,357-patient cohort taking carbamazepine, phenobarbitone, phenytoin, or valproic acid was estimated to be 3 to 4/100,000 prescriptions, with the rate being twice as high in those >60 years of age. The overall rate was 1.2/100,000 prescriptions for neutropenia, 0.9/100,000 for thrombocytopenia, and 0.4/100,000 for hemolytic anemia.[10]

Aplastic Anemia

This is the most severe hematologic abnormality associated with AEDs. Felbamate has the highest potential to cause aplastic anemia; the incidence has been estimated to be 1 per 4,000 to 10,000 exposed patients, compared to an incidence of 2 to 6 per 1 million of the general population.[103] The mechanism is unclear but again is thought to be related to the formation of the toxic atropaldehyde metabolite. Recently, it has been shown that felbamate metabolites can induce apoptosis of hematopoietic cells via redox-sensitive and redox-independent pathways.[46] Patients on carbamazepine have an incidence of aplastic anemia that is five to eight times greater than that in the general population.[43] Aplastic anemia has also been reported very rarely with phenytoin[36] and valproic acid.[1]

Leucopenia and Agranulocytosis

Leucopenia develops in 10% of patients receiving carbamazepine; it is usually transient and of little clinical significance.[43] In some patients, however, carbamazepine can lead to the development of agranulocytosis. A recent population-based study showed that the incidence of community-acquired agranulocytosis was 3.5 per one million patients treated.[47] Carbamazepine was strongly associated with the development of agranulocytosis (odds ratio 115 in an unconditional analysis). Phenytoin was also associated with the development of agranulocytosis with a lower odds ratio (11.6).[47] Patients usually present with fever, oral ulceration, and signs of systemic sepsis. The mechanism is unclear; however, it has been shown that both carbamazepine[33,34] and phenytoin[60,104] undergo bioactivation by neutrophils to toxic metabolites, which may lead to neutrophil depletion either by causing cell death (possibly by apoptosis) or be inducing an immune-mediated reaction.

Thrombocytopenia

Thrombocytopenia has been reported with carbamazepine,[38] phenytoin,[44] lamotrigine,[105] felbamate,[68] tiagabine,[106] primidone,[72] and valproic acid.[24] Most attention has focused on valproic acid. A recent analysis showed that mild thrombocytopenia [platelet count (101–150) × $10^3/mm^3$] was seen in 9% of patients on valproic acid, whereas moderate thrombocytopenia [(40–1,000) × $10^3/mm^3$] occurred in 2% of patients. Age (>65 years) and dose (>1 g/d) were identified as risk factors.[21] More-severe falls in platelet count associated with bleeding have also been observed; these may be accompanied by the presence of antiplatelet antibodies.[86] Valproic acid can also induce abnormal platelet function, prolong bleeding time,[95] and lead to the development of acquired von Willebrand disease type I.[1]

The potential problems of hemostasis in patients on valproic acid have led to concern that it may lead to increased blood loss in patients undergoing surgery. Although no increased blood loss has been detected in patients undergoing neurosurgery,[95] patients undergoing orthopedic procedures on valproic acid do seem to have increased blood loss and postoperative blood transfusion requirements[14,17,108] compared with patients not on valproic acid.

Management

As with the other idiosyncratic adverse effects, prompt recognition, withdrawal of the drug, and specialist referral and care are essential. Detection of neutropenia should lead to close follow-up and, if clinically relevant, further investigation. The treatment strategies used in patients with drug-induced hematologic abnormalities are beyond the scope of this chapter, and readers should refer to specialized texts. Although some product information sheets recommend routine monitoring of hematologic parameters, this is not commonly undertaken in clinical practice, largely because the clinical utility has not been defined and monitoring would have to be so frequent as to make it impractical.[82] Frequent clinical assessment, together with

P.1206

patient education, is therefore important to detect these adverse reactions as early as possible. Patients on valproic acid who are due to undergo surgery do not routinely need to have their valproic acid discontinued. However, patients undergoing major surgery may need assessment of their hemostatic profile, including bleeding time, at least 1 month before their scheduled surgery.[108]

Valproic Acid–Induced Pancreatitis

Valproic acid (VPA) may increase serum amylase concentrations. A review of a database of 3,007 treated patients in 34 clinical trials showed that 2 cases of pancreatitis were probably related to valproic acid, indicating that it is a rare idiosyncratic event unrelated to dose or serum concentration.[77] It can rarely lead to fatalities.[6] Pancreatitis usually presents with progressive epigastric pain, nausea, and vomiting. Symptoms may occur for days, weeks, or months. Younger patients may be at higher risk; a review of 39 patients with pancreatitis showed that most cases (77%) occurred before age 20 years.[6] Twenty-four percent of these patients were on valproic acid monotherapy. Approximately one half of them had been exposed to VPA for <3 months, and in two thirds, pancreatitis appeared during the first year of treatment. In 41% of patients, an associated static encephalopathy was observed (developmental delay, cerebral palsy). Rechallenge is strictly contraindicated because of the risk of recurrence. Any patient on valproic acid who presents with abdominal pain and vomiting should have his or her amylase levels checked. In patients with an elevated amylase in the absence of symptoms, discontinuation of valproic acid is not necessary provided that the other pancreatic enzymes (elastase, lipase, trypsin) are normal.[70] It is important to stress that routine checking of amylase levels in the absence of other clinical signs and symptoms is of little value in predicting pancreatitis.[77]

Vigabatrin-Induced Visual Field Constriction

Vigabatrin was first reported to cause visual field constriction in 1997.[29] The visual field defects occur in approximately 40% of patients.[41,52,54] The prevalence of field defects was 59% using multifocal electroretinography.[61] The mechanism of the retinal damage is unclear, although the visual field defects appear to be the result of peripheral retinal atrophy rather than optic nerve damage. A recent study in rats showed that vigabatrin preferentially accumulates in the retina, and that its toxic effects may be mediated via the γ-aminobutyric acid C receptor, which is highly expressed in the retina.[97] Genetic predisposition has been postulated, but no genetic factors have been identified.[50a]

The evidence suggests that the onset of symptoms varies from 1 month to several years after starting vigabatrin. In virtually all cases, visual field defects have persisted despite discontinuation of vigabatrin, although fortunately there is rarely any further deterioration.[42,51] Male patients appear to be at higher risk of developing retinal toxicity,[49] and cumulative doses > 1,500 g have been found to correlate with the severity of the visual field defects.[58] Patients are usually unaware of the visual field defect, the condition being detected on visual field testing. The typical picture is of bilateral concentric visual field constriction (with some temporal sparing) or of binasal visual field loss. Studies using electroretinograms have shown that vigabatrin affects the inner retina rather than the outer retina. Most of the electroretinographic studies have reported a reduction in *b*-wave amplitude, which may indicate effects on Müller cells, the principal glial cells in the retina, which remove neurotransmitters from the extracellular space after their release from synaptic terminals.[56,91]

Vigabatrin therapy should only be initiated and supervised by an appropriate specialist. Except for the treatment of West syndrome, in which many physicians consider it as a treatment of choice (particularly in infants with spasms associated with tuberous sclerosis),[4,40a] vigabatrin should only be used when all other AEDs have failed.[22] Ophthalmologic consultation and visual field assessment should be undertaken before starting vigabatrin and repeated at 6-monthly intervals during treatment for 3 years, after which screening can be reduced to yearly. Screening should be performed by either Humphrey or Goldmann perimetry. Patients or parents should be counseled about the risk, and patients should be warned to report any new visual symptoms that develop. Those patients with symptoms should be referred for an urgent ophthalmologic opinion with a view to discontinuation of therapy. However, a clinical risk–benefit judgment needs to be made in each case, depending on seizure control and the degree of visual impairment. Patients who have had an excellent antiepileptic response to vigabatrin and demonstrated only mild visual changes may be able to continue therapy safely with close visual monitoring.[73] Vigabatrin should not be used in those patients with preexisting visual field defects, and the dose should not exceed 3 g daily.[4] The use of vigabatrin in young children is further complicated by the fact that conventional perimetry is unsuitable. The use of electroretinography and field-specific visual-evoked potentials may be helpful in the assessment of the pediatric population.[98]

Summary and Conclusions

Idiosyncratic adverse reactions are unpredictable reactions that occur in susceptible individuals and cannot be predicted based on the known mechanisms of action of the offending drug. These reactions are not uncommon following administration of AEDs, and for at least two AEDs (felbamate and vigabatrin) their frequency and severity are sufficiently high as to contraindicate their early use in the treatment algorithm. Typically, there is no clear relationship between the occurrence of the idiosyncratic adverse reactions and the dose administered to the patient; nevertheless, for some reactions, there is evidence of a relationship to dose and/or the speed of titration, as in the case of phenytoin- and lamotrigine-induced skin rashes. The most common idiosyncratic reactions associated by AEDs include cutaneous reactions, which sometimes occur in association with multiorgan involvement (the so-called AHS). Serious idiosyncratic reactions of AEDs also include hepatotoxicity, many hematologic reactions, valproic acid–induced pancreatitis, and vigabatrin-induced visual field defects. Some idiosyncratic reactions involve immune-mediated mechanisms, others have a metabolic basis, and for many the underlying mechanisms are not fully understood. For some reactions, for example, valproic acid–induced liver toxicity, high-risk groups have been identified, and avoidance (or very cautious use) of the offending drug in these groups minimizes their occurrence. Generally, management of idiosyncratic adverse drug reactions requires rapid withdrawal of the causative agent, coupled with supportive measures as appropriate.

Chapter 107

Long-term Adverse Events

Alison M. Pack

Barry E. Gidal

Introduction

Treatment with an antiepileptic drug (AED) may be prolonged. Recognizing long-term adverse effects of AEDs will have a significant effect on the health of the person with epilepsy. This chapter reviews potential long-term effects of AED therapy.

Cosmetic Effects

AED treatment can result in numerous cosmetic findings including hirsutism, alopecia, changes in hair structure, gingival hyperplasia, and facial feature changes. Valproate use may increase androgen levels, resulting in hirsutism and alopecia in women, whereas phenytoin, carbamazepine, gabapentin, and phenobarbital treatment are associated with hirsutism independent of hyperandrogenism. The hair growth typically occurs on the face and trunk and can last a year or longer after discontinuation. Valproate therapy can also change the texture of hair, producing a kinky hair structure. Gingival hyperplasia is common in phenytoin-treated persons, necessitating good oral hygiene in persons prescribed this AED. Finally, prolonged phenobarbital and phenytoin treatment may result in subtle facial changes characterized by coarsening of facial features. Recognizing these cosmetic changes is important as discontinuation of the AED can result in reversal of findings over time.

Alterations in Body Weight

Many AEDs are associated with changes in weight. Changes in body weight, particularly weight gain, may not only pose substantial health risks, but may lead to reduced adherence to AED therapy. Addressing potential weight change before initiating AED therapy and monitoring weight change during therapy is necessary to understand its effect and impact.

Overall, treatment with valproate appears to be consistently associated with weight gain, both in adult as well as adolescent patients.[55] Weight gain may occur in up to one half of treated patients receiving this medication, and can occur in both men and women. Increases in body weight may be seen relatively early in treatment (within 1 to 2 months), and in one study, did not plateau even after over 6 months of treatment.[5] Although many patients report an increase in appetite, others do not. While the mechanisms underlying weight gain due to valproate are still uncertain, several mechanisms, including reduced energy expenditure due to impaired fatty acid metabolism as well as hyperinsulinemia and insulin resistance, have been proposed.[17,26] The potential development of insulin resistance may be most concerning, as this not only may lead to excessive weight gain, but also may play a role in the development of polycystic ovary syndrome, which has been associated with valproate therapy.[23]

Although the effect appears to be less than valproate-associated weight gain, carbamazepine treatment may also result in weight gain. In a multicenter study comparing carbamazepine and valproate, 32% of patients started on carbamazepine reported weight gain.[35] The reported weight gain was less than with valproate, as only 8% exhibited a gain of >5.5 kg. Increased appetite likely mediates the weight gain and other mechanisms may also be a factor.[22,31]

Weight gain has been noted in association with gabapentin and pregabalin,[58] both newer-generation AEDs that are γ-aminobutyric acid (GABA) analogs and are closely related. Weight gain (10% to 15% increases in body weight) may occur in up to one half of patients treated with gabapentin. Increased appetite is commonly reported in patients receiving this agent.[9] Weight gain associated with pregabalin may be dose related.

In contrast to weight gain seen with several of both older and newer AEDs, weight loss has been reported in patients receiving either felbamate, topiramate (10% to 20% of patients), and, to a lessor extent, zonisamide. In obese patients receiving topiramate, a mean weight loss of approximately 4 kg was seen at 3 months, and 11 kg at 1 year. Reductions in body weight appear to be sustained over time.[4] The mechanisms involved in weight loss are unclear, but patients receiving felbamate or topiramate commonly report substantial reductions in appetite.

Neither lamotrigine nor levetiracetam have been associated with significant changes in body weight, and may therefore be considered to be weight neutral.[16]

Reproductive Health

Effects on reproductive health can occur in childhood, adolescence, and adulthood in women and men with epilepsy. Reproductive dysfunction may be secondary to epilepsy per se, AED treatment, or a combination of both. In females, common symptoms include hyperandrogenism, menstrual disorders with ovulatory failure, polycystic ovary–appearing ovaries or polycystic ovary syndrome (PCOS), and hyperinsulinemia. In males, effects on sperm quality and motility and small testicular size have been described.

AEDs differentially affect steroid hormone levels, depending on how the individual AED affects the cytochrome P450 enzyme system.[41] Treatment with enzyme-inducing AEDs (carbamazepine, phenytoin, and phenobarbital) in women with epilepsy reduces estrone, free testosterone, and androstenedione when compared to a control population without epilepsy. Also, sex hormone–binding globulin (SHBG) is significantly higher in women with epilepsy, further reducing bioavailable sex steroid hormones. In contrast, valproate, an enzyme-inhibiting AED, increases free testosterone in women with epilepsy. Lamotrigine and gabapentin both have no effect on the cytochrome P450 enzyme system and are not associated with changes in sex steroid hormone concentrations. Studies also suggest an independent effect of epilepsy on reproductive hormones. Women with temporolimbic dysfunction had

P.1210

reduced serum estradiol and dehydroepiandrosterone sulfate (DHEAS) levels in one study.[21] Interestingly, these findings were more pronounced in women with left temporal lobe epilepsy.

Women with epilepsy are at increased risk for menstrual cycle abnormalities and anovulation, which may occur in association with PCOS or independent of this endocrinopathy. PCOS is a common endocrinopathy in women. The classification and definition of PCOS have changed as our understanding of the syndrome evolves. A recent consensus group proposed that the syndrome be diagnosed when at least two of the following exist: Oligo-ovulation or anovulation; elevated levels of circulating androgens or clinical manifestations of androgen excess; and polycystic ovaries as defined by ultrasonography.[1] Chronic anovulation most often manifests as oligomenorrhea (less than nine menses per year) and may lead to decreased fertility. Clinical manifestations of androgen excess include hirsutism, androgenic alopecia, and acne. Polycystic ovaries are defined by the number of follicles in the ovary (12 or more) measuring 2 to 9 mm in diameter and/or increased ovarian volume.[1] The syndrome is characterized by obesity, elevated androgen levels (free testosterone), and insulin resistance. Associated health risks of PCOS include impaired glucose tolerance, type II diabetes, hypertension, dyslipidemia, coronary disease, obstructive sleep apnea, and endometrial malignancy.[11] Other reported menstrual cycle disorders include those with abnormal menstrual cycle intervals, oligomenorrhea, polymenorrhea, increased variability of cycle interval, and menometrorrhagia. Increased menstrual cycle disorders have been reported with both temporal lobe epilepsy and idiopathic generalized epilepsy.[19,42]

AEDs, and in particular valproate, may be independently associated with PCOS in women with epilepsy. Hyperandrogenism has been described in reproductive-aged girls and women with epilepsy treated with valproate.[23,38,44,45,64] The findings are significant when compared to control populations that are age and pubertal status matched. Interestingly, this potential effect of valproate has been described in both women with epilepsy and women with bipolar disease.[29,52,53] Of clinical relevance, after discontinuation of valproate, these reproductive abnormalities reverse.[26,42]

Men with epilepsy have reduced fertility, which may be a result of epilepsy and/or AED treatment. Having epilepsy can produce alterations on the hypothalamic-pituitary-gonadal axis as well as effects on sex hormone production and metabolism.[3,39] Testosterone controls both the expression of secondary sex characteristics and production of sperm. Disturbances in testosterone and other male reproductive hormones as well as sperm quality have been described in men with epilepsy.[3,24,27,54,56] Carbamazepine, oxcarbazepine, and valproate are all associated with sperm abnormalities. Testicular volume may also be reduced.[24]

Sexual Dysfunction

Sexual dysfunction, manifested variously as reduced libido, decreased arousal, erectile dysfunction, or anorgasmia, has been reported to occur in 20% to 30% of women and up to 50% of men with epilepsy.[18,39] Both the seizure disorder itself as well as treatment with certain AEDs contribute to this spectrum of adverse effects. Seizures, particularly those arising from the temporal lobe, may alter the release of hypothalamic and pituitary hormones. Epileptic discharges may either stimulate or inhibit the hypothalamus. Treatment with AEDs, particularly the enzyme-inducing drugs including phenytoin, phenobarbital, and carbamazepine, has been associated with decreased sexual function and physiologic arousal in both men and women, as compared to either healthy controls or patients with epilepsy receiving noninducing AEDs.[43] Finally, concomitant psychosocial issues, such as social isolation and low self-esteem, as well as anxiety and comorbid depression can also contribute to dysfunction in both men and women.

Enhanced metabolism of sex hormones as decreased hormone-free fraction has been the most commonly proposed mechanisms involved in both male and female dysfunction. As discussed previously, AEDs that induce the hepatic cytochrome P450 isoenzyme system can increase the metabolism of both gonadal and adrenal hormones. In addition, increased synthesis of SHBG may also be increased in patients receiving enzyme-inducing drugs. Reduced levels of both total and free testosterone, as well as dehydroepiandrosterone and androstenedione, have been reported in patients receiving inducing AEDs. Reductions in bioactive testosterone have been associated with reduced sexual function in both men and women.[20,40] Although prospective studies are warranted to confirm this, it is reasonable to speculate, therefore, that treatment with non–enzyme-inducing AEDs may be less likely to cause these adverse effects.

Bone Health

Fracture rates are increased in patients with epilepsy.[36] Although this increase may in part be secondary to seizure activity, AED effects on bone also contribute. The twofold increased incidence rate among patients with epilepsy compared to controls in a pharmacoepidemiologic based registry highlights this increased risk.[62]

Presently, the most clinically relevant predictor of fracture is reduced bone mineral density (BMD). BMD may be decreased with AED use, particularly enzyme-inducing AEDs. Studies describe higher rates of osteopenia and osteoporosis than expected in persons treated with AEDs.[49] In addition, longitudinal bone loss is evident in men and women treated with enzyme-inducing AEDs, particularly phenytoin.[2,12] Although most of the evidence suggests that enzyme-inducing AEDs result in reduced BMD, valproate use has been associated with decreased BMD in children and adults with epilepsy.[57,59]

In addition to effects on BMD, biochemical indices including calcium, vitamin D metabolites, parathyroid hormone, and markers of bone turnover (formation and resorption) may be affected in association with AED treatment.[47] Many studies find lower calcium, phosphate, and vitamin D metabolite concentrations in persons treated with enzyme-inducing AEDs. Parathyroid hormone levels and markers of bone turnover have been shown to be increased in individuals treated with enzyme-inducing AEDs. These findings are consistent with the theory that enzyme induction results in increased catabolism of vitamin D, leading to a relative hypocalcemia, increased parathyroid hormone, and increased bone turnover to restore calcium concentrations.[13] However, recent studies do not find a correlation of vitamin D with BMD reduction and some find no significant reduction in vitamin D metabolite concentrations in persons treated with enzyme-inducing

AEDs.[48] In addition, evidence of abnormalities in bone health associated with valproate use suggests that other mechanisms may also be influencing the findings.[57,59] The described abnormalities in biochemical indices suggest an effect of AEDs on markers relevant to bone health. However, the mechanisms to explain why these effects occur or if they result in decreased BMD and most importantly fracture are not yet elucidated.

Much of the above discussion has focused on enzyme-inducing AEDs and valproate. Limited information is available on whether newer AEDs such as lamotrigine, topiramate, zonisamide, and levetiracetam affect bone health.

Clinically, all persons should be instructed to take at least the recommended daily allowance of calcium and vitamin D.[10] The recommended daily allowance of calcium depends on age, sex, and reproductive status. It is recommended that all

persons obtain at least 400 IU of vitamin, with higher amounts necessary for those treated with enzyme-inducing AEDs. BMD screening with dual energy x-ray absorptiometry (DEXA) is warranted for persons with prolonged AED exposure, especially enzyme-inducing AEDs, and those with other risk factors known to affect bone health or increase one's risk for osteoporosis. Screening of vitamin D status may be useful. If a person has evidence of bone disease, consider changing AED treatment and referring that person for an endocrine bone health evaluation.

Thyroid Function

Thyroid hormones may be affected by AED treatment. Low serum thyroid hormone has been described in association with carbamazepine therapy and has been postulated to be secondary to induction of the hepatic cytochrome P450 enzyme system, leading to an increase in thyroid hormone metabolism.[25,68] Recent studies also suggest that oxcarbazepine treatment results in low serum thyroid hormones in women, men, and children with epilepsy.[28,63] Results are mixed and contradictory in studies evaluating effects of valproate on thyroid function.[25,28,63,65] There are no data available for other AEDs.

Thyroxine and free thyroxine levels are low in persons treated with carbamazepine and oxcarbazepine.[28,63,64,66] Induction of the cytochrome P450 enzyme system may be resulting in some of the findings. However, other mechanisms may also be involved as oxcarbazepine induces the cytochrome P450 enzyme system at high doses. Although thyroxine and free thyroxine are reduced, thyrotropin is normal and all studied persons are clinically euthyroid. In addition, in a cohort of young girls, the reported thyroid hormone changes had no effect on growth and pubertal development and normal serum thyroid hormone concentrations were restored after discontinuation of both carbamazepine and oxcarbazepine.[63]

Studies do not find consistent results of the effect of valproate treatment on thyroid function. Thyroid function has been assessed in adults and children with epilepsy treated with valproate. Although some studies report elevated thyrotropin,[63] others find no abnormalities.[25,65] As reported in girls treated with carbamazepine and oxcarbazepine, there were no effects of valproate on linear growth or pubertal development.[63]

Peripheral Neuropathies

Chronic administration of several AEDs including carbamazepine and phenytoin have been associated with peripheral electrophysiologic abnormalities and, occasionally, clinically significant peripheral neuropathy.[33] In particular, chronic administration of phenytoin has been cited as a cause of peripheral neuropathy involving distal extremity weakness, areflexia, and dysesthesias. Alterations in touch, vibration, and proprioception in the legs and feet have been previously reported. In addition, several reports have described slowing of nerve conduction and electromyographic evidence of distal denervation.[60,61] Sural nerve biopsy in a patient presenting with clinical signs of phenytoin-associated peripheral neuropathy demonstrated demyelination of large myelinated fibers and axonal atrophy.[50]

Although the length of drug exposure sufficient to cause either clinical or electrophysiologic changes is unclear, it appears that long-term exposure (>5 years) as well as exposure to relatively high serum concentrations pose the greatest risk. Conversely, Yoshikawa et al. have reported distal paresthesia and motor weakness occurring in a patient only hours following the administration of phenytoin.[67] Although folate deficiency, which may be common in patients receiving phenytoin, may result in peripheral neuropathy, evidence for this is lacking.[46]

Reduced nerve conduction velocities have also been reported in some studies of patients receiving carbamazepine, but not others.[8,14] Chronic treatment with either carbamazepine or sodium valproate does not appear to result in clinical symptoms of neuropathy.[6]

Cerebellar Atrophy

Cerebellar dysfunction with features of ataxia, incoordination, dysarthria, dysmetria, intention tremor, and nystagmus are well-recognized manifestations of acute phenytoin treatment. Most commonly, these symptoms are associated with elevated phenytoin serum concentrations, and are reversible. Less commonly, irreversible cerebellar dysfunction and atrophy have been observed in patients receiving long-term phenytoin treatment.[15,32,37] Cerebellar atrophy has been demonstrated in several patient series using both computed tomography (CT) and magnetic resonance imaging (MRI) techniques.[30,34] Although the relationship between phenytoin dose and/or concentration and the development of cerebellar degeneration is unclear, the available clinical evidence would suggest that patients with chronic exposure to elevated serum concentrations may be at particular risk.

The mechanisms underlying these changes are unclear. Cerebellar histopathologic changes including loss of Purkinje cells and granule cell damage have been experimentally produced in some animal models of phenytoin exposure, but this finding has not been consistent, possibly due to the confounding effects of seizure- and coma-induced hypoxia seen in some animal experiments.[7] It therefore is reasonable to speculate that repeated episodes of hypoxia resulting from repeated convulsions over time may account for these observations. The implication therefore is that cerebellar degeneration may be more of a consequence of poorly controlled seizures, particularly generalized convulsions, than of long-term exposure to phenytoin. However, in one small case series,[37] McLain et al. noted the occurrence of cerebellar atrophy confirmed by CT that was not associated with repeated, generalized seizures. In this series, patients did appear to have phenytoin serum concentrations that were above the commonly accepted therapeutic range (>20 μg/mL). In addition, cerebellar degeneration has also been observed in patients receiving this agent who did not have seizures.[51]

Summary and Conclusions

Potential adverse effects on cosmetic appearance, body weight, reproductive health, sexual dysfunction, bone health, the thyroid, peripheral neuropathies, and cerebellar volume can occur in association with long-term AED treatment. Recognizing these effects, changing AED therapy if possible, and providing acute treatment or referral for treatment is important in providing optimal care of persons with epilepsy.

Chapter 108

General Principles: Teratogenicity of Antiepileptic Drugs

Mark S. Yerby

Dina Battino

Georgia D. Montouris

Introduction

Over the past two decades advances in the management of epilepsy and an increased armamentarium of effective antiepilepsy drugs (AEDs) have permitted persons with epilepsy greater freedom and improved quality of life. Women with epilepsy who in past generations were actively discouraged from marriage and childbearing are now marrying at rates equivalent to women without this disorder. This freedom has presented these patients and their physicians with new challenges. Women with epilepsy are unlikely to be able to discontinue medication during pregnancy and as such are at greater risk for complications of pregnancy and adverse pregnancy outcomes. An increased risk of congenital malformations is well recognized as one of these, but mounting evidence suggests that cognitive dysfunction is also seen with increased frequency.

Major efforts have been made to assess the risk of AED use in pregnancy to minimize the risk to both the mother and the child. In the last few years new data have become available on the AED effects on postnatal development. Therefore, although some critical issues remain unsolved, it is important to review the state of knowledge of reproductive and developmental hazards related to AEDs.

An increase in seizure frequency during pregnancy has been reported in approximately 30% of women, which potentiates the risk of maternal complications and perhaps increases the risk of fetal insult (resulting from bradycardia). This information alone precludes discontinuation of antiepileptic medications during pregnancy.

Historical Aspects

The first report of a malformation associated with an AED described a child exposed in utero to mephenytoin, who developed microcephaly, cleft palate, malrotation of the intestine, and a speech defect, and had an IQ of 60.[186] The pregnancy was also complicated by vaginal bleeding.

In 1964 Janz and Fuchs[120] performed a retrospective survey at the University of Heidelberg to evaluate the problem of AED-associated malformations. Their study included 426 pregnancies in 246 mothers with epilepsy. The rates of miscarriages and stillbirths were increased for these patients, but the malformation rate was only 2.2%, not significantly different from that of the general population of West Germany. The authors concluded that AEDs were not associated with an increased risk of malformations.

Pantarotto et al.[208] described a neonate with aplasia of the bone marrow after phenytoin exposure in utero. Centa and Rasore-Quartino [34] reported the first case of congenital heart disease following intrauterine exposure to phenytoin and phenobarbital. Melchior et al. [176] described orofacial clefts with exposure to primidone or phenobarbital.

In a letter in *Lancet* in 1968, S.R. Meadow reported six cases of children with orofacial clefts, four of whom had additional abnormalities of the heart and dysmorphic facial features. All of these children had been exposed to AEDs in utero. He noted that similar abnormalities had been reported following the unsuccessful use of abortifacient folic acid antagonists. Since some AEDs act as folic acid antagonists, he postulated that this might account for AED teratogenicity, and he asked other clinicians to inform him of similar cases. [173]

The first report of malformations associated with a specific AED was published in 1970. [88] Trimethadione was implicated as a teratogen in 8 of 14 pregnancies in which it was taken in the first trimester.

Dr. Meadow's 1968 inquiry concerning AED-associated malformations resulted in the collection of 30 additional cases. This prompted a retrospective survey in which 427 pregnancies in 186 women with epilepsy were studied. This demonstrated for the first time a clear increase in the malformation rates of infants of mothers with epilepsy (IMEs). Speidel and Meadow concluded that (a) congenital malformations are twice as common in IMEs exposed to AEDs; (b) no single abnormality was specific for AED exposure; and (c) a group of these children would have a characteristic pattern of anomalies, which, at its fullest expression, consisted of trigonocephaly, microcephaly, hypertelorism, low-set ears, short neck, transverse palmar creases, and minor skeletal abnormalities.

During the last two decades, a wide variety of congenital malformations have been reported, and every anticonvulsant, whether old or new, has been implicated as a cause. No anticonvulsant drug can be considered absolutely safe in pregnancy, yet most of these drugs do not produce any specific pattern of major malformations. A possible exception to this is the association of sodium valproate with neural tube defects (NTDs). Robert and Guibaud [219] were the first to relate valproate to NTDs. Working in a birth defects registry in the Rhone Alps region of France, they reported NTDs in IMEs exposed to valproic acid in utero. Between August 1979 and August 1982, there were 72 infants with lumbosacral NTDs born in this region. Nine of the 72 (12.5%) had been exposed to valproic acid, although two of the nine also had a family history of NTDs. The mothers of five of these children took valproate monotherapy, one took valproate and phenobarbital, and one took valproate and clonazepam.

Table 1 Incidence of Congenital Malformations in the Offspring of Mothers with Epilepsy Compared to Control Groups

	Offspring of mothers with epilepsy			Offspring of mothers without epilepsy		
		Malformations			Malformations	
Study design	Total outcomes	Number	%	Total outcomes	Number	%
Historical cohorts[3,9,26,27,41,63,71,76,89,121,124,143,162,196,203,220,227,231,240,242,269,275]	12,310	644	5.2	2,431,065	65,064	2.7
Prospective cohorts[37,52,56,68,70,84,105,109,112,115,122,123,138_141,145,178,181,198,205,218,230,237,239,244,247,260,266,278,281]	5,018	327	6.5	655,009	16,212	2.5
Retrospective cohorts[41,110,150,232,267]	800	41	5.1	95,550	2,563	2.7
	18,128	1,012	5.6	3,181,624	83,839	2.6

In an attempt to clarify this observation further, Robert et al. [220] identified 141 pregnancies in women with epilepsy using a combination of questionnaires and electroencephalogram (EEG) registries. This unselected cohort had a malformation rate of 17.7% in the offspring, including four cases of spina bifida. In all cases, there was intrauterine exposure to valproic

acid, although only one woman was on valproate monotherapy.

Subsequent analysis of these exposures identified spina bifida aperta as the specific NTD associated with the valproic acid exposure. [158] Methodologic problems make frequency estimates imprecise, because most published data are case reports, case series, or very small cohorts from registries that were not designed to evaluate pregnancy outcomes. The prevalence of spina bifida with valproate exposure is approximately 1% to 2%,[157] and with carbamazepine 0.5%.[103,223] However, a prospective study in the Netherlands found that IMEs exposed to valproate had a 5.4% prevalence rate of spina bifida. Average daily valproate doses were higher in the IMEs with spina bifida (1,640 ± 136 mg/day) than in the unaffected IMEs (941 ± 48 mg/day). Another group of investigators found that valproate doses of 1,000 mg/day or plasma concentrations of 70 μg/mL or less are unlikely to cause malformations.[128] Both groups recommend that valproate dosage be reduced whenever valproate must be used in pregnancy.[128,204]

Overall, data available in the literature suggest that IMEs who have intrauterine exposure to anticonvulsant drugs are twice as likely to develop birth defects as infants not exposed to these drugs. Table 1 shows the incidence of malformations reported by historical cohort and prospective and retrospective controlled studies.

Mechanisms of Antiepileptic Drug Teratogenesis

There are a number of factors that could account for the increased rates of malformations seen in IMEs. These include maternal seizures during pregnancy, a genetic predisposition related to having epilepsy, falls and injuries from seizures, and lower socioeconomic status and its attendant limited access to prenatal care. There are, however, a number of observations that strongly implicate AEDs as the cause of such teratogenicity seen. Comparisons of malformation rates in the offspring of mothers with epilepsy treated with AEDs compared to those without AED treatment consistently reveal higher rates in the children of the treated group (Table 2).

The precise mechanisms by which AEDs cause birth defects are not fully known. Susceptibility to AEDs and the expression of teratologic outcome may be under genetic control, as suggested by the variability in the frequency and pattern of malformations found in humans and in experiments with inbred mouse strains.[30,46,73,159,217,246,265]

One of the earliest hypotheses proposed that the teratogenic effects of AEDs are related to their interference with folate metabolism. The rationale is that, in humans, low maternal levels of folate and vitamin B_1 and high levels of homocysteine are associated with an increased risk of NTDs.[38,137,179,279] These observations, together with the finding that periconceptional folate supplementation significantly reduces the risk of birth defects and, in particular, that of NTDs,[29,36,100] suggest that folic acid antagonists may increase the risk of congenital malformations. Low folate levels have been found consistently in pregnant women treated with AEDs.[102] In addition, the risk of adverse outcome increases with rising AED blood concentrations and decreases with folate levels.[44,45,199]

Details of the relationships between AEDs and NTDs and between AEDs and folic acid are not yet clear, as it is difficult to explain (a) why the use of multivitamin supplements containing folic acid reduces the risk of malformations caused by some folic acid antagonists but not that due to AEDs[100] and (b) why the risk of NTDs is associated with valproate rather than with phenytoin and phenobarbital, two drugs that decrease folate levels the most. Nevertheless, the available experimental data support the idea that folate metabolism is likely to be involved in some particular aspects of valproic acid teratogenesis.[5,60,62,107,129,241,254,255,270]

Bioactivation of AEDs by the embryonic cytochrome P450 (CYP) system to arene oxide reactive intermediates, which are thought to be teratogenic, has been a prevailing hypothesis for many years.[6,20,30,74,75,153,155,169,208,215,225,246] This conclusion was consistent with the particular high risk associated with combinations of carbamazepine, phenobarbital, and valproate reported in humans,[155] and interpreted as being the result of the cumulative effects of inducing AEDs and valproate inhibition of epoxide-hydrolase responsible for epoxide elimination. The use of extended-release forms of carbamazepine and valproate may lower the risk factor as peaks and valleys are eliminated in these preparations. Further studies are needed to assess this concept.

Table 2 Incidence of Congenital Malformations in the Offspring of Mothers with Epilepsy Treated with Antiepileptic Drugs and of Untreated Mothers Compared to Control Groups

An argument against the foregoing proposal is that the content of CYP in the embryo is low, making bioactivation of AEDs unlikely. Other information against a bioactivation mechanism for teratogenesis is that the most teratogenic AEDs, such as trimethadione and ethotoin, which cause the same pattern of birth defects as phenytoin, are not metabolized through an

P.1215

epoxide metabolite.[72,271] Potentiation of phenytoin teratogenesis by drugs inhibiting CYP-mediated metabolism[250] further argues against a role for the CYP system in teratogenic bioactivation of phenytoin.

Another postulated bioactivating pathway is AED co-oxidation to free radical intermediates. After interaction with molecular oxygen, these compounds liberate reactive oxygen species (ROS), which may be teratogenic. Deficiency of free radical scavenging enzymes, responsible for eliminating ROS, has been associated with malformations in the offspring of mothers with epilepsy taking AEDs.[210,272,273] A recent hypothesis proposes that reactive intermediates may be produced by AED-induced embryonic bradycardia/arrhythmia. Such arrhythmias cause periods of interrupted oxygen supply and generation of highly toxic ROS in the embryonic tissues during the reoxygenation/reperfusion phase.[12,39]

Other postulated mechanisms are tissue damage due to fetal hemorrhage, possibly involving vitamin K deficiency,[114] or interference with placental carnitine transport.[277]

Recently, mechanisms involving homeobox (HOX) genes have been proposed as an explanation for AED teratogenicity.[194] Retinoic acid signaling, involved in regulating transcription of genes that are critical to early brain development, may be affected by teratogens.[221] Such effects include alteration of the expression of retinoic acid receptor[87] or valproate inhibition of histone deacetylases,[23,61,91,94,212] a key element in the regulation of many genes playing important roles in cellular proliferation and differentiation.[69,133,170] Phosphodiesterase-mediated inhibition of cyclic adenosine monophosphate,[85] increase of ROS levels,[190] disruption of normal pH within the embryonic milieu,[233] or inhibition of the detoxifying epoxide hydrolase could also be relevant to the teratogenic effect of valproic acid.[116]

In summary, the mechanisms behind developmental toxicity of AEDs are presently far from completely understood, are likely to be multiple, and undoubtedly differ between individual AEDs.

Pathophysiology of Neural Tube Defects

NTDs are uncommon malformations occurring in 6 in 10,000 pregnancies. Spina bifida and anencephaly are the most commonly reported NTDs; they occur in approximately 4,000 pregnancies annually, affecting 2,500 to 3,000 births in the United States each year.[113,187] The types of NTDs associated with AED exposure are primarily myelomeningocele and anencephaly, which result from abnormal neural tube closure between the third and fourth weeks of gestational age.

Previous thinking about NTDs visualized the fusion of the neural tube as one in which the lateral edges met in the middle and fused both rostrally and caudally, similar to a bidirectional zipper. Recent studies have suggested that there are multiple sites for neural tube closure,[90,259] and that different etiologies may result in different types of abnormality. There are four separate sites along the neural tube where neurulation develops. The first is midcervical; the second is at the cranial junction of the prosencephalon and mesencephalon; the third, which fuses in a caudal direction only, is at the site of the future mouth or stomadeum; and the fourth is the region over the rhombencephalon between the second and third regions.[259] The timing of closure differs among the various sites.

The majority of human NTDs can be explained by failure of one or more closure sites. Anencephaly with frontal and parietal defects is due to failure at the second closure site. Holoacrania, which also involves defects of the posterior cranium to the foramen magnum, is due to failure of closure of the second and fourth sites. Lumbar spina bifida results from failure of the first closure site. The development of closure sites is under genetic control but is also affected by environmental factors. In twins, concordance rates are only 56% for anencephaly and 71% for spina bifida. In Great Britain there is a male preponderance of lumbar spina bifida and female preponderance of holoacrania and anencephaly. Even valproic acid appears to have species differential effects being associated with spina bifida in humans and exencephaly in mice.[235] A number of risk factors are associated with neural tube defects.

The strongest association for NTDs (relative risk [RR] 3% to 8%) is a previous pregnancy with NTD.[180] There are strong ethnic/geographic associations with NTDs. Rates per 1,000 are 0.22 for Caucasians, 0.58 for persons of Hispanic descent, and 0.08 for persons of African descent. The incidence of NTDs in Mexico is 3.26 per 1,000; for Mexican-born persons living in California, 1.6 per 1,000; and for U.S.-born persons of Mexican descent, 0.68 per 1,000.[97] Diabetic mothers have 7.9 times the rates of NTDs in their offspring.[17] Deficiencies of glutathione, folate, vitamin C, riboflavin, zinc, cyanocobalamin, and selenium and excessive exposure to vitamin A have been linked to NTDs. Higher rates are seen in children of farmers, cleaning women, and nurses.[28,171] Pre-pregnancy weight also seems to be a factor. The RR for NTDs in women weighing 80 to 89 kg is 1.9, and 4.0 for those weighing over 110 kg. AED exposure may be a necessary but not sufficient risk factor for the development of NTDs. Women with epilepsy, as all women

of childbearing age, should be supplemented with folate. The dose recommended by the Centers for Disease Control and Prevention of 400 µg/day may not be high enough for many women who do not metabolize folate effectively. For those individuals with a history of NTDs, 4 mg of folic acid daily is recommended. Even with folate supplementation, women taking valproate should avail themselves of prenatal diagnostic ultrasound to detect NTDs.

Variables Confounding the Association of Antiepileptic Drugs with Malformations

A primary question in evaluating the relation between maternal epilepsy and congenital malformations is whether the association is further confounded by the genetics of epilepsy itself. Genetic susceptibility to teratogenic effects of AEDs is suggested by family studies.[58,64,86,130,144,160,165,206,211,261,268] Several case-control series reported a higher proportion of relatives with epilepsy in patients with cleft palate or lip[2,57,65,78,136] or NTDs.[156,219] Greenberg et al.[93] found extensive use of phenobarbital among 414 children with cleft palate or lip. However, the statistical significance of the association disappeared after exclusion of cases with a positive history of malformations. Other cohort studies have confirmed familial occurrence of fetal abnormalities.[7,9,32,43,48,63,128,138,174,184,192,193,200,205,243,269] Parental epilepsy was also found to increase birth defects,[49,53,128,136,205] although the majority of such studies reported conflicting findings.[18,110,123,156,200,204,228]

Seizure occurrence during pregnancy does not increase malformation rates according to most[9,56,71,76,110,141,192,218,228,237,240,243,244,281] but not all the authors.[126,158,164,192,203] The issue of whether epilepsy per se increases the risk of congenital malformations was first raised by a large American and Finnish study[237] that reported higher rates of malformations in children of treated mothers and fathers with epilepsy. Later studies confirmed these findings and added that even untreated mothers with epilepsy had a higher risk of having a child with birth defects.[18,79,139,141,163,177,216] Other investigators, however, found no increased risk of congenital malformations among children of fathers with epilepsy.[42,80,157]

A recent meta-analysis concluded that malformation rates among offspring of women with untreated epilepsy were similar to that of nonepileptic controls.[77] However, these results should be interpreted with caution because of differences in ascertaining cases and controls, as well as the small number of studies and cases considered. Data from the U.K. Registry, the largest prospective study available today, indicate that among the 3,607 enrolled pregnancies, the malformation rates for 239 women with epilepsy who had not taken AEDs during pregnancy (3.3%) were similar to those of 2,598 women with monotherapy exposures (3.7%).[185] Data from 31 studies including exposed offspring, nonexposed offspring, and healthy controls confirm that while treatment of pregnant women with AEDs undoubtedly increases the risk of birth defects, the increased risk cannot be entirely ascribed to AEDs (Table 2).

The more common malformations found in the offspring of women with epilepsy are heart defects, cleft lip or palate, hypospadias, and limb defects. There is fairly solid evidence of a specific association between NTDs and valproic acid[10,21,32,101,125,157,204,219,231] and, to a lesser extent, carbamazepine.[10,101,223] The effect of valproic acid appears to be restricted almost entirely to the posterior neural cord.[158,160] Some studies suggest that the risk of congenital heart disease is increased in pregnant women exposed to barbiturates.[8,10,32,56,192] This association emerges also from data of the U.S. Registry,[112] although the authors neglected to point out that 4 of 77 children exposed to phenobarbital were born with congenital heart defects (5.2%). The associations between valproic acid and limb reduction defects[10,222] or hypospadias[10,231] and between barbiturates and cleft palate/lip[10,125,192] need to be confirmed.

Each of the older AEDs has been considered the most teratogenic when compared to other AEDs or no treatment. Several studies reported a higher risk for pregnancies exposed to carbamazepine,[52,123,154,230,231] primidone,[128,192] phenobarbital,[112,154,192,203,266] or phenytoin.[56,71,154,203,227,247] In recent years, considerable attention has been paid to valproic acid teratogenicity. The joint analysis of five European countries[230] and a large retrospective controlled study from The Netherlands[231] found an increased risk of malformations with valproate and carbamazepine monotherapy compared to healthy controls. The Joint Japanese, Canadian, and Italian study reported an increased risk for valproate and primidone monotherapy in comparison to nonexposed pregnancies.[128] A large historical cohort from Finland found higher risks associated with both valproate monotherapy and polytherapy compared to untreated pregnant women.[11] Other studies have found an increased risk for valproate monotherapy compared to carbamazepine,[185,275] lamotrigine,[185] or unspecified other monotherapies.[278] In a large prospective single cohort from Finland,[123] logistical analysis demonstrated that valproic acid, carbamazepine, oxcarbazepine, low serum folate concentrations, and low maternal educational levels were independently associated with an increased risk of malformations. Finally, the Australian Registry, an observational and partly prospective study, also found that any exposure to valproate was associated with an increased rate of malformations compared to a small group of 24 untreated patients.[257]

Data indicating a higher risk for pregnancies exposed to valproic acid compared to other AEDs need to be interpreted in consideration of published data that have failed to find an association between increased risk and exposure to valproic acid.[22,48,127,155,192,203,204,227] The lack of evidence for valproic acid teratogenicity compared to other AEDs can be accounted for by confounding bias characterizing the studies in question. For example, a family history of malformations is a relevant factor considering that the risk for NTDs in the siblings of affected individuals ranges from 3% to 8%.[180] These rates are consistently higher than those found in the general population and even higher than the risk posed by exposure to valproic acid or carbamazepine. Nevertheless, of the aforementioned studies, only the Joint Japanese, Canadian, and Italian study, the Australian Registry, and a large single-center prospective study from Finland[123,128,257] have taken into account familial malformations, other maternal diseases, and seizures during pregnancy, while the prospective U.K. Registry considered family history of malformations.[185] Only three studies considered the type of epilepsy,[128,230,231] four maternal smoking,[123,230,275,278] and all but one[278] maternal age. It is remarkable that none of the studies evaluating family history of malformations[123,128,185] demonstrated differences in the rate of birth defects among valproate and other monotherapies, with the exception of the U.K. Registry, which reported a higher risk for valproate (6.2%) compared to carbamazepine (2.2%).[185] The findings of the U.K. Registry[185] suggest that the risk of malformations attributed to valproic acid is likely to depend on confounding factors. In the U.K. Registry, there was a higher rate of malformations among 715 pregnancies exposed to valproic acid (6.2%) than in the 647 exposed to lamotrigine (3.2%), but the significance was lost after adjustment for confounding factors. Moreover, the authors reported similar risks for pregnancies exposed to lamotrigine at daily doses of 200 mg or higher (5.4%) and to valproic acid at mean doses of 600 to 1,000 mg/day (6.1%).

A majority of studies have found that polytherapy carries a greater risk than monotherapy,[126,128,149,185,236,275] nonexposed pregnancies,[11,47] or healthy controls.[110,123,126,128,149,203,236,275] This association of malformations and polytherapy is further supported by studies comparing malformation rates in two chronologic cohorts. In a multi-institutional Japanese study, the malformation rate in 172 IMEs born between 1978 and 1984 was 13.5% but fell to 6.2% in 145 IMEs born between 1985 and 1989. The decline was attributed to an increase in monotherapy: 16.1% in the first cohort but 63.4% in the second.[127] Similar results were reported by two other studies that compared two consecutive cohorts.[158,200] Other authors have failed to find an increased risk associated with polytherapy.[32,52,66,121,123,124,175,204,244,247,257,266]

The only drug for which many studies have reported a significant dose–effect relationship is valproic acid,[11,59,119,128,172,230,231,257] although three recent publications have failed to find such a difference.[123,228,278] Considering new AEDs, the U.K. Registry has recently reported a significant dose–effect relationship for lamotrigine.[185] Data on carbamazepine have consistently demonstrated similar mean daily doses among cases with or without malformations.[123,126,149,172,185,198,204,205,228,230,231,244,257] Data on the other established AEDs are conflicting. Some authors have concluded that the risk of malformations is greater for higher phenytoin[37,43,96,128,181] and phenobarbital[127] dosages, while others reported no significant association for either phenytoin[64,126,149,192,198,230,240,244,257] or phenobarbital.[66,71,123,126,149,181,230,240,244] Discrepant findings on the teratogenic risk related to AED doses or polytherapy may depend on the confounding effects of the severity of epilepsy or on differences in the teratogenic potential of specific combinations.

Use of Newer Antiepileptic Drugs in Pregnancy

Since 1993, a number of effective new AEDs have been introduced in North America. These include gabapentin, felbamate, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, and zonisamide, all of which are now available in the United States. Their more favorable side effect profiles have made them increasingly popular. There is some tendency to think that since the hazards of the older AEDs are known, the new ones are likely to be more than acceptable substitutes. Unfortunately, there is little information to support their safety. The number of exposed pregnancies that have been reported with these drugs is very low, not large enough to determine if there is, or is not, an increased risk of adverse outcome with fetal exposure. Lamotrigine, levetiracetam, and oxcarbazepine concentrations decline during pregnancy, and this may be true for the other new AEDs as well.[251] The following section summarizes what is currently known.

Gabapentin

Despite its extensive use for a variety of conditions, little has been published about gabapentin's effect on pregnancy outcomes. A large postmarketing surveillance study of 3,100 English patients taking gabapentin identified 11 pregnancies, none of which had malformations.[276] A study that included cases that were collected both retrospectively and prospectively evaluated 44 children born to 39 mothers with epilepsy taking gabapentin. Two of 44, or 4.5%, had major malformations. One child exposed to gabapentin and valproic acid had hypospadias. The other, who had only one kidney, was exposed to gabapentin monotherapy until the 16th week of gestation and then switched to phenobarbital. A single case of minor anomalies, a slight malformation of the left external ear canal and two skin tags at the angle of the jaw, occurred in a child exposed to gabapentin and lamotrigine.[182] One malformation was reported in 31 offspring of mothers exposed to gabapentin monotherapy by the U.K. Registry.[185]

Lamotrigine

A Swedish birth registry study has reviewed 1,398 infants exposed to AEDs: Five malformations occurred among 90 children exposed to lamotrigine monotherapy (5.6%). A recent report from the U.K. Pregnancy Registry found a dose-response effect: Higher rates of malformations were found in infants exposed to lamotrigine doses of >200 mg/day (5.4%) compared to those exposed to lower doses (1.9% at doses of 100 to 200 mg and 1.5% at doses <100 mg).[185] The International Lamotrigine Pregnancy Registry has now identified 1,224 pregnancies reported in women taking lamotrigine in the first trimester. There is a significant difference in malformation rates for lamotrigine used in (a) monotherapy 2.8% (20 of 707 with a 95% confidence interval of 1.8% to 4.9%); (b) polytherapy with valproic acid 11.8% (14 of 119 with a 95% confidence interval of 6.8% to 19.3%); and (c) polytherapy without valproic acid 2.7% (7 of 256 with a 95% confidence interval of 1.2% to 5.8%).[148] No dose-response effect was found in the Lamotrigine Pregnancy Registry.[148]

Lamotrigine crosses the placenta, and at delivery the fetus and mother have similar plasma concentrations. Elimination in infants appears to be slow. Seventy-two hours postpartum, infant plasma levels are 75% that of the mother. Median milk:plasma ratios are 0.61.[201]

Oxcarbazepine

In the first 12 reported cases of pregnancy with oxcarbazepine, there were nine live births and three spontaneous abortions. In a prospective series of 11 pregnancies, there was one child with spina bifida who had been exposed to oxcarbazepine in polytherapy.[80] In the postmarketing period, the manufacturer has been notified of five cases of fetal malformations. One of these was a cardiac defect. There were also three cleft palates and one facial dysmorphism. Three of the five were exposed to AED polytherapy. The largest prospective series reported to date evaluated 42 oxcarbazepine-exposed pregnancies in Buenos Aires. There were no malformations in the 25 monotherapy cases. One child with a ventricular septal defect was exposed to oxcarbazepine and phenobarbital.[214] In a retrospective study from Finland of 133 women with epilepsy, 101 of these were monotherapy exposures and not associated with malformations. In 17 polytherapy exposures, there was one malformation: A ventriculoseptal defect.[117] Oxcarbazepine crosses the placenta with equivalent maternal and fetal cord levels.[189] A recent review of the published world literature on oxcarbazepine exposure in pregnancy suggests that the risk of malformations is similar to that of the general population.[183]

Topiramate

We have little information of the number of pregnancies with topiramate exposure. There is one case report of a child exposed to topiramate monotherapy who developed growth deficiency, hirsutism, a third fontanelle, an upturned nasal tip, and distal digital hypoplasia. During the clinical trials 28 pregnancies were reported with one malformation and

two anomalies.[207] Postmarketing surveillance has identified 76 prospectively collected pregnancies. In 57 of these pregnancies there was maternal epilepsy. Twenty-nine were exposed to monotherapy. Eight of the 76 (10.5%) had malformations; seven of eight were exposed to polytherapy.[147] Two malformations were reported in 35 pregnancies exposed to topiramate monotherapy enrolled in the U.K. Registry.[185]

Topiramate crosses the placenta with cord and maternal plasma levels being equivalent at delivery. Milk:plasma concentration ratios average 0.86. Infant elimination appears to be substantial with little measurable drug found in the plasma of breastfed infants 2 to 3 weeks postpartum.[201]

Zonisamide

There have been 26 reported pregnancies with zonisamide exposure. Two of the 26 (7.7%) had congenital malformations. One child was also exposed to phenytoin and the other to both phenytoin and valproic acid.[142]

Zonisamide also freely crosses the placenta with transfer rates of 92%. Though data is available from only two children, milk:plasma ratios are 0.8 and elimination half-life ranges from 61 to 102 hours.[147]

Pregnancy Registries

The need to assess the teratogenic risk of old- and new-generation AEDs has led to the development of pregnancy registries. At the time of this writing, pregnancy registries have been created in the United Kingdom and several other European countries, North America, Australia, and India. The existing registries (EURAP, Australia, and India) agreed with the need to pool "protocols" instead of pooling previously collected information (albeit with very similar designs and methods) in order to achieve properly collected data from larger, heterogeneous populations. The U.K. Epilepsy and Pregnancy Registry, the North American AED Pregnancy Registry (NAREP), and the International Registry of AEDs and Pregnancy (EURAP) are the largest efforts to date. The U.K. and the North American registries originated in 1996 to 1997, and EURAP in 1999. The latest registry originated in several European countries but has since continued to expand to include more centers and countries from Asia, Oceania, and Latin America.

Using somewhat different methodology, each the three registries now include from 3,500 to 5,500 prospective pregnancies. The main differences concern method of recruitment, collection of maternal data, frequency of follow-up, and release of results.

Patients are referred to the U.K. registries by physicians and other health care professionals caring for women with epilepsy and by women themselves. NAREP requires patients themselves to report, while EURAP relies only on physicians. The U.K. and North American registries collect data three times: At enrollment, 7 months of gestation, and 8 weeks after delivery. EURAP participants complete five subforms: One at enrollment, one at the end of each trimester, and the last 14 months after birth. Each subform is submitted in real time to a national coordinator, who checks it for completeness and accuracy before forwarding it to the central registry in Milan. The national coordinators and the central registry are responsible for auditing and solving any inconsistencies or missing data by interacting with reporting physicians.

NAREP discloses malformation rates associated with specific treatments as soon as they are found to differ significantly from the rate in a control group exposed to other unspecified monotherapies. The U.K. registries published the results of a multivariate analysis using category of AED exposure (monotherapy, polytherapy, and no AED exposure), individual AED exposures with more than 25 cases, maternal age at delivery, parity, sex of newborns, periconceptional folic acid intake, and family history of malformations as the independent variables. EURAP is waiting until the number of registered pregnancies will be large enough to perform a multivariate analysis including as independent variables potential risk factors, such as maternal age, type of epilepsy, family history of malformations, exposure to other known teratogens, and maternal educational level.

Several pharmaceutical companies have developed their own registries. The International Lamotrigine Pregnancy Registry collects voluntary prospective reports of lamotrigine exposure during pregnancy.[152] There is a Gabapentin Pregnancy Registry organized by Dr. Georgia Montouris. There is also a registry for vigabatrin, but this drug has not been approved for use in the United States. A pregnancy registry for levetiracetam has also recently been established.

To date, the most productive industry registry has been the Lamotrigine Pregnancy Registry, with 1,224 prospectively registered pregnancies. However, even for this registry lack of comparative data represents a main limitation.

Fetal Antiepileptic Drug Syndromes

Minor anomalies are structural deviations from the norm that do not constitute a threat to health and by definition occur in <4% of the population.[166] Such anomalies frequently occur in normal unexposed infants. Combinations of several anomalies are less common and can form a pattern, or a dysmorphic syndrome, which may indicate a more severe underlying dysfunction.

A variety of syndromes associated with AED exposure in utero have been described. Facial dysmorphisms such as hypertelorism, depressed nasal bridge, low-set ears, micrognathia, and distal digital hypoplasia, sometimes in combination with growth retardation and developmental delay, were first reported in association with exposure to phenytoin.[95] Subsequently, however, similar patterns have been reported with exposure to carbamazepine.[122] Valproate exposure has been claimed to cause a somewhat different dysmorphic syndrome characterized by high forehead, a small and flat nose, long philtrum, and long digits. However, there is a considerable overlap in the various dysmorphisms, and their specificity for a particular drug has been questioned. A more general term, fetal or prenatal anticonvulsant syndrome, has therefore been suggested.[282]

The pathogenesis of these AED-associated dysmorphic syndromes is still somewhat controversial. Some authors have attributed most of the minor anomalies to genetic factors rather than drug exposure.[82] For example, similar dysmorphic features have been described in the pre-anticonvulsant era[13,213] and in children of untreated epileptic mothers.[198] However, a recent study examined only infants born to women not taking AEDs in pregnancy.[109] None of these infants had features of the fetal anticonvulsant syndrome. The long-term outcome and significance of these anomalies are unclear. In the relatively few cases that have been followed into early childhood and reported, the minor anomalies have tended to disappear as the child grew older.[37,134,141,151]

Table 3 Incidence of Major Congenital Malformations by Timing of Assessment

Timing of malformati

Study design	Within the neonatal period			
		Malformations		
	Total outcomes	*N*	%	c
Historical cohorts[3,9,11,26,27,41,49,63,71,76,89,121,124,143,196,203,220,227,231,240,242,269,275]	14,016	668	4.8	
Mainly prospective cohort[4,175,257]	193	10	5.2	
Prospective cohorts[24,25,44,54,56,59,68,70,84,92,106,108,111,115,122,123,138,139,140,141,142,146,172,176,181,185,200,228,230,234,236227,228,229,230,231,232,233,234,235,236,237,238,239,244,247,278,281]	7,383	327	4.4	
Retrospective cohorts[15,42,88,110,120,150,152,168,177,182,229,232,243,267]	2,141	100	4.7	
	23,733	1,105	4,7	

Finally, it should be emphasized that minor anomalies are much more difficult to assess objectively than major malformations, and equally difficult to quantify. A few studies have focused on methodologic issues involved in recognizing minor anomalies in children of epileptic mothers. The findings showed that observer and context bias are likely to occur in such studies. [33,98]

Summary and Conclusions

The risk of major congenital anomalies is increased in the offspring of mothers with epilepsy and is largely due to AEDs. However, evaluation of published studies reveals a 10- to 20-fold variation in malformation rates.[14] Consistent differences are also observed for risk associated with AED polytherapy and high doses. [14] The variability of data within the literature reflects methodologic differences. Such differences are usually significant enough to prevent pooling of data for meaningful meta-analyses. [253] The populations studied also vary considerably: Some reports have considered only women exposed to AEDs or only women with epilepsy, whereas others have also included women not taking AEDs or women taking AEDs for reasons other than epilepsy. Different authors have adopted variable exclusion criteria such as maternal malformations, chronic or genetic diseases, twins, and siblings. Differences in the denominators used to calculate birth defects (women, pregnancies, live births only or live births and therapeutic abortions and/or stillbirths and/or spontaneous abortions) also play a major role. Consider, for example, that excluding therapeutic abortions reduces the rate of several malformations present in the general population by about 5%. [67]

Other relevant factors are differences in the timing of outcome assessment and in the teratogenic end-points. Many birth defects are not detectable at birth, while others may disappear after birth. Table 3 shows that the risk of underestimation prevails: The incidence of major structural malformations is increased by about one third when the follow-up ends at birth. In terms of teratogenic end-points, there is a lack of standardized criteria for classifying malformations and of a clear-cut distinction between major malformations, minor anomalies, and postural deformities. In many papers, definitions are not given or malformations are poorly described. The gradient for incidence of malformations at birth between studies considering only severe structural malformations and those including any structural malformation or structural malformations plus minor anomalies is shown in Table 4. As expected, the rates of major and minor anomalies are, on average, twofold higher than those of major congenital malformations only. On the other hand, restricting studies to severe structural malformations only reduces by about one third the incidence of congenital malformations.

Such discrepancies in the literature mirror the variability among study designs and tested populations. Other shortcomings characterize nearly all the studies published to date. [14,16,55,253] For example, most have been based on small samples that fail to reach statistical power; only a few have enrolled more than 500 cases. [11,22,27,121,123,124,128,185,192,230,231,240,275] As a consequence, the majority of old and more recent studies compare the malformation rates of individual AEDs without adjustment for other potential risk factors such as maternal age, ethnicity, social status, other diseases or exposures, and the genetic background. In addition, information on confounders related to epilepsy, such as timing of exposure, severity of epilepsy, duration of epilepsy, and the frequency of and timing of seizures during pregnancy, is also often missing. Finally, randomized trials are lacking for ethical reasons. Therefore, even with rigorous methodology the available evidence is primarily derived from observational studies that are prone to confounding, selection, and measurement bias. [253]

A few observations are firmly established. The first is that maternal epilepsy increases the risk of birth defects by two- to threefold over population rates. The second is that the increased risk is primarily associated with AED treatment, especially polytherapy. A number of congenital anomalies have been observed in cohorts of IMEs, but these cannot be considered major malformations. Their impact on the health of the child is minimal, or they are easily treatable. The most severe malformations are detectable in utero with modern ultrasound techniques. This allows physicians and patients to plan for immediate and early interventions. In the case of valproic acid, there is convincing evidence for an increased risk of neural tube defects in fetuses exposed to the drug. The data for most AEDs, however, are limited to comparing malformation rates of exposed infants to population rates. There are no head-to-head comparison studies, and thus, care must be taken when discussing comparisons between specific AEDs. There is also need for detailed information on the specific frequencies of major structural malformations for second-generation antiepileptic medications. Hopefully, the ongoing prospective registries will clarify these issues, as well as the relative contribution of AEDs and other factors, such as genetic predisposition and maternal epilepsy.

Table 4 Incidence of Congenital Anomalies Detected within the Neonatal Period by Teratogenic End-point

Study design	Teratogenic end-point						
	Severe structural malformations			Any structural malformation			
	Total outcomes	*N*	%	Total outcomes	*N*	%	o
Historical cohorts[3,11,26,27,41,63,71,89,121,124,143,162,196,203,220,227,231,240,242,247,269,275]	2,391	90	3.8	11,625	578	5.0	
Mainly prospective cohorts[4,19,66,175]				193	10	5.2	
Prospective cohorts[24,25,54,56,59,68,70,84,108,112,115,123,126_128,136,138,142,145,149,155,167,176,178,185,193,198_200,204,218,228,230,234,236,239,247,263,266,278,281]	1,055	34	3.2	6,328	293	4.6	
Retrospective cohorts[15,18,22,88,110,120,121,131,150,152,164,168,182,229,231,232,243,267]				2,141	100	4.7	
	3,446	124	3.6	20,287	981	4.8	

It should be remembered and emphasized that more than 90% of women with epilepsy will give birth to healthy

children without birth defects or developmental delay, but a more precise estimate of individual risks and the effect of genetic and environmental factors has yet to be determined. Prenatal counseling should be performed when possible, and close monitoring during pregnancy is essential.

Chapter 109

Neurodevelopmental Effects

Eija Gaily

Kimford J. Meador

Introduction

The increased risk of major malformations after prenatal exposure to antiepileptic drugs (AEDs) has been established by research extending over three decades (see Chapter 110). The neurodevelopmental effects of in utero exposure to AEDs have not been as extensively investigated as AED-induced somatic abnormalities. This may be because the assessment of functional outcomes is more complicated and time consuming than major malformations that are usually detected at birth and are less affected by confounding factors.

Teratogens interact with genotype to produce both anatomic and behavioral defects. Whether a defect occurs depends on a susceptible genotype and may involve the interaction of multiple-liability genes.[30] The mechanism of anatomic and behavioral teratogenesis may well differ since it appears that the highest risk of anatomic defects is from first-trimester AED exposure, while the highest risk of behavioral defects appears to be from exposure during the third trimester, when neuronal migration and synaptic organization occur.[76]

Animal studies have clearly demonstrated that prenatal AED exposure can produce behavioral as well as anatomic defects. In contrast to somatic malformations in animals, which usually require AED dosages several times above human therapeutic dosages, behavioral impairments can occur at lower dosages and at blood levels similar to human therapeutic levels.[31,42]

The first report of mental deficiency after prenatal AED exposure in children with typical minor anomalies but no major malformation was published in 1975.[18] After that, a number of studies have investigated the relationship between typical minor anomalies and cognitive impairment in AED-exposed children, and several antiepileptic drug syndromes have been proposed. More recent studies have also addressed the question of whether prenatal antiepileptic drug exposure increases the risk of cognitive impairment even in the absence of detectable anatomic teratogenesis.

Animal Data

Behavioral Data for Individual Antiepileptic Drugs

Benzodiazepines

Neonatal benzodiazepine exposure produces widespread apoptotic neuronal cell death in rats (see Mechanism section). Gestational or neonatal exposure to benzodiazepines can affect brain chemistry and behavior.[18] For example, diazepam can affect behavior differentially depending on the stage of development at which the exposure occurs. Midgestation exposure causes transient hyperactivity but no learning or retention deficits on a choice discrimination task. Late prenatal exposure caused no hyperactivity but resulted in poor learning and retention. Early postnatal exposure resulted in lasting hyperactivity as well as learning and retention deficits.[34]

Carbamazepine

Despite the common use of carbamazepine in humans, very few neurobehavioral studies in animals have been published. In utero carbamazepine exposure did not produce hyperexcitability in primates, unlike phenytoin.[70] A preliminary report found that neonatal rats dosed with carbamazepine slightly above the ED50 for anticonvulsant action produced widespread neuronal apoptosis similar to several other AEDs[49] (see Mechanism section).

Phenobarbital

Perinatal phenobarbital exposure in rats reduces brain weight.[21] Phenobarbital causes apoptotic neuronal cell death in neonatal rats (see Mechanism section). Mice exposed prenatally to phenobarbital have neuronal deficits, reduced brain weight, impaired development of reflexes, open-field activity, schedule-controlled behavior, spatial learning, and catecholamine brain levels.[32,57,61,62,103,104] Rats that had seizures induced by kainic acid as neonates exhibited deficits in water maze (a measure of visuospatial memory) and open-field activity when tested subsequently. Rats receiving kainic acid followed by phenobarbital exhibited even greater disturbances in memory, learning, and activity levels.[63] In contrast, this effect was not seen with topiramate, as described below.

Phenytoin

Gestational and neonatal exposure to phenytoin reduces brain weight.[43,83] Phenytoin alters neuronal membranes in the hippocampus.[94] It also alters critical genes and delays neurodevelopment.[8] Dose-dependent apoptotic neuronal cell death occurs in neonatal rats (see Mechanism section). Prenatal phenytoin at subteratogenic dosages (100 to 200 mg/kg) in rats produces impaired spatial learning and motor coordination.[26,64,77,89,90,91,93,97] A dose-effect relationship was noted at maternal levels (10 to 25 μg/mL) overlapping the human therapeutic range. The adverse behavioral effects do not resolve as the rats grow older.[93,94] Prenatal exposure to phe-nytoin in rats results in hyperactivity.[91,97] Similarly, primates who have in utero exposure to phenytoin are hyperactive and hyperexcitable, but those exposed to carbamazepine or stiripentol are not.[70]

Primidone

Gestational primidone can produce behavioral deficits in rats.[71] When tested as adults, the rats that had been exposed in utero to primidone were impaired in their performance of an eight-arm radial maze task and had reduced open-field activity.

P.1226

Topiramate

Topiramate has been shown to produce adverse cognitive effects in adults. In contrast, the effects of topiramate in neonatal animal models appear to be protective. Topiramate protects against hypoxic-ischemic white matter injury and decreases the subsequent neuromotor deficits when administered posthypoxic insult in neonatal rats.[33] Rats that are treated with to-piramate after a series of 25 neonatal seizures performed significantly better in the water maze than rats treated with saline.[106] These findings are in contrast to the adverse effects of phenobarbital in the same animal model.

Valproate

An in vitro study using rat hippocampus cultures found that valproate interferes with formation of the pyramidal cell layer.[29] In utero valproate can alter neuronal membranes in the hippocampus and cortex of rats.[95] Early postnatal exposure to valproate decreased brain weight in mice.[85] Exposure of neonatal rats to valproate resulted in widespread neuronal apoptosis (see Mechanism section). Adverse neurobehavioral effects in rats have been seen following in utero exposure at doses of 150 to 200 mg/kg,[87,92] although these effects were not as marked as phenytoin in the same animal model.

Antiepileptic Drug Effects on Neurodevelopment: Potential Mechanisms

Folate-related Mechanisms

Folate demands are increased during pregnancy, and women with epilepsy who have lower folate levels are more likely to have abnormal pregnancy outcomes.[20] Several AEDs are known to affect folate metabolism. Phenobarbital, phenytoin, and primidone, but not carbamazepine, deplete folate.[12,13,15,16] Valproate alters folate metabolism.[12]

Ischemia/Hypoxia

Phenytoin can affect cardiac function in fetal rats, and animals exposed in utero to ischemia develop defects that resemble phenytoin-induced defects.[19]

Neuronal Suppression

AEDs suppress neuronal irritability and could reduce neuronal excitation, altering in utero synaptic growth and connectivity and producing long-term behavioral deficits.

Reactive Intermediates

The teratogenesis of AEDs may be mediated by toxic intermediary metabolites rather than the parent compound.[98,99] Oxide intermediates (epoxides) are generated during the metabolism of some AEDs and are highly reactive and can bind nucleic acids. However, the theory of the epoxide mechanism has been questioned because the cytochrome P450 enzymes required for conversion of an AED to an epoxide are not expressed in embryonic tissues.[53] An alternative theory posits that AEDs may be metabolized to free-radical reactive intermediates by prostaglandin H synthetase or lipoxygenases, which are active in the fetus.[98,99] Then, these reactive oxygen species could bind to DNA, protein, or lipids, resulting in teratogenesis.

Antiepileptic Drug–induced Neuronal Apoptosis

The observation that third-trimester gestational ethanol exposure can produce widespread neuronal apoptosis and neurobehavioral deficits led to the hypothesis that the adverse behavioral effects of AED exposure might be due to a similar mechanism.[48] The effect of ethanol is mediated by combined *N*-methyl-D-aspartate (NMDA) glutamate receptor blockade and γ-aminobutyric acid $(GABA)_A$ receptor activation,[48] which are receptor mechanisms affected by some AEDs. Recently, several AEDs have been tested for similar apoptotic effects in a neonatal rat model. Widespread neuronal apoptosis occurs as a result of neonatal exposure to clonazepam, diazepam, phenobarbital, phenytoin, vigabatrin, or valproate.[9,10] The effect appears to be due to reduced expression of neurotrophins and levels of protein kinases, which are important for neuronal growth and survival. Of note, the adverse effects were ameliorated by β estradiol, which has neurotrophic effects.[6,10,39] Similar apoptotic effects were not seen at therapeutic dosages for levetiracetam or topiramate.[39,56,60] Additional studies are needed to examine the effects of other AEDs in this animal model, extend the studies to gestational animal models, and determine if a similar mechanism occurs in humans.

Human Data from Offspring of Mothers with Epilepsy

Syndromes and Minor Anomalies

The fetal hydantoin syndrome (FHS) was first described by Hanson and Smith[42] in five unrelated children whose mothers had epilepsy. Four mothers had taken 100 to 400 mg of phe-nytoin (one monotherapy) and one had been treated with 300 mg of mephenytoin during pregnancy. Four children had also been exposed to barbiturates and one to additional phensuximide. All displayed a characteristic pattern of craniofacial abnormalities (including short nose with low nasal bridge, and hypertelorism) (Fig. 1[65]), hypoplasia of nails and distal phalanges, and postnatal growth deficiency, and four had motor or mental deficiency. In a later cohort study, Hanson et al.[41] estimated that 11% of phenytoin-exposed children showed enough unusual features to be clearly classified as having FHS. Patterns of minor anomalies similar to phenytoin combined with developmental delay have been described in association with prenatal carbamazepine[52] and primidone[66] exposure, but these have never been established as separate syndromes. A different pattern of abnormalities has been described for valproate, as discussed below.

Of the typical FHS features, distal digital hypoplasia (Fig. 2) has been most consistently associated with prenatal phenyt-oin exposure in prospective studies blinded to exposure.[4,55,37] Two studies have used anthropometric methodology. Kelly[54] made a radiologic diagnosis of distal phalangeal hypoplasia based on measurements from hand radiographs in 15 of 47 phenytoin-exposed and one of ten control children. In a controlled population-based study, prenatal phenytoin exposure was observed to have a significant dose-related negative correlation with distal phalangeal length measured from hand radiographs.[36] A radiologic diagnosis of distal phalangeal hypoplasia was made in 8 of 75 (11%) phenytoin-exposed children compared with 1 of 130 children not exposed to phenytoin ($p = 0.003$).[36] In most of these children, distal digital hypoplasia was not obvious on a clinical examination. Growth and intelligence were within the normal range in all.

Controlled prospective and retrospective studies blinded to prenatal AED exposure have consistently shown that the craniofacial minor anomalies considered typical of FHS are increased in children of mothers with epilepsy compared with control children of mothers without epilepsy.[37,46,67,101,105] Most studies observed no increased minor anomalies in

nonexposed children of mothers with epilepsy,[46,101,47] while one study found that some of the facial features such as epicanthus were increased not only in the nonexposed children, but also in the mothers with epilepsy.[37] Although the results on whether these typical anomalies are associated with impaired cognitive development are controversial,[35,45] multiple minor anomalies in general are known to be associated with delayed development[81,86] and should alert the clinician to do a systematic developmental evaluation and follow-up.

FIGURE 1. A: Child exposed to phenytoin monotherapy, aged 18 months. Note telecanthus; short nose with flat nasal bridge and anteverted nares; long, shallow philtrum; and thin upper lip. **B:** Same child aged 15 years and 3 months. Note that the nose has grown to a more normal appearance. The nasal root

is prominent. The philtrum remains shallow and the upper lip thin. (Reproduced with permission from Moore SJ, Turnpenny P, Quinn A, et al. A clinical study of 57 children with fetal anticonvulsant syndromes. *J Med Genet*. 2000;37[7]:489–497.)

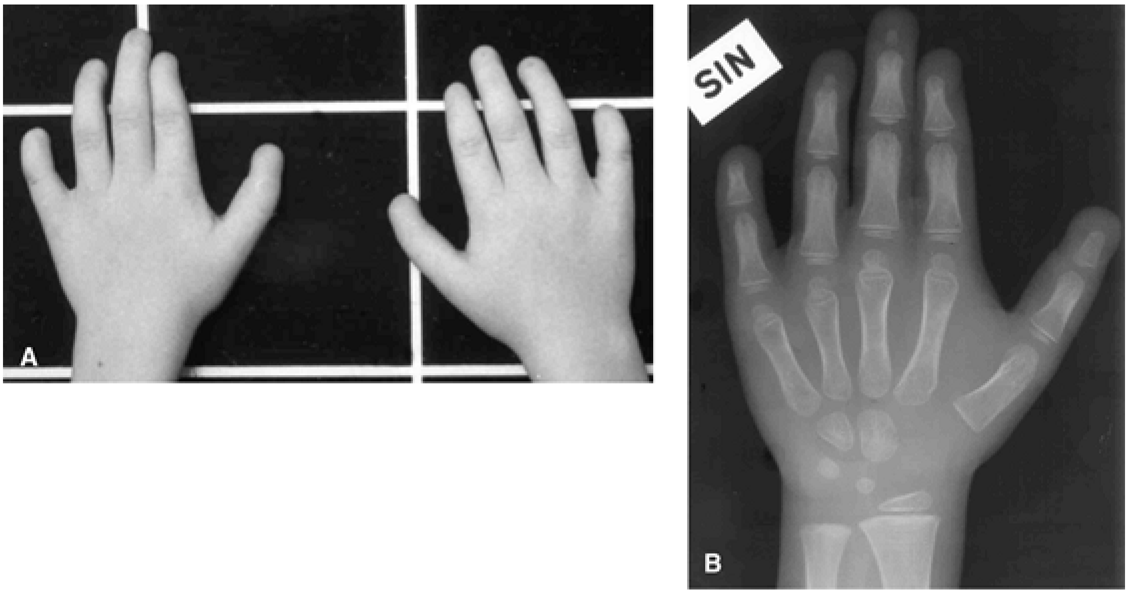

FIGURE 2. A: Severe distal phalangeal hypoplasia in a child with prenatal phenytoin (86 umol/L) and phenobarbital exposure, aged 5 years and 4 months. The child also had mild hypertelorism (not shown). Growth and intelligence were normal. **B:** Left-hand radiograph of the same child at age 5 years and 4 months, showing aplastic distal phalanges in fingers 2 and 5 and hypoplastic distal phalanges in fingers 1, 3, and 4.

The fetal valproate syndrome (FVS) was first described by DiLiberti et al.,[22] later verified by Ardinger et al.[5] in 19 valproate-exposed (eight monotherapy) children of 18 mothers with epilepsy, and reviewed by Clayton-Smith and Donnai.[17] The characteristic craniofacial features include trigonocephaly, bifrontal narrowing with indentation of the outer orbital ridge, medial deficiency of eyebrows, long shallow philtrum with long and thin upper lip, and broad or flat nasal bridge (Fig. 3[59]). Major malformations may also occur: The most common are neural tube defects, congenital heart defects, oral clefts, genital abnormalities, and limb defects. Developmental delay is observed in most children with this pattern of minor anatomic abnormalities; some also have autistic features.[102,73] Pre- and postnatal growth are usually normal.

FIGURE 3. Fetal valproate syndrome. Note especially trigonocephaly, medial deficiency of eyebrows, broad nasal root, anteverted nares, shallow philtrum, and long and thin upper lip. Patients 1–3, 4 and 5, and 6 and 7 are siblings. Patient 2 was also exposed to phenytoin and patient 7 to vigabatrin; others were exposed to valproate monotherapy only. (Reproduced with permission from Malm H, Kajantie E, Kivirikko S, et al. Valproate embryopathy in three sets of siblings: further proof of hereditary susceptibility. *Neurology*. 2002;59[4]:630–633.)

The incidences of FHS and FVS are unknown. Based on a prospective population-based study, FHS with mental deficiency appears to be quite rare (<1%), at least in the Finnish population.[35] There is only one prospective study on minor anomalies in valproate-exposed children, observing significantly increased anomalies in valproate-exposed children compared to controls,[51] but there are no prospective data on the incidence on FVS. Case reports describing drug-exposed multiple pregnancies have found different outcomes after similar exposures. Phelan et al.[69] described a dizygotic heteropaternal twin pair exposed to 230 mg of phenytoin during pregnancy, with one twin showing all typical symptoms and signs of FHS, while the other twin was healthy. Bustamante and Stumpff[11] reported trizygotic triplets, exposed to 300 mg of phenytoin and 450 mg of phenobarbital, who showed very different manifestations of FHS. Malm et al.[59] described three families in which all valproate-exposed siblings had FVS, and Kozma[58] reported one family with FVS in two siblings. These observations strongly support the hypothesis that genetic susceptibility

P.1228

significantly enhances the risk of serious adverse outcome after prenatal phenytoin or valproate exposure.

Intelligence

In addition to the rare AED syndromes, there is a recognized risk that prenatal antiepileptic drug exposure may have effects on cognitive development even without signs of anatomic teratogenesis. Studies looking at long-term postnatal development face many challenges. Enrolling children in the study during the mother's pregnancy is mandatory to get reliable prospective exposure data, including maternal drug doses, seizures during pregnancy, and other pregnancy complications. Children must then be followed at least until preschool or early school age. Developmental data acquired from questionnaires or from records not designed for investigational purposes may not be reliable; only standard IQ testing provides data that are comparable across different exposure groups and studies. Before the age of 5 years, cognitive tests have limited predictive power[40] and it is not possible to document milder cognitive deficits than moderate to severe mental deficiency reliably. This results in long study durations with a high risk for loss of follow-up and increasing effect of confounding effects. Maternal education[84] and especially maternal IQ[75] are significant predictors of intelligence in the offspring. Psychosocial and socioeconomic disadvantage associated with epilepsy[50,44] as well as maternal depression[7] may affect postnatal development of children of mothers with epilepsy. Women with epilepsy or a history of epilepsy have lower marriage rates than controls,[79] possibly reflecting a limited choice of partners and resulting in an increased risk of inherited cognitive dysfunction from the paternal side.

Table 1 Intelligence Scores in Children of Mothers with Epilepsy and Control Children from a Population-based Prospective Study

IQ score group	Number of children	Verbal Mean ± SEM	Nonverbal Mean ± SEM	Full-scale Mean ± SEM
Study group all	182	92.8 ± 1.3	100.3 ± 1.2	96.0 ± 1.2
No drug exposure	45	94.3 ± 2.6	98.6 ± 2.9	95.6 ± 2.8
Monotherapy exposure	107	94.4 ± 1.7	101.9 ± 1.4	98.0 ± 1.6
CBZ monotherapy	86	96.2 ± 1.9	103.1 ± 1.5	99.7 ± 1.8
VPA monotherapy	13	83.5 ± 3.8	96.3 ± 4.8	89.7 ± 3.6
Other monotherapy[a]	8	91.1 + 6.4	96.9 + 4.6	93.6 + 5.0
Polytherapy exposure[b]	30	84.9 ± 2.5[c]	97.1 ± 2.9	89.5 ± 2.4
Control group all	141	94.9 ± 1.2	102.4 ± 1.2	97.6 ± 1.4

SEM, standard error of the mean, CBZ, carbamazepine, VPA, valproate.

[a] Six phenytoin, two clonazepam.

[b] Seventeen combinations included valproate.

[c] F = 8.6, $p = 0.004$ versus controls, and F = 5.2, $p = 0.02$ versus study children exposed to monotherapy by covariance analysis, with maternal education and test (WPPSI-R or WISC-R) used as covariates.

Reproduced (slightly modified) with permission from Gaily E, Kantola-Sorsa E, Hiilesmaa V, et al. Normal intelligence in children with prenatal exposure to carbamazepine. *Neurology.* 2004;62(1):28–32.

Possibly the most important confounding factor for prenatal AED effects is maternal epilepsy. Prenatal drug exposure is not random. The choice of treatment prescribed for the mother is determined by maternal epilepsy type or syndrome and the severity of seizures. Several observations suggest that some epilepsy-associated genes may also have an influence on cognitive development. Siblings of children with epilepsy show increased cognitive dysfunction.[25] Cognitive deficits may be present already at onset of idiopathic and cryptogenic epilepsies.[94] Idiopathic partial epilepsies and developmental cognitive disorders (such as dysphasia) overlap.[23] Low socioeconomic status has been found to be a risk factor for epilepsy of unknown etiology.[44] As the risk of cognitive impairment and drugs of choice probably covary in different epilepsy syndromes, the child of a mother with epilepsy may show cognitive impairment that appears to be related to a specific drug but is actually based on genetic traits associated with that particular type of epilepsy. This also makes it impossible to have a perfect control group in cognitive studies. In a control group of children of mothers without epilepsy, not only the prenatal drug exposure, but also the epilepsy factor, is missing. If different drug exposures are compared with each other and with nonexposed children with mothers with a history of epilepsy, we may well be comparing different forms of epilepsy and different genetic risks. To control for the epilepsy factor as

well as possible, carefully determining maternal epilepsy type and etiology as well as obtaining data on maternal intelligence (or at least educational level) are necessary in studies dealing with prenatal AED effects on development.

Carefully conducted prospective clinic-based studies give a good description of what kind of problems may be anticipated in children of mothers with epilepsy and may provide data on the relative risk of different AEDs. The applicability of their results, however, is limited by selection of the study population. Only population-based studies (i.e., studies in which it is possible to reliably estimate what proportion of the population is included in the study) allow a reliable estimation of the magnitude of the risk for cognitive development in children of mothers with epilepsy compared to the general population.

A recent Cochrane review[3] assessed all prospective studies reporting cognitive outcome in children of mothers with epilepsy published from 1966 through 2003. Thirty-one reports based on 18 independent cohorts were included in the review. Eleven studies were considered clinic based and four studies population based (not identified in the review), and the others provided insufficient data on recruitment. Most studies had limited quality and a small number of participants; only seven cohorts included more than 50 AED-exposed children. Attempts to control for confounding factors were described in about half of the studies. Assessment of outcome was blinded in nine studies. Comparison groups varied from study to study, with some studies giving their results only in pooled mono- or polytherapy subgroups and others reporting individual drug exposures (carbamazepine, phenytoin, phenobarbitone). The results were largely conflicting, and the authors concluded that there was very little evidence as to which specific drugs would be more harmful to the prenatally exposed child.

Two controlled, prospective, population-based studies including 50% to 60% of the population[35,78] (both included in the Cochrane review) provided data on intelligence scores at 4[78] and 5[35] years of age in a total of 297 children of mothers with epilepsy. Cognitive assessments were blinded to the prenatal exposures. Two hundred and five children were exposed to phenytoin (81 monotherapy). The most common combination was phenytoin and phenobarbitone. Forty nonexposed children of mothers with epilepsy were also included. Maternal phenytoin levels were measured by Gaily et al.[35]: All except one were well under the upper limit of the reference range. Both studies reported lower IQ values in children of mothers with epilepsy than controls, but no significant associations were observed to any drug exposure or to exposure to maternal seizures.[35]

Hanson et al.[41] extracted data on 104 children exposed to phenytoin (24 monotherapy) from the same data source as Shapiro et al.[78] (i.e., the Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disorders and Stroke[80]). These children were matched for maternal socioeconomic status, maternal age, race, and institution of birth with 100 control children of mothers without epilepsy. Eighty-three children in both groups were tested by Wechsler Intelligence Scale for Children (WISC) at 7 years of age. The mean full-scale score was 92 in the phenytoin-exposed children and 97 in controls (p <0.05). In the absence of other exposure groups and nonexposed children of mothers with epilepsy, it is impossible to know how much of the IQ difference was related to prenatal phenytoin exposure and how much to other epilepsy-related factors.

Two recent population-based studies[100,38] (the former not included in the Cochrane review) reported cognitive outcome in a total of 248 children of mothers with epilepsy with carbamazepine monotherapy as the most common AED exposure. Both studies included approximately 50% of the population of children born to mothers with epilepsy in their catchment areas. The investigator performing the cognitive testing was blinded to exposure. Wide et al.[100] used the Griffiths test at 2 to 8 years and found no difference between 35 carbamazepine-exposed children and 66 control children of mothers without epilepsy. Gaily et al.[38] administered the age-appropriate Wechsler scale at 5 to 11 years. The study included 107 monotherapy exposures (86 carbamazepine), 30 polytherapy exposures (17 including valproate), 45 nonexposed children, and 141 control children of mothers without epilepsy. No impairment was found in the children exposed to carbamazepine compared to nonexposed or controls (Table 1). Verbal IQ was significantly reduced in the polytherapy subgroup. No associations of IQ to maternal epilepsy type or maternal generalized tonic–clonic seizures during pregnancy were observed.

So far prospective data on cognitive outcome in children with prenatal valproate monotherapy exposure are available

only for 26 children from two population-based studies.[38,27] In both studies, the mean verbal IQ was 11 to 13 points lower in the valproate monotherapy–exposed group than in children with no AED exposure or exposed to carbamazepine monotherapy. A significant negative correlation between valproate dose of the mother during pregnancy and verbal IQ in the offspring was observed.[38] Although attempts to control for maternal epilepsy type, educational level,[38] and maternal IQ[27] were made, it was impossible to reliably rule out confounding by genetic and environmental factors. Retrospective studies have reported increased educational needs[1] and impaired verbal IQ[2] in children exposed to valproate monotherapy, even when controlled for maternal IQ. The reduction of verbal IQ in the valproate monotherapy group in the retrospective study[2] was in the same order of magnitude (10 points) as in the prospective studies.[38,27] The impairment found in the valproate group has been limited to verbal IQ in all studies except one.[27] The findings highlight the urgent need for prospective studies with sufficient power and careful documentation of maternal epilepsy characteristics to investigate the possible harmful effect of valproate on cognitive development.

Table 2 Incidence of Mental Deficiency in Children of Mothers with Epilepsy, Based on Pooled Data from Three Prospective Population-based Studies[a]

Antiepileptic drug exposure	Number with mental deficiency per total exposed (%)	Comment
Phenytoin monotherapy	0/60	
Carbamazepine monotherapy	2/105 (1.9)	One West syndrome
Valproate monotherapy	3/34 (8.8)	One mother of child with mental

Other monotherapy	0/4	deficiency had subnormal IQ
Polytherapy[b]	1/84 (1.2)	Phenytoin, carbamazepine, and alcohol abuse
No drug exposure	2/64 (3.1)	One Down syndrome
Total	8/351 (2.3)	

[a] The Eriksson et al. study provided population-based data for the valproate monotherapy group only. Included were born in 1975 to 1979 (Gaily E, Kantola-Sorsa E, Granstrom ML. Intelligence of children of epileptic mothers. *J Pediatr*. 1988;113(4):677–684.), 1989 to 1994 (Gaily E, Kantola-Sorsa E, Hiilesmaa V, et al. Normal intelligence in children with prenatal exposure to carbamazepine. *Neurology*. 2004;62(1):28–32), and 1989 to 1997 (Eriksson et al. study).
[b] Twenty-six combinations included valproate.

Fetal growth, major malformations, and minor anomalies in infants born to women receiving valproic acid. *J Pediatr*. 1986;108(6):997-1004.

Incidence of Mental Deficiency

In the studies reporting intelligence scores, most participating children have performed well within the normal range. As no follow-up data after IQ testing are available from any of the cognitive studies, it is not clear whether the statistically significant group impairments have any clinical significance that would signal an increased risk for learning problems. Mental deficiency, however, has an obvious impact on the child's educational achievement. Prospective population-based data on the incidence on mental deficiency in children of mothers with epilepsy are available from two Finnish studies.[35,38] A third study[27] provided population-based data on valproate monotherapy–exposed children only. The children were tested at age 5 to 13 years. All studies defined mental deficiency as both verbal and nonverbal IQ below 70. Based on the pooled data, the incidence of mental deficiency was 8 of 351 (2.3%) in children of mothers with epilepsy and 3 of 246 (1.2%) in control children of mothers without epilepsy (relative risk [RR] 1.9, 95% confidence interval [CI], 0.5 to 7.0). For comparison, the incidence of mental deficiency in a birth cohort of 12,000 children in Northern Finland was found to be 1.2%.[72] The breakdown of the data to AED exposures and other relevant etiologic information are shown in Table 2. Based on the pooled data, children exposed to valproate monotherapy had a higher risk of mental deficiency (3 of 34, 8.8%) than other children of mothers with epilepsy (5 of 317, 1.6%) (RR 5.6, 95% CI, 1.4 to 22.4).

Human Data from Subjects with No Maternal Epilepsy

Long-term cognitive effects of prenatal phenobarbital exposure was studied by Reinisch et al.[74] based on data from the Danish Perinatal Cohort. This database comprised the offspring of 9,006 deliveries that took place at the largest hospital in Copenhagen between 1959 and 1961. Demographic, socioeconomic, and medical variables (including drug treatment) were recorded prospectively. Phenobarbital exposure was recognized if maternal treatment had lasted for at least 10 days during pregnancy (range 10 days to entire pregnancy). Two separate cohorts of men were later selected from this database with the criteria of phenobarbital exposure and absence of other significant other risk factors (including maternal epilepsy) during pregnancy. Controls were matched for a number of potential confounders, including a maternal complaint score reflecting indication. The study subjects were given either the Wechsler Adult Intelligence Scale (WAIS) (33 subjects, mean age 23 years) or the Danish Military Draft Board Intelligence test (81 subjects, mean age 19 years). Total phenobarbital dosages varied

from 225 to 22,500 mg. Men exposed to phenobarbital showed approximately 0.5 standard deviation (SD) lower scores than expected. The IQ impairment was most marked after exposure in the third trimester, and the effects were increased in those from low socioeconomic status and unwanted pregnancy.

A randomized placebo-controlled blinded study[28] investigated the cognitive late effects of postnatal phenobarbital exposure of toddler-aged children with febrile seizures. Two hundred and seventeen children were randomized to receive either phenobarbital 4 to 5 mg/kg/day or placebo. There was no difference in Bayley scores between the groups at the beginning of the study. At 2 years after the assignment to treatment, the mean IQ was 8.4 points lower in the children assigned to the phenobarbital group compared to placebo ($p < 0.01$). Six months after offset of the medication, there was still a 5.2-point difference in the mean IQ. Sixty-four percent of these children were later examined at the age of 7 years by the Wide Range Achievement Test (WRAT-R) and the Stanford-Binet Intelligence Scale.[82] The children who had been assigned to the phenobarbital group showed significantly impaired performance in WRAT-R reading scores but not on the Stanford-Binet Scale compared to the placebo group. This long-term follow-up study suggests that exposure to phenobarbital during early childhood may have long-term adverse cognitive effects on the skills (especially language) that are actively acquired at that age.

Summary and Conclusions

Neurobehavioral adverse effects have been observed in animal studies after prenatal exposures to benzodiazepines, phenobarbital, phenytoin, primidone, and valproate. Prenatal exposure to carbamazepine in a primate study did not find adverse neurobehavioral effects. Two studies on perinatal topiramate exposure did not find adverse neurobehavioral effects, and to-piramate even appeared protective against ischemia or seizures. Widespread neuronal apoptosis has been found in neonatal rats exposed to benzodiazepines, phenobarbital, phenytoin, valproate, and vigabatrin, but did not occur to therapeutic dosages of levetiracetam or topiramate. Animal data concerning the behavioral effects of in utero AED exposure are, however, incomplete, especially for AED combinations and the newer AEDs. Further, intraspecies differences exist in susceptibility to AED-induced anatomic malformations, and may also exist for behavioral teratogenesis. Although animal data need to be interpreted cautiously and will ultimately require confirmation in humans, investigations in animals can control for a variety of confounding factors and offer insight.

Prenatal exposure to antiepileptic drugs in humans may result in syndromes with mental deficiency and characteristic minor anomalies as the typical features. The incidences of the fetal hydantoin and valproate syndromes are unknown but are probably rare. Case reports from multiple pregnancies and siblings suggest that genetic susceptibility is required for full syndrome expression.

The results of prospective studies investigating IQ at preschool or school age are somewhat controversial. Most studies have observed a mild but statistically significant IQ reduction in children of mothers with epilepsy compared to control children of mothers without epilepsy. There are several important confounding factors, and the contribution of prenatal AED exposure remains unconfirmed. Data from controlled, prospective, population-based studies have provided no evidence that prenatal phenytoin or carbamazepine exposure would impair intelligence. One perinatal cohort study including subjects with no maternal epilepsy and another study including children with febrile convulsions treated in the toddler years suggest that prenatal or early postnatal exposure to phenobarbital may cause permanent mild IQ impairment. The results of retrospective studies suggest that prenatal valproate exposure may reduce verbal IQ, but prospective data on valproate are until now very limited.

The incidence of mental deficiency has been investigated by three population-based studies; the results suggest that the incidence may be slightly increased in children of mothers with epilepsy. Two studies included mainly phenytoin and carbamazepine exposures and established no increased risk in those children. Insufficient data on valproate exposure from two prospective studies raise concern that prenatal valproate may be associated with an increased risk of cognitive impairment, a concern supported by a retrospective study. Further investigation is needed to completely define the cognitive risk of valproate. However, given the increased incidence of major congenital malformations related to in utero valproate exposure,[68] it may be prudent to avoid valproate as a drug of first choice in women of childbearing age. There are no data on cognitive outcome after prenatal exposure to other currently used antiepileptic drugs.

Presently our data on cognitive effects of prenatal exposure to antiepileptic drug are almost limited to IQ only. There is a need in the future to look at other aspects of cognition (e.g., memory and attention) beyond IQ.

Chapter 110

Drug–Drug Interactions

René H. Levy

Blaise F.D. Bourgeois

Houda Hachad

Introduction

Within the context of the pharmacologic treatment of epilepsy, the topic of drug interactions has received much attention. Because antiepileptic drugs (AEDs) have narrow therapeutic ranges, treatment is generally individualized, and unpredicted alterations in drug levels might require dose adjustments. Most of the older AEDs are prone to interactions with other AEDs, as well as with other concurrent medications such as anticoagulants, antidiabetic agents, and antidepressants. As a result, the literature associated with AED interactions is extensive. This chapter focuses on recent advances and the integration of pharmacokinetic and pharmacodynamic interactions.

Pharmacodynamic Interactions

The concept of pharmacodynamic interactions between AEDs is quite different from the concept of pharmacokinetic interactions. Whereas pharmacokinetic interactions determine changes in levels of a drug, pharmacodynamic interactions determine changes in pharmacologic effects when another drug is added or discontinued. These pharmacodynamic interactions, therefore, can determine whether it is meaningful for two particular drugs to be prescribed together. In contrast, pharmacokinetic interactions require only dose adjustments; they are unrelated to the qualitative aspects of drug combinations. The amount of information available about pharmacokinetic interactions between AEDs is considerably larger than that available about pharmacodynamic interactions, in part because it is easier to measure drug levels than to quantify various drug actions. In addition, for pharmacodynamic interactions, several pharmacologic actions of drugs can be involved, whereas with pharmacokinetic interactions there is always only one end point, namely, the drug concentration. To analyze pharmacodynamic interactions, it is necessary to understand what the possible interactions can be. Pharmacokinetic interactions can cause a change in drug absorption, metabolism, or elimination or a displacement from serum proteins. Pharmacodynamic interactions are distinguished by whether they are purely additive, supraadditive, or infraadditive. When the interaction is additive, the combined effect of the two drugs administered together for a given pharmacologic effect is equal to the expected sum of the corresponding activity of each drug used alone. For instance, if concentration *x* of drug *A* produces a certain effect, and concentration *y* of drug *B* produces the same effect, one-half of concentration *x* of *A* in the presence of one-half of concentration *y* of *B* will produce the same effect. One-half of *x* and one-half of *y* represent an equivalent "bolus," and this concept forms the basis of the so-called "isobolographic" analysis, an established method for the quantitative assessment of pharmacodynamic interactions.[21] When the interaction is supraadditive, or potentiated, the combined effect of the two drugs is greater than the expected sum of the individual effects of the two drugs. In the foregoing example, less than one-half the concentration of each drug would be required to achieve the same effect. Finally, if the interaction is infraadditive, or antagonistic, the combined effect is less than the expected sum of the individual effects, and, for instance, more than one-half the concentration of each drug would be required to achieve the same effect.

How does this apply to pharmacodynamic interactions between AEDs? AEDs form a heterogeneous group; their common denominator is the ability to prevent the occurrence of seizures. They also all tend to produce toxicity, in particular neurologic toxicity, at certain concentrations. The antiepileptic pharmacodynamic interaction between two drugs is irrelevant in itself. A supraadditive interaction is not necessarily beneficial. The concentration of a single drug could be increased indefinitely if it were not for the occurrence of toxicity. The same upper limit, however, will also apply to two drugs administered simultaneously. Therefore, for a combination of two AEDs to be advantageous, the seizure protection provided by the combination at a certain degree of toxicity (e.g., the threshold for overt toxicity) must be stronger than that with either drug alone at the same level of toxicity. Thus, the antiepileptic and the neurotoxic interactions must differ in favor of the antiepileptic interaction. In clinical reality, this issue is complicated by the fact that side effects of AEDs are not limited to neurotoxicity. In addition, a totally different situation in which a combination of two AEDs can be advantageous can arise when a patient has two different seizure types, each of which responds to a different drug.

Based on these considerations, it is understandable that the information on pharmacodynamic interactions between AEDs is limited. These interactions are difficult to quantify in patients. Even the available data from animal experiments are limited because certain studies considered only the antiepileptic interaction. In many other studies, the analysis was based on doses only. When drug effects are quantified on the basis of drug dose alone, pharmacokinetic interactions can falsify the analysis of pharmacodynamic interactions. For instance, earlier studies based on the analysis of doses in animals suggested an antiepileptic potentiation between phenytoin and phenobarbital.[28,172] This turned out to be a pharmacokinetic artifact due to an acute inhibition of phenytoin elimination in the presence of phenobarbital. Later studies revealed that, in the presence of phenobarbital, single doses of phenytoin produce higher phenytoin brain levels than when phenytoin is administered alone and that the antiepileptic interaction between phenobarbital and phenytoin is purely additive when brain levels are used for the analysis.[20,91]

The results of the first series of experimental studies in which antiepileptic as well as neurotoxic interactions between AEDs were quantified are summarized in Table 1. These studies reveal that the majority of antiepileptic interactions are strictly additive and that antiepileptic potentiation is the exception

rather than the rule. In contrast, neurotoxic interactions are divided about equally between those that are infraadditive and those that are additive. These experimental data suggest that only a few combinations among the older AEDs are possibly superior to the corresponding monotherapies. These combinations include valproate with carbamazepine, valproate with ethosuximide, and valproate with phenytoin. Although an infraadditive neurotoxic interaction between phenytoin and phenobarbital was found, the therapeutic index of phenobarbital alone was very low, and the combination still had a lower therapeutic index than did phenytoin alone.[20]

Table 1 Pharmacodynamic interactions between antiepileptic drugs in animal models

	Interaction		
Drug	Antiepileptic	Neurotoxic	Ref.
A. Older drugs			
PHT + PB	Additive	Infraadditive	20
PHT + CBZ	Additive	Additive	129

CBZ, carbamazepine; CBZ-E, carbamazepine epoxide; CZP, clonazepam; ESM, ethosuximide; FBM, felbamate; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; OXC, oxcarbazepine; PB, phenobarbital; PEMA, phenyo-ethyl-malonamide (primidone metabolite); PHT, phenytoin; PRM, primidone; TGB, tiagabine; TPM, topiramate; VPA, Valproate. *Source:* Modified from Bourgeois BFD, Dodson WE. Antiepileptic and neurotoxic interactions between antiepileptic drugs, In: Pitlick WH, ed. *Antiepileptic Drug Interactions.* New York: Demos; 1988:209–219.

Interactions between low doses of clonazepam and valproate or ethosuximide were all found to be supraadditive for antiepileptic and for neurotoxic effects, but they result in a superior therapeutic index for both valproate and ethosuximide.[22] Using a similar model, Gordon et al.[64] studied the pharmacodynamic interactions between felbamate and older AEDs. They found a potentiation of the antiepileptic activity of felbamate by phenytoin, carbamazepine, valproate, and phenobarbital. In contrast, the neurotoxicity was not potentiated, and the protective index of felbamate was raised by the addition of any one of these four drugs.

Many additional experimental studies of pharmacodynamic interactions have been carried out in recent years, involving mostly the newer AEDs (Table 1).[38] Overall, these studies again reveal that various combinations can have any possible type of association of antiepileptic and neurotoxic interactions. Accordingly, some drug combinations are more promising than others, at least on the basis of this experimental model.

In the end, whether a combination of two AEDs is beneficial for patients needs to be determined by careful clinical assessments. Although pharmacodynamic interactions are more difficult to study in patients than in experimental animals, valuable clinical data have accumulated. One of the first clinical studies addressing in a systematic manner the issue of the beneficial value of an AED combination was reported by Hakkarainen.[70] Among 100 newly diagnosed patients, 33 were refractory to carbamazepine alone and to phenytoin alone. Of those, five (15%) became seizure free on the combination. Rowan et al.[140] demonstrated that absence seizures could be fully controlled by valproate–ethosuximide combination therapy in a few

patients who had been refractory to either drug alone. Walker and Koon[169] found that some patients who had not responded to valproate alone and to carbamazepine alone became seizure free on the combination.

A positive synergism between valproate and lamotrigine has also been suggested. Among 347 patients refractory to monotherapy with valproate, carbamazepine, phenytoin, or phenobarbital, the seizure reduction was significantly greater when lamotrigine was added to valproate than when it was added to the other drugs.[24] In a rigorous systematic study of add-on valproate versus add-on lamotrigine, among 13 patients who had not responded to the addition of either one of the two drugs, 4 became seizure free when both drugs were added.[123] When 14 patients whose seizures had not been controlled by monotherapy with carbamazepine and with vigabatrin were given both medications, 5 (36%) became seizure free.[159]

In addition to potentially favorable pharmacodynamic interactions, clinical observations have also revealed that adverse effects of one AED can be potentiated by those of another. An increase in tremor when lamotrigine was prescribed in combination with valproate was observed in two studies.[80,123] An increase in side effects characteristic of carbamazepine was noted in four patients in whom levetiracetam was added to carbamazepine in polytherapy.[156] An exacerbation of carbamazepine toxicity also was noted after the addition of lamotrigine, and this could not be attributed to a pharmacokinetic interaction.[16] Chorea occurred in three patients on phenytoin and lamotri-gine in combination only, and it resolved when one medication was tapered.[175] Finally, it appears that valproate encephalopathy is more likely to occur in the presence of another AED, and it can resolve when either valproate or the other drug is discontinued.[104] More recently, two reports suggested that the addition of topiramate may enhance some side effects of valproate, in particular hyperammonemic encephalopathy.[63,101]

Pharmacokinetic Interactions

Metabolic and Pharmacokinetic Characteristics of Antiepileptic Drugs

Table 2 summarizes the principal metabolic (enzymes with major or minor roles) and pharmacokinetic (route of elimination, half-life and extent of plasma protein binding) characteristics of older (established) and newer AEDs that are relevant to a mechanistic understanding of drug interactions.

Interactions Associated With Older Antiepileptic Drugs

Effects of Established Antiepileptic Drugs on Other Drugs

These interactions result principally from the induction of several metabolic enzymes (cytochrome P450 1A2 [CYP1A2], CYP2C9, CYP2C19, CYP3A4, and glucuronyl transferases) by carbamazepine, phenobarbital, phenytoin, or primidone and the inhibition of a few enzymes by valproic acid.

Table 3 provides a comprehensive listing of drugs affected by the enzyme-inducing effects of carbamazepine, phe-nytoin, and phenobarbital. These include many CYP3A4 substrates, narrow-therapeutic-range drugs such as warfarin, and drugs that are mainly glucuronidated such as lamotrigine. Recent studies show large decreases in serum concentrations for quetiapine (7.5-fold increase in clearance)[66] and tipifarnib (5-fold increase in clearance).[32] CYP2B6 induction by phenyt- oin was observed in a patient taking two CYP2B6 substrates—thiothepa and cyclophosfamide.[41]

Valproic acid behaves as an inhibitor of CYP2C9, CYP2C19, and CYP3A4. It increases the serum levels of phenobarbital, phenytoin, and warfarin. It also inhibits some glucuronyl transferases and elevates the serum levels of lamotrigine[59] and other drugs such as lorazepam,[147] naproxen,[1] and zidovudine.[92] The effects of valproic acid on lorazepam pharmacokinetics were studied in two groups with different uridine glucuronyl transferase (UGT) genotypes—UGT2B15*1/*1 and UGT2B15*2/*2. Results indicated that during the valproic acid–inhibited state, lorazepam clearance was lower in the *2/*2 group, although the percentage changes from baseline did not differ significantly by genotype.[29] Valproic acid produced small increases in area under the serum concentration curve (AUC) and in the peak serum concentration (C_{max}) of the recently approved drug aripiprazole with minimal effects on its active metabolite.[30]). Because valproic acid has the potential to benefit patients suffering from HIV-associated cognitive impairment,[148] its effects were studied in HIV-1–infected patients receiving efavirenz or lopinavir/ritonavir. Valproic acid did not affect efavirenz disposition, but it increased lopinavir concentrations.[44]

Effects of Other Drugs on Established Antiepileptic Drugs

Because established AEDs are substrates of metabolizing enzymes, they are subject to a number of interactions resulting from the inducing or inhibitory effects of coprescribed drugs. These interactions are summarized in Table 4. Inhibitors of CYP3A4, such as ketoconazole, clarithromycin, erythromycin, fluvoxamine, nefazodone, diltiazem, and ritonavir, increase carbamazepine levels. The CYP2C9/2C19-mediated metabolism of phenytoin is inhibited by fluconazole, sulfaphenazole, phenylbutazone, amiodarone, ticlopidine, and more recent drugs such as voriconazole. Other drugs known to reduce the clearance of (S)-warfarin (substrate of CYP2C9) such as zafirlukast are expected to affect phenytoin disposition in a similar fashion. Moreover, concomitant administration of lopinavir/ritonavir and phenytoin results in a two-way drug interaction: phenytoin increased lopinavir clearance via CYP3A4 induction, and lopinavir/ritonavir increased phenytoin clearance via CYP2C9 induction.[98]

There are numerous case reports of decreased or increased valproate valproic acid exposure in the presence of known modulators of transport systems. In the case of carbapenem antibiotics, there is a consistent and marked decrease in valproic acid concentrations often accompanied by breakthrough seizures.[31] The mechanisms of this decrease in valproic acid concentration have not been elucidated.[115]

Interactions Associated with Newer Antiepileptic Drugs

Recently developed AEDs as a group appear to exhibit fewer pharmacokinetic drug interactions. This is the result of a direct attempt to avoid or minimize oxidative metabolism when these drugs were developed (Table 2). Felbamate, lamotrigine, oxcarbazepine and its monohydroxy derivative (MHD), topiramate, and zonisamide are substrates for metabolizing enzymes (CYPs or UGTs), whereas gabapentin, levetiracetam, and vigabatrin are mostly eliminated by renal excretion.

Felbamate

Felbamate undergoes partial hepatic metabolism, with almost 50% of the dose excreted unchanged in the urine of healthy volunteers.

Table 2 Pharmacokinetics and elimination pathways of antiepileptic drugs in adults

Drug	Half-life (h)	Protein binding (% bound)	Elimination (main route)	Enzyme with major role	Enzymes with minor role	Additional data
			Older AEDs			
Carbamazepine	5–26	75	Oxidation to 10,11-epoxide metabolite (65%); glucuronidation (15%)	CYP3A4	CYP1A2, CYP2C8	Epoxide metabolite is active and cleared by epoxide hydrolase
Ethosuximide	40–60		Oxidation (65%)	CYP3A4		
Phenobarbital (primidone: prodrug)	77–128	55	Oxidation to *p*-hydroxy metabolite (20%); *N*-glucosidation; renal excretion	CYP2C9	CYP2C19 CYP2B6	
Phenytoin	7–42	90	Oxidation to 5-(4-hydroxyphenyl)-5-phenylhydantoin (90%)	CYP2C9	CYP2C19	
Valproic acid	9–15	90	Glucuronidation (50%); beta-oxidation (10%–20%)	UGT2B7	UGT1A6, 1A9	Beta-oxidation by mitochondrial oxidases and CYPs
			Newer AEDs			
Felbamate	16–22	20–25	Oxidation (15%); renal excretion	CYPs		
Gabapentin	5–7	3	Renal excretion			
Lamotrigine	30	55	Glucuronidation >65%	UGT1A4		
Levetiracetam	6–8	10	Renal excretion; hydrolysis		Hydrolase	Hydrolysis (25%)
Oxcarbazepine (MHD active metabolite)	9 (MHD)	40 (MHD)	Glucuronidation (MHD)		Aldoketoreductase converts oxcarbazepine to MHD	Oxcarbazepine is a produg converted to MHD
Pregabalin	6		Renal excretion (>90%)			
Tiagabine	7–9	98	Oxidation (>30%)	CYP3A4		
Topiramate	18–23	15	Renal excretion; oxidation (15%)		CYP	
S-Yigabatrin	4–7		Renal excretion			

Table 3 Drugs whose serum concentrations are decreased by coadministration of carbamazepine, phenytoin, and phenobarbital

Coadministered agent	Drugs used in epilepsy whose concentration is decreased by the coadministered agent	Other drugs whose concentration is decreased by the coadministered agent
Carbamazepine	Alprazolam	Amitriptylline
	Clobazam	Albendazole
	Conazepam	Citalopram
	Clorazepate	Bromperidol
	Diazepam	Bupropion
	Midazolam	Caffeine
	Ethosuximide	Clozapine
	Felbamate	Cyclosporine
	Lamotrigine	Dexamethasone
	Levetiracetam	Doxepin
	Oxcarbazepine (MHD)	Doxycycline
	Phenobarbital	Etizolam
	Primidone	Felodipine
	Phenytoin	Fentanyl
	Tiagabine	Haloperidol

	Warfarin

MHD, monohydroxy derivative.

Table 4 Drugs that have been reported to inhibit the metabolism and to increase the serum concentration of carbamazepine, phenytoin, phenobarbital, and valproic acid

Affected drug	Metabolic inhibitor
Carbamazepine	Cimetidine
	Clarithromycin
	Danazol
	Dextropropoxyphene
	Diltiazem
	Erythromycin
	Fluconazole
	Fluoxetine
	Fluvoxamine
	Isoniazid
	Ketoconazole
	Metronidazole
	Nefazodone
	Quetiapine
	Risperidone
	Ritonavir
	Sertraline
	Ticlopidine
	Trazodone
	Troleandomycin
	Verapamil
	Viloxazine

Compounds with enzyme-inducing activity increase felbamate clearance: in two population pharmacokinetic studies, felbamate clearance was 40% higher when felbamate was coadministered with carbamazepine and phenytoin compared to monotherapy; however, phenobarbital treatment did not have any significant effect.[11,84] In a large retrospective evaluation, a prolongation in felbamate half-life from 24 to 32.4 hours was found in patients taking concomitantly gabapentin compared to monotherapy, but this effect is still unexplained.[75]

The disposition of various AEDs can be altered by felbamate. Reductions in carbamazepine levels between 18% and 31% were observed when felbamate was coadministered, with corresponding increases in serum carbamazepine-10,11-epoxide (CBZ-E) levels of 33% to 57%.[4,65,168] Recently, Egnell et al.[52] suggested that induction of CYP3A4 is a possible mechanism for the interaction between felbamate and carbamazepine. Increases in estrogen and progestin clearance have also been associated with felbamate.[141] The only isoform inhibited in vitro by therapeutic concentrations of felbamate was CYP2C19 (K_i = 225 μmol/L).[62] This observation is consistent with clinical findings of increased serum concentrations of phenytoin[62,65,141,143] and might account for the reduced clearance of phenobarbital[130] and the higher levels of norclobazam and clobazam[34] in patients comedicated with felbamate. Felbamate has also been shown to decrease valproic acid clearance by 20% to 50%, presumably via inhibition of the β-oxidation metabolic pathway.[21,22,23,24,25,34,62,130,143,167]

Lamotrigine

Effects of Other Drugs on the Disposition of Lamotrigine.

Lamotrigine is extensively metabolized by glucuronidation mediated by UGT1A4 and excreted in urine predominantly as the inactive 2*N*-glucuronide conjugate.[155] Comedication with enzyme-inducing AEDs enhances the metabolic clearance of lamotrigine through induction of UGT1A, and higher doses of lamotrigine are needed when the drug is given concurrently with phenytoin, carbamazepine, primidone, and phenobarbital.[7,105,106] Oxcarbazepine and its corresponding monohydroxy metabolite are less potent enzyme inducers than carbamazepine, but they can also decrease serum lamotri-gine concentrations.[105] Methsuximide can also lower lamotri-gine levels, leading to deterioration in seizure control in some cases.[15]

When lamotrigine and felbamate were administered concurrently to 21 healthy individuals, serum concentrations of lamotrigine were similar to those obtained with lamotrigine and placebo,[33] and similar findings were obtained in patients.[57] Levetiracetam did not affect the steady-state serum concentrations of lamotrigine.[58,121] Similarly, treatment with pregabalin, 600 mg/d for 7 days, had no effect on lamotrigine steady-state concentrations.[25] Coadministration of escalating doses of to-piramate in a group of 25 patients resulted in only slight decreases in average lamotrigine levels compared with baseline: lamotrigine levels were decreased 20% to 30% in three of the patients, consistent with the notion that topiramate is a weak enzyme inducer.[14] Steady-state dosing of zonisamide in 20 patients stabilized on lamotrigine monotherapy (150 to 500 mg/d) did not significantly affect lamotrigine C_{max}, AUC, or clearance, but it decreased significantly renal lamotrigine clearance.[95] A 22% increase in lamotrigine clearance has been reported in healthy individuals after administration of retigabine; this interaction was unexpected because retigabine did not show enzyme induction in other interaction studies.[71]

Lamotrigine metabolism is strongly inhibited by valproic acid, resulting in twofold increases in lamotrigine half-life and serum concentrations.[6,80,174] The lamotrigine/valproic acid combination has been associated with an increased risk of toxic epidermal necrolysis.[56] The risk of skin rash seems to

correlate with a high starting dose of lamotrigine and fast dose uptitration when the drug is added to valproic acid. However, Faught et al.[55] analyzed the incidence of rash in patients who had lamotrigine added to their valproic acid treatment regimen and found that the occurrence of rash was not greater than when lamotrigine was added to other drugs, especially when la-motrigine was titrated up very slowly. Other studies confirmed these findings.[173] In combination therapy including valproic acid and AEDs with inducing effects, the inhibitory effect of valproic acid on lamotrigine metabolism appears to be stronger than the inducing effects of phenobarbital or carbamazepine on lamotrigine. However, when valproic acid is combined with phenytoin, the effects of both drugs on lamotrigine disposition seem to compensate each other.[106] Decerce et al.[42] reported that when valproic acid is added to lamotrigine, the greatest impact on the serum level of lamotrigine occurs at dose introduction. In spite of this potentially adverse pharmacokinetic interaction, a favorable pharmacodynamic synergism between valproic acid and lamotrigine was reported by Kanner and Frey.[80] When valproic acid was added to lamotrigine therapy, a significant reduction in the seizure frequency occurred in patients with refractory epilepsy, resulting in seizure-free patients.[80] However, recently two cases of lamotrigine toxicity were reported when the drug was coadministered with valproate; the patients developed downbeat nystagmus, and truncal ataxia occurred in conjunction with toxic lamotrigine serum levels.[5]

Drugs used to treat conditions other than epilepsy have also been reported to affect lamotrigine metabolism. The enzyme-inducing agent rifampicin was found to increase lamotrigine clearance by 97%.[51] Oral contraceptives may also increase lamotrigine clearance, and their intake has been associated with a mean 50% decrease in serum lamotrigine levels.[131,142] In a study with patients using either no hormonal contraception (n = 18), an ethinylestradiol-containing contraceptive (n = 11), or a progestogen-only contraceptive (n = 16), Reimers et al.[131] demonstrated that it is the ethinylestradiol component that interacts with lamotrigine and not the progestogen. A dose adjustment for lamotrigine might be needed in women taking oral contraceptives.[154]

In a parallel, placebo-controlled study in healthy volunteers, coadministration of lamotrigine with olanzapine (5 to 15 mg for 2 weeks) resulted in a small decrease in exposure to lamo-trigine (20% decrease in AUC), suggesting some induction by olanzapine of the glucuronidation pathway of lamotrigine.[153]

Coadministration of acetaminophen enhances the urinary elimination of lamotrigine after single doses of the anticonvulsant (decreases in lamotrigine AUC and serum half-life of 20% and 15%, respectively) when compared to placebo.[43]

There are two reports of patients who experienced an increase in serum lamotrigine concentration following the addition of sertraline; one patient exhibited toxicity when his lamotrigine levels doubled. The authors suggested inhibition of glucuronidation as a possible mechanism for this interaction.[83]

Effects of Lamotrigine on the Disposition of Other Drugs.

During repeated treatment, lamotrigine was shown to induce its own metabolism, resulting in a 25% decrease in its half-life. Consistent with this observation, the addition of lamo- trigine to valproate produced a small (25%) but significant decrease in steady-state serum valproic acid concentration. However, the formation clearances of the hepatotoxic valproic acid metabolites 4-ene- and 2(E),4-diene-valproate were unaffected by lamotrigine administration.[6] Lamotrigine has no significant effect on steady-state concentrations of phenyt-oin, phenobarbital, or primidone.[76,77,100] Increases in serum CBZ-E concentrations and neurotoxicity have been reported following the addition of lamotrigine to a stable drug regimen with carbamazepine.[171] However, this observation was not confirmed in other studies,[16,53,103] suggesting that the interaction with lamotrigine and carbamazepine is pharmacodynamic rather than pharmacokinetic. When pregabalin disposition (600 mg/d for 8 days) was studied in patients taking lamotrigine (100 to 600 mg/d chronically), pregabalin steady-state pharmacokinetic parameters were similar to those found in historical healthy individuals receiving pregabalin alone.[25]

Although an early study suggested that lamotrigine does not increase ethinylestradiol and levonorgestrel clearances,[72] a more recent investigation identified a moderate decrease in serum levonorgestrel levels when lamotrigine (300 mg/d) was given to women taking an oral contraceptive.[154] Although in that study intermenstrual bleeding was reported by 32% of women during coadministration of lamotrigine and the oral contraceptive (and follicle-stimulating hormone [FSH] and luteinizing hormone [LH] concentrations were increased by 4.7-fold and 3.4-fold, respectively), the low serum progesterone concentrations suggested that suppression of ovulation was maintained and that oral contraceptive efficacy was not impaired.[154]

Oxcarbazepine

Oxcarbazepine is a keto analog of carbamazepine that can be considered as a prodrug because it is rapidly converted to its 10-monohydroxy derivative (MHD), which is primarily responsible for the pharmacologic effect. MHD is metabolized by conjugation with glucuronic acid.[54] A small proportion (4%) of MHD is oxidized by the CYP system to the inactive 10,11-dihydroxy derivative. More than 95% of a dose is recovered in the urine as follows: <1% as unchanged oxcarbazepine, 49% as inactive glucuronide conjugates of MHD, and 27% as MHD.[162] No autoinduction of metabolism has been observed with oxcarbazepine.

Although structurally similar to carbamazepine, oxcarbazepine is predominantly metabolized by noninducible ketoreductases. However, coadministration of carbamazepine, phenobarbital, or phenytoin decreases the serum concentrations of MHD, probably by inducing its metabolism.[10,74,110] There is no evidence of a major effect of valproic acid on oxcarbazepine metabolism, and the association with valproic acid should not require any adjustment of oxcarbazepine dose.[10,110]

Several studies evaluated the effects of other drugs on the metabolism and elimination of oxcarbazepine and its major metabolite. In patients comedicated with topiramate, the serum MHD concentration-to-oxcarbazepine dose ratio was not different from that in patients taking oxcarbazepine monotherapy.[10] In the same study this ratio was not altered in patients taking lamotrigine.[10] No significant changes were observed in oxcarbazepine disposition when the drug was concomitantly administered with cimetidine,[86] dextropropoxyphene,[114] erythromycin,[85] verapamil,[88] or viloxazine.[122]

Studies in human liver microsomes showed that oxcarbazepine and its pharmacologically active metabolite MHD have little or no capacity to inhibit the CYP1A, CYP2D, and CYP2E families of isozymes. However, CYP2C19 was significantly inhibited by oxcarbazepine.[165] This inhibition is consistent with the observation of increases in serum phenytoin concentrations up to 40% in patients taking concomitantly oxcarbazepine and phenytoin.[74] Addition of oxcarbazepine to carbamazepine treatment can lead to a small decrease in serum carbamazepine concentration.[110] On the other hand, phenobarbital serum concentrations increased by 14% in patients receiving oxcarbazepine, but this change is not clinically important.[74]

Oxcarbazepine had no effect on the anticoagulant activity of warfarin in ten healthy volunteers.[89] Coadministration of oxcarbazepine to healthy women receiving oral contraceptives has been associated with 47% and 36% decreases in

P.1243

ethinylestradiol and levonorgestrel AUCs, respectively.[87] When receiving oxcarbazepine with an oral contraceptive, four of six women developed breakthrough bleeding.[99] Repeated coadministration of oxcarbazepine resulted in a 28% decrease in felodipine AUC and a 34% decrease in felodipine C_{max}. The reduction in felodipine bioavailability was much smaller than that observed after coadministration of carbamazepine (i.e., 94%).[176] Oxcarbazepine had no effect on androgen levels in men or on pubertal development in girls with epilepsy.[128] The topiramate concentration-to-dose ratio was not affected by chronic intake of oxcarbazepine.[2]

In its use as a mood stabilizer, oxcarbazepine caused only minimal and no significant changes in the mean serum levels of risperidone, 9-hydroxy-risperidone, and olanzapine, confirming its weak inducing effect on drug-metabolizing enzymes.[137]

When treatment with carbamazepine is changed to treatment with oxcarbazepine, the serum concentrations of various concurrent drugs might increase because of a decrease in he- patic induction. Leinonen et al.[90] described two epileptic patients with major depression and panic disorder whose serum citalopram levels increased and antidepressant response changed following the substitution of oxcarbazepine for carbamazepine. Furthermore, seven patients with schizophrenia or organic psychosis had 50% to 200% increases in serum concentrations of haloperidol, chlorpromazine, and clozapine on switching from carbamazepine to oxcarbazepine.[127,164]

Tiagabine

Extensive metabolism of tiagabine occurs in the liver and is mediated by CYP3A,[18] with possible contributions from CYP1A2, 2D6, 2C9, 2A6, and 2E1. Only 2% of the dose is excreted unchanged in urine, whereas 25% and 63% of the dose is excreted in urine and feces, respectively, primarily as the 5-oxo and glucuronide metabolites.[17]

Concurrent administration of enzyme inducers such as phenytoin, carbamazepine, and phenobarbital reduces considerably tiagabine half-life (which can decrease to 3.8 to 4.9 hours) and accelerates tiagabine clearance (by 50% to 65%).[133,146,158] In contrast, chronic treatment with valproic acid did not have any significant effect on serum tiagabine concentrations in patients.[3,133,146,158] Concomitant administration with ethanol[81] or triazolam[134] did not affect tiagabine pharmacokinetics in healthy volunteers. Similarly, interaction studies with theophylline,[111] digoxin,[157] or warfarin[111] showed that serum tiagabine concentrations were not changed. Coadministration of cimetidine (800 mg/d) to patients taking tiagabine chronically had no effect on tiagabine pharmacokinetics (Gabitril package insert, Abbott Laboratories). When concomitantly administered, erythromycin, a CYP3A inhibitor, did not significantly affect the C_{max}, AUC, or half-life of tiagabine.[163] This lack of effect of erythromycin is unexpected and remains unexplained.

In healthy volunteers, tiagabine treatment did not affect the clearance or the half-life of antipyrine.[69] In addition, the pharmacokinetics of either carbamazepine or phenytoin is not affected by tiagabine.[3,68,69,81,111,134,146,157,163] There was a small decrease in mean valproic acid C_{max} and AUC during concomitant administration of tiagabine, but this change is not clinically relevant.[68]

In healthy volunteers, administration of tiagabine did not alter the steady-state pharmacokinetics or pharmacodynamics of warfarin,[111] digoxin,[157] triazolam,[134] or ethanol.[81]

Mengel et al.[112] studied the effect of low tiagabine doses (8 mg/d for 12 days) on the pharmacokinetics of oral contraceptives in ten healthy women. Tiagabine did not alter the serum concentrations of ethinylestradiol, levonorgestrel, or desogestrel. Similarly, the levels of progesterone, FSH, and LH did not change with tiagabine therapy. The effects of higher doses of tiagabine on the disposition of oral contraceptives have not been reported.

Topiramate

Topiramate is not extensively metabolized, and 55% to 66% of the dose is eliminated unchanged in the urine.[47,79,150] Six metabolites have been identified in humans and result from hydroxylation, hydrolysis, and glucuronidation. These metabolites are inactive, and the isozymes responsible for their formation have not been characterized.

When concomitantly administered with enzyme-inducing AEDs, the proportion of topiramate metabolized by the liver increases, resulting in a shorter half-life and a higher total clearance. Topiramate dose adjustments might be necessary after discontinuation or addition of enzyme-inducing AEDs such as phenytoin, phenobarbital, and carbamazepine.[19,79,144] Recently, the metabolic profile of a topiramate single dose was characterized during induction by carbamazepine (600 mg/d) in 12 healthy individuals. Topiramate remained appreciably excreted unchanged in urine (41%), even though its oral clearance increased twofold. 2,3-*O*-Des-isopropylidene-topiramate (2,3-diol-TPM) was identified as the most prominent urinary metabolite, with recoveries accounting for 3.2% and 7.9% of the topiramate dose under noninduced and induced conditions, respectively. The AUC(metabolite)/AUC(drug) ratio for 2,3-diol-TPM increased threefold after carbamazepine treatment.[23] Concurrent use of topiramate and valproic acid can result in a slight decrease (15%) in topiramate concentrations.[139] Two studies reported no change in topiramate pharmacokinetics in patients given fixed-dose lamotrigine therapy.[2,48]

Topiramate is a weak inducer of CYP enzymes, and, as such, it can decrease ethinylestradiol concentrations at doses >200 mg/d but not at lower doses.[49,138] There is conflicting evidence on whether 200 mg/d of topiramate also reduces ethinylestradiol levels, but any influence of this dose is likely to be small and of dubious clinical significance.[49,138] In a single-dose trial with digoxin, topiramate resulted in a small (13%) increase in digoxin clearance.[97] The effect of multiple dosing with topiramate on the pharmacokinetics of a single dose of haloperidol showed slight increases in haloperidol serum concentrations, although 90% confidence intervals for the ratio of AUC means were within bioequivalence limits.[48]

Topiramate has no major effects on the pharmacokinetics of carbamazepine,[144] primidone, phenobarbital,[46] or valproic acid.[139] Similarly, the serum MHD concentration-to-oxcarbazepine dose ratio was not altered in patients taking topiramate compared to a monotherapy group.[10] Coadministration of escalating doses of topiramate in a group of 25 patients resulted in only slight decreases in average serum la- motrigine levels compared with baseline.[14,47] When phenytoin metabolism is at or near saturation, topiramate can increase phenytoin concentrations by 25%,[60] possibly by inhibiting CYP2C19.[93]

Zonisamide

Zonisamide undergoes acetylation and reduction to form the *N*-acetyl and 2-sulfamoylacetylphenol metabolites, respectively. Of the excreted dose, 35% is recovered unchanged, 15% as *N*-acetyl zonisamide, and 50% as the glucuronide of the 2- sulfamoylacetylphenol metabolite. Reduction of zonisamide is mediated by CYP3A.[116] Recently, Mc Jilton et al.[109] reported that some autoinduction of zonisamide metabolism can occur with chronic dosing.

Concurrent medication with enzyme-inducing AEDs increases the metabolism and clearance of zonisamide and shortens its half-life. In patients taking carbamazepine and phenyt- oin, zonisamide half-life was 36.4 and 27.1 hours, respectively, indicating a pronounced effect on zonisamide metabolism.[119]

P.1244

The inducing effects of these drugs on zonisamide metabolism were confirmed by Shinoda et al.,[152] who found that the concomitant administration of zonisamide with phenobarbital, phenytoin, or carbamazepine significantly decreased the ratio of steady-state serum zonisamide concentration to the administered dose (C/D ratio).[152] In that study, clonazepam and valproic acid comedication did not change the zonisamide C/D ratio.

Concurrent administration of cimetidine with zonisamide did not alter zonisamide pharmacokinetics in healthy volunteers.[67] A lack of interaction between ritonavir and zonisamide has been reported in a patient taking the protease inhibitor concomitantly with carbamazepine and zonisamide: Ritonavir administration resulted in a significant elevation in carbamazepine levels, leading to toxicity, without affecting serum zonisamide levels.[82] A single case of decrease in serum zonisamide concentrations after coadministration of risperidone in a patient with schizophrenia was reported.[120] An elevation of serum zonisamide concentration (from a value of 27 to 33 to a value of 61.8 to 64.6 μg/mL) following the addition of lamotrigine was described in two patients receiving stable therapy with zonisamide. One patient also developed signs of zonisamide toxicity after the introduction of lamotrigine.[108]

In vitro studies of the inhibitory effects of zonisamide using human liver microsomes showed that zonisamide does not inhibit CYP1A2 and 2D6 and only weakly inhibits CYP2A6, 2C9, 2C19, and 2E1. The estimated K_i for zonisamide inhibition of CYP3A4 was 1076 μM, 12 times higher than the usual therapeutic serum unbound zonisamide concentration.[126]

The potential effects of zonisamide on carbamazepine pharmacokinetics have not been well characterized, with contradictory literature reports: Some authors found no alterations in carbamazepine or CBZ-E levels by zonisa-mide,[26,113,149] whereas others reported a rise in carbamazepine concentration,[145] and others reported a fall in CBZ-E/carbamazepine ratio.[152] Recently, the effect of zonisamide, up to 400 mg/d, on the steady-state pharmacokinetics of carbamazepine and CBZ-E was studied in 18 patients with epilepsy.[126] The results indicated no statistically significant differences for mean C_{max}, time to C_{max}, and $AUC_{(0\text{-}12\ h)}$ of total and free carbamazepine and CBZ-E measured before and after zonisamide administration. However, CBZ-E renal clearance was significantly (p <.05) reduced. Several studies revealed no significant effects of zonisamide on the serum concentration or protein binding of phenytoin or valproic acid.[26,126,160] However, in a population pharmacokinetic analysis, a statistically significant increase (16%) in serum phenytoin concentration was observed in patients taking zonisamide.[118] This effect was not confirmed in a prospective study designed to measure the effect of the addition of zonisamide (gradually increased to 400 mg/d) on phenytoin pharmacokinetics under steady-state conditions in patients[96]; no significant changes in phenytoin disposition were observed.

Gabapentin, Levetiracetam, Pregabalin, and Vigabatrin

Because gabapentin is not metabolized, interactions via this mechanism are not expected. Indeed, several studies have shown no interaction in either direction with the established AEDs— phenobarbital,[74] carbamazepine,[124] valproate,[124] and phenytoin.[37] A statistically significant but clinically irrelevant decrease (14%) in the oral clearance of gabapentin was reported with concurrent use of cimetidine (Product Information for Neurontin, 1999). A case report indicated that the addition of gabapentin to existing therapy with phenytoin, carbamazepine, and clobazam resulted in increased phenytoin levels from 42 to 177 μM, leading to phenytoin toxicity.[166] An increase in serum phenytoin levels following the addition of gabapentin 900 mg daily was also reported by others.[37] However, adding gabapentin to single-drug therapy with phenytoin did not significantly affect phenytoin levels.[8] Hussein et al.[75] described a pharmacokinetic interaction between gabapentin and felbamate. The study was a large retrospective evaluation in patients taking felbamate alone (n = 40) or felbamate and gabapentin (n = 18); a 50% prolongation of the half-life of felbamate was observed in the patients taking gabapentin.[75] A mechanism for this effect is not evident. In addition, there is no need to adjust the dose of gabapentin when it is coadministered with levetiracetam.[58]

Levetiracetam is eliminated by renal excretion, with 66% of the dose excreted unchanged and 27% as inactive metabolites. The major metabolic pathway of levetiracetam is an enzymatic hydrolysis of the acetamide group, which is not cytochrome P450 dependent, leading to the inactive metabolite UCB-L057 (24% of dose); two other minor metabolites account for <3% of the dose.[170]

Concomitantly administered AEDs do not alter the pharmacokinetic profile of levetiracetam to a clinically important extent. Analysis of serum levetiracetam data obtained during placebo-controlled clinical studies indicated that phenyt- oin, carbamazepine, and phenobarbital can modestly increase levetiracetam clearance by 20% to 30%.[35,107] Lamotrigine and gabapentin do not influence the pharmacokinetics of levetiracetam.[121] In healthy volunteers, multiple-dose coadministration of valproate did not modify the pharmacokinetic or excretion profile of levetiracetam.[27] Likewise, pharmacokinetic parameters of levetiracetam, when it was coadministered with oral contraceptives (Product Information for Keppra), digoxin,[95] or warfarin,[126] were comparable to those of individuals receiving levetiracetam alone.

Levetiracetam and its major metabolite were tested for their effects on different drug-metabolizing enzymes in human liver microsomes. An absence of inhibitory effect of levetiracetam on CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, CYP2A6, UGTs, and epoxide hydrolase was observed.[117] Levetiracetam did not modify the pharmacokinetic parameters of phenytoin in healthy individuals[27] and in patients.[121] Levetiracetam also had no effect on the serum levels of carbamazepine, valproic acid, phenobarbital, lamotrigine, clobazam. and gabapentin.[40,121,151] In a similar way, prospective studies with digoxin[94] and warfarin[125] indicated that levetiracetam does not affect any of the pharmacokinetic or pharmacodynamic parameters of these drugs. Ethinylestradiol and levonorgestrel pharmacokinetic and pharmacodynamic profiles, assessed during coadministration with levetiracetam for two menstrual cycles, were identical to those observed during coadministration of the contraceptive with placebo.[61]

Pregabalin has been approved recently as adjunctive treatment for partial seizures and for the treatment of neuropathic pain. Single- and multiple-dose studies have shown that >90% of a pregabalin dose is recovered unchanged in urine.[36] This implies that there is no concern for metabolically based drug interactions affecting pregabalin pharmacokinetics, but there is a need for dose adjustment in patients with renal impairment. A recent study was performed in patients receiving carbamazepine, lamotrigine, phenytoin, and valproate with and without 600 mg/d of pregabalin for 7 days.[25] The trough concentrations of these drugs were not affected by pregabalin. Serum pregabalin concentrations in this study were also compared to those of historical controls and no difference was found, implying that these drugs have no effect on the excretion of pregabalin.

Vigabatrin is eliminated essentially unchanged via renal excretion,[13] and two minor urinary metabolites have been detected in humans.[50] Coadministration of valproic acid did not produce significant changes in steady-state serum concentrations of vigabatrin in children with refractory epilepsy.[9] In

healthy volunteers, felbamate administration for 8 days had no effect on the AUCs of S(+)-vigabatrin and R(-)-vigabatrin.[129]

Several studies have shown that vigabatrin has no significant effect on the serum concentrations of carbamazepine, phenobarbital, primidone, valproic acid, clonazepam, clobazam, ethosuximide, oxcarbazepine, and felbamate.[39,102,129,132] However, in another study with 66 patients with epilepsy, vigabatrin was added to carbamazepine therapy, and 69.7% of patients exhibited an increase (at least 10%) in serum carbamazepine concentration. A negative correlation between the increase and the initial level of carbamazepine prior to vigabatrin addition was found, which suggested that the lower the initial carbamazepine level, the higher is the increase in concentration after vigabatrin addition.[78] Significant decreases in serum phenytoin levels (up to 30%) have been reported in patients receiving vigabatrin as add-on therapy.[135,136,161] Serum phenytoin levels generally fall after several weeks of combined therapy, and the mechanism of this interaction has not been elucidated.

Bartoli et al.[12] studied the effect of vigabatrin on in vivo indices of hepatic microsomal enzyme activity and the pharmacokinetics of oral contraceptives in healthy individuals. Results indicated a lack of effect on ethinylestradiol and levonorgestrel disposition and also no effect on hepatic microsomal enzyme activity.[12]

Summary and Conclusions

There is evidence for a few pharmacodynamic interactions, some of which are useful, such as the combinations of valproate with carbamazepine, ethosuximide, phenytoin, and lamotri- gine. Others involve an increase in neurotoxicity, such as that observed when lamotrigine is added to carbamazepine. Most clinically relevant interactions of AEDs are pharmacokinetic. Four established AEDs—carbamazepine, phenytoin, phenobarbital, and primidone—are potent inducers of the cytochrome P450 (CYP450) and UDP-glucuronosyltransferase (UGT) isozymes and affect large series of drugs. By comparison, only three of the new AEDs—felbamate, topiramate, and oxcarbazepine—have mild inducing properties, and this is of concern only in the case of oral contraceptives, for which additional precautions or alternative contraception should be taken. A moderate reduction of the serum levels of levonorgestrel, a progestogen component of oral contraceptives, has also been reported with lamotrigine. Among the new AEDs, felbamate, topiramate, and oxcarbazepine can cause CYP2C19 inhibition and may alter the metabolism of phenytoin.

When considered as substrates, a few new AEDs (felbamate, lamotrigine, tiagabine, topiramate, and zonisamide) are affected by established AEDs with enzyme-inducing properties. However, new AEDs are less sensitive to inhibition by other drugs, only lamotrigine being significantly inhibited by valproic acid. Finally, pregabalin, gabapentin, vigabatrin, and levetiracetam do not present any significant pharmacokinetic interactions with other drugs.

Chapter 111

Drug Treatment in Children

John M. Pellock

Douglas R. Nordli Jr.

Olivier Dulac

Introduction

Childhood epilepsy differs from that seen in adults because of age-related seizures, the etiology of seizures in children, the presence of both benign and malignant epilepsy syndromes, and the frequent concomitant presence of neurologic abnormality, mental retardation, or behavioral difficulties.[31] All of these factors have important implications for treatment selection. In addition, children respond differently to antiepileptic drugs (AEDs), with regard to both efficacy and side effects. For those with lesional epilepsy, seeming brain plasticity offers a special opportunity for early surgical intervention. This chapter concentrates primarily on how the medical treatment and evaluation of childhood epilepsy differ from those in adults.

Diagnostic Considerations

Seizures should be treated acutely, and their cause should be determined. If they recur, they should be carefully investigated before chronic therapy is initiated. Febrile seizures or those that occur with minor trauma and those associated with or following sleep deprivation all represent types of seizures that may not go on to be recurrent and, therefore, infrequently need chronic antiepilepsy drug therapy.[30] Neonatal seizures, however, are usually symptomatic of significant or longer-lasting central nervous system (CNS) derangements.[33] Besides the varying etiologies of neonatal seizures requiring extensive evaluation, the semiology of seizures may be quite different from that seen in children of older age and in adults.

In contrast to adults, focal seizures in the very young do not necessarily imply the presence of a focal structural lesion or even a localization-related epilepsy. Indeed, disorders that confer a diffuse susceptibility to seizures, like Dravet syndrome, for example, can express themselves with multifocal seizures. This phenomenon is important to consider because treatment of focal seizures with drugs often used as first choice in adults (carbamazepine, phenytoin, lamotrigine, etc.) can actually exacerbate the seizures, worsen myoclonus, or both. Therefore, although the seizure type is an important consideration in the selection of treatment, the epilepsy syndrome is even more important.

Another important difference between children and adults is the presence of infantile spasms as a fairly unique seizure type. Although this characteristically presents between 6 to 9 months of age, it may occur outside this age range and may be preceded by the presence of focal seizures.[21] Narrow-spectrum agents that are commonly indicated to treat focal seizures may make spasms worse.[28] For these reasons, broader-spectrum agents may be superior for younger children with multifocal seizures, mixed seizure disorders including focal seizures, and focal seizures coexisting with infantile spasms.

In other children with seizures, either no chronic therapy or AED treatment for only a limited time may be needed because of the benign character of a particular epilepsy syndrome.[20] Examples of these benign syndromes include febrile seizures and benign epilepsy with centrotemporal spikes. In the condition of febrile seizures, the workup is simply to ensure that meningitis is not present at the onset. In the case of absence epilepsy, recognition of the syndrome allows one to tailor the evaluation to the physical exam—including hyperventilation—and then to proceed with the electroencephalogram (EEG). Rarely should imaging studies be performed in these children unless there are other significant findings or unless neurologic abnormality is present. In those with classic childhood absence, treatment with a specific drug such as ethosuximide, valproate, or lamo-trigine is given because of the multiple recurrent daily seizures for a limited time because most children need to be treated for only approximately 2 years. In the case of benign epilepsy with centrotemporal spikes, both evaluation and treatment are also tailored by realization of this syndrome. The classic clinical description of nocturnal or early-morning seizures that may have a focal component and EEG that clearly shows the centrotemporal spikes makes the diagnosis. Some authorities question whether these seizures should be treated at all with anticonvulsants, but others would treat for a limited period of time, perhaps 2 years.[10,22] In the case of the encephalopathic epilepsies in children, multiple comorbidities exist, and one must consider not only seizure types and epilepsy syndrome, but also the effect of medications on the child's performance and behavior. Deterioration of function or progression of the epilepsy should always make one suspect a progressive or degenerative condition rather than a static condition. For example, in some children with ceroid lipofuscinosis, early diagnosis of Lennox-Gastaut syndrome may have been made, but as the child continues to lose milestones and the ability to walk or even crawl, it is clearly evident that this is a degenerative process. In addition, at initiation, if the predominant ictal type is myoclonic seizures, the diagnosis of Lennox-Gastaut syndrome should be questioned because its predominant seizure types are axial tonic, atonic, and atypical absence seizures.[1]

The pediatric epilepsies are a conglomeration of a number of conditions or syndromes, each of which must be investigated and treated according to associated hallmark symptoms. Children may manifest a single syndrome or may evolve through different epilepsy syndromes as their seizure characteristics change with maturation.[8,22,31] Understanding this clinical evolution and the required pharmacokinetic changes that occur during childhood sets pediatric epilepsy apart as a true special consideration.

The etiology of childhood epilepsy significantly varies from that seen in adults.[14,31] Whereas lesional epilepsy is much more common in adults and genetic or idiopathic epilepsy is less common, the reverse is true in children. The highest incidence of hereditary or genetic epilepsy has its onset during childhood.

Mid-childhood may be the most common age for these syndromes to occur, with an extension of onset age up to late adolescence. On the other hand, whereas strokes and tumors increasingly are noted as the cause of epilepsy in older adults, they rarely cause epilepsy in younger children. Neoplasia is responsible for only approximately 1% of epilepsy in children. The incidence of vascular disease as an etiology of childhood epilepsy depends on the population being examined. An overall figure of 5% is given by Hauser,[14] but in populations with a greater percentage of black individuals, more children will have epilepsy associated with sickle cell anemia–related strokes. Nevertheless, the proportion will still be far less than that seen in adults, in whom cardiovascular disease appears in much higher proportions of the population. Central nervous system malformations and migrational errors are a cause of epilepsy more commonly recognized in children.

Although far more uncommon, nearly all inherited metabolic disorders responsible for seizures will present in childhood, and the majority are expressed in infancy.

In summary, the evaluation and treatment of epilepsy in children must consider the most likely syndromes and their etiologies to enhance diagnostic and therapeutic efficiency. The diagnosis of epilepsy syndromes and their associated treatments are discussed fully in other portions of this text. Here, we cover some general themes regarding pediatric epilepsy treatment.

Acute Symptomatic Seizures

Acute symptomatic seizures are relatively common in childhood. Epidemiologic studies suggest, for example, that >100,000 children in the United States each year present with febrile seizures.[31] If they are prolonged, these seizures need to be terminated, but there the risk–benefit ratio of subsequent prophylaxis is considered to be so unfavorable that continued treatment outside of the acute period is not recommended in most children.

Idiopathic Localization-Related Epilepsies

Some authors consider these disorders to fall into a spectrum in which the clinical and electrographic presentation is, in part age dependent but also variable in terms of clinical severity and associated comorbidities. For the most part, treatment need not be automatic, and, in fact, it should probably be reserved for those children with persistent seizures that negatively affect the child's quality of life. Expert opinion favors carbamazepine or oxcarbazepine as the drug of first choice.[34] See Table 1. An important subgroup of children may actually worsen with drug treatment, particularly with sodium channel blockers.[28]

Symptomatic Localization-Related Epilepsies

Nearly all medications approved for use by the Food and Drug Administration for therapy of refractory partial seizures in adults are used for the same indication in children, although only a subset have been formally approved for this use. See Table 2.[12,13]

Generalized Idiopathic Epilepsies

These disorders respond well to agents that cover a broad spectrum of seizures (Fig. 1). In addition to the epilepsy syndrome, the types of seizures will influence treatment selection. For example, patients with idiopathic generalized epilepsies with prominent absence seizures will need treatment with an agent that covers absence seizures. Valproate efficacy is established, but adverse events require consideration of other medications, particularly in female adolescents.[34]

Generalized Symptomatic Epilepsies

Agents that cover a broad spectrum of seizure types are commonly used. In addition to the epilepsy syndrome and seizure types, comorbid features are particularly important to consider in this group. These children may be particularly sensitive to the added impairments caused by behavioral disorders, cognitive impairment, cerebral palsy, and learning disabilities. In addition, they may be more vulnerable to adverse events because of limited cerebral reserves and the common need for polytherapy to control their seizures.

Genetically Determined Metabolic Diseases

As mentioned earlier, genetically determined metabolic diseases should be considered when children do not fit into one of the broad groups of epilepsies described previously. They often present early in life, often in etiologically nonspecific ways that make diagnosis challenging. Sometimes, there are useful clues that help to identify the particular disorder. There may be particular physical features, constellation of symptoms, or unique EEG features. In the majority of cases, however, these disorders present as one of the age-related but etiologically nonspecific syndromes that could broadly be considered as epileptogenic encephalopathies. If the metabolic derangement is so severe that the patient presents shortly after disconnection from the maternal–fetal homeostatic mechanisms, then young infants may demonstrate severe disturbances of diffuse cerebral dysfunction on EEG including multifocal sharps, appearance of dysmature features, and extreme discontinuity to the point of burst-suppression patterns. This could appear as early myo-clonic epilepsy as described by Aicardi, early infantile epileptogenic encephalopathy, or Ohtahara syndrome. Prototypic etiologies include nonketotic hyperglycinemia, syndromes with severe lactic acidosis, and urea cycle defects, among other conditions. They may have a variety of primitive seizure types, including multifocal seizures, myoclonus, and tonic postures. If the disturbance becomes manifest later in infancy, then infantile spasms will be a prominent feature with concurrent hypsarrhythmia. Etiologies here include peroxisomal disorders, pyruvate dehydrogenase deficiency, pyruvate carboxylase, and other conditions. Later expressions may show diffuse slowing on the EEG, the appearance of multifocal spikes, and sometimes development of well-organized generalized spike-wave discharges with concurrent generalized seizures, as is the case with myo-clonus epilepsy associated with ragged-red fibers (MERRF), the later expression of glucose transporter type 1 deficiency syndrome (GLUT-1 DS), and the sialodoses, to name a few. These disorders may thus fall into the broad group of symptomatic generalized epilepsies, or epilepsies with both focal and generalized features (see later discussion). Treatment should primarily be aimed at correction of the metabolic defect, wherever possible. When that is not possible, and antiepileptic medication is used, then care should be taken to avoid agents that might potentially exacerbate the underlying condition.

Recognition of metabolic disorders may have several important treatment ramifications. First, some of these disorders have specific treatments, which if administered promptly can result in strikingly good outcomes (Table 3). Examples of this include the B6-responsive epilepsies, central creatine deficiency, pyridoxal phosphate–responsive conditions, and phenylketonuria (PKU) deficiency. Second, these disorders are notoriously

P.1251

P.1252

refractory to standard antiepileptic treatment, and identification of the cause can be an important factor guiding the expectations of treatments. Third, there can be severe adverse effects peculiar to certain conditions and treatments (Table 4). Patients with pyruvate carboxylase deficiency, for example, often present with intractable seizures, which might prompt the consideration of alternative treatments. Administration of the ketogenic diet, however, could have lethal consequences, and adrenocorticotropic hormone (ACTH) can worsen spasms in this condition.

Table 1 Comparison of Recommendations for the Treatment of Pediatric Epilepsy

Seizure type or epilepsy syndrome	Pediatric Epilepsy Consensus Survey	ILAE	SIGN	NICE	French study[a]	Approved by U.S. Food and Drug Administration

Metabolic disorders should be suspected when either a specific etiology or a well-recognized idiopathic syndrome is not established. For the most part, these disorders present in an etiologically nonspecific but age-related manner. Multifocal seizures, myoclonic seizures, tonic postures, and spasm are commonly reported in these inherited disorders of metabolism. The EEG features often show slowing of the background with multifocal spikes. In neonates, burst-suppression patterns are often seen. In infancy, hypsarrhythmia is noted, and diffuse spike-wave patterns are seen in the older children.

Table 3 Examples of Metabolic Disorders With Specific Treatments

Disorder	Specific treatment
Pyridoxine-responsive epilepsies	Pyridoxine, pyridoxal phosphate
Central creatine deficiency	Creatine
Phenylketonuria	Dietary restriction
GLUT-1 DS[a]	Ketogenic diet
Pyruvate dehydrogenase deficiency	Ketogenic diet
Some disorders with lactic acidosis	Thiamine Leukovorin

[a]Glucose transporter deficiency syndrome.

Table 4 Conditions That May Worsen With Certain Antiepileptic Medications

Disorder or epilepsy	Condition	Treatments that may worsen
Metabolic derangements	Pyruvate carboxylase deficiency	Ketogenic diet, adrenocorticotropic hormone
	Organic acidurias	Ketogenic diet
	GLUT-1 OS	Phenobarbital
	Conditions with lactic acidosis	Carbonic anhydrase inhibitors (could worsen acidosis)
	Mitochondiral disorders	Valproate

Epilepsies With Both Focal and Generalized Features

These epilepsies may present in the very young with focal seizures and later may develop generalized interictal or ictal features. In striking contrast to adults, focal seizures in the young do not necessarily imply the presence of a focal structural lesion or even localization-related epilepsy. Truly generalized tonic–clonic seizures are rarely observed in infants, and well-synchronized generalized spike-wave discharges are not common until the toddler years. This is similar to the ontogeny

of sleep architecture, in which synchronized diffuse discharges such as synchronized sleep spindles, vertex waves, and K complexes are not present until after age 2 years. Instead, infantile disorders that confer a diffuse susceptibility to seizures, like metabolic disorders or channelopathies, are often expressed with multifocal seizures in the first years of life. Initially, the interictal features are characterized by multifocal spikes, or fragments of generalized epileptiform discharges, that occur with shifting laterality across the hemispheres. Later in life, well-developed generalized spike-wave discharges and generalized seizures may occur. This makes it difficult to classify these epilepsies as either focal or generalized forms of epilepsy because they have both features. Two examples of this phenomenon are the glucose transporter protein deficiency syndrome (GLUT-1 DS, or De Vivo syndrome), which is not an independent epilepsy syndrome but rather a neurologic disorder; and severe myoclonic epilepsy of infancy (Dravet syndrome), which, of course, is a bona fide epilepsy syndrome. In both, focal seizures predominate in the first year of life, but later evolution to generalized seizures (atypical absence) is seen at >2 years of age.[8,22]

These diagnostic considerations can affect drug selection in several ways. First, a treatment other than standard antiepileptic medication may be indicated, as is the case with GLUT-1 DS, in which the ketogenic diet provides an alternative fuel source to the brain. Second, some medications that work well for focal seizures in older children and adults can actually exacerbate these pleomorphic epilepsies in the immature child. In Dravet syndrome, for example, carbamazepine, phenytoin, and lamo-trigine may exacerbate seizures, worsen myoclonus, or both. In GLUT-1 DS, phenobarbital may theoretically cause more neuronal dysfunction and intensify seizures. (Phenobarbital, caffeine, and other substances interfere with glucose transport across the blood–brain barrier.)

Summary of Diagnostic Considerations

Thus, whereas seizure type is an important consideration in the selection of treatment, the epilepsy syndrome, etiology, comorbid features, and possibility of exacerbating seizures are equally important in guiding selection of therapy. The diversity of epilepsy syndromes, the changes in expression as a function of age, and the rich complexity of underlying etiologies make drug selection far from a routine exercise and in fact a continued intellectual challenge for the clinician treating children with epilepsy.

Pharmacokinetics in Relationship to Age

Three relatively distinct pharmacokinetic periods can be seen in children.[7] The first is that represented in newborns. The next is in young children prior to puberty. Then, with puberty, the adolescent pharmacokinetic profile is similar to that seen in adults. General pharmacokinetic concepts will not be discussed in this section (see Chapter 102). Drug utilization patterns in these three childhood stages, however, will be described and compared. Drugs that have linear and nonlinear characteristics in adults show a similar pharmacokinetic pattern in children of any age.

Utilization or clearance rate is age dependent. The age of the child may not only determine the clearance rate, but it also definitely affects how much drug can be bound to protein. The binding of ethosuximide, phenobarbital, and primidone and most of the newer AEDs is low, whereas that of phenytoin, valproate, and tiagabine is high. Newborns and very young infants have reduced drug protein binding because of relative hypoalbuminemia. Higher unbound levels of drugs such as carbamazepine, phenytoin, and valproate are noted; they produce increasing toxicity with what seems to be typical dosing. Disease states can further alter protein binding. Not only the age, but also the entire drug burden affects drug elimination. Antiepileptic drugs induce metabolic pathways. Newborns exposed to drugs in utero usually eliminate antiepileptic drugs at rates comparable to those in adults. Newborns, however, are typically not born to mothers who have needed to receive antiepileptic drugs, and, therefore, they eliminate medications

more slowly than does any other age group. In addition, injury to hepatic or renal systems, as would be seen with hypoxia, may further retard drug elimination in these fragile infants. In term-born infants, postnatal maturation of renal and he-patic systems is rapidly accomplished in the first 6 to 8 weeks of life. More-immature infants who are healthy undergo these maturational changes at about the same rate, whereas others lag behind because of systemic complications. Premature newborns have less capacity than do full-term infants to metabolize drugs such as diazepam and methylxanthines; this is performed through *N*-dealkylation. In the absence of prior drug exposure, the newborn's relative capacity for *N*-dealkylation is approximately 20% of adult values at birth and gradually increases to adult capacity by age 2 years. Cytochrome metabolism is similar but is more rapidly converted to the rapid pattern seen in infants. Therefore, after a loading dose of phenytoin or phenobarbital for the treatment of neonatal seizures, blood levels should be followed before maintenance dose is initiated. Following the initial dose and with maturation over weeks or months, drug clearance may increase two- to fourfold and drug levels may decline by 50% to 70%, so that doses must be increased. Asphyxiation may, however, decrease this capacity.

Changing from intravenous to oral drug administration with phenytoin may lead to slower drug absorption, significantly lowering derived blood levels from the same dose. Slowed absorption causes a reduction in the apparent bioavailability of phenytoin by 20% to 30%. Thus, the total dose may not be as important as following blood levels in neonates and young infants. The appearance of induction, more rapid metabolism (utilization), and decreased absorption may require that large milligram-per-kilogram doses be given to very young infants receiving phenytoin.

Following the neonatal period, two major differences exist between the pharmacokinetics of antiepileptic drugs in children and those in adults. Children have a higher relative clearance than do adults, and children have a greater within-group variability in elimination kinetics. This means that, in general, much larger doses relative to weight will be required to maintain appropriate levels in children as opposed to adults. In addition, because of a decreased apparent half-life, dosing once or twice a day that is appropriate in adults may not be appropriate in children, who require more frequent dosing intervals. Unless extended-release preparations are used, children require twice-daily dosing of phenytoin, three- or four-times-daily dosing of carbamazepine, and three- or four-times-daily dosing of valproate to allow the smoothest pharmacokinetics and to fully protect children at all hours of the day. Extended-release formulations of carbamazepine and valproate should be used whenever possible.[23] The greater within-group of variability in elimination kinetics among children may vary up to 50% of average values for children who are <5 years old. This fact may suggest that drug levels are especially useful in children because of this wide fluctuation.

Drug utilization remains relatively stable through the middle and later years of childhood, and children tend not to outgrow their drug doses. With adolescence, a growth spurt occurs, but it rarely necessitates a dose adjustment because of the dramatic change in relative drug clearance seen at puberty. In general, lowered levels of anticonvulsants are secondary to noncompliance or drug interactions rather than to pharmacokinetic changes.[7] Alterations of AED clearance seen in children are directly related to hepatic mass, relative caloric requirements, and surface area relative to body mass during growth to adult size. Compared to adults, children have a larger surface area relative to body mass, and they are hypermetabolic. With growth, there is increasing body mass. Surface area relative to body mass decreases, and less energy is required.

Adverse Effects of Antiepileptic Drugs

Once the physician and family have made a decision to treat the child that has epilepsy, the need for seizure control must be balanced with expected acute and chronic AED toxicity.[20,35,36] The AED without side effects is not yet available. Successful AED therapy is based on proper diagnosis of the seizure type and epilepsy syndrome and a careful assessment of the pharmacokinetic and pharmacodynamic properties of the chosen treatment. Children have an individual variation in response to each AED and the interactions with other medications they might be receiving. In most children, AEDs will be given in moderate to high doses for many years. In others, relatively low doses will be acceptable and given for only a few years. In all these patients, some adverse effects may occur. Pharmacokinetic effects are those that are measurable and show a clear relationship to drug levels. Pharmacodynamic effects may also occur as adverse reactions but are responses at the target organ without a concomitant measurable change in plasma concentration of medication.

Adverse effects that are also non–dose-dependent may produce drug-induced disease or idiosyncratic reactions acutely or following chronic use. The use of a single AED (monotherapy) and even higher doses and levels of single AEDs is often superior to the use of low or even subtherapeutic levels of multiple agents because of decreased numbers of adverse responses. The advantages of AED monotherapy include less frequently noted and easier management of toxicity and elimination of drug interactions, improved compliance, and reduced costs.[23] In resistant epilepsy, which is estimated to occur in up to 30% to 40% of cases, polytherapy should be considered when monotherapy is unsuccessful. Chapter 121 discusses rational polypharmacy. The adverse effects seen with antiepileptic drugs are discussed in other chapters. This chapter will review only specific issues noted more frequently in children.

Neurotoxicity is the most common acute and chronic adverse effect secondary to treatment with antiepileptic drugs. In adults, this is typically characterized by difficulty concentrating, lethargy, poor coordination, and minor movement disorders such as tremor. Many of these same symptoms are present in children. However, more subtle forms of cognitive and behavioral symptoms can be observed in some children, manifested only as difficulty in school. Observing the behavior and school performance of children with epilepsy is a very important part of monitoring for neurotoxicity of anticonvulsant drugs. Of course, there are many other factors that determine the child's performance in the classroom, but medications may play a significant positive or negative role in the child's ability to concentrate, attend, learn, and perform in this setting.

Especially in children with encephalopathy, sedative drugs may cause problems. Sedative agents such as barbiturates or benzodiazepines may lead to increased seizures because of the sedation or to other behavioral difficulties. Clonazepam and related compounds may increase oral secretions to such an extent that respirations may be comprised, and associated hypotonia may cause marked difficulties for these children, who already have motor difficulties with oral buccolingual incoordination. Medications that typically sedate adults and older children may lead to extreme irritability or hyperactivity in younger children. The well-known hyperirritability and hyperactivity seen in some children when treated with barbiturates may also be produced when benzodiazepines or other "sedative" drug classes are administered.

Systemic complications from medications are also noted. Although hyponatremia is less frequently noted in association with carbamazepine therapy, it has been noted in some children, especially those institutionalized or on set diets with

P.1255

decreased salt intake. When high-dose phenobarbital is administered to neonates, hypotension may result, such that appropriate cerebral perfusion is not maintained. In the past, very high doses of phenobarbital were used to treat neonatal seizures, but levels >60 μg/mL are no longer recommended. A particular problem in children with disabilities is one of bone abnormalities in children treated with enzyme-inducing antiepileptic drugs who are not exposed to sunlight. Broader attention has concentrated on the bone health of all children treated with AEDs. In children with retardation or those who have frequent trauma, one should pay particular attention to this complication, which may be asymptomatic until increased fractures occur.[17] AED toxicity, therefore, may affect multiple systems and result in hepatic, hematologic, connective tissue, bone, motor, cerebellar, immunologic, cognitive, and behavioral disorders. Several factors predispose to chronic toxicity, including early age of epilepsy onset; long duration of therapy; polytherapy; conditions associated with increased vulnerability, including institutionalization; poor diet; pregnancy; chronic illness or disability; genetic factors; repeated or prolonged acute toxicity; physician lack of awareness; and incorrect diagnosis of epilepsy. Dependent children, especially those with multiple disabilities, share all these risk factors.[25]

Antiepileptic drug idiosyncratic reactions most commonly include hematologic, dermatologic, and hepatic reactions. The mechanisms for these reactions are frequently unknown, but in some situations, particular age groups seem at greater risk. Aplastic anemia, agranulocytosis, and pancytopenia actually seem to be less common in young children than in adults.[27] This is true both for carbamazepine[29] and for the more recent experience with felbamate.[26] Valproate-associated thrombocytopenia is not an idiosyncratic reaction but is rather a dose-dependent adverse reaction. This is seen at all ages.

Dermatologic reactions are the most common adverse effect of any of the idiosyncratic reactions and are more commonly reported in children than in adults. Most, however, represent fleeting symptoms and frequently are not associated with the administered anticonvulsant. The physician thus must differentiate between the reactions that signal a more generalized systemic hypersensitivity response and those that are more innocent. Associated desquamation, mucous membrane ulceration, and painful dermatitis usually herald more intense reactions. The distribution of the rash frequently can differentiate a contact or exposure dermatitis from a generalized hypersensitivity reaction. Medications should be stopped when there is doubt, and skin biopsy can often distinguish benign dermatitis from those with more widespread subcutaneous vasculitis and generalized hypersensitivity reactions. Associated symptoms suggesting other organ involvement should be recognized to diagnose the anticonvulsant hypersensitivity syndrome or drug rash with eosinophilia and systemic symptoms (DRESS)[2] (see Chapter 120). The latter may require systemic steroids or treatment as for burns. In children receiving lamotrigine, rash is increased by rapid dose titration and coadministration of valproate.[19] If rechallenge is performed because of an unclear past history of a possible reaction to an anticonvulsant, the patient's family and physician must be extremely cautious. Nevertheless, far more children have been removed from AEDs because of nonspecific rash or intercurrent disease than have ever experienced a true idiosyncratic dermatologic reaction, but history of prior drug rash to an antiepileptic drug must be taken seriously and may place the child at increased risk for this reaction when a new medication is administered.[15]

Hepatotoxicity associated with anticonvulsant use may be of three broad types. The first type is a drug-related hepatic necrosis, is usually part of a generalized hypersensitivity reaction, and is seen in the first 10 weeks of treatment. The second type presents as acute or subacute hepatic failure leading to stupor and coma, bleeding, and other signs of hepatic disease. Valproate-associated hepatic toxicity of this type occurs most frequently in the first 90 days of therapy. The third type is a chronic hepatic injury that occurs after long-term treatment. Valproate-induced hepatic toxicity seems to have been more commonly identified in young children.[5] This potentially fatal idiosyncratic type of liver failure associated with microvesicular steatosis may be associated with specific, underlying inborn metabolic defects or acquired mitochondrial dysfunction. Valproate hepatic toxicity is most common with AED polytherapy in children <2 years of age who have preexisting encephalopathy or underlying metabolic disease. During polytherapy, omega oxidation through cytochrome P450 is enhanced with the production of a toxic 4-ENE metabolite. This compound, along with other possible toxic metabolites, may be responsible for mitochondrial failure and the pathologic appearance of microvesicular steatosis. Related changes in mitochondrial fatty acid beta oxidation and the production of these metabolites may also be factors in some patients. The role of a relative carnitine deficiency in these patients is unclear, but carnitine administration has proved to be helpful in some cases of severe hepatotoxicity.[11,16] In addition, free radical scavenger deficiencies may play a partial role in valproate hepatotoxicity.[36] It is thus recommended that patients be evaluated for the presence of prior mitochondrial dysfunction or disease states that would put them at higher risk for acquiring valproate-associated hepatotoxicity.[27] Especially in young children, polytherapy is relatively contraindicated whenever possible. The role of carnitine supplementation in preventing valproate hepatotoxicity is unclear.

Monitoring

Because adverse effects may generally be separated into drug-induced diseases and dose-related toxicity, one should monitor with these two categories in mind. In general, the regularly scheduled monitoring of blood levels, hematology, chemistry, and other routine studies is likely to be helpful only if the patient is immediately presymptomatic or shows abnormal signs and symptoms.[27,35] Therefore, the role of this routine laboratory testing for most children is unwarranted (see also Chapter 120). Pretreatment laboratory evaluation prior to AED initiation is almost always indicated as part of the initial evaluation of epilepsy. Specific risk factors may suggest further initial or laboratory studies or monitoring. Examples of these risk factors would be children <2 years of age for whom valproate therapy seems most advantageous or those with prior idiosyncratic drug reactions. In addition, patients debilitated by other disease processes or chronic neurologic dysfunction or institutionalized patients may also have need for more extensive initial and ongoing evaluations. In most patients, chronic monitoring should depend on the clinical state. If a symptom complex develops and suggests possible need for either blood level or systemic blood monitoring, the appropriate evaluations should be performed. In practice, the performance of laboratory tests every few years is probably indicated as a child develops and continues on medication. However, the monthly or bimonthly screening that was done in the past is not being performed and seems wasteful. The best strategy is to alert the patient and parents to a list of significant symptoms that should cause alarm. The patient and referring physician should be aware of these symptoms so that examination of the patient and appropriate laboratory testing should be done when indicated. Frequently, the neurologist will not be contacted for these complaints unless there are difficulties. Blood level monitoring is best performed when answering a specific question such as compliance, toxicity, drug preparation efficacy, autoinduction or interactions, and changes in levels with maturation.[6] Once

P.1256

the neonatal and early childhood development periods pass, pharmacokinetic patterns stay relatively stable, and dosing requirements change only slightly as children enter puberty and adolescence.

Choice of Drug

The antiepileptic drug of choice should produce complete control of seizures without producing adverse effects. The physician must make a decision to treat with a given drug that is likely to control symptoms in a patient while producing the least amount of toxicity. In children with concomitant diseases, behavioral disorders, or other symptoms, one must select drugs that would be least likely to exacerbate existing symptoms.[20,24] Children with motor disturbances should not receive medications likely to aggravate incoordination. Those already exhibiting tremor will probably do more poorly on medications that produce or intensify tremor. Those children who have eating disorders must have medications considered so that obesity or anorexia is not exacerbated. Because generalized or mixed seizures are more common in some syndromes of pediatric epilepsy in children, those treating pediatric epilepsy will be more likely to use medications such as ethosuximide, valproate, lamotrigine, topiramate, and levetiracetam. Carbamazepine, phenytoin, gabapentin, tiagabine, pregabalin, and vigabatrin should, of course, be given appropriately for partial seizures and convulsions. For many years pediatricians have used phenobarbital exclusively for all types of epilepsy. This practice should be reconsidered because of its ample toxicity and the availability of equally effective AEDs.

Choosing the best AED for chronic treatment of a given patient must depend on seizure type and epilepsy syndrome. Table 2 demonstrates the selection of drugs by expert consensus groups,[34] and FIGURE 1 places AEDs into categories effective by seizure type. Some children with epilepsy, especially those who are encephalopathic, have breakthrough clusters of acute repetitive seizures or have repeat episodes of prolonged seizures or status epilepticus. The home or out-of-hospital treatment of these individuals with rectal diazepam or other benzodiazepine has been quite successful and cost-effective.[3,9,18] This option should be discussed for children with frequent clusters or prolonged seizures. Home therapy with oral benzodiazepines might also be helpful for those able to swallow medications. Continued use of benzodiazepines in children, however, is more frequently associated with increased adverse effects and may lead to increased seizures.

Assessing the Impact of Drug Treatment in Children

In addition to inquiring about medication effectiveness and side effects, an assessment of the impact of epilepsy and its treatment upon the child's ability to function is critical. Quality-of-life instruments specific to children have been developed. In addition, it is particularly useful in the school-aged child to inquire about school placement, performance, and the need for additional resources. This can be done verbally during the interview or as part of a standardized visit questionnaire.

Summary and Conclusions

The complete care of the child with epilepsy requires one to combine consideration of the child's lifestyle with consideration of the disorder. Stopping all seizures is important, but function must be maintained. The initial evaluation must be tailored to include behavioral, cognitive, and functional status. Frequently, the neurologist spends at least as much time in modifying the educational setting for the child as in treating the seizures. Comorbidities of hyperactivity, inattention, mental retardation, spasticity, and their deficits require special attention. Length of therapy is clearly determined by the epilepsy syndrome and the response to medications. In treating the child with epilepsy, one also treats the family. Truly effective treatment of epilepsy includes selection of drug, or surgical procedure along with drug; optimal dosing; indoctrination of the patient and caretakers regarding necessity for timely administration of the agent; eliminating seizure stimuli when these are present; proper social, psychological, and educational support and placement; and, finally, patient monitoring. This monitoring must encompass more than drug toxicity and neurologic status; it must include all aspects of the life of the child with epilepsy.

Chapter 112

Drug Treatment in Adolescents

Eileen P. G. Vining

Introduction

In general, the incidence of epilepsy tends to decrease slightly in adolescence. It appears to range from 20 to 60 per 100,000 with a prevalence of 1.5% to 2%.[40] Certainly maturation itself, and specifically the effects of sexual maturation and menarche, may play a significant role in the development of seizures during this period of life. Trauma is an important cause of seizures in adolescents, and the idiopathic epilepsies appear to peak in this time frame. Mesial temporal sclerosis, causing temporal lobe epilepsy, frequently is recognized as intractable epilepsy during this period, and some of the rare progressive epilepsies (Unverricht-Lundborg disease, Lafora disease, ceroid lipofuscinosis, and some of the mitochondrial disorders) may also emerge in adolescence. The juvenile idiopathic epilepsies are very distinct entities that require accurate diagnosis and understanding for appropriate and comprehensive therapy. The drugs that are used for these epilepsies (juvenile absence, juvenile myoclonic epilepsy, and epilepsy with grand mal on awakening) are the focus of this chapter, as are issues that are of particular importance to adolescents. Unfortunately, treatment guidelines from the International League Against Epilepsy (ILAE),[19] the American Academy of Neurology (AAN), and the American Epilepsy Society (AES)[13,14] routinely demonstrate how meager the evidence is for our choice of medications, particularly in younger patients. A review of the recent ILAE treatment guidelines indicates that no medication reaches the highest levels of evidence for efficacy in adults with generalized tonic–clonic (GTC) seizures. Carbamazepine (CBZ), lamotrigine (LTG), oxcarbazepine (OXC), phenobarbital (PB), phenytoin (PHT), topiramate (TPM), and valproic acid (VPA) may be considered for initial therapy in adults with GTC. With the exceptions of LTG and OXC, the same statement can be made for children with GTC seizures. Ethosuximide (ESM), LTG, and VPA are possibly efficacious/effective for children with absence seizures. Finally, and of particular importance to this chapter, are the recommendations for juvenile myoclonic epilepsy. At a very low level of evidence (Class IV), clonazepam (CZP), LTG, levetiracetam (LEV), TPM, VPA, and zonisamide (ZNS) may have some efficacy for patients with newly diagnosed juvenile myoclonic epilepsy (JME).[19] The AAN and AES note that TPM is recommended (Class A) for refractory generalized tonic–clonic seizures.[14] In studies of mixed populations with both partial as well as generalized seizures, LTG, TPM, and OXC are effective, and LTG is effective in children with new-onset absence.[13] Given the limitations of evidence-based recommendations, these medications are discussed based on clinical experience and reflect many of the observations made in a recent survey of treatment of pediatric epilepsies.[39] Medications that are particularly useful for the partial epilepsies are appropriately covered in the chapter on adult medications, although the issues that are critical to adolescents are addressed in this chapter.

Medications that are Useful in the Juvenile Generalized Epilepsies

Ethosuximide

Ethosuximide is an extremely effective medication for childhood absence epilepsy (CAE) and may play a role in controlling JAE and sometimes myoclonic seizures. However, since the majority of patients with JAE also have GTC seizures, ethosuximide is usually not considered a good therapy because it does not prevent the GTC events. Occasionally, when other medications are not controlling the absence and/or myoclonic seizures, ethosuximide can be effective when added to other regimens that are controlling the GTC seizures. It can be given once a day, and the side effect profile is acceptable: Gastrointestinal disturbance, headache, rarely rashes, and joint pain.

Valproic Acid, Sodium Valproate

Valproic acid was the first medication that successfully controlled the seizures in the majority of patients with juvenile myoclonic epilepsy.[11] It is effective in controlling myoclonic, absence, and GTC seizures. However, a number of side effects and the availability of alternative medications have diminished its use in the last decade. Weight gain has been recognized as a problem since the early 1980s.[30] When weight gain is going to occur, it usually occurs in the first 10 weeks of use and it persists.[7] It may be more prevalent in those who are heavy to begin with.[30] Many explanations have been postulated, including an increase in serum leptin[37] that would stimulate appetite. VPA may also decrease the binding affinity of albumin for palmitate, leading to an increased availability of long-chain fatty acids. This increases insulin levels and lipogenesis, resulting in decreased lipolysis, and decreases glucose. This then may stimulate appetite via hypothalamic glucoreceptors.[38] VPA has also been associated with hair loss in about 10% to 12% of patients. This may be dose related and is generally mild, and hair tends to grow back well, perhaps with more curl.[22,28] Endocrine issues have cosmetic and general health importance for adolescents. VPA has been associated with hyperandrogenism, especially when started in adolescence,[35] and this may be related to polycystic ovary syndrome, which is reported in as many as 43% of women taking valproic acid.[21] This syndrome can include obesity, menstrual disturbances, hyperandrogenism, and infertility, and may ultimately lead to dyslipedemia, diabetes mellitus, cardiovascular problems, and endometrial carcinoma. Another major concern to women in their childbearing years is a recognized association with neural tube defects and fetal malformations. This risk is typically considered to be 1% to 2%. However, some studies have found rates of adverse pregnancy

P.1260

outcomes as high as 20%. Of growing concern is the possible association of the medication with an adverse impact on the cognitive development of the children of mothers exposed to the medication.[18,27,44] These problems may be dose related, especially at doses >1,400 mg/d.[36] VPA has also been associated with hepatic dysfunction (even liver failure) and other gastrointestinal problems, as well as hematologic problems. On the positive side, VPA has mood-stabilizing effects and is important in migraine therapy.[12,32]

Lamotrigine

When LTG was introduced in 1994 it was quickly seen to be effective in the generalized seizures of Lennox-Gastaut syndrome and was soon adopted as a therapy in the juvenile generalized epilepsies because of perceived fewer side effects. Both VPA and LTG can be efficacious against absence seizures, although VPA shows a much faster onset of action, at least in part because of its shorter titration schedule.[9] The American Academy of Neurology and the American Epilepsy Society also found evidence of its efficacy in absence epilepsy.[13] Some studies suggested that LTG is as effective as VPA in JME, but most of these studies were retrospective in nature, and there is some evidence that myoclonic seizures may not be as well controlled with LTG as with other medications or combinations of medications; there is also some evidence that it can even worsen myoclonic seizures.[20,31] Although LTG appears to have a generally good risk profile with respect to teratogenesis, further experience is required to understand the complete profile. The major disadvantage in using LTG is the slow titration (8–12 weeks) that is suggested to minimize the risk of developing a rash that might progress to Stevens-Johnson syndrome. This risk appears somewhat greater in children and if it is coadministered with VPA. The risk was virtually abolished when these guidelines were followed.[43] Other side effects that have been reported include dizziness, somnolence, nausea, tics or tremor, and sleep disturbances.

Topiramate

Topiramate has been found effective in controlling refractory generalized epilepsy and has been evaluated in JME, with some suggestion that it might be more effective in controlling the primary generalized seizures but not as effective as other medications in controlling absence or myoclonic seizures.[5,34] It is considered a second-line antiepileptic drug (AED) by the National Institute for Clinical Excellence (NICE-UK) criteria for juvenile absence and JME, but may be a first-line drug in generalized tonic–clonic seizures on awakening.[28a]

Side effects include nephrolithiasis, dizziness, fatigue, ataxia and paresthesias, oligohydrosis, and glaucoma. Weight loss, a potentially beneficial side effect, can be sustained, especially in overweight patients.[3] In addition, cognitive effects have been reported. This includes what is sometimes described as a "fuzziness in thinking" as well as word-finding problems. These effects may be less frequent when the medication is titrated slowly.[6] A major advantage is its concomitant efficacy in treating headache.[42]

Levetiracetam

In a group of patients with idiopathic generalized epilepsy that had failed therapy with at least one other anticonvulsant, LEV was added on or prescribed as monotherapy; 40% became seizure free. The authors noted that some patients with absence seizures did not respond.[25] Many authors have documented its particular efficacy in controlling myoclonic seizures.[26] It is also considered a second-line AED in juvenile absence and JME by the NICE-UK criteria.[28a]

The most common side effects that would be worrisome to adolescents are sleepiness, headache, and behavioral issues. Irritability, agitation, and anxiety are noted, and rarely psychosis. These problems may be ameliorated by slow titration, and particular care should be taken if this medication is used in a patient with an underlying behavioral problem.[4,23,41] A major advantage of the medication is the rapidity with which it can be introduced and its lack of interaction with other important medications.

Zonisamide

Zonisamide is a broad-spectrum anticonvulsant that has been shown to be effective in JME. It was found that 69%, 62%, and 38% of patients were free of GTC, myoclonic, and absence seizures, respectively.[24] It is also considered effective in other disorders in which myoclonus is a significant component. As with TPM, nephrolithiasis, glaucoma, and oligohydrosis are occasionally seen. The most common side effects are lethargy, dizziness, and ataxia. A major advantage is its very long half-life and minimal interaction with other medications.

Adolescent Issues that are Crucial to Therapy

Adolescents are in a critical developmental period, and epilepsy is routinely perceived as a barrier to achieving the independence and lifestyle of a normal teenager.[29] Chronic medication adherence is particularly problematic because it acknowledges and accentuates the restrictions inherent in having a seizure disorder. It further reduces an already damaged self-esteem.[15] Medication regimens must recognize this, and once-daily or, at most, twice-daily schedules are particularly important to this age group so that medication (and the social stigma of going to the nurse's office) does not need to be given at school.

In choosing a medication for an adolescent, efficacy is paramount. Some medications should be avoided because they can exacerbate myoclonic and absence seizures: These include CBZ, gabapentin (GBP), OXC, PHT, tiagabine (TGB), and vigabatrin (VGB).[17] In some individuals LTG can also worsen myoclonic seizures.[16] Because there are no randomized, controlled trials that compare the new antiepileptic drugs with each other or against the traditional antiepileptic drugs, prescribing a medication is often based on consideration of a number of factors that include efficacy, cost, and particularly the side effect profile of the drug. The side effects that are of critical concern to adolescents involve their appearance, their abilities, and to some extent their future. These considerations should be carefully individualized and discussed with the patient.

Teenagers are generally very concerned about how they look. The critical elements in this assessment are weight, skin, and hair. Several medications are known to influence weight. VPA is particularly associated with weight gain, whereas topiramate produces some weight loss in many individuals. Rashes are seen with LTG, and hair loss is seen with VPA.

The functional impact of these medications is also critically important to the adolescent. Teenagers are often tired, typically related to late-night activities (homework, socializing with friends, game playing, watching videos, etc.) and early-morning school schedules. Medications that increase this are typically problematic, and all of the anticonvulsants can produce a feeling of tiredness in some patients. Another area that can cause concern is an adverse impact on coordination. This can seriously affect the young person's athletic prowess or simply interfere with his or her video-game skills. Either can be socially damaging. Some adolescents will be concerned if the medication adversely affects their cognitive abilities, and any changes in academic abilities should be carefully monitored. This could be due to a variety of causes, including depression and anxiety, problems that are frequently seen in young people with epilepsy,[1,2,8] but it may also be due to the medication that is prescribed. Although some of these medications are known to be mood stabilizers (VPA and LTG), others are associated with irritability and other behavioral changes that should be carefully monitored and perhaps, in some vulnerable individuals, avoided (LEV, TPM).

Depending on the age of the adolescent, many other aspects of maturation are of great importance. In particular, this includes driving. Complete seizure control is of concern as this privilege is being pursued. Adolescents must be able to communicate with their treating physician to be sure that therapy is optimized and this full control is achieved. Patients need to feel safe in reporting seizure breakthroughs and reassured that the goal of seizure freedom can be attained. Sexuality is another emerging area of concern for these young people. Contraception is a particularly important area to address. Many of the medications used for the adolescent generalized juvenile epilepsies (VPA, LEV, ZNS) do not interfere with oral contraceptives. Many of the medications that are used for partial epilepsy (CBZ, OXC, PHT, higher doses of TPM, and probably LTG) do require somewhat higher-dose oral contraceptives to achieve successful birth control. Issues pertaining to the risks of teratogenicity need to be explored, when appropriate. Women with epilepsy have a somewhat higher risk of fetal malformations than the overall population, and this is increased considerably with VPA (7%), CBZ (3%), and LTG (3%). The risk for the even newer medications is not yet clear.[10] Young women on anticonvulsant medication should be advised to take folate, although there is no definitive evidence concerning the best dose. Most recommend 1 to 5 mg/d.

Parental Issues that are Important to Therapy

Parents are worried about many of the same things as their children, but the hierarchy of concerns may be somewhat different. They clearly understand the importance of complete seizure control, in terms of both safety and driving. They are more focused on health issues, particularly whether their children need to be monitored for adverse effects on liver and bone marrow. They are more likely to understand the seriousness of severe drug rashes, and they are more likely to use the Internet to search out all the possible adverse events associated with a medication. They will be the ones concerned about how often various parameters need to be monitored. They will need to understand that many of the new medications do not have established and useful therapeutic ranges, and that the physician must prescribe based on dose ranges and the careful monitoring of control versus toxicity. They will not feel relief (as would their child) that their doctors do not advocate frequent blood work to look for toxicities that cannot be foreseen.

Beyond the obvious medical issues, they will be focused on their child's performance, behavior, and school and social life. They will be looking further into the future and will have concerns about whether their child will be able to go to college, how the child will deal with diminished supervision, and whether epilepsy will limit vocational possibilities. Although they are often uncomfortable with issues of sexuality for their children, they need to be aware of the issues. Specifics, however, should be discussed in private with the patient unless he or she gives permission for parents to participate.

Duration of Therapy

In most seizure disorders of childhood and adolescence, physicians will want to consider whether medications can be stopped after a period of complete control. In general, this would be at 2 years of seizure freedom, when the chance of successfully discontinuing medication is about 70%.[33] It is important to approach this topic as early in successful therapy as possible, especially in adolescents, because it will affect the ability to drive. About 80% of those who recur will have declared this by 6 months. This may be an appropriate period of time to counsel young would-be drivers to refrain from driving and to find out whether they will need ongoing medication. Unfortunately, this optimistic prognostication does not pertain to teenagers with the juvenile generalized epilepsies. The majority of these youngsters will need lifelong therapy. Only about 10% will be able to have medication stopped successfully. In the future, genetic studies may help us determine which subset can actually be successfully weaned with minimal risk.

Summary and Conclusions

Unique forms of epilepsy present in adolescence along with those that are more commonly seen throughout various age ranges. In addition, patients in this age range are dealing with a very unique period of life, when they are emerging from the protection and shelter of childhood into the independence of adulthood. It is a stressful period, even in the best of circumstances, for both the young person and his or her family. Epilepsy is a major complication, especially some of the particular epilepsies seen in this age range. The clinician must be able to make a correct diagnosis to provide both the appropriate therapy and counseling regarding the likely impact of the seizure disorder on the adolescent's future. The clinician must be able to negotiate the difficult pathways of working with the patient, who is neither a child nor an adult, and the parents, who still have considerable responsibility and concern (if not control). Prescribing and monitoring medication for these patients requires sensitivity to all of the issues that are critical to the person's rapidly changing life and creativity in finding ways accurately to measure its effects. Successful treatment is likely to have long-ranging effects on whether the adolescent negotiates this difficult transition well and becomes a healthy, productive, and well-adjusted adult.

Chapter 113

Gender Issues for Drug Treatment

Anne Sabers

Cynthia L. Harden

Introduction

Potential health risks associated with long-term drug treatment raise specific concerns and considerations for the treatment of epilepsy across reproductive ages. The incidence of epilepsy is not significantly different between men and women, and the fundamental principles for managing men and women with epilepsy are very similar. However, gender differences include the effects of menstruation, pregnancy, and menopause on the course and treatment of epilepsy in women, obviously not considerations for men with epilepsy. Women are of particular concern due to the potential impact of antiepileptic drugs (AEDs) on reproductive hormones, contraception, pregnancy, and fetal outcome. However, men and women with epilepsy are both at risk for reduced sexual and reproductive functioning. Epilepsy and its drug treatment have profound implications on quality of life and ability to establish intimate relationships. This chapter discusses the specific gender-related considerations for AED treatment for women and men.

Reproductive Dysfunction

Fertility

The definition of infertility is pregnancy not occurring after 1 year of normal sexual activity for a couple not using contraceptives. Birth rates of live offspring to women and men with epilepsy are decreased compared to the general population[1] and same-sex siblings,[66] suggesting that persons with epilepsy are at risk for infertility. Although these studies adjust for marriage rates, they cannot determine the exact factors accounting for lower birth rates, such as choosing not to bear children in the setting of a chronic illness. One clear biologic factor that may affect fertility is the higher number of anovulatory menstrual cycles per year for women with epilepsy.[48]

Polycystic Ovary Syndrome, Epilepsy, and Valproate Use

Women with epilepsy also have higher rates of polycystic ovary syndrome (PCOS), which is a frequent cause of infertility, than the general population.[4] The current definition of polycystic ovary syndrome is the presence of two of the following three factors: (a) polycystic ovaries, (b) oligo-/anovulation, and/or (c) clinical or biochemical evidence of hyperandrogenism.[25] Other frequently present features of PCOS include an elevated ratio of luteinizing hormone (LH) to follicle-stimulating hormone (FSH) and insulin resistance with or without obesity.[40,56]

The association between PCOS and epilepsy is complex because epilepsy itself may be a cause or precipitant for PCOS. Epilepsy dysregulates hypothalamic activity by propagation of ictal and interictal discharges through the structure, and it therefore disrupts normal LH pulsatility. Several studies have shown altered LH pulsatility in both men and women with epilepsy compared to normal control subjects.[15,27] LH pulsatility is altered in men with epilepsy, although the effects on LH pulsatility differ in the interictal and postictal states.[55] For men in the interictal state, the pulsatile secretion of LH is slower in onset and has higher peak concentrations compared to healthy controls, whereas postictally the pulsatility becomes more irregular.[55]

The alteration of this exquisitely balanced hypothalamic-pituitary-gonadal axis may be further dysregulated via increased gonadotropin-releasing hormone (GNRH) secretion caused by contiguous ictal and interictal physiologic activity. Increased GNRH secretion preferentially increases the LH-to-FSH ratio.[38] Consistent with this postulated effect, elevated LH-to-FSH ratios have been documented in women with epilepsy.[48] LH stimulates ovarian steroidogenesis, and an elevated LH-to-FSH ratio will produce follicles that do not fully mature but, rather, become numerous and cystic. Immature follicles are deficient in aromatase, which is the enzyme that produces estrogen in the ovary by converting it from its precursor testosterone. In this manner, the PCOS ovarian follicle primarily manufactures androgens.

The question of whether valproate can cause, exacerbate, or imitate PCOS remains unclear, but it is clear that valproate is associated with the three primary features of PCOS. Valproate is associated with increased androgens[31,32,45,49,70] and cystic ovaries.[31,32] However, the association between valproate and anovulation has not been consistently found,[32,49,50] but, when present, could contribute to difficulty conceiving. The contribution of valproate to PCOS is confounded by an increased occurrence of PCOS in women with epilepsy in general; a similar rate of PCOS in women with epilepsy taking carbamazepine, valproate, or no AEDs has been reported, around 11% for each group.[4] Valproate itself inhibits aromatase and can block the conversion of testosterone to estrogen and, in this manner, among other mechanisms, contribute to hyperandrogenism.[22,71] Another well-known adverse effect of valproate now clearly emerging as an endocrinopathy is weight gain, which occurs in 40% to 50% of patients.[32] The mechanism of valproate-induced obesity may be due to its association with increased insulin and leptin levels and consequent decreased ghrelin and adiponectin levels.[20]

Because valproate is an effective AED for many persons with epilepsy, the decision to use or continue it despite the risk of endocrine dysfunction is difficult. For women with evidence of reproductive dysfunction, such as anovulation, hyperandrogenism, or PCOS itself, valproate should not be the first choice of AED because it may exacerbate these features. Weight gain with valproate use is also a reason for discontinuation for both

P.1264

men and women, not only for cosmetic reasons, but also due to the health risks associated with obesity.

Sexuality

Decreased levels of free testosterone have been found in a large group of men with epilepsy (n = 200) compared to normal controls (n = 105).[5] Some nuances were found, however, within the epilepsy group. Decreased testosterone-to-LH ratios were present in the temporal lobe epilepsy group only, whereas this important ratio was normal for patients with idiopathic generalized epilepsy. This ratio is an indicator of testicular function because LH increases in response to low testosterone levels and stimulates testicular testosterone production. Therefore, an increased testosterone-to-LH ratio suggests testicular dysfunction and an inability to respond to LH stimulation. Carbamazepine-treated men in this study had the most altered free testosterone and testosterone-to-LH ratios, consistent with the postulated effect of carbamazepine in increasing the hepatic production of testosterone-hormone binding globulin and inducing aromatase, which metabolizes the conversion of testosterone to estradiol. Valproate, on the other hand, was associated with normal total testosterone and testosterone-to-LH ratios, although the free testosterone level was still significantly decreased.[5]

In an evaluation of 65 men with epilepsy on AEDs, a higher rate of sperm abnormalities, including sperm morphology, motility, and concentration, was found.[33] Of the AEDs evaluated in this report, oxcarbazepine had the least detrimental effect on sperm quality compared to carbamazepine and valproate. The authors stated, therefore, that AED use could be a cause of infertility for men with epilepsy.[33]

In an evaluation of 63 men with localization-related epilepsy, low bioactive testosterone (similar to free testosterone) was found in men not taking AEDs (n = 9) and in men taking hepatic enzyme-inducing AEDs (n = 36).[28] Enzyme-inducing AEDs were associated with increased sex-hormone–binding globulin as well. Men taking lamotrigine (n = 18) showed more normalized bioactive testosterone and better testicular functioning based on the bioactive testosterone-to-LH ratio compared to enzyme-inducing AEDs,[28] indicating that lamotrigine has less detrimental effect on reproductive and sexual functioning than do enzyme-inducing AEDs.

Lamotrigine has been reported to be associated with improved sexual functioning in 141 women and men with epilepsy, including those who were initiated on monotherapy or switched to monotherapy from another AED.[19] Women with epilepsy reported decreased sexual functioning in association with phenytoin use and with low levels of estradiol and dehydroepiandrosterone sulfate, as well as mild depression.[47]

Enzyme-inducing AEDs therefore appear to increase the risk of sexual and reproductive dysfunction in persons with epilepsy, whereas valproate may have less of this negative effect, although it has the risk of other endocrinopathies. Evidence shows lamotrigine to be more neutral with regard to these variables, but epilepsy itself is associated with reproductive disturbances.

Perimenopause and Menopause

Perimenopause is a life epoch when seizures tend to increase, and therefore alterations in epilepsy treatment in response to this increase may be required.[24] At menopause, however, seizures may decrease with the cessation of menses, especially if there had been a catamenial pattern during the reproductive years.[24] An earlier age at menopause has been reported in women with epilepsy, particularly in those with frequent seizures, but no clear relationship to AEDs has been found.[23] However, only a few of the newer-generation AEDs were evaluated in this study.[23]

Hormonal Contraception

General Uses

Treating women with epilepsy of childbearing age should include systematic, ongoing, and accurate counseling concerning optimal choice of contraception. A computerized database study demonstrated that 16.7% of women with epilepsy are prescribed oral contraceptives (OCs) compared to 25% of nonepileptic women at fertile age in an English population.[69] OCs and AEDs can interact in two ways: AEDs can alter the effects of OCs, and OCs can influence the metabolism of AEDs.

Table 1 Interactions Between Antiepileptic Drugs (AEDs) AND ORAL CONTRACEPTIVES (OCs)

AEDs that increase the eliminiation of OCs	AEDs that do not affectthe elimination of OCs
Carbamazepine	Ethosuximide
Felbamate	Gabapentin
Phenobarbital	Lamotrigine
Phenytoin	Levetiracetam
Primidone	Valproate
Oxcarbazepine	Vigabatrin

Topiramate	Tiagabine
	Zonisamide

The Effect of Antiepileptic Drugs on the Pharmacokinetics of Oral Contraceptives

Combined Oral Contraceptives

The potential for pharmacokinetic interactions between AEDs and combined OCs was first suggested in 1972, >10 years after the introduction of the combined OCs.[36] A higher incidence of breakthrough bleeding and contraceptive failure among women with epilepsy has been observed and correlated with the time when the ethinylestradiol fraction of OCs was decreased from 50 to 100 µg to <50 µg to diminish the risk of thromboembolic side effects.[9] Contraceptive failure, therefore, may depend mainly on the concentration of the estrogen fraction.

Currently available combined OC preparations contain much lower estrogen doses, 20 to 35 µg of ethinylestra-diol and <1 mg of progestogen. The major part of the estrogen compound is hydroxylated to inactive metabolites by the hepatic cytochrome P450 (CYP) 3A4 or directly conjugated. AEDs that induce the CYP 3A4 isozyme include carbamazepine,[11] phenobarbital,[2] phenytoin,[11] oxcarbazepine,[18] and topiramate,[59] as shown in Table 1. These AEDs therefore accelerate the hepatic elimination of OCs. A recent study of topiramate with an OC containing 35 µg of ethinyl estradiol demonstrated that topiramate monotherapy at a dose of <200 mg did not significantly affect the clinical efficacy of the OC.[14]

The consequence of this drug interaction is a risk of contraceptive failure and unwanted pregnancy. Therefore, women who are prescribed enzyme-inducing drugs should use

high-dose OCs with the dose of the estrogen compound of at least 50 µg. They should also be advised to use additional barrier methods of contraception, especially in case of intramenstrual bleeding. The extent of enzyme induction is correlated with the dose of the drug but is difficult to quantify because genetic and environmental factors also influence the hepatic isozyme expression.[53,74]

Current data suggest that gabapentin,[16] levetiracetam,[57] losigamone,[13] tiagabine,[44] vigabatrin,[3] and zonisamide[21] do not influence the metabolism of OCs and can be administrated without risk of contraceptive failure. One study demonstrated a modest and probably not clinically relevant decrease of the levonorgestrel compound of the OCs by lamotrigine but no change in the pharmacokinetic parameters of ethinyl estradiol.[68] This is in agreement with the earlier study by Holdich et al.,[30] which found no effect of lamotrigine on the elimination of OCs. A similar finding has been demonstrated with felbamate, which caused a 42% decrease in gestodene first-24-hour area under the curve $AUC_{(0\text{-}24)}$ but had no effect on the metabolism of ethinyl estradiol.[60] These studies,[60,68] however, were performed with a moderate dose of reproductive hormones, namely 30 µg ethinyl estradiol, 150 µg levonorgestrel, and 75 µg gestodene. Ovulation might not be suppressed in women who use low-dose OCs (<30 µg ethinyl estradiol and < 75µg progesterone). Midcycle bleeding should therefore always alert the physician and the patient to the risk of contraceptive failure.

Synthetic Progestogens

Data on possible interactions between AEDs and progesterone-only pills, injections, and implants are very sparse. One study demonstrated that the subdermal levonorgestrel implants have a high failure risk in women receiving phenytoin.[26] These contraceptives are therefore generally regarded as less reliable and should not be prescribed in women who are treated with enzyme-inducing drugs. Intrauterine contraceptives do not appear to be affected by AEDs, including those that induce hepatic enzymes.

The Effect of Oral Contraceptives on the Pharmacokinetics of Antiepileptic Drugs

Lamotrigine

OCs can increase the metabolism of glucuronidated drugs by induction of the uridine diphosphate glucuronosyltransferase system.[46,47] Several studies have demonstrated that the elimination of lamotrigine, which is metabolized in the liver primarily by glucuronic acid conjugation, is significantly and substantially (>50%) increased by combined OCs.[58,62,68] The drop in lamotrigine plasma concentration after introduction of OCs is associated with increased seizure frequency or seizure recurrence in most cases.[61]

These pharmacokinetic alterations show considerable interindividual variability due to both genetic factors and whether other AEDs are coadministered. The induced metabolism of lamotrigine can be greatly attenuated and almost blocked by valproate.[73] Because the level of altered elimination is unpredictable for the individual patient, it is recommended that the plasma level of lamotrigine be carefully monitored and doses adjusted before and after introduction or discontinuation of OCs.

The change in lamotrigine metabolism has been attributed to the estrogen rather than the progestin component of the OC.[58] The lack of estrogens affects the pharmacokinetics acutely, and the plasma level of lamotrigine increases in a fairly rapid and linear manner[8,68] already within the "pill-free" week. The hormonal effect shows great interindividual variation, and the concentration at the end of the washout week is up to twofold higher than when coadministrated in the 3-week period before and after.[8] Because of the rapid and significant increase of the plasma level, the authors suggested that uptitration of the lamotrigine dose should not occur in the "pill-free week" to avoid titration-related tolerability problems.

Valproate and Oxcarbazepine

Recent results suggest that similar interactions may exist between combined OCs and valproate. Like lamotrigine, valproate is eliminated mainly by hepatic glucuronidation.[29] The pharmacologically active monohydroxy derivative of oxcarbazepine is also mainly eliminated by glucuronidation.[42] The clinical relevance of this potential effect of OC for the elimination of valproate and oxcarbazepine needs to be further explored.

Pregnancy

General Considerations

The goal of AED treatment in women of childbearing age with epilepsy is to achieve the best possible control of seizures with the minimal adverse effects for both the mother and the offspring. Most AEDs have comparable efficacy when used for the appropriate syndromes, which means that the selection among AEDs with similar efficacy may be done on the basis of their adverse effects. Each AED has its own unique adverse effect profile, which must be carefully considered prior to its selection. Many factors must be taken into account before planning a pregnancy, including the mother's ability to care for an infant, the genetics of her epilepsy, and her current medication regimen. Consideration of these factors serves to open a dialogue with the patient about her fears and worries.

Epilepsy-related difficulties during pregnancy include fluctuating AED plasma levels, an increased risk of seizures, and possible teratogenetic effect of the AEDs. If treatment with AEDs during the pregnancy is necessary, monotherapy at the lowest effective dose needed to control seizures is recommended.

Effects of Epilepsy on Pregnancy

Women treated with AEDs have a two- to threefold higher risk of having a child with an anomaly or malformation than the background population.[35,64] In women with epilepsy who are not treated with AEDS, the risk of teratogenicity is lower.[63] Paternal epilepsy does not influence the risk of teratogenicity.

Several factors may contribute to the poor outcome, including genetic factors, a direct teratogenic effect of the AEDs, or indirect effects via an interference with folic acid metabolism or other genetically determined pathways. The teratogenic risk of individual AEDs and folic acid supplementation are comprehensively covered in Chapter 108. Delivery at a high-risk obstetric unit affiliated with a pediatric department and with experienced neurologists available is recommended.

Effects of Pregnancy on Epilepsy

The pharmacokinetics of AEDs are influenced by the dynamic physiologic changes that occur during pregnancy.[51] These include reduced gastric motility, nausea and vomiting, increased drug distribution, changes in protein binding, and increased renal elimination and altered hepatic enzyme activity. In

addition, there is growing appreciation that many women are not fully compliant with therapy during pregnancy because of concerns about the potential adverse drug effects on the developing fetus.[76]

Pregnancy-induced effects on the plasma levels of AEDs increase the risk of increased seizures or seizure breakthroughs. In the prospective international EURAP study, increased seizure frequency was observed in 17% of 1,718 pregnancies, with the highest risk in patients with localization-related epilepsies and those on polytherapy.[17] Earlier studies disagreed about when in the pregnancy seizure risk is highest. Some, for example, have reported that risk of deteriorating seizure control is highest during the first trimester,[37,65] whereas other studies found that seizure frequency was greatest in the last trimester.[72] The recent EURAP report found no relation to specific trimesters.[17]

The clinical consequences of the drop in plasma levels are controversial; some women do not experience deterioration in seizure control even in the face of decreased plasma levels. Adjustment in dose to prevent or correct a fall in plasma levels has been found necessary in >70% of patients treated with phenytoin, carbamazepine, and barbiturates.[39] With some AEDs, however, that are highly protein bound, such as phenytoin and valproate, the free concentration remains unchanged or even increases during pregnancy because of alteration in protein binding.[72] Furthermore, because teratogenicity is likely related to the drug dose, routinely increasing the dose of AEDs could increase the risk of teratogenicity.

Treatment with lamotrigine poses specific problems during pregnancy because the pharmacokinetics of this drug is especially influenced by gestation.[51,54,75] Seizure frequency increased in 75% of patients on lamotrigine during pregnancy.[12,54] This deterioration was associated with a 40% decrease in the ratio of plasma lamotrigine concentration to dose, which occurred primarily between weeks 20 and 30 of gestation. It has therefore been recommended that careful attention be paid to maintaining stable lamotrigine plasma levels throughout pregnancy to prevent increased seizure frequency.

Recent studies indicate that oxcarbazepine also exhibits major changes in clearance during pregnancy.[7,43] The elimination of the pharmacologically active monohydroxy derivate of oxcarbazepine might be affected by pregnancy because the elimination of the derivate occurs largely by glucuronidation in a way similar to that for lamotrigine. In the prospective EURAP registry study,[17] oxcarbazepine monotherapy was associated with increased seizure frequency.

Little is known about the effect of pregnancy on the pharmacokinetics of other, newer AEDs.

Vitamin K Supplementation

For many years it has been suggested that pregnant women treated with enzyme-inducing AEDs (carbamazepine, phenytoin, and barbiturates) should be given oral supplement of vitamin K in the last month of pregnancy to protect the infant against hemorrhagic disease of the newborn. A recent study, however, has demonstrated that this may not be necessary,[34] and the usefulness of vitamin K at the end of pregnancy remains speculative, although the general tendency is to give the supplement.

Family Planning

The possibility of pregnancy, whether desired or not, must always be considered when prescribing AEDs for women of childbearing age. Comprehensive care of women with epilepsy during the reproductive years should include systematic appropriate and accurate counseling concerning optimal choice of contraceptive method. Ideally, issues related to family planning should be discussed well in advance of any planned pregnancy to allow informed and well-considered choices.

Unfortunately, several surveys have demonstrated that a surprising number of physicians do not have adequate knowledge about specific issues related to family planning in women with epilepsy, and approximately 50% of women with epilepsy taking OCs indicate that they were never given information about a potential interaction between their AEDs and the OCs.[11,41] Shorvon et al.[69] demonstrated that of 2,000 women taking enzyme-inducing AEDs, >50% were taking OCs with an estrogen content <50 µg. A resent survey showed that women with epilepsy of childbearing age do not always recall being given information on contraception and prepregnancy planning, which highlights the need for regular repetitions.[6]

A reevaluation of the diagnosis of epilepsy and need for continued treatment should be central to the counseling process. Women who have been seizure free for 2 to 5 years may be able to withdraw from medication. Any change in the AED treatment and addition of folic acid as a daily supplement should be performed before attempting conception. When a patient treated with lamotrigine is planning to discontinue OC to become pregnant, the plasma concentration of lamotrigine should be closely monitored and the dose reduced to avoid exposing the fetus to unnecessary high drug concentrations.[61]

Factors in Drug Selection in Women of Childbearing Age

The primary goal for the treatment of epilepsy must always be to gain the best possible control of seizures with the least adverse effects. The AED most effective for the specific syndrome and that is the best tolerated should be selected. However, choosing an AED in a woman of childbearing age requires, in addition, specific consideration of the complexities of reproductive health.

Traditional Drugs—Pros and Cons

The older AEDs (carbamazepine, phenobarbital, phenytoin, primidone, sodium valproate) share some less desirable characteristics, such as having complex pharmacokinetics and effects on the activity of hepatic enzyme systems. On the other hand, these older drugs collectively have a broad familiarity, lower cost, known efficacy, and long-term experience.

Carbamazepine, phenobarbital, phenytoin, and primidone induce the hepatic CYP 3A4 isozyme, which accelerates the elimination of endogenous and exogenous sex steroid hormones, including interactions with other drugs, including OCs. Valproate has multiple endocrine effects in both men and women, and it can contribute to anovulation, infertility, and teratogenicity.

Newer Drugs—Pros and Cons

In comparison, several of the newer AEDs appear to have certain advantages. Gabapentin, lamotrigine, levetiracetam, losigamone, pregabalin, tiagabine, vigabatrin, and zonisamide have relative simple pharmacokinetic properties and do not alter plasma levels of steroid sex hormones or interfere with the effectiveness of other drugs, including hormonal contraceptives. Oxcarbazepine and topiramate may selectively affect the efficacy of hormonal contraception. The disadvantages of newer AEDs, however, include limited long-term experience with regard to safety in pregnancy, lack of comparison studies among the drugs, and lack of unequivocal information about teratogenic risk.

P.1267

Lamotrigine has been recommended as a desirable treatment option for women of fertile age because it is not associated with weight gain, does not disrupt the menstrual cycle, and may have low teratogenic potential. However, after >5 years of clinical use, it became evident that elimination of lamotrigine is affected significantly by sex hormones, which complicate maintaining a stable plasma concentration during pregnancy and while using hormonal contraception.

Another example of delayed recognition of adverse effects is that it took 10 years to recognize the retinal toxicity of vigabatrin. Whether intrauterine exposure to vigabatrin potentially affected the developing retina has not been fully explored.

Summary and Conclusions

The gender issues for drug treatment are based primarily on altered metabolism of AEDs by reproductive hormones or, conversely, changes in the metabolism of reproductive hormones by AEDs. The impact of these interactions is complicated by the effects of epilepsy itself on reproductive health. Valproate likely contributes to, or perhaps mimics, PCOS in women with epilepsy, whereas the enzyme-inducing AEDs have relatively more adverse effects on reproductive parameters for men with epilepsy. The evidence indicates that lamotrigine does not contribute to hormonally related reproductive dysfunction.

Lamotrigine has emerged as an example of how an AED can be affected by exogenous or endogenous hormonal induction of the uridine diphosphate glucuronosyltransferase system, which has important consequences during oral contraceptive use and with pregnancy. Two other AEDs share this pharmacokinetic vulnerability—oxcarbazepine and valproate. There is a need for further information on these interactions.

Chapter 114

Drug Treatment in the Elderly

Ilo E. Leppik

Angela K. Birnbaum

Introduction

The elderly are the most rapidly growing segment of the population, and demographic trends predict that their number is projected to increase in the United States from an estimated 40 million in 2010 to 71.5 million in 2030.[1] Similar increases are expected throughout the world. The incidence (new cases) of epilepsy is higher in the elderly than in any other age group.[33,34] Because of the rapid growth in their numbers and their propensity to develop epilepsy, elderly persons will represent an increasingly large group of patients needing expert care for this disorder. In the United States, approximately 181,000 persons developed epilepsy in 1995, and approximately 68,000 of these were >65 years of age.[21] Similar high rates have been reported from the Netherlands and Finland.[19,72] Problems faced by the elderly with epilepsy are different and more complex than those faced by younger adults with this disorder. These issues are medical (making the correct diagnosis, selecting the correct medication, working with comorbid illnesses), social, emotional, and economic.

One complicated area is selecting the appropriate antiepileptic drug (AED), which requires the consideration of a number of factors. These include changes in organ function, increased susceptibility to adverse effects, use of other medications known to interact with AEDs, and economic limitations. In addition, the elderly population is heterogeneous, and broad statements about the elderly may not be relevant to each individual patient. Treatment in the elderly carries more risks than in younger persons because they may experience more side effects, have a greater risk for drug interactions, and be less able to afford the costs of medications. In addition to their use in epilepsy, AEDs are prescribed for a variety of other disorders affecting the elderly, including pain and psychiatric disorders. As a cause of adverse reactions among the elderly, AEDs rank fifth among all drug categories.[54] Unfortunately, very little research has been done in this vulnerable population, and only general recommendations can be made at this time.

The Elderly Are Not a Homogenous Population

Like the pediatric population, the elderly (65 years and older) are not a single cohort. Medical issues in persons up to age 18 years cannot be properly interpreted without using the subcategories of newborn, infant, child, and adolescent. Similarly, elderly persons should also be subdivided into appropriate cohorts. A widely used system divides the elderly into the "young-old" (those 65–74 years of age), the "middle-old" or "old" (those 75–84 years of age), and the "old-old" (those 85 years or older). However, because persons develop health issues at different times, further subdivisions have been proposed as shown in Table 1: (a) the elderly healthy (EH) who have epilepsy, (b) the elderly with multiple medical problems (EMMP), and (c) the frail elderly (FE), usually in nursing homes.[48] Thus, one must tailor studies and interventions to nine categories of elderly with epilepsy. In addition, pediatricians must cope with the emotions of adult parents of children, who are often very caring and protective. Similarly, the physician caring for an elderly person with epilepsy must deal with the emotions of adult children of parents. Approaches needed by both groups of physicians have similarities.

In addition, there are major differences between the community-dwelling elderly (independent living) and those residing in nursing homes. Clearly, drug side effects, efficacy, absorption, and other factors may be markedly different between a 93-year-old healthy person living independently and a 68-year-old frail person residing in a nursing home. In addition, issues regarding health care delivery will likely differ between the community-dwelling elderly and the nursing home elderly. Studies should be designed with specific populations in mind, and reports should specify the populations studied.[50]

Diagnosis of Epilepsy in the Elderly

The diagnosis of epilepsy is difficult in the elderly. In the Veterans Administration (VA) study #428, a large portion of patients with epilepsy had been initially misdiagnosed.[68] Other conditions such as cardiac insufficiency, metabolic conditions, convulsive syncope (micturition syncopy, cough syncope), and other conditions must be eliminated before it can be concluded that an event was an epileptic seizure. In the elderly, the most common identifiable cause of epilepsy is stroke, which accounts for 30% to 40% of all cases. Brain tumor, head injury, and Alzheimer's disease are other major causes. However, in a large number of cases, the precise cause cannot be identified and the etiology is cryptogenic. Because most seizures in the elderly are caused by a focal area of damage to the brain, the most common seizure types are localization related. Complex partial seizures are the most common seizure type, accounting for nearly 40% of seizures in the elderly population.[31] Both simple and complex seizures may spread and develop into generalized tonic–clonic seizures. All major AEDs have a U.S. Food and Drug Administration (FDA) indication for use in the types of seizures encountered in the elderly.

Table 1 Categorization of the Elderly with Epilepsy

Young-old, healthy EH	Middle-old, healthy EH	Old-old, healthy EH
Young-old, multiple medical problems	Middle-old, multiple medical problems	Old-old, multiple medical problems
EMMP	EMMP	EMMP
Young-old, frail	Middle-old, frail	Old-old, frail
FE	FE	FE

EH, elderly healthy; EMMP, elderly with multiple medical problems; FE, frail elderly.

P.1270

Pharmacoepidemiology of Antiepileptic Drug Use in Elderly

Antiepileptic Drug Use in Community-Dwelling Elderly

The largest study of AED use in community-dwelling elderly in the United States was the VA study coordinated by Berlowitz.[63,64] Of a total of 1,130,155 veterans of age 65 years and older identified from the national data base of 1997 to 1999, 20,558 (1.8%) were identified as having epilepsy by having an ICD-9-CM (International Classification of Diseases, 9th Revision, Clinical Modification) code representative of this condition.

Approximately 80% were receiving one AED and 20% were being treated with two or more. Phenytoin was used as monotherapy by almost 70%, whereas phenobarbital was used as monotherapy by approximately 10%. Another 5% were using phenobarbital in combination, mostly with phenytoin. Carbamazepine was used by just >10%, and newer AEDs (gabapentin and lamotrigine) were used by <10%.[63,64] (Levetiracetam was not available at the time of the survey.) Smaller studies in community-dwelling elderly non-VA patients have found a similar distribution of AED use, with phenytoin by far the most widely used AED in the United States in this population.

Antiepileptic Drug Use in Nursing Homes

As people age, their need for nursing home care increases due to greater frailty and disease. For patients aged 65 years and older, there is a lifetime risk of 43% to 46% of ever becoming a resident in a nursing home (NH).[41,73] At any one time, 4.5% of the elderly U.S. population is residing in a NH.[37] In any research concerning NHs, the distinction must also be made between *residents* and *admissions*. A resident cohort includes all residents in the facility at a specified time, which is usually a cross-sectional sample and consists of a mixture of newly admitted residents and others who have been in the NH for different periods of time. In contrast, an admission cohort includes all people admitted to a facility during a specified time period.[26]

In a study of the residents residing in various nursing homes in the United States during the spring of 1995,[25] the mean age of the 21,551 residents was 83.78 years (SD, 8.13 years). The age group distribution was young-old 15%, middle-old 36%, and old-old 49%. This distribution is similar to the population of 1,557,800 people ≥65 years of age in NHs in the year 2000, based on data from the U.S. Census Bureau.[37] Of the residents in this NH sample, 10.5% had one or more AED orders on the study day, and 9.2% had a seizure indication (epilepsy or seizure disorder) documented in the chart. Phenytoin was used by 6.2% of the residents, followed by carbamazepine (1.8%), phenobarbital (1.7%), clonazepam (1.2%), valproic acid (0.9%), and all other AEDs combined (1.2%); these percentages exceed 10.5% due to AED polytherapy. Approximately 90% of AED use was for an epilepsy/seizure indication. If these results are extrapolated to all 1,557,800 elderly residents in U.S. NHs in 2000,[37] then as many as 163,569 people were likely to have been receiving an AED. Of note, this prevalence is approximately five times that of AED use in the community.[19,32] Age was inversely related to AED use. Of the young-old, 23.7% were prescribed an AED, with 16.4% for seizure indication and 7.3% for other. In the middle-old, 12.2% were prescribed an AED, with 8.3% for seizure and 3.9% for other; whereas the old-old had only 5.8% use, with 3.7% for seizure and 2.1% for other (Fig. 1). This finding was unexpected because of the upward curve in the incidence of epilepsy/seizure disorder with advancing age. Thus, one of the major findings of the study of AED use in U.S. nursing homes is that the young-old are three to four times more likely to be prescribed an AED than the old-old either prior to admission or after admission. Similar results were reported from a study in Italy.[24]

A study of admissions employing a longitudinal design to explore AED use at the time of admission used two study groups: (a) all persons aged ≥65 years admitted between January 1 and March 31, 1999, to one of the 510 Beverly Enterprises NH facilities in 31 U.S. states (N = 10,318) and (b) a follow-up cohort (n = 9,516) of those in the admissions group who were not using an AED at NH entry.[26] This cohort was followed up for 3 months after their individual admission dates or until NH discharge, whichever occurred first. Approximately 8% (n = 802) of the admissions group used one or more AEDs at entry, and among these, greater than half (58%) had an epilepsy/seizure disorder indication. The AEDs used by newly admitted individuals with epilepsy/seizure disorder (n = 585) included phenytoin (n = 315; 54%), valproic acid (n = 57; 10%), carbamazepine (n = 52; 9%), and gabapentin (n = 27; 5%).

Among residents in the follow-up cohort in the same study (n = 9,516) who were not using an AED at admission, 260 (3%) were initiated on an AED within 3 months of admission. Factors associated with the initiation of AEDs during this period included epilepsy/seizure, manic depression (bipolar disease), age group, cognitive performance (Minimum Data Set Cognitive Score [MDS-COGS]), and peripheral vascular disease (PVD). Thus, many persons admitted without a diagnosis of epilepsy are diagnosed as such after entry, and the incidence of newly diagnosed epilepsy in the nursing home far exceeds that in other populations. A crude estimate is 600 in 100,000 per 3 months, or four to six times that reported for elderly community-dwelling elderly. The AEDs used by those in this group with an epilepsy/seizure indication were phenytoin 48%, valproic acid 8%, gabapentin 13%, carbamazepine 12%, and phenobarbital 7%; and the remainder others. There was also an inverse relationship between age group and initiation of an AED. Compared to the young-old, those in the old group (aged 75–84 years) were one third less likely to have an AED initiated ($p < 0.05$), and the oldest-old (aged ≥85 years) were only half as likely ($p < 0.0001$).[26]

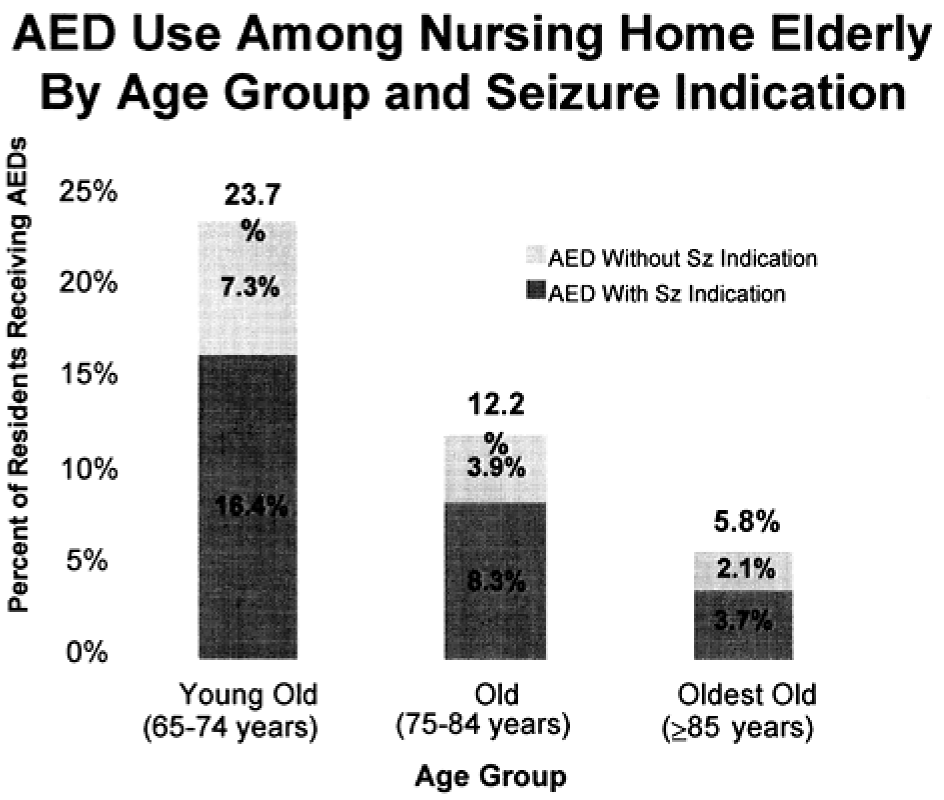

FIGURE 1. The young-old are much more likely to be treated with an antiepileptic drug than are the old-old, the inverse of what is observed in community-dwelling elderly. (Data from Garrard J, Cloyd J, Gross C, et al. Factors associated with antiepileptic drug use among elderly nursing home residents. *J Gerontol A Biol Sci Med Sci*. 2000;55:M384–M392.)

Table 2 Frequency of Use of Comedications With Potential Pharmacokinetic or Pharmacodynamic Interactions With Antiepileptic Drugs in 4,291 Residents of Nursing Homes

Drug category	Use with antiepileptic drugs (%)
Antidepressants	18.9
Antipsychotics	12.7
Benzodiazepams	22.4

Thyroid supplements	14.0
Antacids	8.0
Calcium channel blockers	6.9
Warfarin	5.9
Cimetidine	2.5

Modified from Lackner TE, Cloyd JC, Thomas LW, et al. Antiepileptic drug use in nursing home residents: effect of age, gender, and comedication on patterns of use. *Epilepsia*. 1998;39:1083–1087.

Another issue is that many elderly are using other drugs (Table 2). In addition to AEDs, the average elderly nursing home patient takes six medications concomitantly, greatly increasing the risk for side effects and drug interactions.[44]

P.1271

Clinical Pharmacology of Antiepileptic Drugs in the Elderly

The theoretical basis for age-related changes in drug pharmacokinetics was described many years ago but has not been widely applied to AEDs. Drug concentration at the site of action determines the magnitude of both desired and toxic responses. The unbound drug concentration in serum is in direct equilibrium with the concentration at the site of action and provides the best correlation with drug response.[79] Total serum drug concentration is useful for monitoring therapy when the drug is not highly protein bound (<75%) or when the ratio of unbound to total drug concentration remains relatively stable. Three of the major AEDs (valproic acid, phenytoin, and carbamazepine) are highly bound, and binding is frequently altered.

The age-related physiologic changes that appear to have the greatest effect on AED pharmacokinetics involve protein binding and the reduction in liver volume and blood flow.[29,69,78,80] Reduced serum albumin and increased α1-acid glycoprotein (AAG) concentrations in the elderly alter protein binding of some drugs.[29,78,79] By age 65 years, many individuals have low normal albumin concentrations or are frankly hypoalbuminemic. Albumin concentration may be further reduced by conditions such as malnutrition, renal insufficiency, and rheumatoid arthritis. The concentration of AAG, a reactant serum protein, increases with age; further elevations occur during pathophysiologic stress such as stroke, heart failure, trauma, infection, myocardial infarction, surgery, and chronic obstructive pulmonary disease.[78] Administration of enzyme-inducing AEDs also increases AAG.[74] When the concentration of AAG rises, the binding of weakly alkaline and neutral drugs such as carbamazepine to AAG can increase, causing higher total serum drug concentrations and decreased unbound drug concentrations. Because of the complexity of confounding variables and the lack of correlation between simple measures of liver function and drug metabolism, the effect of age on hepatic drug metabolism remains largely unknown.[17,18] Genetic determinants of hepatic isozymes may be more important than age in determining a person's clearance.[42]

Renal clearance is the major route of elimination for a number of the newer AEDs. It is well known that an elderly person's renal capacity decreases by approximately 10% per decade, but this also is highly dependent on the general state of health.

Despite the theoretical effects of age-related physiologic changes on drug disposition and the widespread use of AEDs in the elderly, few studies on AED pharmacokinetics in the elderly have been published. The reports generally involve single-dose evaluations in small samples of the young-old (65–74 years). There is a lack of data regarding AED pharmacokinetics in the oldest-old (>85 years), individuals who may be at greatest risk for therapeutic failure and adverse reactions.

Variability of Antiepileptic Drug Levels in Nursing Homes

Studies have shown that in compliant patients, the variability of AED concentrations over time is relatively small. One study

P.1272

of phenytoin showed that in institutionalized patients, the variability between serial measurements over time was on the order of 10%. In the same study, compliant clinic patients had variability of approximately 20%.[49] Approximately 5% of this can be accounted for by measurement instrument variability, although laboratories not following rigid quality control standards may have a much larger variability. The remainder of the variability arises from day-to-day alterations in absorption or metabolism or differences in AED dose content. The variability for carbamazepine and valproate is on the order of 25%, possibly due to their shorter half-lives and thus increased variability from sampling times.[27] A small study found that phenytoin levels may fluctuate in the nursing home elderly.[55] This was confirmed in an analysis of serial phenytoin levels from nursing home patients across the United States who had no change in dose, no change in formulation, and no additions of other medications.[6] Some residents had a difference of two- to threefold from the lowest to the highest phenytoin concentrations. It is also interesting that some had very little fluctuation and were similar to the younger adults studied, as mentioned earlier. Similar but less severe fluctuations were observed for carbamazepine and valproate. These findings suggest that elderly frail nursing home residents may have great variability in absorption of drugs. Factors that contribute to this must be identified and strategies developed to minimize its effects.

Clinical Trials of Antiepileptic Drugs in the Elderly

All major AEDs have an FDA indication for use for the seizure types most likely to be encountered in the elderly. However, there are few data relating specifically to these drugs in the elderly, and those that are available have been limited to community-dwelling elderly. One post hoc study of the VA cooperative study of carbamazepine and valproate found that elderly patients often had seizure control associated with lower AED levels than seen in younger individuals. However, side effects were also observed at levels lower than those seen in younger persons.[65] A multicenter, double-blind, randomized comparison between lamotrigine and carbamazepine in elderly patients (mean age 77 years) with newly diagnosed epilepsy in the United Kingdom showed that the main difference between the groups was the rate of drop out due to adverse events, with a rate for lamotrigine of 18% compared to a rate of 42% for carbamazepine.[11] The VA Cooperative Study #428, an 18-center, parallel, double-blind trial on the use of gabapentin, lamotrigine, and carbamazepine in patients 60 years or older, found that efficacy did not differ, but the main finding favoring the two newer AEDs was tolerability.[68]

Choosing Antiepileptic Drugs for the Elderly

There are few data regarding the clinical use of AEDs in the elderly. The paucity of information makes it very difficult to recommend specific AEDs with any confidence that the outcomes will be optimal. A drug choice optimal for the EH group may not be appropriate for the EMMP or FE group due to differences in pharmacokinetic or pharmacodynamic properties among these groups. Phenytoin is still the most commonly used AED in both community-dwelling and nursing home elderly in the United States, although expert opinion may disagree with this practice.[64] Before practice can change, evidence must be developed to support opinion. The next section first discusses the most commonly used AEDs, for which there are more data, and then presents an alphabetical review of the newer AEDs. Table 3 summarizes the properties of most AEDs.

Phenytoin

Phenytoin is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly.

Evidence for this can be gathered from the VA cooperative study, which included some elderly and found that phenytoin was as effective as carbamazepine, phenobarbital, and primidone, but that phenytoin and carbamazepine were better tolerated.[52] Phenytoin has a narrow therapeutic range, is approximately 90% bound to serum albumin, and undergoes saturable metabolism, which has the effect of producing nonlinear changes in serum concentrations with changes in dose or absorption. Clinical studies in elderly patients have shown decreases in phenytoin binding to albumin and increases in the free fraction.[29] The binding of phenytoin to serum proteins correlates with the albumin concentration, which is typically low normal to subnormal in the elderly. One study compared the pharmacokinetics of phenytoin at steady state after oral administration in 34 elderly (60–79 years), 32 middle-aged (40–59 years), and 26 younger adults (20–39 years) with epilepsy. All patients had normal albumin concentrations and liver function and received no other medications, including other AEDs known to alter hepatic metabolism. The maximum rate of metabolism (*V*max) declined with age, and significantly lower values were seen in the elderly group compared to younger adults.[4] Other, smaller studies have also shown that phenytoin metabolism is reduced in the elderly[2,35,45,76]; therefore, smaller maintenance doses of phenytoin may be needed to attain desired unbound serum concentrations. Relatively small changes in dose (≤10%) are recommended when making dosing adjustments. Thus, in the elderly, a daily dose of 3 mg/kg appears to be appropriate, rather than the 5-mg/kg per day used in younger adults.[47] This 3-mg/kg dose is only 160 mg/day for a 52-kg woman and 200 mg/day for a 66-kg man. Several nursing home studies revealed that residents were taking phenytoin (PHT) doses similar to those used in younger adults.[6] In addition, a gender effect was found in this population because women required higher doses than men of PHT to achieve similar serum concentrations.[6] A recent study of age and genotype, however, found that the presence of a mutant cytochrome P450 (CYP) 2C9 or 2C19 isozyme was far more predictive of phenytoin dose than age.[42]

Due to the high protein binding of PHT, unbound PHT concentrations may be a better indicator of efficacy and toxicity than total concentrations. Measurement of unbound phenytoin concentrations is essential for elderly patients who have (a) decreased serum albumin concentration, (b) total phenytoin concentrations that are near the upper boundary of the therapeutic range, (c) total concentrations that decline over time, (d) a low total concentration relative to the daily dose, or (e) total concentrations that do not correlate with clinical response. A range of 5 to 15 m/L total may be more appropriate as a therapeutic range for the elderly.[47]

Table 3 Antiepileptic Drug Pharmacokinetics in the Elderly

Drug	Protein binding (%)	Elimination	Comments
Carbamazepine	75–85	Hepatic, CYP 3A4/5	Protein binding decreases with age Levels are increased by erythromycin, prophoxyphene, and grapefruit juice Decreases levels of calcium channel blockers (dilitiazem, verapamil) Decreases effect of warfarin Decreases tricyclic antidepressant levels
Felbamate	<10	Hepatic	—

Gabapentin	<10	Renal	Elimination correlates with creatinine clearance No drug interactions
Lamotrigine	55	Hepatic glucuronide conjugation	Levels are decreased by inducing agents: carbamazepine, phenytoin, some hormones, and others yet to be determined Levels increased by vaproate
Levetiracetam	<10	Renal	Very water-soluble, intravenous formulation available No drug interactions
Oxcarbazepine	40	Hepatic	Causes hypontremia
Phenobarbital	50	Hepatic, renal	Induces metabolism of many drugs
Phenytoin	80–93	Hepatic, CYP 2C9, CYP 2C19	Protein binding decreases with reduced serum albumin and renal failure Decreases levels of calcium channel blockers (dilitiazem, verapamil) Has a complicated interaction with warfrin Decreases tricyclic antidepressant levels Interacts with diabetes and arthritis medications Decreases effectiveness of cancer chemotherapy
Topiramate	9–17	Hepatic, renal	Inhibits CYP 2C19 and increases serum phenytoin and other drug levels Induces CYP 3A4 isozymes
Valproic acid	87–95	Hepatic, multiple pathways	Protein binding is decreased in the elderly Inhibits glucuronidation and may increase levels of lamotrigine and other drugs Decreases platelet function

CYP, cytochrome P450.

Phenytoin has many drug–drug interactions and should be used cautiously in EMMP patients receiving other medications. Valproic acid, which is also highly protein bound, competes with phenytoin for albumin-binding sites and inhibits phenytoin's metabolism. Carbamazepine induces phenytoin metabolism and necessitates higher phenytoin doses. Phenobarbital is thought to induce phenytoin's metabolism; however, the data are controversial.[13] There is also some indication that SSRI antidepressants may inhibit the cytochrome 2C family of P450 enzymes responsible for metabolizing phenytoin.[59] Fluoxetine and norfluoxetine are more potent inhibitors of this enzyme, followed by sertraline and paroxetine.

The latter two selective serotonin-reuptake inhibitor (SSRI) antidepressants may prove to be a safer choice in the elderly. Coumadin has a very complicated interaction with phenytoin, and often doses of both need to be manipulated.[47]

Phenytoin has some effects on cognitive functioning, especially at higher levels.[75] It is not known whether the elderly will be more sensitive to this problem. In addition, phenytoin may cause imbalance and ataxia. It is likely that EMMP patients, especially those with central nervous system (CNS) disorders, may be more sensitive.[10] In a study of the elderly, among the various lifestyle, demographic, and health factors that contributed to an increased risk, phenytoin was the only drug that was associated with a significant increase in fractures.[8] However, this study could not determine whether this was due to falls from ataxia or seizures or was an effect of bone changes. Phenytoin also is known to be a mild blocker of cardiac conduction and should be used cautiously in persons with conduction defects, especially heart blocks. In spite of its limitations, phenytoin is the least expensive major AED. This and its long record of use may account for it being the most widely used AED.

Carbamazepine

Carbamazepine (CBZ) is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. Evidence from two large VA studies showed it to be as effective as phenytoin, phenobarbital, primidone, and valproate but better tolerated than the latter three.[52,53] Two studies of new-onset epilepsy in the elderly found it to be as effective as lamotrigine, but it had a higher incidence of side effects.[11,68]

Apparent clearance of carbamazepine is reported to be 20% to 40% lower in the elderly than in other adults.[2,14,28] A population analysis of patients from ambulatory neurology clinics at three medical centers also showed that the apparent oral clearance of CBZ was 25% lower in patients who were >70 years old.[28] Decreases in clearance result in a prolonged elimination half-life. These changes in carbamazepine pharmacokinetics indicate that lower and less frequent dosing in elderly patients may be appropriate.

Carbamazepine has some significant drug–drug interaction with medications that inhibit the cytochrome P450 enzyme responsible for carbamazepine metabolism, CYP 3A4. Among the inhibitors are erythromycin, fluoxetine, ketoconazole, propoxyphene (Darvon), and cimetidine (Tagamet). At least one food (grapefruit juice) has been identified as interacting with carbamazepine to cause increases in CBZ serum concentrations. EH patients need to be cautioned about these and should be instructed to inform the physician whenever they are beginning a new medication, including over-the-counter medications. Many other drug interactions occur, so that carbamazepine is one AED that needs to be used cautiously in EMMP patients receiving other medications.[47] Carbamazepine

can also induce the CYP 3A4 system, reducing the effectiveness of other drugs.

Carbamazepine has some effects on cognitive functioning, especially at higher levels. It is not known whether the elderly will be more sensitive to this problem. In addition, carbamazepine may cause imbalance and ataxia. It is possible that EMMP patients, especially those with CNS disorders, may be more sensitive to these effects.

One of the major concerns with carbamazepine is its effect on sodium levels.[36] Hyponatremia is a well-known phenomenon with carbamazepine use and may cause significant problems in younger adults, especially if there is polydipsia. The hyponatremia associated with carbamazepine is more pronounced as a person becomes older.[20] This may become more problematic if a person is on salt restriction or a diuretic. Because of the mild neutropenia associated with carbamazepine use in younger adults, the effects of this AED on hematopoietic parameters in the elderly will need to be studied. Carbamazepine also is known to affect cardiac rhythms and should be used cautiously, if at all, in persons with rhythm disturbances.

One of the pharmacokinetic problems of carbamazepine is its short half-life and the possible need to take it multiple times a day. In the elderly, however, the half-life may be longer, and slow-release formulations may overcome the need to dose multiple times each day and may also overcome some of the side-effect problems caused by a rapid time to a high peak (short T_{max} and high C_{max}). Carbamazepine is a moderately priced drug, and should not present a significant cost issue.

Phenobarbital

Phenobarbital is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. However, the VA cooperative study demonstrated that phenobarbital and primidone are less well tolerated than carbamazepine or phenytoin.[52] Thus, although phenobarbital is the least expensive of the AEDs, its side-effects profile, which may worsen cognition and depression, make it an undesirable drug for the elderly, especially in the nursing home setting in which declines in cognition are already present.

Valproic Acid

Only a few studies have compared the pharmacokinetics of valproic acid (VPA) in young and old patients.[4,13,62] In a study of steady-state valproate pharmacokinetics in six young adult and six elderly volunteers (66–72 years), the average unbound fraction of valproate was 10.7% in the elderly compared with 6.4% in the younger participants. In the elderly participants, mean unbound concentrations were 57% higher and unbound clearances were 40% lower than in younger adults.[4] Valproic acid, like phenytoin, is associated with reduced protein binding and unbound clearance in the elderly. As a result, the desired clinical response may be achieved with a lower dose than usual. A nationwide elderly nursing home study showed that VPA dose and total VPA concentrations decrease within the elderly age groups.[7] Because the serum elimination half-life is prolonged, the dosing interval can be extended. If the albumin concentration has fallen or the patient's clinical response does not correlate with total drug concentration, measurement of unbound drug should be considered. Because of its effects on mood stabilization, it may be especially appropriate for elderly with a dual diagnosis.

Felbamate

Felbamate is effective for localization-related epilepsies and appears to have a broader spectrum of effectiveness than some of the other AEDs. Elderly subjects had a lower mean clearance (31.2 vs. 25.1 mL/min; 90% confidence interval [CI] -11.4 to -0.9; $p = 0.02$) than adults in a study involving 24 elderly healthy volunteers.[67] It is primarily metabolized by the liver and is known to have a number of drug–drug interactions, both inhibitory and inductive, and therefore may not be a good choice for EMMP patients.

Gabapentin

Gabapentin is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. Gabapentin is not metabolized by the liver, but rather it is renally excreted; therefore, there are no drug–drug interactions.[66] Thus, it may be especially useful in EMMP patients. There is a reduction of renal function with advancing age, and so doses may need to be adjusted in both EH and EMMP patients. Levels must be monitored after initiation and doses adjusted accordingly. However, gabapentin does appear to have some sedative side effects, especially at higher levels, and the elderly may be more sensitive to this problem.

Gabapentin has a short half-life, necessitating that it be given multiple times a day. In the elderly, however, the half-life may be longer because of decreased renal elimination. Because gabapentin is effective in treating neuralgic pain, it would be additionally beneficial for someone suffering from both epilepsy and pain.

The VA Cooperative Study #428 study compared carbamazepine with gabapentin and lamotrigine. Efficacies were similar, but withdrawal related to side effects was highest for carbamazepine.[68]

Lamotrigine

Lamotrigine is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. However, very few studies regarding lamotrigine in the elderly have been published. Lamotrigine is primarily metabolized by the liver using the glucuronidation pathway, not the P450 system, and this pathway may be less affected by age.[61] Data from a population pharmacokinetic study of 163 epilepsy patients that included 30 patients >65 years, only 10 patients between 70 and 76 years, and no individuals from the old-old age group (≥85 years) showed that age did not affect lamotrigine (LTG) apparent clearance.[40] Based on a study of 150 elderly subjects, the drop-out rate due to adverse events was lower with LTG (18%) than with CBZ (42%). LTG subjects had fewer rashes (LTG 3% vs. CBZ 19%) and fewer complaints of somnolence (LTG 12% vs. CBZ 29%).[11] Lamotrigine clearance is increased by approximately two to three times with coadministration of phenytoin and carbamazepine, whereas lamotrigine clearances decrease twofold when valproic acid is coadministered.[81] The drug interaction studies included very few elderly subjects; therefore, the extent of the changes in clearance with administration of comedications in the elderly is not known. Some caution may need to be observed in EMMP patients on other drugs.

Levetiracetam

Levetiracetam has been approved as adjunctive therapy for partial-onset seizures in adults. It is extremely water-soluble. This allows rapid and complete absorption after oral administration. Levetiracetam is not metabolized by the liver, and thus it is free of nonlinear elimination kinetics, autoinduction kinetics, and drug–drug interactions. Lack of protein binding (<10%) also avoids the problems of displacing highly protein-bound drugs and the monitoring of unbound concentrations. Lack of drug interactions would make it useful for treating elderly epilepsy patients, particularly those patients who have

other illnesses and are taking other medications.[60] The manufacturer reports a decrease of 38% in total body clearance and an increased half-life up to 2.5 hours longer in elderly patients (age 61–88 years), who exhibited creatinine clearances ranging from 30 to 74 mL/min. Doses do need to be adjusted, depending on the renal function of the patient as measured by serum creatinine and levetiracetam concentrations.[23]

One prospective phase 4 study indicates a favorable efficacy profile in the elderly.[56] Levetiracetam also appears to have a favorable safety profile. It was initially studied as a potential agent for treating cognitive disorders in the elderly, and thus a considerable amount of data regarding its tolerability in this age group is available. Analysis of this in a review of 3,252 persons involved in studies of levetiracetam for epilepsy and other conditions demonstrated that it was well tolerated by the elderly.[16]

Oxcarbazepine

Oxcarbazepine is rapidly metabolized by first-pass metabolism to 10-hydroxcarbazepine (10 monohydroxy metabolite or MHD); the 10-OH-carbamazepine metabolite is considered the active compound. MHD is then metabolized further by glucuronidation and excreted by the kidneys.[22] The most extensive elderly oxcarbazepine study involved low doses of oxcarbazepine given to 12 young and 12 elderly healthy male and 12 young and 12 elderly female volunteers. At low doses of oxcarbazepine (300–600 mg/d), a significantly higher maximum concentration, higher area under-the-curve parameters, and a lower elimination rate constant were observed in the elderly volunteers.[77]

Oxcarbazepine can have an effect on the cytochrome P450 system. Oxcarbazepine can induce the metabolism of the P450 3A4 enzyme that is responsible for the metabolism of dihydropyridine calcium antagonists and many other drugs.[43,82] Plasma levels of carbamazepine (a P450 3A4 substrate) can be decreased 15% when it is coadministered with oxcarbazepine.[38] Oxcarbazepine, however, appears to have a more powerful effect on sodium balance than carbamazepine, and this effect increases with age.[20]

Pregabalin

Pregabalin is related to gabapentin but is more potent; doses generally one fifth of those of gabapentin are needed for therapeutic effect. Its absorption also appears to be more predictable because of the lower amounts needed for transport across the intestinal system. Although it may prove to be a favorable AED for the elderly, its cost and lack of experience may limit its use.

Tiagabine

Tiagabine is effective for localization-related epilepsies and has an efficacy profile appropriate for the elderly. It is primarily metabolized by the liver (CYP 3A4). Comedications that affect CYP 3A4 substrates also affect the metabolism of tiagabine, giving it a drug interaction profile similar to that of carbamazepine. A major feature of tiagabine is its potency; the usually effective doses is 20 to 60 mg/d, and the effective concentration is 100 to 300 ng/mL, or as much as 100-fold lower than that of the other AEDs.

Topiramate

Topiramate is effective for localization-related epilepsies and thus has an efficacy profile appropriate for the elderly. Topiramate is approximately 20% bound to serum proteins and is both metabolized by the liver and excreted unchanged in the urine. The enzymes involved in topiramate's metabolism have not been identified; however, the cytochrome P450 system may be involved. Topiramate has not been studied in the elderly, but topiramate clearance may decrease with age, causing higher-than-expected serum concentrations at topiramate doses that are used in younger adults. In addition, topiramate metabolism can be induced in the presence of inducing comedications such as carbamazepine and phenytoin.[70] There is also some indication that topiramate can inhibit CYP2C19 activity,[51] and so levels need to be monitored to ensure that the topiramate dose given does not result in higher-than-expected serum concentrations. Topiramate does have some effects on cognitive functioning, especially at higher levels. It is not known whether the elderly will be more sensitive to this problem.

Drug Interactions With Non–Antiepileptic Drugs

Concomitant medications taken by elderly patients can alter the absorption, distribution, and metabolism of AEDs, thereby increasing the risk of toxicity or therapeutic failure. Comedications are frequently used by patients in nursing homes receiving AEDs (Table 2). No data are available for elderly outpatients. Calcium-containing antacids and sucralfate reduce the absorption of phenytoin.[57] The absorption of phenytoin, carbamazepine, and valproate may be reduced significantly by oral antineoplastic drugs that damage gastrointestinal cells.[9,58] In addition, phenytoin concentrations may be lowered by intravenously administered antineoplastic agents.[58] The use of folic acid for treatment of megaloblastic anemia may decrease serum concentrations of phenytoin, and enteral feedings can also lower serum concentrations in patients receiving orally administered phenytoin.[30]

Many drugs displace AEDs from plasma proteins, an effect that is especially serious when the interacting drug also inhibits the metabolism of the displaced drug; this occurs when valproate interacts with phenytoin.[30] Several drugs used on a short-term basis (including propoxyphene and erythromycin) or as maintenance therapy (such as cimetidine, diltiazem, fluoxetine, and verapamil) significantly inhibit the metabolism of one or more AEDs that are metabolized by the P450 system. Certain agents can induce the P450 system or other enzymes, causing an increase in drug metabolism. The most commonly prescribed inducers of drug metabolism are phenytoin, phenobarbital, carbamazepine, and primidone. Ethanol, when used chronically, also induces drug metabolism.[71] The interaction between antipsychotic drugs and AEDs is complex. Hepatic metabolism of certain antipsychotics such as haloperidol can be increased by carbamazepine, resulting in diminished psychotropic response. Antipsychotic medications, especially chlorpromazine, promazine, trifluoperazine, and perphenazine, can reduce the threshold for seizures. The risk of seizures is directly proportional to the total number of psychotropic medications being taken, their doses, any abrupt increases in doses, and the presence of organized brain pathology.[15] The epileptic patient taking antipsychotic drugs may need a higher dose of antiepileptic mediation to control seizures. In contrast, central nervous system depressants are likely to lower the maximum dose of AEDs that can be administered before toxic symptoms occur.

Dosing

Compliance is a potential challenge in the elderly due to multiple medications, memory problems, and visual problems. In general, twice-daily dosing is preferable. In the long-term care facilities, compliance may be less of an issue than with the

community-dwelling elderly, but reducing staff time spent administering multiple daily doses of medication to many patients may reduce errors and cost.

Summary and Conclusions

The elderly with epilepsy have issues that may alter the approach to their treatment with AEDs. Information obtained from studies of younger adults can sometimes be applicable to the elderly, but in other instances they cannot. The community-dwelling elderly resemble the younger elderly more closely than they do the nursing home elderly. Two major conclusions that deserve special consideration can be reached at this time. The first is that AED levels may fluctuate significantly in the elder nursing home population and dose changes based on a single level may exacerbate the unstable levels. This is particularly true for the older AEDs, but whether the newer or water-soluble AEDs are better needs to be demonstrated. The second is that although age may be an influence on hepatic clearance, earlier studies may have overestimated the degree of this effect and the genetic makeup of the isozymes may have a much greater influence. Of the newer AEDs, gabapentin, lamotrigine, and levetiracetam are the most widely researched and used. As patents expire, their cost may lessen, which may lead to increased use. Much more research is needed, however, to determine the best treatments for the EH, EMMP, and FE cohorts.

Chapter 115

Mechanisms of Drug Resistance

Sanjay M. Sisodiya

Heinz Beck

Wolfgang Löscher

Annamaria Vezzani

Introduction

For most patients with a diagnosis of epilepsy requiring drug treatment, the outlook is favorable. In mature economies, about 70% of patients can expect to become seizure free with antiepileptic drug (AED) treatment.[69] This percentage is an overall figure and may differ for subgroups, and most probably depends on etiology and syndrome.[33,72] Although some patients undoubtedly have complex response patterns that change over time for no obvious reason and defy categorization, some 30% of patients will never have any sustained period of seizure freedom—for example, >12 months—in the history of their epilepsy. Scientific inquiry into the concepts and mechanisms of such resistance to AED treatment has gained significant momentum recently. The resulting body of work constitutes the subject of this chapter.

Epilepsy is a heterogeneous group of conditions. The pathophysiologic derangements in the brain are complex and not fully understood for any single seizure type or epilepsy syndrome. There are only a limited number of ways in which the brain, despite its complexity, can actually manifest its function or dysfunction: Epilepsy and seizures are final common manifestations of a wide range of disruptions in brain structure and function. Of course, many of these disruptions share commonalities at various levels, and advantage is taken of these shared characteristics in labeling, understanding, diagnosing, and treating “epilepsy.” Both shared and syndrome-specific characteristics might complicate and hamper these same efforts at managing seizures and epilepsy in humans. As a biologic and clinical phenomenon, resistance to AED treatment is one such shared, complex, multifactorial, and adaptive aspect of epilepsy biology. The study of drug resistance might therefore not only improve rational treatment for patients with drug-resistant epilepsy, with its associated morbidity and mortality, but also cast light on disease pathophysiology, determinants of natural history, and predictors of prognosis.

Recent comprehensive reviews have thoughtfully discussed not only the biologic bases of refractory epilepsy, but also the definition of such epilepsy.[32,72] There may be two patients with the same demography, the same syndrome, and the same underlying imaging and histologic pathology, one of whom responds to the first AED tried and the other who never responds with any prolonged period of seizure freedom despite years of administration of a series of differing AEDs. The effect of AEDs on prognosis in an individual is unknown.[32] AEDs generally have a limited spectrum of potential mechanisms of action, and they may undoubtedly render some individuals seizure free, a state associated with proven benefits. Therefore the question of why some individuals have epilepsy refractory to currently available AEDs is both valid and important.

As an illustration of some of these concepts, it is worthwhile considering epilepsy caused by a particular neurodevelopmental abnormality, periventricular heterotopia (PVH) caused by mutation in the X-linked gene *FLNA*, encoding filamin A. Deleterious mutations in this gene can underlie some cases of familial or sporadic PVH:[21] In some cases, the PVH goes on to cause epilepsy, which may be drug resistant, whereas other patients do not even develop epilepsy.[22] We have a reasonable understanding of the role of filamin in neurodevelopment.[76] We know much about the pathologic anatomy of periventricular nodules themselves, including the disruptions of neurohistologic and immunophenotypic profiles, the abnormal electrical activity that may arise from such nodules, their connectivity with the rest of the brain, and their appearance on imaging. It is clear that even following a single pathologic nucleotide alteration in one gene causing epilepsy as its primary manifestation, a tangled multilayered raft of changes occurs at multiple temporal, spatial, and functional time points, leading eventually in a proportion of cases to drug-resistant epilepsy. Most cases of refractory epilepsy are due to more common pathologies, such as hippocampal sclerosis, but remain in some ways less well understood at root, even though they have been longer studied. It is therefore unsurprising that the biologic bases of AED resistance should be so poorly comprehended.

There are two main hypotheses for the underlying cause of refractory, or drug-resistant, epilepsy: (a) the “target” and (b) the “transport” hypotheses. In essence, the former focuses on pharmacodynamic resistance involving the postulated mechanism of AED action; the latter hinges on pharmacokinetic resistance, positing that overactive transport mechanisms prevent AEDs from reaching their targets in sufficient concentrations in the first place. These hypotheses will be considered in greater detail. Eventually, a number of mechanisms are likely to emerge as important to greater or lesser extents in a range of syndromes. Some other potential mechanisms are also considered.

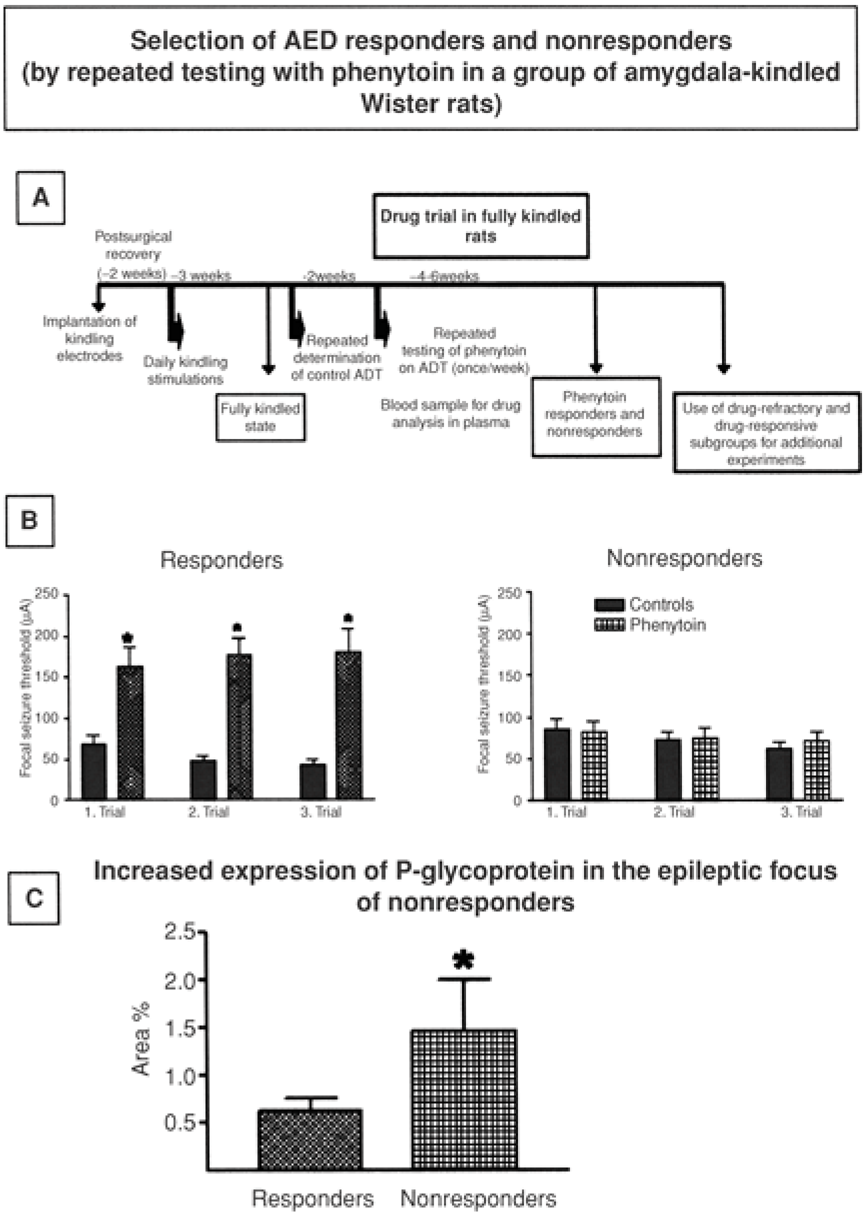

FIGURE 1. Selection of responders and nonresponders to antiepileptic drug (AED) treatment in the kindling model of temporal lobe epilepsy. **A:** The experimental protocol used to select responders and nonresponders from a large group (usually >50) of amygdala-kindled Wistar rats. ADT, afterdischarge threshold. **B:** The results of a typical selection experiment. Responders always react with a significant increase of focal seizure threshold in each trial with administration of phenytoin, whereas nonresponders do not show any anticonvulsant effect of phenytoin at the same doses. Results shown are means and SEM, $^*p < .05$. **C:** The expression of the drug efflux transporter P-glycoprotein (P-gp) in brain capillary endothelial cells that form the blood–brain barrier. Nonresponders exhibit significantly higher expression of P-gp than do responders in the epileptic focus, that is, the kindled amygdala. The expression is shown as area of brain capillary endothelial cells immunohistochemically stained for P-gp. This area was determined by computer-assisted image analysis of brain sections. Data are from Brandt C, Bethmann K, Gastens AM, et al. The multidrug transporter hypothesis of drug resistance in epilepsy: Proof-of-principle in a rat model of temporal lobe epilepsy. Neurobiol Dis. 2006;24(1):202–211.

Animal Models of Drug-Resistant Epilepsy

Animal models of epilepsy allowing selection of pharmacoresistant and pharmacosensitive subgroups of animals constitute a valuable tool for studying mechanisms of intractability and developing more effective treatment strategies.[36,38] Only one model with these characteristics has been extensively explored: The amygdala-kindled Wistar rat, from which phenytoin-resistant and phenytoin-sensitive rats can be selected by repeated testing with phenytoin (Fig. 1).[36,38] Phenytoin-resistant rats are also resistant to various other AEDs, thus offering parallels with the clinical presentation of multidrug-resistant temporal lobe epilepsy. Phenytoin-resistant kindled rats have been used to study mechanisms of drug resistance, described in more detail later. In short, breeding and other studies have indicated that genetic factors and kindling-associated brain alterations are involved in drug resistance in this model.[37] However, one major drawback of this model is that kindled

P.1280

rats do not exhibit spontaneous recurrent seizures, so that elicited seizures have to be used for drug studies. This is also true for the 6-Hz “psychomotor” seizure model in mice, which has been proposed as a useful model of therapy-resistant limbic seizures.[3]

Some recent studies have indicated that rats with spontaneous recurrent seizures developing after status epilepticus differ in their individual response to AEDs, thus allowing selection of drug-resistant and drug-responsive subgroups.[8,19] This group of models reflects most closely a common form of human drug-resistant epilepsy, the mesial temporal lobe epilepsy (mTLE) syndrome. By using drug-resistant epileptic rats selected from such a post-status epilepticus model of mTLE, it was recently shown that drug-resistant rats differ from drug-responsive rats in (a) expression of multidrug efflux transporters in the brain,[99] (b) expression of drug targets in the brain,[97] and (c) morphologic alterations in the hippocampus.[97] Thus, such post–status epilepticus models, allowing selection of drug responders and nonresponders, are interesting tools for studying mechanisms of drug resistance. As reported recently, they can also be used to study whether overcoming the mechanism(s) counteracts drug resistance.[6]

Apart from selecting subgroups of drug-resistant rats from models of mTLE, another approach is to use models in which all animals appear per se resistant to treatment with certain AEDs.[38] Such models include the 6-Hz “psychomotor” seizure model in mice,[3] the MAM (methylazoxymethanol acetate) model of cortical dysplasia in rats,[82] and certain post–status epilepticus models of TLE.[20] Furthermore, several in vitro brain slice preparations have been proposed to be useful in studying mechanisms of drug resistance.[38,105] As with all models of drug-resistant epilepsy, one major problem in validating these in vitro models is the lack of a positive control, that is, a novel AED with clinical efficacy in the management of refractory epilepsy. As a consequence, it is not known whether novel compounds that are found to be active in models of drug-resistant seizures will be subsequently found to be effective for the management of human refractory epilepsy.[104]

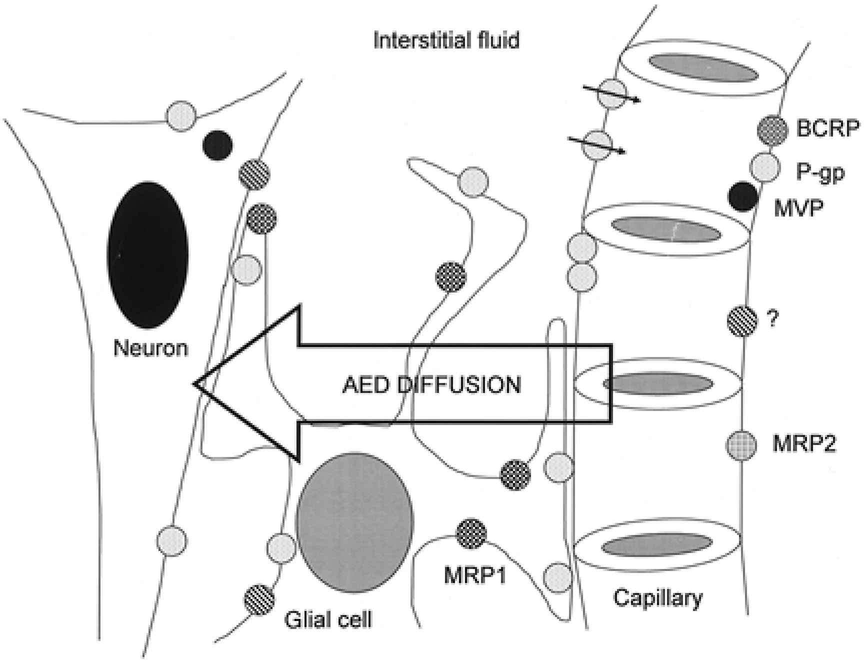

FIGURE 2. Schematic illustrating the transport hypothesis. Most antiepileptic drugs (AEDs) diffuse from the capillary lumen to the interstitial fluid and their targets, usually on the surface of or within neurons. Nonspecific, multidrug transporters (represented by variously filled circles) are present in particular distributions for given transporters. Thus, for example, multidrug-resistance–associated protein 1 (MRP1, *checkered circles*) is overexpressed on glial cells in epileptogenic tissue. The transport hypothesis maintains that AED concentration at the neuron is reduced by the transport activity of various transporters on capillary endothelial cells, glia, and neurons, reducing diffusion of AEDs to their desired site of action and thus reducing their antiepileptic effects. The circle marked with a question mark has been added to emphasize that we do not yet know all the transporters that might be relevant. BCRP, breast cancer resistance protein; MVP, major vault protein; P-gp, P-glycoprotein.

Drug Transport Hypothesis

Background

The "transport" hypothesis embodies the concept that sustained failure of AEDs to stop seizures is due to a subtherapeutic local concentration of AEDs at their site of action caused by the activity of multidrug transporters (Fig. 2). The idea arose by analogy with drug resistance in oncology:[32,47,89] The in vitro dissection of the mechanisms of resistance of cultured tumor

P.1281

cells to anticancer drugs showed that the activity of the archetypal transport protein, P-glycoprotein (P-gp, where "P" stands for permeability), was important in cell survival. Extensive subsequent studies in cancerous cells both in vivo and in vitro have revealed a spectrum of transport or transport-related molecules with more or less proven roles in the flux or sequestration of anticancer drugs. Tishler et al. in 1995[89] were the first to explore this possible mechanism in drug-resistant human epilepsy, showing both increased expression of P-gp in resected epileptogenic human temporal lobe tissue and reduced accumulation of labeled phenytoin in cultured cells artificially expressing P-gp in comparison to the parent wild-type cells not expressing P-gp.

The field has advanced considerably since. In oncology, the field has somewhat stagnated after initial excitement that modulation of the activity of transporters might offer dramatic new treatment options in refractory cancer; human studies failed to bear out this optimism. Belatedly, oncologists have established that a number of reasons render questionable the negative results obtained in early studies. For example, the presence of transporters mediating resistance was often presumed and not proven in the particular tumors in particular patients; resistance itself was presumed to be present when it may not have been in all cases involved in trials of inhibitors; the inhibitors used were usually preexisting compounds pressed into service but that had poor inhibitor potency or marked interactions with anticancer agents; and when inhibitors were used, absence of surrogate markers of inhibition meant that the degree to which successful inhibition of transporters in tumoral tissue had been achieved in individual patients was not known.[4] Despite these realizations, the area of study has become somewhat discredited (indeed, it is interesting to note that oncology has largely moved to developing specific therapies for specific targets, e.g., herceptin, trasmuzutab[24]). In epilepsy research, although parallels with cancer should not be drawn too far, we would do well to learn from the experience in oncology.[47]

Critically, it is important that work on the transporter hypothesis is pursued rationally. One approach is to consider criteria that need to be satisfied to accept a particular transport mechanism as contributing to resistance in human epilepsy. One set postulated is as follows:[80]

1. Mechanisms must be detectable in epileptogenic brain tissue
2. Mechanisms must have appropriate functionality
3. Mechanisms must actually be active in drug resistance
4. Overcoming the mechanisms should affect drug resistance

Considerable experimental data exist addressing criteria 1 to 3, reviewed below. Criterion 4 will remain the most demanding, complicated particularly by natural redundancy among the many known and unknown transporters, whose presumptive evolutionary purpose includes the protection of cells, organs, and organisms from environmental or endogenous toxins.

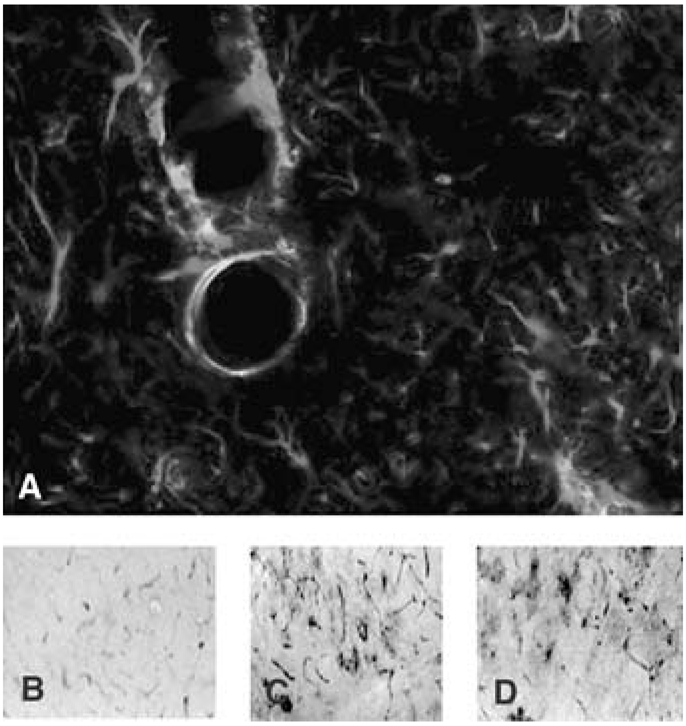

FIGURE 3. Overexpression of P-glycoprotein (P-gp) in an animal model. **A:** Merged image (20×) showing P-gp immunolabeling (*green*) and glial fibrillar acidic protein (GFAP)-positive astrocytes (*red*) in the rat cortex 18 hours after pilocarpine-induced status epilepticus. Colocalization signal (*yellow*) depicts P-gp

expression in astrocytic endfeet adjacent to brain microvessels. **B, C, D:** Representative immunohistochemical micrographs (10×) depicting P-gp immunolabeling in control rat hippocampus **(B)** and 18 hours after pilocarpine-induced status epilepticus. Note that in the control panel only, vessels are lightly labeled, whereas seizures induced P-gp overexpression both in vessels and in astrocytes **(C, D)**. (See the color insert.)

Animal Data: Multidrug Transporter Proteins in Experimental Models of Seizures

Expression Studies

Experimental models of seizures mimicking the neuropathologic features of drug-resistant TLE have been used for studying the molecular mechanisms of intractability.[1,11,14,36,73,83] Suitable models should fulfill at least two criteria: (a) the type of seizures should be similar to those occurring in human epilepsy on both behavioral and electrographic manifestations; (b) standard AEDs should be inactive or weakly active as compared to efficacy in models of primarily generalized seizures that are easily suppressed by AEDs. Although the first aspect has been verified in the case of complex partial seizures,[36] responsiveness of experimentally induced seizures to AEDs has only rarely been addressed (e.g., in models of status epilepticus evolving to spontaneous seizures[83] and in kindled rats[36]).

P-gp is overexpressed in endothelial cells, and ectopically in astrocytes, after induction of sustained limbic seizures in rodents; neuronal expression has been also reported in some instances.[35,75,90,98,106] (Fig. 3). Upregulation of the mRNA of the multiple-drug resistance 1 gene (*mdr1,* which codes for P-gp) was detected in rat brain during both acute seizures[67] and spontaneous seizures[90] caused by status epilepticus. After audiogenic seizures in genetically epilepsy-prone rats, P-gp and *mdr1* mRNA upregulation was specifically detected in brain regions involved in the onset and propagation of epileptic activity.[34] Because limbic seizures were induced in these studies in otherwise normal rodent brain, these experimental findings indicate that epileptic activity per se can increase the expression

of P-gp. These findings are compatible with the observations reported in human TLE tissue (see later discussion).

More recently, Volk and Löscher[99] reported that phenobarbital-resistant epileptic rats exhibit significantly higher endothelial expression of P-gp in limbic brain regions compared to drug-responsive epileptic rats, providing further support for the multidrug transporter hypothesis of drug-resistant epilepsy. Drug-resistant and responsive rats were selected from a post–status epilepticus model of TLE.[99] The severity or duration of status epilepticus or frequency of spontaneous recurrent seizures developing after the status epilepticus did not differ significantly between responders and nonresponders, indicating that drug resistance and overexpression of P-gp may be genetically mediated.

Functional Studies

Rizzi et al.[66] reported that *mdr1* mRNA is overexpressed in mouse hippocampus after the induction of limbic seizures. When phenytoin was systemically administered to these mice, its brain-to-plasma ratio was 30% less than in mice not subjected to seizures, thus indicating reduced drug concentrations in brain. It is still unknown whether the magnitude of changes in brain phenytoin levels is pharmacologically relevant to reduction of the anticonvulsant activity of this drug, and indeed whether the change in *mdr1* mRNA is the unique underlying cause or changes in other, unmeasured entities might also contribute. Potschka et al.[53,54] reported that the efficacy of phenytoin in inhibiting generalized clonic seizures in rats was enhanced by probenecid, the nonspecific inhibitor of a subfamily of multidrug transporters, the multidrug-resistance associated proteins (MRPs), and in MRP2-deficient rats; increased efficacy was associated with ~30% increase in brain-to-plasma concentration ratios of phenytoin. In kindled rats, a widely used model of TLE, significant upregulation of P-gp was reported in brain capillary endothelial cells of limbic brain regions.[100] In these rats, brain-to-plasma concentration ratios of phenytoin in the hippocampus were about 30% lower than those measured in control animals.[57] When kindled rats were divided into phenytoin responders and nonresponders, nonresponders exhibited a significantly higher expression of P-gp in capillary endothelial cells in the epileptogenic focus (i.e., the kindled amygdala) compared to the same region in responders (FIGURE 1).[58]

These findings support a link between the level of expression of *mdr1* mRNA, P-gp protein or MRP2 protein, and the AED-extrusion function of these drug transporters (e.g., increased *mdr1* mRNA/P-gp protein is associated with decreased brain phenytoin levels, whereas decrease in MRP2 protein is associated with increased brain phenytoin levels); in addition, changes in phenytoin brain concentrations of ~30% appear to affect its efficacy in experimental models.

An important aspect to be considered is the subcellular localization of the ATP-binding cassette (ABC) family of drug transporters, of which P-gp is the archetype.[70] Thus, only those proteins localized at the apical membrane of endothelial cells of brain capillaries will be able to decrease whole-brain AED uptake by active extrusion into the blood stream. Examples include P-gp, MRP2, MRP4, and breast cancer resistance protein (BCRP). In contrast, drug transport proteins localized at the basolateral membrane of epithelial cells in the choroid plexus (e.g., MRP1) or in microvasculature (e.g., MRP3 and MRP5) may increase brain uptake of their substrates. Other local changes in the expression of transporters (e.g., in glia) might affect local drug disposition in superimposed local microgradients.

The current hypothesis is, therefore, that P-gp, MRP2, and BCRP localized in microvascular endothelium represent the first barrier for extruding AEDs from the brain. A second barrier may be represented by the presence of P-gp and other transporters in astrocytic endfeet in close apposition with microvasculature. It is notable that parenchymal astrocytes and dysplastic neurons in certain human lesional epileptogenic tissues often express P-gp and MRP1 (see later discussion). The functional consequences of this cell-specific expression are unclear. One speculation is that this multidrug-resistant phenotype in astrocytes and neurons may function as a nonspecific cellular protective mechanism against xenobiotics or toxic compounds that may enter the brain, or be produced in situ, in pathologic conditions. Protective roles for both P-gp[28] and MRPs[63,64] have been proposed.

Table 1 Drug efflux transporters in central nervous system and antiepileptic drug substrate status

Protein	Gene name	Central nervous system expression	Transported antiepileptic drug in humans
ATP- binding cassette (ABC) family			
MDR1, P-gp	ABCB1	Endothelial cells, BBB[a]	Carbamazepine,[b] phenytoin Felbamate, lamotrigine Topiramate, phenobarbital
MRPs			
MRP1	ABCC1	Epithelial cells, choroid plexus	Carbamazepine, phenytoin[c]

MRP2	ABCC2	Endothelial cells,[d] BBB	Phenytoin
MRP3	ABCC3	Endothelial cells,[d] BBB	
MRP5	ABCC5	Endothelial cells,[d] BBB	
BCRP	ABCG2	Endothelial cells,[d] BBB	

Central nervous system expression represents protein localization in normal human brain tissue as assessed by immunohistochemistry or by reverse transcriptase–polymerase chain reaction analysis of mRNA in isolated endothelial cells from brain capillaries as for multidrug-resistance-associated protein 3 (MRP3) and MRP5.[16] The multidrug-resistance (MDR) family of proteins consists of P-glycoprotein (P-gp or MDR1), MDR2, and MDR3 genes in humans and *mdr1a, mdr1b*, and *mdr2* in rodents. MDR1, *mdr1a*, and *mdr1b* DNA confer multidrug resistance. BBB, blood–brain barrier; BCRP, breast cancer resistance protein.

[a]P-gp expression has also been reported in choroid plexus.[60]

[b]One report does not support this evidence.[49]

[c]These results were obtained using probenecid, a broad-spectrum blocker of MRP function. A recent report showed that levetiracetam is not transported by P-gp or MRP1/2.[53]

[d]Endothelial localization of MRP proteins is controversial.[70] Data on antiepileptic drug transport have been obtained in vitro using epithelial cell lines[72,90] or in vivo in rodent brain.[39,52-56,67,79]

Antiepileptic Drugs: Substrates of Multidrug Transport Proteins?

In vitro studies using epithelial cell lines expressing the MDR1 gene provided the first evidence that P-gp can mediate phenytoin efflux from intracellular compartments.[89] Subsequent pharmacologic studies in rodents indicated that both P-gp and MRPs mediate brain efflux of phenytoin, phenobarbital, carbamazepine, oxcarbazepine, lamotrigine, topiramate, and felbamate.[40,41] This evidence was obtained using normal rats given broad-spectrum inhibitors of multidrug transporter function intracerebrally[55] or using genetically modified rodents lacking *mdr1*[67,78] or *mrp2* genes.[53]

In particular, interstitial rat brain concentrations achieved after systemic administration of phenytoin, carbamazepine, felbamate, lamotrigine, phenobarbital, and oxcarbazepine are increased by blocking P-gp or MRP function with the broad-spectrum antagonists verapamil and probenecid.[12,41] The P-gp-mediated transport of phenytoin was further substantiated

P.1283

using PSC833, a more selective blocker of P-gp function.[56] Brain-to-plasma concentration ratios of phenytoin, carbamazepine,[67] and topiramate[78] were found to be higher in mice lacking P-gp because of a deletion of the *mdr1* gene[71] than in wild-type mice. In contrast with previous evidence, one report showed no changes in carbamazepine brain concentration in mice lacking the *mdr1a/b* gene.[48] This discrepancy may be explained by methodologic issues (e.g., measurements of AED in whole brain tissue[48] rather than in specific brain regions[67] or in the extracellular space[55]).

The brain concentration of phenytoin was increased in rats lacking the *mrp2* gene and the encoded protein,[53] whereas the concentrations of carbamazepine, lamotrigine, felbamate, or phenobarbital were not modified, suggesting that, among these AEDs, phenytoin only is transported by MRP2. Thus, under normal physiologic conditions, P-gp and MRPs (e.g., MRP2) appear to mediate brain extrusion of various AEDs (Table 1) because pharmacologic blockade of their function or their absence due to gene deletion results in increased intracerebral levels of those AEDs.

One limitation of these pharmacologic studies is that they are based on the use of P-gp or MRPs blockers with poor selectivity. However, the recent availability of more selective antagonists and the use of rodents with specific multidrug transporter gene deletions may provide adequate tools for strengthening the available evidence. Further experiments will also need to assess the possible upregulation of other transporters in animals lacking a particular transporter: Very likely, there remain transporter proteins yet to be discovered.

Demonstration that multidrug resistance could be prevented or reversed by inhibition of such transporters would be the final step, and the most important one for patients, in considering the multidrug transporter hypothesis of drug resistance in epilepsy. Brandt et al.[6] recently used AED nonresponders that were selected from a post–status epilepticus rat model of TLE. As described earlier, these nonresponders differ from responders in overexpression of P-gp in brain capillary endothelial cells of limbic brain regions such as hippocampus.[99] Combined treatment of phenobarbital-resistant rats with phenobarbital plus the third-generation, highly-selective P-gp inhibitor tariquidar reversed resistance to treatment in dose-dependent fashion, so that most rats became drug-responsive by this treatment.[6] In accord with these findings, using rats that exhibit spontaneous seizures after electrically evoked status epilepticus, van Vliet et al.[91] recently found that a 7-day treatment with therapeutic doses of phenytoin suppressed spontaneous seizure activity but only partially. However, almost complete, but transient, control of seizures by phenytoin was obtained in all rats when this AED was coadministered with tariquidar. P-gp upregulation was confirmed in brains of these chronic epileptic rats along with ~20% reduction in brain phenytoin levels. These findings show that inhibition of P-gp significantly improves the anticonvulsant action of both phenobarbital and phenytoin in these animal models in the short term. More studies are required, however, before therapeutic use of such inhibitors might be considered in humans with refractory epilepsy.

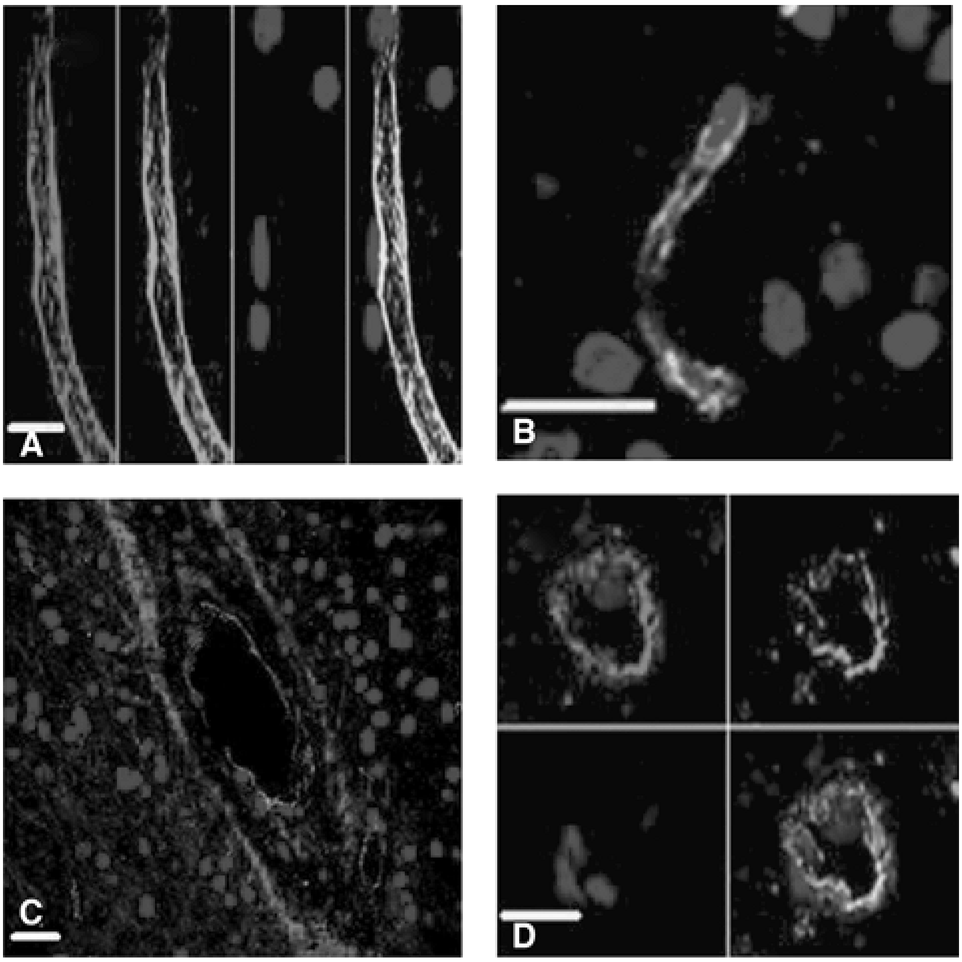

FIGURE 4. Overexpression of multidrug transporters in human epileptogenic brain tissue. Immunohistochemistry using fluorescently labeled antibodies shows colocalization of fluorescence, and thus labeling, for a combination of transporters and presumptively transporter-related proteins in microvasculature in a section of hippocampus resected from a patient with refractory epilepsy due to hippocampal sclerosis. Blue labels cell nuclei. **A:** Red labels P-glycoprotein (P-gp), green labels breast cancer resistance protein (BCRP), and, in the extreme right panel, the two are shown to colocalize by the merged yellow color. **B:** Colocalization, although to a lesser extent, of P-gp (*red*) and major vault protein (*green*). **C:** P-gp (*green*) does not colocalize in these sections with multidrug-resistance–associated protein 1 (MRP1, *red*). **D**: BCRP (*green*) colocalizes with P-gp (*red*). In all sections, the scale bar represents 30 μm. (See the color insert.)

Human Data

In comparison to animal data, information in humans is necessarily more limited. There are considerable data on transporters detectable in human epileptogenic brain tissue; some on their AED transport activity in cultured human cells; some, more controversial, on the role of variation in genes encoding transporters—as surrogate for in vivo activity; and anecdotal information only on overcoming transporters in clinical practice.

P-gp; the related transporter proteins MRP1, MRP2, and BCRP; and the unrelated but resistance-associated major vault protein (MVP) have all been found to be present in normal human brain and also to be ectopically expressed in human epileptogenic pathologies (Fig. 4). Specifically, hippocampal sclerosis, focal cortical dysplasia, dysembryoplastic neuroepithelial tumors, and ganglioglioma have been found to show ectopic expression of combinations of these proteins in certain parenchymal cell subpopulations (for a comprehensive review, see Kwan and Brodie[32]). Discrepancies among studies are likely to be due at least partly to the adoption of different immunohistochemical protocols, a vagary previously confronted in oncology.[5] Nevertheless, it is clear that transporters *could* contribute to human refractory epilepsy because they are at least present and in fact are often coexpressed.

Whether these transporters are capable of transporting AEDs has proved more difficult to establish in humans. Only one recent study has provided in vivo data relating to brain pharmacokinetics of AEDs; it showed an inverse correlation between brain *MDR1* mRNA levels and intraparenchymal concentration of MHD (the active monohydroxy derivative of oxcarbazepine), which has also been shown to be a P-gp substrate in a model system.[12,43] There are no ex vivo data on living human brain tissue nor on any cultured human brain cells for AEDs. Peripheral blood lymphocytes do express P-gp, and at least one study has used these to test whether P-gp in this tissue is capable of transporting carbamazepine (and found that it is not[48]). More such studies are required, incorporating proof that such lymphocytes are satisfactory surrogates for brain transporters. Pharmacogenetics offers an indirect approach to this problem, by determining whether naturally occurring variation in the genes encoding transporters relates to clinical phenotypes. Only variation in one gene (*MDR1*) has been studied in any detail: Although one study showed an association between a particular polymorphism (C3435T) and drug resistance,[77] a replication study failed to support the original report.[87] Others have suggested that a broader haplotype may be relevant.[24] The importance and uncertainty of these findings mandate further work,[79] although it is of interest that it has recently been shown that the 3435T allele affects *MDR1* mRNA stability, at least in liver.[103]

With regard to actual clinical inhibition of transporters in drug-resistant epilepsy, only anecdotal data exist: Two single case reports suggested improvement in refractory epilepsy on addition of verapamil,[25,86] a first-generation, comparatively nonspecific P-gp inhibitor that of course also has additional pharmacokinetic and pharmacodynamic effects.

Altered Target Hypothesis

Development of Hypothesis

Following permeation through the blood–brain barrier, drugs have to bind to one or more target molecules to exert their desired action. The *target hypothesis* of pharmacoresistance contends that molecular changes in drug targets may cause them to be less responsive to AEDs. This reduced sensitivity on a cellular level might then contribute to pharmacoresistance on a clinical level.

Changes in Antiepileptic Drug Targets

A large number of AED targets have been identified in the brain, most of them neurotransmitter receptors and

voltage-gated ion channels. Voltage-gated ion channels are involved in the anticonvulsant effects of drugs such as phenytoin, carbamazepine, valproate, and lamotrigine. Transient and persistent sodium currents respond to all of these AEDs. Calcium channels are also targets for AEDs (i.e., ethosuximide, valproate, phenytoin, or gabapentin), and potassium channels are emerging as potential targets for AEDs (i.e., retigabine). Another large group of drugs, among them benzodiazepines, barbiturates, vigabatrin, and tiagabine, act to enhance the efficacy of synaptic inhibition. It should be noted, however, that the list of targets for established AEDs is almost surely incomplete and will expand as their actions on novel targets are examined.

Altered Antiepileptic Drug Sensitivity of Drug Targets: Data from Models and Human Tissue

Among the known drug targets, a large number display defined changes both in human and experimental epilepsy. Voltage-gated Na^+, Ca^{2+}, and K^+ channels, mixed cationic channels such as those mediating the H-current, as well as neurotransmitter receptors such as the γ-aminobutyric acid (GABA) A receptor, are altered at the molecular level in chronic epilepsy. The many molecular changes cannot be exhaustively enumerated here, but they lead to the next key question: Do drug targets in chronically epileptic brain display decreased sensitivity to AEDs? The first indication that this might be the case was provided in a study demonstrating that a change in the subunit composition of $GABA_A$ receptors in hippocampal dentate granule neurons results in reduced benzodiazepine sensitivity of the receptor complex in the pilocarpine model of epilepsy.[9]

Similar findings have been obtained with respect to voltage-gated Na^+ channels. Generally, the effects of anticonvulsant drugs like carbamazepine or phenytoin on the inward Na^+ current (I_{Na}) are considered to be threefold: (a) a voltage-dependent reduction of I_{Na} amplitude, (b) a shift of the voltage dependence of steady-state inactivation in a hyperpolarizing direction, and (c) a slowing of recovery from inactivation.[2,10,33,61,65] The latter mechanism may be particularly relevant for antiepileptic action because slowing of the recovery from inactivation causes a pronounced frequency-dependent reduction of I_{Na} availability. This mechanism is thought to produce an inhibition of I_{Na} amplitude especially during abnormal high-frequency discharges such as those observed in chronic epilepsy. It is of interest that a complete and long-lasting loss of use-dependent blocking effects of carbamazepine was found in the pilocarpine model of epilepsy in hippocampal dentate granule cells, as well as in epilepsy patients with carbamazepine-resistant temporal lobe epilepsy.[65] A similar loss of efficacy was observed to a lesser extent for phenytoin. Interestingly, this effect was not observed for other AEDs such as lamotrigine or valproic acid.[66] Notably, in tissue obtained from pharmacoresistant patients, no differences regarding valproic acid effects on I_{NaT} were observed.[101,102] Collectively, these results suggest that epileptogenesis causes changes in the pharmacologic properties of I_{NaT} in some but not all cell types. It will be necessary to test the target hypothesis also for other drug targets.

Relationship of Changes in Cellular Antiepileptic Drug Sensitivity to Pharmacoresistance Observed In Vivo

The results just described, although suggestive, leave open the major question of whether loss of AED sensitivity on the level of an ion channel, for example, is associated with pharmacoresistance in intact animals. This question could be ideally answered experimentally by first examining pharmacosensitivity in intact animals and subsequently comparing these in vivo results to the cellular effects of AEDs in the same animals. So far, this approach has only been implemented in a few experiments,[27] which assessed phenytoin-responsive and nonresponsive kindled rats.[39] Such models will prove enormously valuable in probing the molecular underpinnings of altered pharmacosensitivity in groups of animals defined by the AED response.

Investigation of tissue resected from patients with epilepsy during epilepsy surgery permits correlation of clinical responsiveness to AEDs with in vitro data from the same patients. For instance, in patients with epilepsy, the properties of the transient inward Na^+ current (I_{NaT}) seem to differ when patients are separated into two groups—one resistant to carbamazepine and a smaller one responsive to carbamazepine. In the former, use-dependent block of I_{NaT} by carbamazepine was abolished, similar to the findings in experimental epilepsy. In contrast, carbamazepine-responsive patients showed potent use-dependent effects of carbamazepine on I_{NaT}. Thus, the sensitivity to carbamazepine on a cellular level appeared to correlate with the clinical responsiveness to the drug.[65] The same correlation was observed when seizure-like events were induced in human slices by elevation of the extracellular K^+ concentration.[18] Such seizure-like activity was not affected by carbamazepine in vitro at concentrations as high as 100 μM when the corresponding patient was clinically resistant to this drug. In marked contrast, seizure-like activity in tissue from patients who were clinically sensitive to carbamazepine was sensitive to carbamazepine in vitro. These findings are also interesting because in these in vitro experiments, the primary blood–brain barrier is not operative. Thus, the correlation between clinical drug response and in vitro data cannot be explained by changes at the blood–brain barrier and implies that, at least for carbamazepine, there is likely to be a change in a drug target.

These findings seem straightforward; however, there are a number of conceptual issues that remain enigmatic. It should be noted, for instance, that patients who are resistant to carbamazepine very frequently are resistant also to other AEDs.[32] The data, however, indicate that altered sensitivity of Na^+ channels may not account for altered efficacy of other AEDs such as valproic acid or lamotrigine.[66] This finding suggests that resistance to AEDs in epilepsy patients is a complex phenomenon that is likely to involve multiple mechanisms.

Future Directions of Research for the Target Hypothesis

The evidence for a role of target changes in drug resistance is suggestive but does not prove the relevance of this mechanism in a clinical setting. What key pieces of evidence should we consider mandatory to support the target hypothesis? A number of experimental data should be obtained:

- Evidence that an AED influences a target ion channel or receptor at clinically relevant concentrations, preferably both in animal and human systems.
- Evidence that the drug target is altered in such a way that it is less sensitive to an AED in chronic human and experimental epilepsy. Functional and molecular changes should correlate with sensitivity of seizures to AEDs in experimental animals or epilepsy patients.
- Evidence that genetic or pharmacologic manipulation of drug targets in intact animals affects sensitivity of spontaneous seizures to AEDs in chronic models of epilepsy.

In addition, we should attempt to generate the following data in human subjects:

- Association of polymorphisms in drug target genes with clinical pharmacoresistance. This could also include association of polymorphisms with drug target pharmacology measured in vitro in tissues obtained from epilepsy surgery.

What Are the Mechanisms Leading to Altered Target Sensitivity?

So far, the mechanisms under most scrutiny have been changes in the transcription of ion channel subunit genes. It has become evident that seizures cause a highly coordinated change in transcription of certain groups of ion channel subunits both in rat models of epilepsy and in humans with epilepsy. This seizure-induced transcriptional plasticity appears to be differentially regulated in different neuron types. In addition to transcriptional mechanisms, seizure activity may also evoke multiple posttranscriptional modifications of ion channel proteins. These could include altered protein transport and targeting, but also changes in phosphorylation or glycosylation. That the latter changes can in principle influence AED sensitivity of channel proteins was shown by Curia et al.:[15] Increased phosphorylation of sodium channels by protein kinase C affected responsiveness to the AED topiramate. It is quite possible that similar mechanisms may also apply to other ion channel proteins or AEDs.

Both transcriptional and posttranscriptional changes would constitute acquired changes in AED sensitivity. A recent study supports the idea that preexisting genetic factors may also influence target sensitivity. Lucas et al.[42] examined the pharmacology of Na^+ channels containing a mutant β_1 subunit causing the generalized epilepsy with febrile seizures plus (GEFS+) syndrome. The surprising result was that Na^+ channels containing mutant β_1 subunits displayed a dramatic and selective loss of use-dependent block by the AED phenytoin that was very similar to the effects observed in chronic experimental epilepsy for phenytoin and carbamazepine.[65,66]

Individual genetic variation may predispose to some forms of target "alteration" leading to altered sensitivity—including resistance—to AEDs. For example, common variation in gene promoter regions might influence gene transcription responses to stresses, including seizures and drug exposure. Recently, it was shown that a common variation in the sodium channel 1A gene (*SCN1A*), which encodes the alpha subunit of the cerebral neuronal sodium channel, affects the alternative splicing of the gene as well as the maximal prescribed daily doses of drugs targeting this channel.[88]

Rapid Development of Drug Resistance in Status Epilepticus

Resistance to AEDs can also be observed in vitro in some models of recurrent seizure-like events. Such activity can be provoked, for instance, by exposing brain slices to the potassium channel blocker 4-aminopyridine or low extracellular magnesium concentrations. It is of interest that this activity is initially responsive to many AEDs, including valproic acid, carbamazepine, phenytoin, barbiturates, and benzodiazepines. If slices are treated with 4-aminopyridine or low-magnesium-containing solution for prolonged periods (more than approximately 2 hours), however, some of the descriptive features of this seizure-like activity change. More importantly for the purposes of this chapter is the finding that seizure activity is no longer blocked by the very AEDs that were previously effective. Thus, resistance to AEDs in vitro can develop in a matter of hours in the presence of continuous epileptiform activity. This suggests that the underlying mechanisms must be fast and probably do not depend on transcription.

What could these mechanisms be? One important hypothesis is that metabolic dysfunction may be responsible. A number of studies have provided evidence of mitochondrial dysfunction, the onset of which may coincide with the appearance of AED-resistant late activity. This is thought to have two consequences: First, the availability of ATP may be reduced, and second, there may be increased generation of reactive oxygen species (ROS). It is entirely possible that both phenomena could result in target molecule modifications, the onset of which could be rapid. It is interesting to note that mitochondrial function is also profoundly disturbed in chronic experimental and human epilepsy. It might well be that ROS-mediated damage or energy depletion also plays a significant role in chronic epilepsy. In addition, rapid increases in the expression of some multidrug transporter-encoding genes in animal models[67] and widespread increased immunoreactivity for P-gp in a single anecdotal human case[81] have been shown, suggesting another possible contribution to rapid development of resistance.

Other Mechanisms of Resistance to Antiepileptic Drugs

Other, more speculative, mechanisms have been postulated that may also contribute to drug resistance.

Pharmacokinetic/Pharmacodynamic Changes Due to Disease-Related Mechanisms

Intractable epilepsy is often associated with structural brain lesions such as malformations of cortical development, hippocampal sclerosis, and brain tumors,[62,85] suggesting that disease-specific morphologic alterations in the brain (e.g., neuronal cell loss, heterotopia, dysplasia, neovascularization, synaptic reorganization, reactive glia, etc.) may alter neuronal targets and/or reduce their responsiveness to AEDs (see previous paragraphs). These lesions may also cause reduced AED availability at their neuronal targets because of physical or biologic barriers determined by the tissue pathology. For example, AEDs may be sequestered in the perivascular regions because of the presence of edema or entrapped in glial ectopic masses (e.g., tumor or sclerotic tissues), reducing their concentration in the epileptic focus. In addition, vascular malformations or ectopic microcirculation may favor AED delivery to cerebral regions that are not pivotal for effective seizure control.

Cytochrome P450 in the Brain

Metabolic tolerance may occur if one specific AED increases its own metabolism by induction of the cytochrome P450 (CYP) system in the liver,[50,95] but there is no evidence that this phenomenon occurs to any significant extent in human refractory epilepsy. Nevertheless, the expression of CYP species has been detected in neurons and astrocytes in various brain areas.[23,29,45,96] It is of interest that astrocytic CYPs appear to exert significant control over the metabolism of phenytoin.[45] Because reactive astrocytosis and glial cell proliferation occur to a significant extent in drug-resistant epileptogenic tissue, the levels of CYPs in epileptogenic brain regions may play a critical role in enhancing drug degradation in very localized areas.

Nonconventional Interactions of Antiepileptic Drugs With Neuromodulatory Systems

Recurrent seizures and the process of epileptogenesis per se can induce continuing molecular, cellular, and network changes in brain that in turn produce long-term alterations in neuronal and glial cell phenotypes and in the extracellular concentration of neuroactive compounds and molecular adaptations in voltage-gated or metabotropic receptors that often dramatically change the ability of neurons to respond not only to xenobiotics but also to endogenous neuroactive molecules such as classical neurotransmitters or neuromodulators (e.g., neuropeptides, inflammatory mediators).[51]

AEDs act on diverse molecular targets to modify neuronal excitability largely through effects on voltage-gated sodium and calcium channels or by interacting with GABA and glutamate systems.[68] Limited information is available, however, on “nonconventional” effects of AEDs on neuromodulatory systems that are involved in ictogenesis. In this regard, two notable examples exist of interactions between some AEDs and inflammatory mediators or neuropeptides that may play a role in pharmacoresistance.

Antiepileptic Drugs and Inflammation

Concentrations of proinflammatory cytokines and related molecules have been measured in the central nervous system (CNS) and plasma in experimental models of seizures and in patients with epilepsy.[93] It is notable that pronounced inflammatory reactions have been described in the epileptogenic areas in clinical cases of drug-resistant epilepsies.[93] Studies in rodents show that inflammatory reactions in the brain can be proictogenic by enhancing neuronal excitability, lowering the threshold for seizure occurrence and increasing the duration of seizures. Moreover, some nonsteroidal antiinflammatory treatments reduce seizures in experimental models.[93] These findings suggest that the extent and/or the persistence of inflammation in the brain may be involved in mechanisms of hyperexcitability. There is in vitro evidence that some AEDs such as valproate and carbamazepine have antiinflammatory properties because they decrease the lypopolysaccaride-induced activation of nuclear factor (kappa) B (NFkB) and the production of nitric oxide and prostaglandins in rat glial cells or human glioma cells,[26,44] suggesting that the anticonvulsant efficacy of some AEDs may involve also their ability to reduce inflammation in epileptogenic tissue. The therapeutic efficacy of AEDs may therefore be reduced by the extent and/or persistence of inflammation in the brain of pharmacoresistant individuals.

Antiepileptic Drugs and Neuropeptides

A second point of interest concerns the possible functional interactions between AEDs and some neuropeptides endowed with significant anticonvulsant properties such as neuropeptide Y (NPY) and somatostatin.[49,74,92,94] Significant correlations have been reported between CSF levels of phenytoin, valproic acid, and carbamazepine and some neuropeptides, such as somatostatin, NPY, cholecystokinin (CCK), and corticotrophin-releasing factor (CRF), in the interictal or postictal period in patients with complex partial or secondarily generalized seizures. In general, a negative correlation was found between AED levels and these neuropeptides.[16,75] Although no evidence is available on the ability of AEDs to increase directly or indirectly the function of inhibitory neuropeptides, one attractive hypothesis is that defective action of AEDs on specific neuropeptide systems may contribute to the therapeutic failure of these drugs.

Antiepileptic Drugs and Tissue Plasticity

An alternative, not mutually exclusive scenario is that the failure of AED efficacy may depend on the significant changes in neuronal networks, and in the associated glial elements, that occur in drug-resistant epileptogenic tissue. Maladaptive structural and functional alterations in such tissue, including the failure of endogenous inhibitory systems, may decrease the excitability threshold of neurons to such an extent that AEDs alone do not provide sufficient inhibitory control. In this respect, preclinical and clinical research has led to the identification of new nonconventional targets and therapeutic approaches for effective inhibition of seizures, including intraparenchymal brain delivery of therapeutic genes or compounds with long-lasting anticonvulsant properties (for review see Costantin et al.[13] and Noe' and Vezzani[46]). Such strategies could lead to the development of drugs with novel actions, possibly circumventing the mechanisms of pharmacoresistance, which may act in synergy with currently used AEDs.

Summary and Conclusions

The experimental results described in this chapter indicate that functionally relevant alterations can be found in both AED targets and AED transporters. These mechanisms are not mutually exclusive. It is entirely possible that decreased penetration of AEDs into brain tissue in synergy with changes in targets for these drugs together mediate pharmacoresistance. For some AEDs, it could be that drug resistance is predominantly due to one of these two mechanisms. Some lines of evidence, for instance, suggest that carbamazepine is not a substrate of some multidrug transporters,[48] but rather that target sodium channels display a potent loss of sensitivity to carbamazepine.[65] For other AEDs, this may be different. For instance, intraparenchymal phenytoin concentration is potently regulated by multidrug transporters[54,56,67] and epileptic animals lacking a multidrug transporter protein (MRP2) are more sensitive to phenytoin treatment than are wild-type animals.[54] Thus, target mechanisms seem to be less important for phenytoin compared to carbamazepine.[27,66] Although the evidence supporting this view is far from conclusive, it is tempting to speculate that patterns of resistance mechanisms may vary from drug to drug and syndrome to syndrome.

We do not know the chances of either of these schools of thought leading to a definitive explanation of refractoriness. It may be that even if the roles of transport and target alterations are proven, this will not lead to therapeutic benefit. Even if we had an effective drug that counteracts a given derangement, by the time the clinical manifestations have taken place, it is possible that many other changes have occurred, so that even a drug “specific” for the root problem may not work, as illustrated by the example of PVH discussed in the introduction. Increasing data on the many pathophysiologic deviations, often unrelated to the postulated mechanisms of action of current AEDs, seen in some of the more common pathologies causing epilepsy give both reason for reassessment of current concepts and hope for future developments.

Nevertheless, we do have to start somewhere in attempting to tackle the issue of drug resistance. The “target” and “transport” concepts are the best current candidates, especially if we wish to achieve progress in the shorter term in improving the efficacy of available AEDs. Newer methods and strategies may lead, however, to more rapid progress in this field. It is also likely that biologic investigations in this area will at least uncover more of the pathophysiology of disease processes in epilepsy.

Chapter 116

Compliance

Joyce A. Cramer

Introduction

Issues of compliance with drug regimens are universal across all medical disciplines. The impact of taking none or less than the appropriate amount of an antiepileptic drug can have consequences to the patient and to the health care system. This chapter reviews typical problems and suggests potential ways to enhance compliance to achieve the desired outcome—good seizure control with minimal adverse effects or impact on quality of life.

Background

The high prevalence of inadequate compliance is a major contributor to the cost of medical care in every therapeutic area. The National Council for Patient Information and Education estimates that half of the 1.6 billion prescriptions written in the United States annually are not taken properly. No consequence is so severe that all patients comply. The leading cause of organ rejection in transplant patients is noncompliance with immunosuppressant drugs.[12] Despite the best intentions and understanding of the importance of taking drugs, many epilepsy patients do not take their drugs as prescribed. A postal survey of community-based patients revealed not only that many patients acknowledge having missed doses, but also that patients are aware they had seizures because of missed doses.[4]

Lacking a cure for epilepsy, researchers are developing new drugs to provide better control of seizures. Unfortunately, the availability of a plethora of new and highly effective antiepileptic drugs will not alter a pervasive aspect of human behavior—partial compliance with the prescribed regimen. Few patients are willfully noncompliant, but many are negligent—partial compliers who take fewer (rarely more) doses than prescribed. To improve outcome for patients with few or many seizures, it is necessary to understand when and why patients do not take drugs as prescribed.

The Health Belief Model was developed as a predictor of preventive health behavior.[1] It is based on patient perceptions, similar to the approach in quality-of-life measures. In this model, the patient must be ready to address the issue of compliance, have some motivation (e.g., seizure control), learn how to take drugs, and receive support from family and health care providers. Paradoxically, good seizure control leads to complacency about taking drugs and may ultimately result in a relapse. Although education is an important feature in the model, knowledge does not ensure compliance, as demonstrated by declines in compliance after counseling is discontinued.[11] The number of medical professionals who do not complete their own treatment programs (e.g., antibiotics), leading to a superinfection, or who lapse in complying with their birth control system (e.g., daily oral contraceptive), resulting in an unplanned pregnancy, demonstrates this point. Urquhart[13] noted that "technical knowledge does not compete effectively for priority in a busy schedule."

Compliance Monitoring and Feedback System

A novel approach to understanding patient behavior in taking drugs and providing feedback on compliance is incorporated in the new microelectronic monitoring technology (MEMS'250; AARDEX Ltd., Zug, Switzerland). The system combines monitoring of drug dosing using MEMS bottles and immediate reading of the electronically stored information on a personal computer in the office. Information is provided directly to the patient and medical staff about dosing activities since the last visit.[5]

MEMS units are special caps for medication bottles that have a microprocessor chip embedded in the cap to record the date and time when the bottle cap is opened for dosing. Months of dosing data can be stored in the cap until retrieval during a follow-up visit. Patients are asked to use the electronic caps, with the explanation that the physician would like to understand how the patient takes drugs as part of the treatment plan. The cap mechanism is demonstrated to the patient, with instructions not to open the bottle except when the drug is removed for dosing. When the patient returns for a follow-up appointment, the bottle is placed on a communicator apparatus that reads the electronic information and transmits it to the computer. A base rate of compliance can be estimated using the first month as a control period because the patient does not yet know how the data will be used.

Data are displayed on the screen in the format of a monthly calendar showing the number of times the bottle was opened for dosing each day. A second type of display shows the exact date and time of every bottle opening. Both displays show the actual dosing pattern and any unusual patterns of missed doses on weekends or during morning or evening dosing. Provided with this information and a report of seizure frequency or dose-related adverse effects, the clinical staff can quickly determine whether seizures have occurred after periods of missed doses or toxic effects after periods of extra doses. The issue is whether the drug has failed to control seizures or whether the patient has failed to take adequate amounts of the drug. The immediate electronic report helps the physician to determine whether the dosing regimen needs adjustment or whether the patient needs assistance to remember to take doses. The electronic monitoring system prevents either the patient or the physician from having a misconception about lack of drug efficacy when inadequate doses have been consumed. Display of data is objective and nonjudgmental, providing immediate feedback to the patient about behavior. This is an optimal time for the physician or nurse to ask what strategies the patient is using to remember the doses, focusing on the more commonly forgotten days and times. For example, if a patient tends to skip pills during the weekend or misses more doses in the morning than in the evening, those time periods can be discussed in detail.

In a survey of 55 patients observed for an average of 14 weeks, the overall rate of compliance with dosing regimens was 75% (range: 3% to 100%). Mean compliance rates

declined as the number of doses increased (each day, 86%; twice a day, 80%; three times a day, 76%), with a significant decrease to 53% compliance for four-times-a-day dosing.[5,6] In numerous instances, documentation of dosing demonstrates breakthrough seizures occurring only after missed doses. As stated by former Surgeon General Koop, “Drugs don't work in patients who don't take them.”

Who Needs Help with Compliance Planning?

It is not possible to predict which patients will be partially compliant or when doses will be missed.[6] Intelligence, socioeconomic level, personality, age, and education have not correlated well with electronically monitored compliance. Although it is not feasible to use microelectronic monitoring for all patients, those who continue to have seizures or whose seizures occur randomly despite apparently adequate treatment might be candidates for monitoring. Discovery of erratic compliance might be of greater benefit to the patient than frequent changes of dose or drug. Poor compliers might also need to be seen more frequently.[14]

What can Health Care Providers do to Enhance Compliance?

Patients have no trouble taking multiple tablets and capsules at the same time.[5] Polydosing (multiple daily doses) is the problem, not polypharmacy (multiple drugs).

The key elements to enhance compliance that health care providers should keep in mind when prescribing drugs are as follows:

1. Select the fewest possible number of dose times.
2. Schedule when the doses should be taken.
3. Help the patient select a reminder or “cue.”

Selecting a Dose Regimen

The major pharmacokinetic factor to consider when selecting a dose regimen is the duration of action of the drug, based on clearance rates and the effect of interactions with other drugs. Planning a schedule for taking pills that is appropriate for the patient is important. Although numerous reports have demonstrated an improvement in compliance with simpler dose regimens, physicians either forget this fact or consider other pharmacokinetic requirements to be more important than a simple regimen. At times, the initial treatment regimen with multiple small doses is not revised after tolerance develops. Twice-daily dosing for antiepileptic drugs is recommended whenever possible. The twice-daily regimen provides greater tolerance for irregularities in dosing than a once-daily schedule; if the patient misses a single dose, only half the total daily amount is forfeited when the dose is divided. In addition to compliance issues, dividing the total dose into two portions diminishes the risk for adverse effects at peak serum concentrations during absorption.

Because of its complex pharmacokinetic pattern and half-life of <24 hours in many patients (particularly children), phenytoin usually is given twice daily to keep blood levels fairly constant. Many of the newer drugs with a long duration of action are prescribed with a twice-daily dosing schedule. Among older antiepileptic drugs, phenobarbital can be given once daily in *all* patients because of its very long half-life. Four daily doses are so difficult for most patients to achieve (even on a short-term basis) that careful consideration should be given before prescribing this regimen on a long-term basis. Slow-release formulations offer some extension of therapeutic action. These formulations allow for twice-daily dosing with a safety margin for long intervals between doses. Patients commonly take the morning dose between 6 and 7 AM and the evening dose between 11 PM and 12 midnight, leaving a long daytime period during which the drug is not taken.

Scheduling Doses

Coordination of the dosing schedules for the various drugs prescribed for individual patients is important, particularly elderly patients who take multiple drugs. Although a neurologist might prescribe one drug to be taken three times a day, this can create an elaborate schedule for a patient who is already taking several drugs at other times of the day. Instructions for omitting a missed earlier dose or taking it with the bedtime dose should be given by the physician because patients commonly discover a dose omission at bedtime or early the next morning. Clinicians should indicate how to take a divided dose (e.g., 12 hours apart, morning and evening, or morning and bedtime).

Selection of Reminders or "Cues"

Several types of cues can be easily incorporated into a 3-minute session of compliance counseling. The brevity of the counseling is important because physicians typically have little time and need to be concise and direct in their approach to compliance counseling. Development of cues to remind the patient when to take a dose takes careful planning that meshes with individual lifestyles. Three types of cues are suggested for a simple initial program:

1. Clock time. Ask patients if they are usually aware of the time of day using a watch or clock. If they are, suggest that twice-a-day dosing be based on a specific time (e.g., 7 AM and 7 PM).
2. Mealtime. Ask patients if they usually eat meals at a regular time every day. If the answer is yes, suggest that drugs be taken at mealtimes. Explain that a consistent pattern of dosing with or before meals is important because of effects of foods on drug bioavailability.
3. Daily activity. If a patient is neither aware of the time nor eats regular meals, ask what type of daily activities are typical. Ask the patient to establish a specific activity that can be linked to dosing (e.g., combing hair, shaving, removing contact lenses, walking the dog, listening to AM/PM news).

Some patients manage well by using a small *pill box* with a compartment for each day of the week in which a full day's dose can be inserted. This type of packaging was developed for oral contraceptives during the 1960s so that women could see the sequence of daily doses as an aid to remembering whether the current day's pill was taken. However, even such an obvious visual cue can often be missed, as documented by the large number of unexpected pregnancies in women taking oral contraceptive pills. Patients with complex schedules may benefit by use of a *log sheet*, on which they make a check mark after taking each dose, to avoid double dosing or missed doses.

If one cue does not work, another can be tried, or combinations of cues over time. Periodically asking patients about their cues and how well the cues remind them to take drugs not only helps patients to develop a personalized cuing system, but it also makes them aware of the physician's consistent interest in the way they take drugs.

This simple program was found to be effective even with chronically mentally ill patients.[7]

Pitfalls of Erratic Compliance

Therapeutic drug monitoring (measurement of blood levels) is useful primarily in adjusting dose. However, blood levels are a poor surrogate for direct monitoring of compliance because of the relatively short half-life of most antiepileptic drugs. A drug serum concentration in the expected range at a clinic visit should not be assumed to reflect levels throughout the interval since the last visit. It has been shown that compliance declines from an above-average 82% during the 5 days before and after a clinic visit to 67% between visits ($p < .05$).[8] When a patient has a seizure between visits, the physician uses blood levels from the previous and current visits to assess the probable steady-state serum concentration. Without microelectronic monitoring, any omission of doses before the seizure would be unknown. Use of the MEMS system allows both patient and physician to understand that a drug probably works well to control seizures when taken as directed, but that the patient has a low threshold for declining serum concentrations of the drug. If the patient does not remember missing any doses, it is impossible to establish that partial compliance has been responsible for the seizure or that the drug dose might have been increased inappropriately.

In clinical trials, all seizures are considered as a failure of the drug being investigated. Microelectronic monitoring of compliance can be a valuable adjunct to patient reports and can serve as an explanatory variable of differences in outcome. Compliance with multiple antiepileptic drugs was shown to differ from the experimental medication in a short-term clinical trial.[9]

Clinical Monitoring of Compliance

After establishing a simple dosing regimen, explaining when doses should be taken, and helping the patient to select a reminder cue, the message must be reinforced regularly. A brief question can be added to every routine visit: "*How* do you take your medicine?"

Ask *how many* tablets and capsules are taken at each dose, *when* doses are taken, and *which dose* is more difficult to remember. Listening to the patient before ordering a blood level measurement can provide important information about erratic dosing that could confound interpretation of the results. Patients are more likely to comply with the prescribed regimen when they feel accountable. The phenomenon of "white-coat compliance"[10] has been demonstrated by the enhanced rate of compliance before and after scheduled office visits.[8] Regularly asking every patient at every visit about how drugs are taken demonstrates the importance of maintaining the treatment plan.

Summary and Conclusions

Although every person can be considered a potential treatment defaulter, health care providers at all levels can provide simple suggestions and reinforcements to improve compliance, thereby improving treatment outcome. Unfortunately, no single specific strategy works to enhance compliance for all patients. If physicians and other health care providers work in partnership with patients instead of using a didactic approach, they will have a greater influence on compliance.

Chapter 117

Choice of Antiepileptic Drugs

Elinor Ben-Menachem

Jacqueline A. French

Introduction

When the diagnosis of epilepsy has been made and extraneous factors that can provoke seizures are eliminated, then there is usually the decision to treat the patient with an antiepileptic drug (AED). The patient (or parents, when it concerns a child) must be given as complete information as possible about the diagnosis and prognosis and the different treatment alternatives. Without this understanding between the patient and doctor the risk for noncompliance is significant. The goal of treatment is to achieve seizure freedom without side effects, especially those that cause more negative consequences than the seizures themselves and reduce the quality of life.

With the advent of the new era of antiepileptic drugs, heralded by the approval of ten new compounds, all developed in the last two decades, selection of the most optimal therapy is more complex than ever. It often difficult to predict which drug will be the best tolerated and most likely to produce the best seizure control in a given individual. However, it is perhaps possible to narrow the choices among the available drugs to a few optimal selections based on characteristics that are known about each patient when he or she presents. Some patient characteristics can be seen to fall on a continuum, such as that from the newly diagnosed patient, who has a high likelihood of responding to antiepileptic drugs, to the drug-resistant patient, who is unlikely to remit. Another such continuum is that of age, from infancy, through adulthood, and finally advanced age. Different drug choices might be needed at different points on these continua. In addition, within the epilepsy population there are other characteristics that divide patients into subpopulations, including gender, epilepsy syndrome, and comorbidities.

Thus, the choice of AED is based on not only which drug has been shown to be effective for a particular seizure type, but also the patient's age and gender, comorbidities, and whether he or she is newly diagnosed or refractory. Much is known about likelihood of seizure control, drug tolerability, and side effect profile that is specific to each of these characteristics. These characteristics can also inform choices based on potential interactions and even cost. For example, a new AED that is costly but has been shown to be potent as add-on therapy in refractory epilepsy may be warranted in a difficult-to-control patient but not in a patient who is newly diagnosed.

Stages of Disease

Initial Therapy

Studies in patients with newly diagnosed epilepsy have suggested that approximately 40% of patients with newly diagnosed epilepsy will be rendered seizure free on the first therapy tried.[5] Once seizure free, a patient might be unwilling to attempt a change in therapy, even in the presence of side effects. Patient and physician may not choose to risk a medication conversion due to the possibility of destabilization. The stakes become even higher when the patient has returned to previous activities, including driving. The result is that many patients remain on their initial therapy for years, if not a lifetime. For this reason, the choice of initial therapy is a critical juncture in the care of epilepsy.

Efficacy

Although it would be ideal to have efficacy data for all drugs specifically obtained from well-designed trials in the newly diagnosed population, unfortunately there is usually a lag between the time that a new AED is approved and the availability of data on the newly diagnosed. It is unclear whether trials need to be performed prior to using the new drugs in this population. Although it is likely that drugs that work as add-on therapy also work in monotherapy and that drugs that work in refractory patients are also effective in newly diagnosed patients, who are typically considered to be easier to control, it is also reasonable to assume that the pathophysiology underlying refractory epilepsy differs from that of easy-to-control epilepsy, and therefore drugs might be more suitable for one population or the other. For example, vigabatrin was highly efficacious in placebo-controlled add-on trials in refractory patients,[18] whereas it was less effective (but better tolerated) than carbamazepine in a trial of newly diagnosed patients.[8] It does not appear that relative drug efficacy in add-on studies is predictive of better effect in newly diagnosed patients. Despite great hopes, no new AED has been proven to be more efficacious than a “standard” AED in the newly diagnosed population. Trials in newly diagnosed patients have been successfully completed for vigabatrin, lamotrigine, oxcarbazepine, gabapentin, and topiramate, and soon will be for evetiracetam.[1,3,4,5,8,9,11,14,22,31,37]

Safety and Tolerability

The absence of demonstrated efficacy differences between AEDs when tested in newly diagnosed populations puts emphasis on other drug characteristics as a reasonable basis for AED selection in this population. One important issue is drug safety and tolerability. In the presence of an abundance of options, drugs with few or no safety or side effect concerns should be high on the list. The older AEDs, although generally safe, all carry a small risk of potentially life-threatening adverse events such as hepatic failure and aplastic anemia. A number of the newer antiepileptic drugs, although they have not been used for the same duration, or in as many patients as the older drugs, appear to be safer. As experience and duration of follow-up grows, we can hope that this apparent safety will be confirmed. Even now, the newest antiepileptic drug, pregabalin, has reportedly been used in well more than

100,000 unique patients (Pfizer Inc., personal communication). Several older AEDs have also been associated with risk of long-term side effects, such as gum hyperplasia, neuropathy, connective tissue disorders, and osteopenia.[29] Of the newer drugs, vigabatrin has been associated with permanent visual field defects,[25] and topiramate and zonisamide carry a risk of renal nephrolithiasis.[36] So far, no other long-term side effects have been identified for the new AEDs, although it is probably naïve and definitely premature to hypothesize that none exist. It is important to maintain vigilance for such potential effects because they take unexpected forms and may not be identified before hundreds of thousands of patients have been exposed. On the other hand, in the head-to-head comparison trials the new AEDs were almost always as well or better tolerated than the older drugs. Examples are the comparative trials between lamotrigine and carbamazepine[5]; oxcarbazepine and carbamazepine,[14] phenytoin,[3,22] and valproate[11]; topiramate and carbamazepine and valproate[31]; and gabapentin and carbamazepine.[9] Of note, the studies with carbamazepine as a comparator used the immediate-release rather than the currently favored extended-release formulation, and titration rates were not always optimized. Nevertheless, the new drugs probably have better tolerability especially when given in appropriate doses after careful titration. These outcomes might indicate that these drugs should be considered as initial monotherapy in newly diagnosed patients.

Initiation/Dose

Newly diagnosed patients remain at risk for additional seizures until the chosen drug reaches a therapeutic dose. This gives an advantage to drugs that can be initiated at a therapeutic dose or titrated rapidly. Some AEDs, such as lamotrigine, topiramate, and zonisamide, typically require prolonged titration, and this can limit their use in certain patients. Carbamazepine can typically be titrated to an effective dose within 1 to 2 weeks. Other drugs, such as oxcarbazepine, gabapentin, and pregabalin, have been initiated at a therapeutic dose in clinical trials without safety concerns but have been demonstrated to be better tolerated when titrated slowly.[2,16,34] Titration schedules are outlined in Table 1.

Table 1 Initiation schedule for common antiepileptic drugs

Drug	Initiation
Phenytoin	Intravenous/oral load
Carbamazepine	Gradual initiation/1–2 wk
Valproate	Immediate therapeutic dose
Topiramate	Gradual initiation/4–6 wk
Gabapentin	Immediate therapeutic dose
Lamotrigine	Gradual initiation/4–6 wk
Levetiracetam	Immediate therapeutic dose
Zonisamide	Gradual initiation/4–6 wk
Oxcabazepine	Gradual initiation/4–6 wk

It may be difficult to choose a dose to titrate to as initial therapy in a newly diagnosed patient. Table 2 shows the doses that were used in randomized, placebo-controlled trials in newly diagnosed patients. In trials of lamotrigine and oxcarbazepine, variable dosing was permitted in the initial portion of the trial.[4,5,11,14,22] In these cases, it is likely that the average dose used in the trial is a reasonable starting point for newly diagnosed patients. In trials of topiramate and gabapentin, fixed doses were employed. Topiramate 100 mg was better tolerated, and equally as effective, as 200 mg, and gabapentin 900 mg was more effective and better tolerated than 300 or 1,800 mg. However, other doses were not tested.[31]

Table 2 Doses used in randomized, placebo-controlled trials of four new antiepileptic drugs in newly diagnosed patients

Drug	Dose
Gabapentin	Fixed, 300, 900, 1,800 mg[5]

	(900 mg superior)
Lamotrigine	~150 mg[18]
Oxcarbazepine	~1,000 mg (adults)[8,37]
	~18 mg/kg (children)[3]
Topiramate	Fixed, 100 or 200 mg[31]

Hepatic Enzyme Induction

The older AEDs all produce alteration of hepatic metabolism via alteration of the cytochrome P450 system. Most, including phenytoin, carbamazepine, phenobarbital, and primidone, are strong hepatic enzyme inducers. The newer antiepileptic drugs either have no hepatic-inducing properties or are only minimally inducing. This can provide an advantage when a drug will be used over many years, for two reasons. The first is that many intrinsic substances such as vitamins and hormones are subject to induced metabolism. This can produce relative deficiencies. Absence of enzyme induction is a benefit to women during their childbearing years. This will be discussed later. The second issue is that of drug interactions that occur as a result of hepatic induction. Many medications that are eliminated through cytochrome P450 can be subject to induction. Induction produces a shortened half-life, and higher doses are required to maintain effect.[30] This is especially important to consider when initiating a new AED in patients with known concomitant medical conditions and in the elderly, who are likely to be on multiple medications. An example of the potential impact of these interactions can be seen in a study of children with acute lymphoblastic lymphoma. In this study, more deaths occurred in children receiving phenytoin, a classic hepatic inducer. The cause of the higher death rate could be traced to increased metabolism of the standard chemotherapeutic regimen.[32] This is also a concern for younger individuals who might be on other commonly used medications that may require dose adjustments when enzyme-inducing antiepileptic drugs are employed, including statins, oral contraceptives, antidepressants, and antihypertensives.

Evidence for Treatment of Newly Diagnosed Seizures

For partial onset seizures in adults, carbamazepine, phenytoin, and valproate are the drugs that have the best evidence for efficacy.[28] Gabapentin, lamotrigine, oxcarbazepine, and to-piramate are also good choices, but the clinical studies documenting their efficacy in trials up to 1 year are weaker. Oxcarbazepine (OXC), topiramate (TPM), Lamotrigine (LTG), and Gabapentin (GPB) are all new drugs developed after 1980 and registered in the 1990s. More data are needed to determine whether these drugs will be equally effective with, but have fewer side effects than, the older AEDs.

For generalized tonic–clonic seizures the best evidence is for the older drugs as well. However, if the seizure syndrome

causing the tonic–clonic seizures is not known, then treatment with sodium channel blockers such as phenytoin and carbamazepine can unmask other seizure types such as myo-clonias and absence seizures.[20] Ethosuximide has demonstrated efficacy only for typical absence seizures. Lamotri-gine has been compared in a study with valproate for absence seizures,[12] and in this study valproate was slightly but not significantly more effective than lamotrigine at the end of 1 year.

Table 3 Spectrum of activity of new and old antiepileptic drugs

Drug	Partial	Secondary generalized	Tonic-clonic	Absence	Myoclonic
Phenytoin	+	+	+	-	-
Carbamazepine	+	+	+	-	-
Valproate acid	+	+	+	+	+
Phenobarbital	+	+	+	0	?+
Primidone	+	+	+	0	?+
Ethosuximide	0	0	0	+	0
Felbamate	+	+	?+	?+	?+
Gabapentin	+	+	?+	0	?-
Lamotrigine	+	+	+	+	+-
Topiramate	+	+	+	?	?+
Tiagabine	+	+	?	?	?
Zonisamide	+	+	?+	?+	?+
Levetiracetam	+	+	?+	?+	?+
Oxcarbazepine	+	+	+	-	-

Table 3 outlines the current understanding of the spectrum of activity of new and old AEDs.

First Add-On

When patients do not become seizure free on their first or second antiepileptic drug, options for treatment include add-on therapy or sequential monotherapy s bstitution. Substitution can involve the risk of worsening the condition, and sometimes physicians and patients opt to add a second drug. The concept of polytherapy, frowned on in the past, has gained renewed interest with the advent of new drugs with novel mechanisms and fewer drug interactions. Clearly, this is where the newer drugs are at a substantial advantage as compared to older drugs, which were subject to greater risk of side effects when combined, and, due to shared mechanisms such as sodium channel blockade, did not always provide added benefit.[35]

Although combining two drugs with novel mechanisms of action would theoretically provide a better potential for additive benefit, this has not been proven in any clinical study. Most of the new drugs have novel mechanisms, some of which are not elucidated. Even lamotrigine and oxcarbazepine, both of which have putative sodium channel action, may have additional, novel mechanisms and appear to enhance seizure control in patients already receiving other sodium channel blockers.

Drug–drug interactions are important to consider when combining drugs. Interactions can increase the risk of side effects and affect efficacy. The AEDs that have the most risk for interaction are those metabolized in the liver especially through the cytochrome P450 system.[17] The most important drugs with potential interactions are phenobarbital, phenytoin, carbamazepine, primidone, and to some extent topiramate and oxcarbazepine. Even valproate and lamotrigine can interact with each other. The drugs with least interactions, because they are not metabolized in the liver, are gabapentin, levetiracetam, pregabalin, and vigabatrin. These issues are discussed in detail in Chapter 110.

Pharmacodynamic interactions should also be considered. Pharmacodynamic interactions are said to occur when combining drugs causes more than additive toxicity or benefit in the absence of a change in serum concentrations. These can occur for a number of reasons, including similarity of side effects between coadministered drugs exceeding a "threshold" of tolerability (e.g., diplopia or dizziness) or the interaction of two drugs at their site of action in the central nervous system. The first is probably the explanation behind the pharmacodynamic interaction between lamotrigine and carbamazepine, and between carbamazepine and phenytoin. These combinations should probably not be used as a first choice. In some cases a drug combination might provide more benefit than either drug alone. Such a claim, as yet unproven, has been made for the combination of lamotrigine and valproic acid.[6] Some of the newer drugs, such as levetiracetam, gabapentin, and pregabalin, cause fewer pharmacodynamic side effects and seem to be particularly well tolerated as add-on therapy.

Refractory Patients

Refractory patients have been the subjects of study in most clinical trials of new AEDs. Once many drugs have failed, the primary concern is to find a highly efficacious drug. At this point, although side effects, drug interaction profiles, and frequency of dosing are important, they may take a back seat to the goal of seizure freedom. Unfortunately, none of the new AEDs has produced a high percentage of seizure-free patients in controlled trials of this population.[13] Often, seizure-free rates are not even supplied in reports of controlled clinical trials. Fifty percent seizure reduction rates, also called responder rates, are routinely provided. Responder rates have ranged from 15% to 50%.[13] For this reason, treatment of refractory epilepsy often incorporates nondrug strategies such as surgery and the vagus nerve stimulator. Despite less than optimal response even with the new drugs, a proportion of refractory patients are rendered seizure free with AEDs, and efforts at optimizing drug therapy should be continued as long as the patient is willing.

P.1298

Special Groups

Children

It could be argued that AED selection in children is even more critical than for adults due to the potential for impact on the developing brain and on learning. In addition, children can present with quite different seizure syndromes and seizure types. Most drugs during clinical development are initially tested in adults. Drug trials in children are reserved for a later stage and are therefore less frequent and often involve fewer patients. For example, there are 25 randomized, clinical controlled trials for partial onset seizures in children, but only 3 have enough power to be considered as evidence for which drug should be used as initial therapy. The three trials for new-onset seizures were comparisons between clobazam and carbamazepine,[7] oxcarbazepine and phenytoin,[22] and to-piramate, carbamazepine, and valproate.[31] All of the aforementioned drugs were effective in treating children with partial seizures. Because of its potential to produce changes in bone metabolism and retardation of dental growth, phenytoin should probably be reserved as a second-line therapy. In the absence of pediatric data, physicians will begin to use the new AEDs based upon the data from adult clinical trials. Most likely efficacy will be the same as in adults, but the pharmacokinetics and side effect profiles are different in children, and that is why drugs need to be tested in children as well as adults. Children do not always behave like miniature adults. There can be unique tolerability and safety issues in children. Examples of safety issues include serious rash related to lamotrigine, which is more common in children under the age of 16,[21] and fatal hepatotoxicity related to valproic acid, which has an incidence of 1/37,000 in adults but is progressively more common with decreasing age. For children <2 years of age, the incidence is 1/500.[15] Less serious, but important to be aware of, are hypohydrosis with topiramate and zonisamide[19,26] and behavioral disturbance with gabapentin and phenobarbital.[24,38] It is of interest that phenobarbital tends to be sedating in adults but can cause hyperactivity in children. Similar paradoxical effects of the new AEDs might yet be uncovered. Cognitive disturbance caused by AEDs might be a more serious problem in children when it occurs at a critical learning and development stage.

Because of higher bioavailability in small children, the dose in milligrams per kilogram to reach a given concentration is usually higher. Nonetheless, it is usually prudent to start treatment with a low dose and successively increase it. Children with functional handicaps are more sensitive to AEDs and can develop unacceptable side effects at much lower doses than other patient groups, especially in the form of behavioral abnormalities and cognitive problems. Chapter 111 gives a fuller discussion of drug treatment in children.

Women

When treating women of childbearing potential certain considerations need to be made. Enzyme-inducing drugs such as carbamazepine, phenytoin, lamotrigine, oxcarbazepine, and topiramate (doses >200 mg/d) interact with the contraceptive pill and reduce its effectiveness. Sometimes the effect of the AED is reduced instead, as is the case with lamotrigine. High-dose estrogen contraceptive pills or gestagen preparations are more adequate choices in these patients. It is important for women to discuss appropriate contraception with their gynecologist.

Women on antiepileptic drugs should plan their pregnancies so that the treatment with the AEDs can be adapted if needed. In addition, folic acid should be given in doses of 1 to 5 mg/d. The neurologist should discuss pregnancy with patients who wish to have children and discuss especially the risk for teratogenicity as well as the risks of attempting to withdraw AED treatment prior to the pregnancy. It is the hope that the new AEDs will be less teratogenic than the older AEDs. A number of pregnancy registries are ongoing and should provide further information about the relative risks and benefits of each of the antiepileptic drugs. A prospective pregnancy registry specifically for LTG has provided reassuring data indicating that LTG in monotherapy does not seem to be more teratogenic than CBZ and maybe even less so.[39] This information provides reason for optimism, but it needs to be confirmed from the other ongoing registries. The risk for neural tube defects increases with treatment with valproate and carbamazepine. It is especially recommended that women who are treated with these AEDs take folic acid before the planned pregnancy.[40]

Women with epilepsy receiving AED treatment should be closely followed during pregnancy. It is not unreasonable to treat these pregnancies as high risk, and to refer women to high-risk obstetric care, if available. Monotherapy and the lowest possible dose of AEDs should be the goal of treatment. However, decreasing drugs at the risk of breakthrough seizures is a worse alternative.

So far the consensus is that women with epilepsy should be encouraged to breast-feed because the amount of AED that passes into breast milk is not deemed to hurt the infant. The evidence for this is, however, only at the level of expert opinion.

Chapters 109 and 113 discuss these issues and others related to treatment in women.

The Elderly

The incidence of epilepsy rises over the age of 65 years. Treatment of the older patient with epilepsy has specific challenges. As patients age, they undergo physical and psychosocial changes that affect AED choice.

Late-onset epilepsy tends to respond readily to antiepileptic drugs at low doses. Older individuals tend to have lower thresholds for development of side effects, particularly sedation, cognitive dysfunction, tremor, and gait disturbance. In addition, creatinine and hepatic clearance is reduced in individuals >65 years old. Therefore, lower doses are required for drugs that have full or even partial renal clearance. Other pharmacokinetic changes occur during the aging process as well. There may be an age-related reduction in serum albumin, increasing the free (active) fraction of highly protein-bound drugs such as phenytoin, carbamazepine, and valproic acid. In sum, it is prudent to select drugs with benign side effect profiles and initiate and titrate to lower doses than would be employed in a younger individual. It is optimal to begin at a low dose and slowly increase up to an effective dose, that is, the dose with best effect but few or no side effects. With some drugs, especially the older ones, the dose can be established with help of therapeutic drug monitoring by measuring serum concentration of the AEDs. This helps to prevent toxicity.

Two recent multicenter studies compared new epilepsy drugs to older drugs in the elderly population. In the first, carbamazepine was compared to lamotrigine in individuals with a mean age of 77 years. Efficacy was similar between the two drugs, but lamotrigine was better tolerated and produced fewer dropouts.[4] Only 18% of individuals dropped out in the lamotrigine arm, compared to 42% in the carbamazepine arm. These results were confirmed in a recent Veterans Administration Cooperative multicenter study in elderly patients with the first diagnosis of epilepsy, which compared carbamazepine, lamotrigine, and gabapentin. Again, carbamazepine was the least well tolerated, whereas efficacy was

similar for the three drugs. Dropout rates were 27% for carbamazepine, 17% for gabapentin, and 10% for lamotrigine after 12 months.[33]

Older people often have other comorbidities and take medications for other diseases. Thus, interactions can be a problem, and their potential should not be forgotten. Common interactions occur with enzyme-inducing drugs such as phenytoin, phenobarbital, primidone, and carbamazepine. In the elderly, interactions with anticoagulants are of special importance. A good recommendation is to always read about interactions before choosing an AED. A rule of thumb is that when two drugs are metabolized by the same cytochrome isozyme, then there is surely a potential for interaction.[25] Drug treatment in the elderly is further discussed in Chapter 114.

Stopping Treatment

About half of the people with epilepsy have easy-to-control seizures. Many people with epilepsy can achieve long-term remission, and most can reduce or some even stop treatment with AEDs. In children it is possible to try to stop the medication after they have been seizure free for 2 years, whereas for adults the interval of seizure freedom before downtitrating an AED is 3 to 5 years. There are many factors that need to be addressed before recommending downtitration and ultimate cessation of an AED.[10] For one thing, stopping medication is a very individual decision and depends on each person's willingness to accept the possibility of seizure recurrence. This is the decision that should be made with both patient and physician input. For certain syndromes such as juvenile myoclonic epilepsy the risk for recurrence is great so the recommendation for that syndrome is usually to continue medication throughout life. EEG has a marginal importance for making the decision to stop medication. The risk for new seizures after stopping medication is about 35% overall.[10]

Single breakthrough seizures can be an expression of downtitration of a drug and should not cause the physician to necessarily reinstate the drug. Instead, slowing the rate of downtitration is usually the best methodology. In other words, the AED treatment should not be abruptly stopped, but instead it should be slowly decreased. Special care should be taken in downtitration with the older drugs such as clonazepam, phenobarbital, and primidone because these compounds are especially prone to cause withdrawal seizures when reduced. Stopping treatment is addressed further in Chapter 118.

If the treatment does not help

In spite of adequate treatment with AEDs and in spite of adequate compliance on the side of the patients, about 25% to 30% of patients develop refractory epilepsy.[27] If two or three AEDs in both monotherapy or in combination have not had any effect, it is important to refer the patient to a specialized epilepsy clinic for diagnostic reevaluation and for evaluation for potential epilepsy surgery, vagus nerve stimulation, and, for some children, ketogenic diet.

For small children the decision for referral should be made at an earlier date so that the child can obtain maximal treatment to try to prevent mental delay and other catastrophic problems in childhood.

Summary and Conclusions

Choice of antiepileptic drug therapy can have a profound effect on the course of a patient with epilepsy. Selection should be performed carefully and should be based on what is known about the patient coupled with an evidence-based understanding of AED characteristics. Thus, in treating a patient with epilepsy, the physician must weigh many factors in selecting the most appropriate AED and also in deciding when to go on to surgical evaluation and other therapeutic methodologies when the patient is refractory to two or three AEDs.

The National Institute of Clinical Excellence (NICE) guidelines from the United Kingdom are based on extensive cost–benefit analyses for the new AEDs, with the following conclusion:

> Although side-effect profiles of newer and older drugs were different, the Committee considered that the evidence was inadequate to support a conclusion that the newer drugs were generally associated with improved quality of life. The Assessment Group's cost-effectiveness analyses showed a high degree of uncertainty around the costs and benefits of these treatments.[23,28]

It is clear from these statements that more and better data are urgently needed so that the best possible decision-making can be undertaken and optimal quality of life can be achieved for patients with epilepsy.

Chapter 118

Starting and Stopping Treatment

Olivier Dulac

Ilo E. Leppik

David W. Chadwick

Luigi Specchio

Introduction

Although single seizures are common events—as many as 9% of the population have at least one seizure during their lifetime[56] epilepsy develops in only approximately one-third of these people. The decision to start antiepileptic drug (AED) treatment is, therefore, a difficult one. It must be based on the risk–benefit ratio, which depends on the psychosocial circumstances of the patient as well as various characteristics of the seizure disorder, including seizure type(s), epilepsy syndrome, and etiology (see Chapters 96,97,98). In addition, when the issue of starting treatment is raised, questions must be addressed regarding with which drug to use, and for how long (see Chapter 117). Which drug is chosen for treatment depends on the type of epilepsy. The risks of epilepsy and the potential benefits of drug treatment must be compared with the risk of adverse effects from the chosen drug. To improve compliance and avoid the perception of treatment "for life," which is so commonly anticipated by lay people, criteria for terminating treatment must be explained to the patient from the onset of treatment.

Evaluating the Need for Treatment

Many issues must be addressed after a first seizure (Table 1). Perhaps most important is the need to ascertain whether the event in question was indeed epileptic, or a nonepileptic event of physiologic (e.g., hypoglycemic, hypoxic) or psychogenic (e.g., pseudoseizure, "hysterical seizure") origin.

The decision to treat can be divided into three general categories: definitely treat, possibly treat, and probably not treat. These are summarized in Table 2. The clinical research supporting these decisions has been developed in a series of studies of adults and children.[4,5,7,14,16,17,36,54,56,57,73,89,106]

History and Examination

Obtaining a complete history is vital, although often difficult during the first contact. The details surrounding the event are crucial, and past medical history must be reviewed. Provoking factors, such as sleep deprivation, drug use, or hypoglycemia, and specific triggers, such as exercise,[81] hot water immersion,[94] or a history of stress or sexual abuse, must also be evaluated. In adolescence, it is important to determine whether the patient previously had overlooked minor seizures, namely myoclonus in the morning, or simple partial seizures. Some of this information may not be readily forthcoming until a good relationship with the patient has been established. A careful neurologic examination must be performed to determine the presence of Todd paralysis or a more permanent deficit. Screens to detect cardiovascular and metabolic disorders or drug abuse should be done as circumstances dictate.

Seizure Origin

Nonepileptic events must be identified (see Chapter 68). It is particularly important to recognize hyperekplexia and paroxysmal cardiogenic disorders (e.g., rhythm disorders, including prolonged QT syndrome, or pulmonary arterial hypertension), because both are treatable syndromes that may produce sudden unexpected death.[58,77,83,117] Slow waves on electroencephalogram (EEG) are a nonspecific abnormality and may be produced by migraine, breath holding, or syncope. Therefore, the EEG is more reliable in determining the type of epilepsy than in confirming the diagnosis of epilepsy itself.

Occasional seizures raise diagnostic issues. Seizures triggered by fever may range from simple febrile seizures to various kinds of epilepsy that range from benign to catastrophic, such as Dravet syndrome (see Chapter 230). Seizures triggered by photic stimulation, such as video games or television, require long-term treatment with AEDs only if the triggering features cannot be avoided.

If the evaluation leads to the conclusion that the seizure was caused by a transient or treatable disorder, AED treatment is not necessary. If the seizure is determined to be of cerebral origin, and no triggering factor is identified, the next step is to determine the risk for and possible consequences of a second seizure. These may differ considerably between individuals. For example, in some children who have benign partial epilepsy with central-midtemporal spikes, even the small risks associated with treatment may not be warranted, because most patients have only a few seizures before permanent remission occurs, and they cause no danger to the brain[40] (see Chapter 236). On the other hand, for adults working in some occupations, a second seizure could result in harmful consequences. Thus, a specific type of epilepsy should be determined based on seizure type, etiology, family history, and social context, but this may not always be possible when the patient is first seen. An EEG may need to be repeated once or several times, especially during infancy and childhood, and include recordings during sleep.

A number of structural lesions are associated with recurrent seizures, including tumors, cortical dysplasia, and vascular malformations. When these are diagnosed after a single seizure, drug treatment should be started without hesitation.

The recurrence risk for absence and myoclonic seizures is clearly higher than for other types of seizures, and patients referred for treatment usually have already had repeated seizures.

Table 1 Issues to be addressed after a single seizure

Was it a seizure?
Was it really the first seizure?
Are there risk factors for a second seizure?
Abnormal EEG?
Abnormal neurologic examination?
Abnormal structural study?
Sibling history?

Should the person be allowed to drive?

Should there be limitations on work?

What are the risks of not treating?

What are the risks of treating?

Table 2 When to start treatment with antiepileptic drugs after a single seizure

Definitely

With structural lesion

Brain tumor, such as meningioma, glioma, neoplasia

Arteriovenous malformation

Infection, such as abscess, herpes encephalitis

Without structural lesion

History of epilepsy in sibling (but not parents)

EEG with definite epileptic pattern

History of previous symptomatic seizure (seizure in the context of an illness or a childhood febrile seizure)

History of previous brain injury, stroke, CNS infection, significant head trauma

Status epilepticus at onset

Possibly

Unprovoked seizure with none of the above risk factors

Probably not (although short-term therapy may be used)

Alcohol withdrawal

Drug abuse

Seizure in context of acute illness (i.e., high fever triggering simple febrile seizure, dehydration, hypoglycemia)

Postimpact seizure (single seizure immediately after an acute blow to the head)

Specific benign epilepsy syndrome, such as benign epilepsy with centrotemporal spikes

Seizure provoked by excessive sleep deprivation (e.g., college student at examination time)

The indication for an anatomic brain imaging study must be considered, depending of the context (see Chapter 79).

An electroencephalogram (EEG) should generally be obtained as soon as possible after the seizure.

Pseudoseizures may be difficult to diagnose and require prolonged video-EEG monitoring.[19]

Modified from from Leppik IE. *Contemporary Diagnosis and Management of the Patient with Epilepsy*, 2nd ed. Newtown, PA: Handbooks in Health Care; 1996.

Provoked or Unprovoked Seizure

Another step in evaluating the need for treatment is to determine if a seizure was provoked or unprovoked. If a clear provoking factor, such as sleep deprivation or drug abuse, can be identified, the patient should be counseled to avoid the

P.1302

precipitating stressors. However, a much more common situation is that in which the initial evaluation fails to reveal a specific cause or provoking factor. The risk for subsequent seizures must then be carefully evaluated. Data from clinical studies[11,16,17,51,54,56] in the last decade have identified specific risk factors obtained from a complete evaluation. These factors can help identify persons who are at higher risk for additional seizures.

Recurrence Risk

In children, the risk for seizure recurrence depends on the type of seizure, EEG characteristics, and cause of the seizure. When a first seizure has a remote etiology, the recurrence risk has been estimated to reach 65%. The presence of EEG abnormalities (44%) significantly increases the risk of recurrence.[106]

Type of Seizure

In the absence of a definable etiology, and with normal interictal EEG findings, the risk of recurrence following a first convulsive seizure ranges from 30% to 60% during 3 years; most seizures recur in the year following the first seizure.[11,56] The presence of EEG epileptiform activity increases the risk of recurrence to 60%[86] this rate is no different if spikes are generalized or focal (58% vs. 61%). Ambrosetto et al.[3] and Hamada et al.[49] found that a first seizure with rolandic spikes had a recurrence risk of 85% in the first year, but 71% of the patients had rare seizures (six or fewer). Seizures are usually simple partial. The clinical severity of a seizure usually has no prognostic value in children. For example, a single prolonged seizure with Todd paralysis and vomiting is often the only expression of benign occipital epilepsy, whereas so-called minor seizures often are seen in the most serious childhood epilepsies. The use of EEG in determining recurrence risk for convulsive seizures is valid for children and adolescents with generalized tonic–clonic seizures, but not for infants. Indeed, in patients with severe epilepsy beginning in the first year of life, interictal spikes may be lacking during the first 2 or 3 years of the disease.[25] On the other hand, 3% of school-age children without any history of seizures or cognitive troubles exhibit spike-waves.[18] These spikes tend to resolve spontaneously, and these children do not develop epilepsy. The incidence of spikes without epilepsy is even higher in children who suffer various types of cognitive troubles, including developmental dysphasia,[85] mental retardation,[9] and autism.[53] For all these conditions, any nonepileptic paroxysmal event that requires an EEG could therefore be misleading.

Other Risk Factors

In one study of adults and some teenagers,[56] the recurrence risk of all patients who had no previous history of an insult to the central nervous system (CNS) (idiopathic single seizure) was 10% at 1 year, 24% at 2 years, and 29% at 5 years. This group was evaluated for further risk factors. Family history was important: Among those who had a sibling with seizures, the recurrence rate was 29% at 1 year and 46% at 5 years, compared with 9% at 1 year and 26% at 5 years for those without a sibling having epilepsy. A history of seizures in parents or first-degree relatives in this study was not associated with a risk above that of others with idiopathic single seizures. Another important predictive factor was the EEG. Patients with a pattern of generalized spike-and-wave discharges had a recurrence risk of 15% at 1 year and 58% at 5 years, compared with 9% at 1 year and 26% at 5 years for those with a normal or nonspecific EEG pattern. Another important factor was the history of a previous acute symptomatic seizure; that is, a previous seizure in the context of an illness or a childhood febrile seizure. These persons had a risk of 10% at 1 year and 39% at 5 years. Age, sex, seizure type, abnormal EEG pattern other than

generalized spike-and-wave, and abnormal neurologic examination did not elevate the risk above others in the idiopathic group.[56] Another group in this study was categorized as *remote symptomatic*. These were patients with a history of head trauma, stroke, CNS infection, or static encephalopathy from birth, with mental retardation or cerebral palsy. These patients had a risk for a second seizure of 26% at 1 year, 41% at 2 years, and 48% at 5 years—markedly higher than the corresponding rates of 10%, 24%, and 29% in the idiopathic group. Within the remote symptomatic group, increased risk for recurrence was noted in those with Todd postictal paresis: 41% at 1 year and 75% at 5 years. If a previous symptomatic acute seizure occurred, the risk for a second seizure was 60% at 1 year and 80% at 5 years. If status epilepticus (SE) or multiple seizures occurred at onset, the recurrence rate was 37% at 1 year and 56% at 3 years.[56] Thus, persons with a previous history of CNS insult, a sibling with seizures, prior acute seizure, or an EEG pattern of generalized spike-and-wave discharge have a significantly higher risk of a second seizure than do patients without those risk factors. Most neurologists would treat these patients with AEDs.

Absence of Other Risk Factors

A more difficult decision arises in the case of patients with none of the additional risk factors, for whom the probability of a second seizure is less than 10% in the first year and approximately 20% by the end of 2 years after the single seizure.[56] Is this rate high enough to warrant the risks of treatment? There is no single answer to this question. The decision regarding whether to treat must be based on an evaluation by the patient and physician of the perceived risks and benefits. The risk of treatment with presently available AEDs is generally low. The risk of a second seizure depends on the lifestyle of the patient. In the case of those who need to drive, or for whom a second seizure may pose a significant risk of injury or loss of esteem, treatment may be indicated. There is a great need to emphasize patient choice and involvement in decision making here. The risk for recurrence is greatest in the first 2 years; thus, if treatment is initiated, it probably can be discontinued after the period of highest risk has passed.

Some brain lesions are clearly epileptogenic and occasionally produce severe epilepsy. However, it is often difficult to evaluate whether AED treatment has the ability to prevent epilepsy—particularly severe epilepsy—or the associated motor or cognitive deterioration.[63] Risk factors for epilepsy have been disclosed for both adults and children. In children, the risk for epilepsy following head trauma is increased when a focal cerebral lesion is evident, as indicated by focal neurologic signs, depressed skull fracture, or cerebral contusion on computed tomographic (CT) or magnetic resonance imaging (MRI) scan, and when seizures occur in the initial stage for more than 24 hours[60] (see Chapter 255).

Neurocutaneous Syndromes

The risk for epilepsy varies in different types of neurocutaneous syndromes. In Sturge-Weber syndrome, the first seizure often consists of SE in the first year of life, related to pial angioma, when the cutaneous angioma involves the first root of the trigeminal nerve.[37] Some authors advise prophylactic treatment from the neonatal period to prevent SE.[116] The question of prophylactic treatment arises with the detection of tuberous sclerosis in utero. The highest incidence of onset of epilepsy is in the middle of the first year of life. To date, no data are available to make any scientifically based decision.

Seizure-Related Risks

In terms of treatment, a number of factors must be considered. For an older adolescent or adult, the most important question is that of driving. In most situations, a single seizure is not considered grounds for restricting driving privileges, but the presence of epilepsy, as demonstrated by the occurrence of two or more seizures, subjects patients to numerous restrictions. Thus, some patients, after reviewing the likelihood of recurrence with their physician, elect to begin treatment after a single seizure. These decisions are difficult, and should never be made unilaterally by the physician for the patient. Rather, the patient should be aware of the risks and benefits of the alternative strategies, and the key elements of the decision must be recorded in the chart. In children, there may be less pressure to treat, and the side effect profile of certain AEDs may be less favorable than in adults.[17,106]

Seizure-related risks include sudden unexpected death, direct physical injury, vehicular accidents, brain damage, and psychosocial consequences.

Sudden Unexpected Death

Sudden unexpected death may occur in various situations (see also Chapter 189). Some data suggest that the risk is significant only for remote symptomatic epilepsy.[55] In a community-based study of mortality in children with epilepsy, Harvey et al.[52] found that mortality was not increased in idiopathic epilepsy compared with the general population. However, they found that, in symptomatic epilepsy, the risk of death was 50-fold higher. Gaitatzis et al.[40] concluded that life expectancy was reduced by up to 10 years. Other studies[69,79] suggest that “subtherapeutic” drug levels, mainly in adolescents with rare seizures and poor compliance, may precipitate cardiac arrhythmia or pulmonary edema. Therefore, the risk for death should not be a factor in the decision to start therapy, although the need for good compliance should be emphasized if treatment is initiated.

The risk for suicide is also higher in patients with epilepsy than in the general population, and some AEDs (i.e., phenobarbital) seem to contribute to this increase.[13]

Physical Injury

Falling during a seizure may produce various physical injuries, and patients may drown when alone, either in the bath or when swimming. In adults, the risk depends on the patient's usual activities and seizure type (e.g., if there is an aura, the patient may be able to anticipate and alleviate danger by shutting off the gas flame or water tap, or stopping the car). A survey of a nonselected series of 1,000 adults with epilepsy disclosed five severe head injuries, 22 fractures, and seven burns.[48] In a group of 138 children with epilepsy followed over a 10-year period, six patients sustained physical injuries caused by seizures, none of which produced sequelae.[122] Four of these injuries were the first manifestation of epilepsy.

The incidence of vehicular accidents resulting from epileptic seizures is difficult to estimate. In one population study,[50] the rate slightly exceeded that of the general population. In another series,[42] one-third of patients with epilepsy had seizures when driving, which produced accidents in half the patients. The type of seizure influences the risk for accident; a third of accidents involve seizures with an aura, and two-thirds of accidents involve seizures that lack an aura. Driving regulations vary from country to country.[65] Although a first seizure does not indicate epilepsy, in countries where efficient public

transportation is not available, the risk for a second seizure may be considered sufficient reason to start treatment.

Brain Damage

Brain damage and sequelae from very brief seizures are very unusual, and prospective studies[34] have failed to demonstrate any brain damage from short seizures. Damage following SE seems to result mainly from the underlying cause of status.[75] The only exception is prolonged convulsive seizures with fever in infancy, because there is a significant risk of brain damage affecting the mesial temporal structures or the whole hemisphere.[2,101] The overall risk for development of SE in patients with newly diagnosed epilepsy is unknown, but it must be very small.

Psychosocial Factors

It is particularly difficult to evaluate the potential impact of drug treatment on the psychosocial consequences of recurrent seizures. The unpredictability of infrequent seizure recurrence can be extremely difficult for patients. Indeed, seizure control has been shown to be inversely related to self-esteem in adolescents.[57] For younger children, seizures that occur exclusively at home, primarily during sleep, usually have no psychosocial impact.

Cognitive Impact

Growing evidence suggests that continuous or nearly continuous spike activity that persists for months may produce cognitive impairment.[111] The type of cognitive dysfunction depends on age and the area of spike predominance: Speech is involved in Landau-Kleffner syndrome,[61,63] and frontal lobe functions may be affected adversely in epileptic encephalopathy with continuous spike waves in slow sleep (EECSWS).[55] Because overt seizure activity may be absent, the question of the epileptic nature of these conditions has long been disputed.[6] AEDs or steroids treatment clearly improve the cognitive course.[105] However, it may be difficult to distinguish such conditions from congenital cognitive disorders, such as dysphasia, in which the occurrence of spike activity on EEG is common. Whether they contribute to the genesis of cognitive dysfunction remains a matter of discussion.[31,32] The distinction between these two conditions is based on clearly deteriorated cognitive abilities.

Treatment Goals

This topic is also discussed in Chapter 98. Antiseizure therapy aims to prevent symptoms related to seizure recurrence. Treatment is predicated on the assumption that recurrent seizures can be prevented with adequate medication. Some studies show that AEDs may not clearly alter the recurrence rate, but this may be related to poor compliance[17,51,54] after an unprovoked first seizure. Only three major randomized studies have evaluated the efficacy of treatment to prevent recurrent seizures after a single seizure. In one study[89] 397 patients aged 2 to 70 years, who had had a single unprovoked generalized tonic–clonic seizure were randomized to receive treatment with an AED or remain untreated. The treated group had a calculated risk of seizure recurrence at 24 months of 25%, compared with 51% for the untreated persons. Thus, limited clinical studies and intuition would suggest that treatment may prevent some but not all patients from having additional seizures. A prospective randomized study[15] showed carbamazepine to be better than no treatment after a single unprovoked seizure in childhood. In a randomized controlled study of 1,443 patients, comparing immediate versus deferred treatment, there was significant delay of time lag to first and second seizure, and to generalized seizure in the immediate treatment arm, but the incidence of seizure freedom did not differ.[73] Despite excellent compliance, only 52% of children[16] and 38% of adults[74] became seizure-free in the first year of treatment.

The highest risk for recurrence occurs among patients with neurologic deficits and partial epilepsy. The most successfully treated patients are children with age-related idiopathic epilepsies[39] that will probably remit. However, it is most likely that this group is one for whom treatment is the least useful in preventing a chronic neurologic disease.

Antiepilepsy therapy aims at preventing both seizure recurrence and the development of epilepsy, particularly intractable epilepsy, as a chronic disease with cognitive and motor deterioration. Open data are conflicting in indicating whether early treatment may help prevent the development of chronic epilepsy in adults. Reynolds et al.,[91,92] Elwes et al.,[35] and Goodridge and Shorvon[46] have shown that the frequency of convulsive seizures tends to increase with time and that the likelihood of seizure control decreases with time. On the other hand, Hauser et al.,[54] Camfield et al.,[16,17] and Annegers et al.[5] found other factors, such as brain lesions, to be more predictive than early treatment. It is still not clear whether the kindling model or mirror foci have any correspondence in human epilepsy.[45] In West syndrome, early treatment may be antiepileptogenic and may prevent the development of pharmacoresistent epilepsy. A retrospective study of West syndrome caused by Down syndrome showed that early treatment significantly reduces the incidence of chronic epilepsy and major cognitive trouble.[33] This could apply to other childhood epileptic encephalopathies as well.

Pharmacoresistance

In some types of childhood epilepsy therapy, the development of intractability seems to be related partly to inadequate medication. The duration of absence epilepsy has been clearly reduced by changing therapy from barbiturates and phenytoin to valproate and ethosuximide.[24] Open data suggest that, in infantile spasms caused by tuberous sclerosis,[21] the risk for developing intractable generalized epilepsy has been greatly reduced by early treatment with vigabatrin. Although partial seizures persist in half the cases, major cognitive effects are prevented.[59] In infants, the highest risk for severe recurrence involves the early seizures,[2] which may produce hemiconvulsion–hemiplegia syndrome.[1,41] The usefulness of medical therapy cannot, therefore, be addressed in terms of an all-or-nothing result.

Frequent Seizures from Onset

Occasionally, seizures occur several times a day from the onset, particularly in children. Such conditions may be the first manifestations of various epileptic syndromes with a wide range of severity. Some are benign and last only a few days, particularly in newborns and infants.[86,118] Others may later prove difficult to treat, such as Lennox-Gastaut syndrome or myoclonic-astatic epilepsy (see Chapter 234). Although rapid aggravation may be sufficiently alarming to require immediate control of ictal events, it is often useful to determine the type of seizures on video-EEG, which helps to determine the optimal strategy for treatment.

P.1305

Recurrent Seizures

In rare instances, particularly in children with benign rolandic epilepsy, seizures pose no risk of brain damage or seizure-related physical injury, and have a very moderate psychosocial impact. In such cases, many authors advise against treatment unless seizures become frequent enough to be annoying to the child and to have psychosocial consequences.[3]

Drug-Related Risks

Dose-related Side Effects

Normal dose-related side effects are specific for each given drug and involve 3% to 30% of patients. The highest risk is usually during the first weeks of treatment, especially for rash with carbamazepine or lamotrigine therapy. This is minimized by slow increases in dose[121] but may be challenging when the patient exhibits dozens of seizures daily. The administration of benzodiazepines or of a ketogenic diet[80] may protect the patient against the traumas due to frequent drop attacks during this escalating period.

Idiosyncratic Reactions

Normal idiosyncratic reactions to AEDs are unpredictable, occurring in 1 in 1,000 to 1 in 50,000 patients. They are specific to the drug administered. Although idiosyncratic reactions cannot be prevented, their severity can be reduced if physicians and patients are alert to the initial signs of the side effect. For example, knowing the first clinical signs of hepatic toxicity caused by valproate (vomiting, somnolence, and increased seizures) seems to have reduced the incidence of lethal cases, because the condition may be reversed with quick drug withdrawal.[62] An informational handout helps the patient or caregiver to recognize these symptoms early.

Proper choice of treatment is a crucial point. An inappropriate choice may precipitate new seizures or even new types of seizures.[67,110] Benzodiazepines may provoke tonic seizures[112]; carbamazepine may trigger or exacerbate myoclonic seizures[109] or atypical absences. Vigabatrin may precipitate myoclonic or absence seizures.[68] An experimental model in the newborn rat showed that this aggravation is not reversible.[87]

Withdrawal Seizures

Seizures may occur on withdrawal of AEDs. Although phenobarbital, carbamazepine, clonazepam, and vigabatrin are supposed to have the highest risk of producing withdrawal seizures, one structured study failed to confirm this.[20] This is a particular problem when drugs are changed during the course of epilepsy after a more accurate diagnosis has been obtained.

Choice of Drug

This topic is discussed more fully in Chapter 117. Once the decision to treat has been made, the most critical choice is which drug to prescribe. Factors that must be considered when choosing treatment are type of seizure, epileptic syndrome and etiology, and tolerability and price of the drug. Price is particularly relevant in regards to the newest generation of drugs, which cost three to five times more than second-generation drugs, and over ten times more than first-generation drugs. In most instances, monotherapy is preferred to polytherapy when treatment is initiated, because the benefits of polytherapy are only moderate[100] and clearly outweighed by the risk for toxicity and even a paradoxical increase in seizure frequency.[107] However, in epileptic encephalopathies with many daily seizures, polytherapy may be relevant from onset when any single medication is known to be ineffective and slow increase is requested, such as in myoclonic–astatic epilepsy.[80] The choice of drug must take into account pharmacokinetic characteristics: *absorption*, which is unpredictable for phenytoin and carbamazepine in the neonatal period,[84,90] and *half-life*, which is age-related, dropping abruptly at the end of the first month of life and then increasing progressively to adult values at 10 years of age. These affect the risk of withdrawal, which may be necessary in case of gastrointestinal problems in infants. Phenobarbital may therefore be useful in infancy, when the half-life is short. Phenobarbital can alter cognitive development in infants and children of school age,[38] thus most authors recommend valproate.[117] The short half-life is also relevant to the cognitive side effects of carbamazepine, because the epoxide–carbamazepine ratio is particularly high in infants.[66] Any suspicion of an inborn error of metabolism involving the urea cycle, β-oxidation, or the respiratory chain should prevent the use of valproate in infants unless no other compound is effective.[62,96] Vigabatrin can cause hyperkinesia in mentally retarded children,[27] and gabapentin may produce behavioral abnormalities.

Evidence is growing that, in infancy and childhood, AEDs are most efficacious when given according to specific epilepsy syndromes and etiology.[120] For example, when infantile spasms are caused by tuberous sclerosis, vigabatrin is significantly more effective and better tolerated than steroid treatment,[22] whereas steroids seem to be more effective than vigabatrin for cryptogenic cases[70,115] but with higher relapse risk.[71] Furthermore, in some cases, such as pyridoxine dependency, which produces agitation and multiple seizure types including myoclonus, partial fits, and spasms from the first hours of life,[78] specific treatment is required. However, syndromic diagnosis is often difficult to determine from the first seizures, particularly in the various generalized epilepsies of childhood.[29] In the absence of an accurate syndromic diagnosis, it is important to minimize the risk of worsening a condition through drugs. Thus, the treatment should be based on the seizure type. Results of clinical trials and extensive experience suggest that valproate is best for absence, myoclonic, and other generalized seizures and that carbamazepine is the best drug for seizures of partial onset. However, in infancy and childhood, the possible switch from partial to generalized epilepsy (i.e., to West syndrome or EECSWS; see Chapters 229 and 244) should be considered before carbamazepine is administered.

Partial Seizures

Prospective studies have failed to demonstrate any difference among phenytoin, carbamazepine, phenobarbital, and primidone in controlling secondarily generalized tonic–clonic seizures in adults. However, primidone and phenobarbital produce more troublesome side effects.[74] Carbamazepine was more successful than phenytoin in completely controlling partial seizures (43% vs. 26%).[74] Preliminary studies by Shakir et al.,[102] Wilder et al.,[119] and Turnbull et al.[113] showed no difference between valproic acid and phenytoin in treating partial seizures, but the former was better tolerated and produced fewer problems related to variable pharmacokinetics. Callaghan et al.[14] prospectively randomized patients with newly diagnosed epilepsy to carbamazepine, phenytoin, or valproic acid, and could not demonstrate any difference in terms of seizure frequency. No differences were noted between carbamazepine and valproate in the long-term control of seizures in adults,[93] although there was a trend to earlier control of partial

P.1306

seizures with carbamazepine. This was interpreted by the authors to be a consequence of the slower escalation of valproate dose relative to carbamazepine.[114]

Primary Generalized Seizures

Primary generalized seizures mainly affect children and adolescents. Valproate seems to be the most valuable first-line drug, because it is effective in absence, myoclonic, and tonic–clonic seizures.[30] According to some authors, childhood absence seizures require treatment with ethosuximide, because the toxicity of valproic acid is higher in children than in adults, and absence seizures are usually the only type of seizure experienced by these patients.[97] The three major risk factors for hepatic fatality are infancy, polypharmacy, and mental retardation, none of which are an issue in childhood absence epilepsy.[26] Recent studies[62] do not report any case of valproate-induced liver failure in patients with childhood absence seizures, and this drug is widely used in Europe as first-line therapy for this population. Juvenile absence seizures are associated with a higher risk for later occurrence of generalized tonic–clonic seizures. Therefore, some authors[76] advise that valproate be used in treating juvenile absence epilepsy, because ethosuximide has been said to occasionally trigger convulsive seizures. However, this remains to be demonstrated.

Isolated tonic–clonic seizures are often the mode of onset of idiopathic generalized epilepsy. Because of the risk of carbamazepine triggering myoclonic seizures, valproate is usually preferred, even if the full-blown syndrome is not present.

Seizure Types that May Be Misleading

It must be emphasized that, in some instances, the type of first seizure may be greatly misleading. In children, atypical absence seizures may be caused by a syndrome of EECSWS, which responds poorly to valproate and may be worsened by lamotrigine[19] and requires treatment with benzodiazepines, ethosuximide, sulthiame, or steroids.[10,72,95] The same syndrome may be precipitated by carbamazepine given for a first seizure of partial benign epilepsy.[103] In infants, severe myoclonic epilepsy often begins with unilateral or partial motor seizures, and may be worsened by carbamazepine. In the first year of life, only patients with proven localization-related epilepsy (based on focal neurologic defect and neuroradiologic data) should be given carbamazepine.

Idiopathic generalized epilepsy with photosensitivity in children or adolescents may produce visual illusions (e.g., micropsia, macropsia), elementary hallucinations, or even partial motor seizures that are often considered to be an indication of partial epilepsy; these patients are erroneously given carbamazepine or phenytoin.[28] For childhood and adult cryptogenic partial epilepsies and for infantile, childhood, and adult symptomatic partial epilepsies, the drug of choice is a sodium channel blocker. Valproate is preferred in other cases, unless a precise syndromic and etiologic diagnosis indicates more specific compounds, such as vigabatrin for infantile spasms, benzodiazepines for EECSWS, ethosuximide for infantile absence seizures, or lamotrigine for Lennox-Gastaut syndrome. In other words, valproate is a wide-spectrum first-line drug, whereas other agents should be reserved for more specific indications.

Initiation of Treatment

Electroencephalogram

Before initiating treatment, an EEG should be performed, and it should include sleep studies. When clinical and EEG characteristics of an idiopathic epilepsy are present, no neuroradiologic investigation is required. In all other cases, and in most infants, radiologic investigation is indicated, usually before any drug treatment is given, because etiology disclosed by the result of radiology may contribute to the choice of drug.

EEG Spikes Without Seizures

In school-age children, spikes may be found on routine EEGs recorded for evaluation of various nonepileptic disorders, including headache and syncope, or following head trauma. Of nonepileptic children of school age, 2% to 3% may exhibit focal spikes or generalized spike-and-wave discharges; the risk for seizures in these children is very low—approximately 10%.[18,82] When seizures do occur in this population, they are usually benign. Therefore, there is no indication in asymptomatic patients to start treatment with AEDs simply because an EEG demonstrates epileptiform activity.

Blood Tests

Routine blood tests (complete blood cell count, liver function tests) should be obtained before treatment is initiated. In infants, clinical and biologic signs of inborn errors of metabolism should be sought. Valproate-associated hepatotoxicity is known to occur in patients with such disorders, but routine blood sampling, measurement of blood levels of AEDs, and repeated EEGs are usually not required for these patients unless clinical signs of toxicity develop.[15]

Adherence

From the beginning of treatment, an effort must be made to promote adherence. Each patient or caregiver should have a good understanding of the disease, the consequences of seizures, and knowledge of the potential side effects of drugs. Preferably, this information should be given to the patient both orally and in writing. Patients should also be urged to keep track of their seizures with a diary. To aid in adherence, an AED should be given once or twice a day, with midday administration avoided. Time of administration does not need to be strict, and the patient should never be awakened to take medication. Patients or caregivers must know that, if a dose is missed, it should be taken as soon as possible after this omission is noticed, provided it is noticed before the time of the next dose. Patients should also be informed about the duration of treatment, or the criteria for terminating treatment. A follow-up visit should be planned 4 to 6 weeks after initiating treatment to assess adherence, tolerability, and efficacy. Treatment may have to be changed or the diagnosis reconsidered at that point.

Termination of Treatment

The decision to stop treatment must be made as carefully as the decision to start. According to Schmidt and Gram,[99] treatment can be withdrawn when adults are seizure-free for 2 to 5 years or longer, and have a normal neurologic examination, normal IQ, and normal EEG. A number of studies have evaluated the recurrence rate of seizures after treatment has been

P.1307

stopped following remission. In one study,[23] adult patients who had been seizure-free for at least 4 years were given the option of withdrawing from therapy. Of 62 patients who withdrew, 15 (24%) had recurrent seizures; of 157 who declined withdrawal, 10 (6%) had recurrent seizures. In another study,[88] 1,013 patients were prospectively randomized to withdrawal after being seizure-free for more than 2 years. Of those assigned to continuing treatment, 12% had seizures, compared with 41% in the slow withdrawal group. In general, factors leading to successful withdrawal were single seizure type, normal findings on neurologic examination, and normal findings on EEG.[88] One literature review of controlled trials comparing early (less than 2 years seizure freedom) versus late (over 2 years) withdrawal found seven eligible controlled trials for pediatrics but none for adults.[108] Early discontinuation was associated with partial seizures and an abnormal EEG. The pooled relative risk was 1.3 (95% confidence interval [CI], 1.02 to 1.7). In a meta-analysis regarding drug withdrawal in children, Berg and Shinnar[8] found a relapse rate at 1 year of 0.25 (95% CI, 0.21 to 0.30) and at 2 years 0.29 (95% CI, 0.24 to 0.34).

Risk factors statistically related to seizure recurrence in the 70 children of one study were greater than 10 seizures before seizure control, an abnormal EEG in the year before AED discontinuation, presence of focal neurologic signs and/or mental retardation, and presence of a mixed seizure pattern.[44] In one study of 264 children, Shinnar et al.[104] found on multivariate analysis significant factors in the idiopathic group, including age at onset above 12 years, a family history of seizures, the presence of slowing on the EEG prior to medication withdrawal, and a history of atypical febrile seizures, to be correlated to seizure relapse. In the remote symptomatic group, significant predictors of outcome included age at onset older than 12 years, moderate to severe mental retardation (IQ <50), and a history of atypical febrile or absence seizures.

The classical mantra of 2-year seizure-freedom before considering withdrawal has been challenged. Comparing relapse rate after 6 months versus 1 year of seizure freedom in a group of 154 children, Geerts et al.[43] showed that patients treated for 6 months had relatively more relapse (59%) than those treated for 1 year (51%). The issue is again that such studies should not pool different types of epilepsy. Indeed, the consequences of relapse following withdrawal are not the same with idiopathic or symptomatic epilepsy. Even if the relapse rate is high for focal idiopathic epilepsy, the consequences of a relapse are benign.

Reviewing 84 cases of postsurgical drug discontinuation, Schiller et al.[98] found that recurrence was facilitated by normal preoperative MRI, but postoperative EEG and seizure-free duration after surgery were not predictive of seizure outcome after AED withdrawal.

One question is the risk of intractable epilepsy following AED treatment withdrawal. One study followed 40 children who experienced relapse following withdrawal after 2 years of seizure freedom.[12] Half the relapses occurred within the first 6 months of withdrawal. No patient experienced SE. At the end of 5.9 years median follow-up, 40% were seizure-free for over 1 year without medication, 30% were seizure-free for over 1 year with medication, and 30% failed to be seizure-free for over 1 year. Age at onset (if over the age of 5) combined with normal intelligence was predictive of an excellent outcome.

Physicians are often poor judges of the degree of risk that is acceptable to a particular family, and individual families view estimates of seizure recurrence quite differently.[47]

Summary and Conclusions

An accurate clinical description of the seizure is mandatory to determine its epileptic nature and its type. It may be more devastating to omit therapy for treatable nonepileptic events than for epilepsy at the onset. Although interictal EEG must be used cautiously in the diagnosis of epilepsy in children, when combined with a seizure type and age of onset, it may permit a syndromic diagnosis.

A single seizure in adults or children usually does not require treatment unless there is evidence of a brain lesion or major abnormalities on the EEG, particularly generalized spike-and-wave discharges. However, a first nonfebrile seizure between 2 and 5 years may be the first manifestation of epilepsy of myoclonic–astatic type that will require vigorous treatment to prevent the development of SE or epileptic encephalopathy. On the other hand, rolandic spikes in children do not indicate the need for drug treatment unless seizures are frequent and upsetting to the family. If a second seizure would be hazardous to an adult, for reasons related to employment or driving, treatment may be warranted after a first isolated seizure, provided that excellent compliance can be anticipated and the seizure is not related to precipitating factors such as sleep deprivation.

The choice of drug is of the utmost importance and depends on the etiology of the seizures and the type of syndrome or, if the syndrome cannot be determined, the type of seizure. Specific syndromes require specific drugs, although valproate is often most suitable for children because it has a broad spectrum of activity and does not usually exacerbate seizures or lead to cognitive impairment. Children with a second seizure 1 or 2 years after the first may not require treatment. Cognitive deterioration associated with continuous spike-and-wave discharges in slow sleep requires treatment even if the patient has not exhibited an overt seizure.

Chapter 119

Routine Monitoring for Safety and Tolerability During Chronic Treatment with Antiepileptic Drugs

John M. Pellock

L. James Willmore

Michael D. Privitera

Introduction

The goal of epilepsy therapy is to control seizures completely without adverse drug effects. This objective is frequently compromised when complete seizure control cannot be achieved because of secondary drug toxicity.[25,26] Dose-related neurotoxic effects of antiepileptic drugs (AEDs) are bothersome, but with patient education they can be minimized and often tolerated. Part of good patient management is to establish a therapeutic alliance with active patient involvement. Toxic effects of drugs provide one endpoint, independent of blood level monitoring, to allow clinical titration to efficacy. However, idiosyncratic effects of drugs, although rare, may be life-threatening. Some have suggested that monitoring programs be established to detect patients at risk for serious systemic toxicity. For example, DeVries[6] proposed that regularly scheduled monitoring of drug blood levels should be embedded within a program of data collection that includes hematologic assessment, routine serum chemistry studies, and urinalysis. Pharmaceutical companies endorsed this approach by incorporating its elements within standard recommendations for drug use in publications in the United States (*Physicians' Desk Reference*[30]) and Canada (*Compendium of Pharmaceuticals and Specialties*[17]). For many clinicians, such reference sources have defined the medicolegal "standard of practice." In contrast, scientific criteria based on available evidence fail to support routine monitoring; such archival data rarely predict the occurrence of serious drug reactions. Although habits and practice vary both within the United States and in other countries, routine assessment of biochemical and hematologic function should at least be obtained at baseline.[28]

Adverse Effects and Standard of Care

When a drug is selected for use, the physician must review relative risks with the patient, and this discussion must be documented in the patient's record. This process of review and information exchange forms the basis for establishing informal informed consent. Patients must understand the goals of treatment, criteria that will be used to measure success, the process of trial and error in drug selection, and how drugs will be changed, if that becomes necessary. Common dose-related side effects are useful as an aid to management, but they also interfere with treatment. The process is one of negotiation. Patients must also know the nature of side effects, what may have to be tolerated, and how the physician will use side effects in the titration process. Serious, life-threatening, idiosyncratic effects of a selected drug should be reviewed clearly but within the context of rarity. Although patients must participate in an informed way in this therapeutic alliance and understand the need to report promptly should symptoms develop, it is the responsibility of physicians to identify those without advocates or with impaired ability to communicate. For these special patients, a specific monitoring strategy may have to be formulated, something that is not needed by most patients with epilepsy.

Packaging information refers to various side effects. *Frequent* adverse events are those occurring on one or more occasions in at least 1/100 patients; *infrequent* adverse events are those occurring in 1/100 to 1/1,000 patients; *rare* events are those occurring in <1/1,000 patients. Events of major clinical importance are described in the Warnings and Precautions sections.

Efficacy and adverse effects of drugs are important considerations in making treatment decisions, and legal actions from adverse effects have had important consequences on treatment, monitoring, and documentation of patient care.[46] Several classic legal cases involving AEDs have involved determinations of medical negligence in dosing and drug selection and questions about informed consent. The drug regulation process is described further in Chapters 142 and 143 on the roles of the U.S. Food and Drug Administration and European regulatory agencies, respectively.

Standards of care in the United States are derived from expert opinion, source publications, or referreed articles that form the basis for evidence-based medicine. Textbooks of medicine and published practice guidelines are another source for such information. In the United States, both the American Academy of Neurology and the Office of Quality Assurance and Medical Review of the American Medical Association publish treatment guidelines.

In medical malpractice or medical negligence cases, determining the standard of care for a particular treatment is of utmost importance.[46] Standard of care extends not only to treatment, but also to the methods used to obtain informed consent. In litigation, the standard of care is usually established by expert testimony using source publications or articles from refereed publications. One such reference source is the *Physician's Desk Reference* (PDR).[3,30]

As with any area of law in which states are given authority, there can be differences from state to state in the exact

manner by which standard of care is determined. These differences are particularly evident with regard to the evidentiary force of the medication package insert and printed information contained in the PDR. States tend to use the PDR and package inserts in one of three ways. Although the differences are not categorical, it is nonetheless useful for educational and discussion purposes to consider them separately. In the first group are states that consider the PDR and package insert as establishing the standard of care [*Haught v. Maceluch*, 681 F.2d 291, reh'ing denied, 685 F.2d 1385 (5th Cir. 1985)].[3] In the second group are states in which the package insert and PDR are considered evidence of standard of care and deviation from the prescribed directions may establish a prima facia case for negligence. In such cases, however, a physician may generally introduce evidence to support his or her basis for using a medication in ways that deviate from the detailed description presented in the PDR and package insert (*Mulder* rule and echo of *Mulder*; see following discussion) [*Thompson v. Carter*, 518 So. 2d 609, 613 (Miss. 1987)]. In *Mulder v. Parke Davis and Co* [181 N.W. 2d 882 (Minn 1970)], the court held that any deviation in drug use from that specified in the PDR requires a physician to explain the reason for that deviation. This requirement is now known as the *Mulder* rule. In light of this, it would seem prudent for the physician who plans to use a drug in ways that vary from recommendations in the PDR or package inserts to record the reasons for doing so and the relevant plan for management in the medical record. In the third group of states, the PDR and package insert as such are given little credence and, in some jurisdictions, are inadmissible without supporting expert testimony. This is known as the "echo" of the *Mulder* rule. [*Spensieri v. Lasky,* 723 N.E. 2d 544 (NY 1999)].[3]

Legal action has also involved issues of informed consent. In *Serigne v. Ivker*, a plaintiff alleged that informed consent had not been obtained because of lack of disclosure of teratogenicity. The court found that the plaintiff had failed to establish a connection between malformations and phenytoin and that informed consent did exist [*Serigne v. Ivker*, 808 So. 2d 783 (La. App. 4 Cir. 2002)]. In the case of *Spano v. Bertocci* [299 A.D. 2d 335, 749 N.Y.S. 2d 275 (N.Y.A.D. 2002)], the plaintiff claimed lack of informed consent based on failure to disclose the teratogenic effects of valproic acid. Trial and appellate courts found that informed consent had been obtained because of the plaintiff's previous knowledge regarding the dangers involved in using valproate during pregnancy.[46]

One landmark decision illustrates the diligence required to provide information for patients with child-bearing potential is well illustrated. In *Harbeson v. Parke-Davis,* claims of failure of informed consent causing wrongful birth and wrongful life were the cause for action when a woman delivered children with fetal hydantoin syndrome. In this case, the court stated that the physicians had a duty to "exercise reasonable care in disclosing 'grave risks' of (any) treatment" that they were advocating. Apparently, the physician had failed to do a literature search that would have uncovered the dangers of using phenytoin during pregnancy, and had this been done, it would have allowed the physician to inform the patient [*Harbeson v. Parke-Davis*, 656 P. 2d 483 (1983)].[46]

Serious skin reactions, including Stevens-Johnson syndrome, have also raised issues of informed consent. In *Shinn v. St. James Mercy Hospital*, the plaintiff claimed that disclosure of serious skin reactions to phenytoin had not been provided. In this case, the court stated that it is not necessary to disclose all adverse effects to a patient, but rather only the most common ones. The court also found that given the patient's particular medical circumstance, the patient would not reasonably have declined treatment even if adverse effects had been delineated. [*Shinn v. St. James Mercy Hospital*, 675 F.Supp 94 (W.D.N.Y. 1987)]. Similarly, in *Williams v. Ciba-Geigy Corporation*, the court found that the warnings in the PDR and package insert diminished the "danger-in-fact" of the medication. The court stated "no reasonable trier of fact could conclude that this …medicine is unreasonably dangerous per se" [*Williams v. Ciba-Geigy Corporation,* 686 F. Supp 573 (W.D.La. 1988)].[46]

Documentation is critical. In *Fritz v. Parke Davis & Co.* a patient treated with phenytoin developed hepatic failure. At trial, the court originally found for the plaintiff. On appeal, that decision was reversed. The appellate court stated, "Viewing the record …the skill and care exhibited by defendant's physicians' diagnosis and treatment were marked by devoted diligence and attention and were wholly consistent with the professional skill …employed by other physicians in treating and controlling …the complex disease of epilepsy" [*Fritz v. Parke Davis & Co.*, 152 N.W. 2d 129 (1967)].[46]

Errors in the use of AEDs that amount to negligence have been the basis of litigation. In *Hendricks v. Charity Hospital of New Orleans*, a patient was to receive Dilantin 500 mg/d, but a prescription was written for 500 mg three times a day. Judgment was for the plaintiff. [*Hendricks v. Charity Hospital of New Orleans* 519 So. 2d 163 (La. App. 4th Cir. 1987)]. High plasma levels of Dilantin were associated with a patient's death, and judgment for the plaintiff occurred in this case as well [*Martin v. Life Care Centers of America Inc.* (No. 95-4124-B, 117th Judicial Dist. Ct. Nueces County, TX, April 1998)]. One court found for the plaintiff in a case of failure to diagnosis pancreatitis associated with the use of valproate [*Pester v. Graduate Hospital* (No. 87-05-00357, Court of Common Pleas, Philadelphia, PA Oct 1992)].[46]

Monitoring Blood Levels of Antiepileptic Drugs

There can be no question that therapeutic drug monitoring has been a major advance in helping to determine compliance, compensating for physiologic (age, pregnancy) or disease-related (uremia, hepatic failure) alterations in drug pharmacokinetics, and avoiding undesirable drug interactions (see Chapter 103). In general, however, routine blood level determinations are performed too frequently and often without a specific question in mind. It is important to remember that drug levels must be interpreted in light of a patient's clinical progress. In the clinical setting, therapeutic effectiveness is best judged by two measures: (a) seizure frequency and (b) the appearance of adverse effects. All too often, however, the blood level, rather than the patient, becomes the goal of treatment: therapy must be optimal if a drug's blood concentration is in the "therapeutic range." This oversimplified view can have undesirable consequences. For example, it is not uncommon for low or "therapeutic" blood levels to be cited as evidence against a patient's complaint of side effects. Conversely, drug dose is frequently reduced because of a "toxic" level, even if there has been good seizure control and no indication of adverse reactions. Finally, meaningful interpretation of blood levels requires knowledge about the timing of a blood sample, the dosing schedule, the interval since the last dosing change, and the clinical situation with

regard to complaints about possible side effects and seizure frequency.

Laboratory Monitoring During Chronic Antiepileptic Drug Treatment

Indications for Routine Laboratory Testing

Physicians should perform baseline studies before the initiation of AED treatment (Table 1). There are two main reasons for this. First, they may help to identify previously unsuspected illness. Second, availability of baseline laboratory data in the medical record provides a basis for comparison with subsequent laboratory studies, especially those obtained because of developing symptoms.

Table 1 Blood monitoring in patients with epilepsy

Routine
CBC, differential, platelet count
Serum chemistry: glucose, BUN, electrolytes, calcium, phosphorus, magnesium, creatinine, urate, iron, cholesterol, bilirubin, alkaline phosphatase, AST, ALT, total protein, albumin, globulin
PT, PTT
High-risk patients
Lactate, pyruvate, arterial blood gases
Urinary metabolic screen: organic acids
Ammonia
Carnitine
Specific tests for suspected underlying disease

ALT, alanine aminotransferase; AST, asparate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood cell count; PT, prothrombin time; PTT, partial thromboplastin time.
Source: From Pellock JM, Willmore LJ. A rational guide to routine blood monitoring in patients receiving

antiepileptic drugs. *Neurology.* 1991;41:961–964; with permission.

Two prospective studies have evaluated the efficacy of routine blood and urine screening in patients being treated long term with AEDs. Camfield et al.[4] performed blood and urine testing in 199 children to evaluate liver, blood, and renal function at initiation of therapy and at 1, 3, and 6 months. The screening studies continued to be repeated every 6 months thereafter. There were no serious clinical adverse effects in the patients treated with phenobarbital, phenytoin, carbamazepine, or valproate. In 6% of children, studies were repeated because of abnormal but clinically insignificant results, and in 2 children therapy was stopped unnecessarily. The authors concluded that routine monitoring provided no useful information and sometimes led to unnecessary responses. A second study of 662 adults treated with carbamazepine, phenytoin, phenobarbital, or primidone failed to detect significant abnormalities in laboratory data during 6 months of monitoring.[23] The authors concluded that routine screening was neither cost-effective nor of significant value for asymptomatic patients. In a double-blind, controlled trial, exposure of 480 patients to either carbamazepine or valproate failed to demonstrate the usefulness of routine laboratory monitoring.[22]

After baseline assessment, laboratory tests should be repeated only to answer specific questions. “Routine” blood monitoring is both costly (estimated at >$400 million/yr in North America in 1998) and ineffective in avoiding serious toxicity.[5] The assumption that hepatic failure, aplastic anemia, or other severe drug reactions can be averted by frequent blood tests is not supported by scientific data.[5,28] A case can be made that asymptomatic patients on monotherapy do not require regular blood tests if initial screening laboratory studies were negative. On the other hand, it is important to try to identify patients, at onset of therapy, who are at increased risk for adverse drug reactions. These include patients with known or suspected metabolic or biochemical disorders, a history of previous drug reactions, and medical illnesses affecting hematopoesis or liver and kidney function. Blood monitoring is also indicated in young children receiving polytherapy that includes valproate (see later discussion) and in patients who are unable to communicate symptoms and their health status effectively.

Common Laboratory Findings

Minor elevations in liver aspartate aminotransferase (AST or SGOT) and alanine aminotransferase (ALT or SGPT) occur in about 25% to 30% of patients with epilepsy, and these neither correlate with clinical symptoms nor predict development of hepatitis or liver failure.[22,23,28] Glucose tolerance test (GTT) levels seem to be particularly useless as indicators of clinically significant liver dysfunction in persons with epilepsy.[15] Although routine monitoring of measures of he-patic function have revealed elevated liver enzymes in 5% to 15% of patients treated with carbamazepine, <20 patients with significant hepatic complications were reported in the United States from 1978 to 1989.[38] There were even fewer reports of carbamazepine-induced pancreatitis.

Nearly 20% of patients taking carbamazepine develop a benign leukopenia, as indicated by white blood cell (WBC) counts <4,000/mm.[12,24] A few patients will have WBC counts that drop transiently below 2,500/mm.[12] The risk of developing aplastic anemia is not increased in this group, and such patients do not have increased rates of infections or other possible complications that might be attributed to leukopenia. Leukopenia is less common with oxcarbazepine.[15]

Table 2 Idiosyncratic reactions to antiepileptic drugs

Reaction	CBZ	ETH	FBM	GBP	LEV	LTG	PGB	PB	PHT	TPM	TGB	OXC	ZNS	VPA
Agranulocytosis	X	X	X					X	X					X
Stevens-Johnson syndrome	X	X				X		X	X					X
Aplastic anemia	X	X	X						X					X
Hepatic failure	X		X					X	X					X

Allergic dermatitis	X	X	X	X		X		X	X	X	X	X	X	X
Serum sickness	X	X						X	X					X
Pancreatitis	X								X					X

CBZ, carbamazepine; ETH, ethosuximide; FBM, felbamate; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; OXC, oxcarbazepine; PB, phenobarbital; PGB, pregabalin; PHT, phenytoin; TBG, tiagabine; TPM, topiramate; VPA valproate; ZNS, zanisamide.
Source: Modified from Willmore LJ, Pickens A, Pellock JM. Monitoring for adverse effects of antiepileptic drugs. In: Wyllie E, ed. *The Treatment of Epilepsy*. Philadelphia: Lippincott Williams & Wilkins; 2006:735–745.

Hyponatremia (<135 mEq/L) is less common in patients taking carbamazepine than in those taking oxcarbazepine,[43] in whom the incidence was 2.5% in controlled trials, but was higher in subsequent studies, especially in the elderly.[11] However, only 2.5% of patients have serum sodium values <125 mEq/L, the level at which symptoms usually start to appear. Most patients are asymptomatic.

Life-threatening Syndromes

Although dose-related toxicity is both common and also useful as a target in titration to efficacy, drug-induced diseases are rare. Nearly all the commonly available AEDs are associated with idiosyncratic reactions (Table 2). Severe adverse reactions include aplastic anemia, agranulocytosis, hepatitis, pancreatitis, exfoliative dermatitis, and bullous skin reactions. The frequency of these reactions varies with each drug, the number of concomitant drugs, age and general health of the patient, and the presence of genetic metabolic

P.1314

and immunologic disorders. Monitoring plans should take into account the rarity and unpredictability of life-threatening reactions, most of which have a frequency of <1/50,000 (see later discussion).[37]

Aplastic anemia or agranulocytosis occurs in 2/575,000 patients, with a mortality rate of approximately 1/575,000 treated patients per year.[38] Only 4 of the 65 cases of agranulocytosis or aplastic anemia occurred in children. A similar epidemiologic picture is noted with felbamate-associated aplastic anemia. No blood or urine test clearly defines persons at risk. Young age tends to be protective, whereas previous exposure to AEDs (and perhaps other drugs), hypersensitivity/idiosyncratic reactions, cytopenia, history of autoimmune disorder (especially lupus erythematosis), and <1 year of treatment are risk factors.[26,27]

Patients developing drug-related hypersensitivity syndrome do so early in treatment using aromatic AEDs.[10] Cross-hypersensitivity between phenytoin and carbamazepine is well recognized,[31,32,40] and a history of prior hypersensitivity to other drugs is a risk factor for lamotrigine-associated rash[13] and felbamate-related aplastic anemia.[27] The AED hypersensitivity syndrome includes rash (which may or may not be pruritic), fever, eosinophilia and, sometimes, lymphadenopathy, exfoliative dermatitis, facial edema, and multivisceral involvement including life-threatening hepatic necrosis.[21,36] The DRESS syndrome (drug rash with eosinophilia and systemic symptoms) is caused most often by AEDs and is probably synonymous with anticonvulsant hypersensitivity syndrome.[1,29] Hypersensensitivity reactions are immune-mediated responses in persons susceptible to such effects.[20,21,31] Although treatment remains controversial, everyone agrees that administration of suspected AEDs should be stopped immediately.[10,12,22]

Table 3 Hepatic fatality rates associated with valproate

	1978–1984		1985–1986	
Age (yr)	**Polytherapy**	**Monotherapy**	**Polytherapy**	**Monotherapy**
0–2	1/500	1/7,000	1/800	0

3–10	1/6,500	1/9,000	1/7,000	1/21,000[a]
11–20	1/11,500	0	0	0
21–40	1/16,500	0	0	0
41+	1/38,500	0	0	0
Overall	1/6,500	1/37,000	1/20,000	1/118,000

[a]One fatality occurred in 1985 and was reported in 1988.

Identification of High-risk Patients

Although the mechanisms are not yet fully understood, there is growing evidence that rash and hypersensitivity syndromes are related, at least in some cases, to pharmacogenetic variation in drug biotransformation.[39] This is discussed more fully in Chapter 106. A genetic abnormality in arene oxide metabolism may be present in patients at higher risk for some types of adverse responses, such as hepatitis,[41] but a screening test for such defects is not yet available. In patients in whom exfoliative dermatitis developed alone or as part of systemic hypersensitivity, abnormal blood test results were not found until clinical symptoms developed.[39] At this time, routine monitoring, as commonly practiced, does not allow anticipation of life-threatening effects associated with treatment using carbamazepine, phenytoin, or phenobarbital.[37]

Dreifuss et al.[7,8] emphasized the importance of identifying high-risk patients before instituting treatment with valproate. Most fatalities occurred in the first 6 months of treatment, but hepatotoxicity developed in some patients up to 2 years after valproate was started. In children <2 years of age who were receiving polytherapy, the risk for fatal valproate hepatotoxicity was 1/500 to 1/800. Negative predictors were identified as well. Patients treated with valproate alone were at negligible risk if they were >10 years of age and did not have indications of underlying metabolic or neurologic disorders. Children at intermediate risk were between the ages of 2 and 10 years on monotherapy, as were all patients requiring polytherapy. The risk for fatal valproate hepatotoxicity continued to decline with increasing age, even with polytherapy, after the first decade of life (Table 3).

The majority of patients with fatal valproate-related hepatic failure have had neurologic abnormalities, including mental retardation, encephalopathy, and decline of neurologic function. Two of four patients >21 years of age had degenerative diseases of the nervous system.[7,8] Another report found that 9 of 16 cases of hepatic fatality had neurologic abnormalities.[35] When patients were divided into groups by age at the time of fatal reactions, no statistically significant pattern of vulnerability was revealed. However, in one series, all patients in the 11- to 20-year age group were neurologically abnormal.[8] Specific biochemical disorders associated with valproate hepatotoxicity include urea cycle defects, organic acidurias, multiple carboxylase deficiency, mitochondrial or respiratory chain dysfunction, cytochrome aa_3 deficiency in muscle, pyruvate carboxylase deficiency, and hepatic pyruvate dehydrogenase complex deficiency in brain.[14,18,34,47] Clinical disorders associated with valproate toxicity include GM_1 gangliosidosis type 2, spinocerebellar degeneration, Friedreich ataxia, Lafora body disease, Alpers disease, and myoclonic epilepsy with ragged-red fibers (MERRF) syndrome.[42] Valproate should be avoided in patients with such disorders because of the increased risk of hepatotoxicity.

At this time, high-risk patients must generally be identified by clinical assessment. Medical history, health status at the initiation of AED treatment, and both patient and physician awareness of clinically important symptoms and signs are more likely to suggest the need for further evaluation. Clinical monitoring, although not perfect, is superior to routine laboratory screening.[44,45] A modification of recommendations regarding

P.1315

routine monitoring has been suggested by the Canadian Association for Child Neurology.[5]

Although it has been the practice of most clinicians to order screening studies routinely, the key to treatment monitoring is patient and parent education and counseling. Everyone involved with a patient must be aware of potential complications and the symptoms that might herald the occurrence of a serious adverse event. Furthermore, physicians must be willing to evaluate patients on an urgent basis when changes are reported that suggest the development of significant adverse drug reactions. Such symptoms include bruising, bleeding, rash, abdominal pain, vomiting, jaundice, lethargy, coma, and deterioration in seizure control. Deterioration of seizure control or marked shortening of seizure-free interval is a cause for review of treatment and survey for the presence of adverse drug effects. The development of any of these potentially ominous symptoms is the best indication for deciding whether laboratory evaluation is needed.

Monitoring Strategies for New Drugs

As new drugs are developed and marketed for treating patients with epilepsy, physicians have an obligation to review source documents and devise a strategy for treatment and monitoring. Treatment indications arise from trials involving selected patients. Age ranges are defined, epilepsy syndromes and seizure types are identified, and patients with associated illnesses are generally excluded. Protocols typically expose limited numbers of patients to the protocol drug for a finite period. During such studies, patients undergo intense scrutiny to identify treatment-related symptoms or adverse effects. These restricted study designs and relatively small numbers of patients may fail to uncover drug interactions or recognize serious adverse effects. Reference should be made to individual chapters concerning specific AEDs for a discussion of specific idiosyncratic life-threatening adverse effects.

Because data are limited, initiation of treatment with a newly available drug requires special caution. Although the process of informed consent remains informal, it is more important than ever to give patients as much information as possible. Industry-produced materials may be useful, and physicians should consider providing copies of package inserts supplemented by material they themselves prepare describing how the drug is to be used and any monitoring strategy planned. Although the guiding principle in monitoring patients being treated with established drugs should be to limit use of routine chemical and hematologic studies, based on evidence that such monitoring is ineffective in detecting the occurrence of serious adverse events, the principle may need to be modified with a newly introduced drug, depending on the information available. The following approach may be useful. As with the established drugs, baseline laboratory data should be obtained. Communication is essential, and the patient and/or family must agree to keep the physician informed, and the physician must facilitate such communication. Company inserts and Food and Drug Administration advisories or requirements may specify chemical and hematologic monitoring. Although recommendations may seem excessively conservative, it is best to follow such guidelines until a larger experience has been obtained and postmarketing data become available. This admonition is best illustrated by the experience reported following introduction of felbamate and, more recently, vigabatrin. Only following the initial reports of visual filed deficits associated with vigabatrin administration did formal programs identify the typically asymptomatic visual disturbance that occurs in approximately 40% of children and adults treated chronically.[2] Clinicians should provide patients with symptoms and signs of significance, such as a flu-like illness, abnormal bruising or bleeding, changes in urine color, or any type of skin rash. Emphasis should be on reporting these promptly. Any skin rash occurring during treatment with an AED should be evaluated, carefully and without delay, especially if it occurs within the first 4 to 6 weeks of treatment. The AED should be discontinued at the first sign of rash, unless the rash is clearly not drug related. The vast majority of drug-induced skin rashes are benign and resolve after the drug has been stopped. Only rarely do rashes evolve into full exfoliative reactions including Stevens-Johnson syndrome or toxic epidermal necrolysis. However, when a patient first develops a rash, there are no specific indicators that allow distinction between benign and serious conditions. If there is any indication of mucous membrane involvement, blistering, arthralgias, adenopathy, fever, facial swelling, or exfoliative lesions, the patient should be seen immediately. Rechallenge with an AED after a presumed drug rash is not recommended.[9]

Summary and Conclusions

Recommendations for routine monitoring for safety and tolerability during chronic treatment with antiepileptic drugs must be individualized for patients. Screening laboratory studies should be obtained before initiation of AED treatment as part of the diagnostic evaluation. Data are unavailable regarding the yield of such testing, but baseline studies provide a benchmark and

P.1316

can identify patients with special risk factors that could influence drug selection. Ongoing blood and urine monitoring in otherwise healthy and asymptomatic patients being treated with AEDs is not necessary. Patients should be advised of specific symptoms possibly associated with toxicity of the prescribed AED, and testing should be done dependent on the appearance of these clinical symptoms. High-risk patients must be identified at the inception of treatment. These patients include those with presumed biochemical disorders, altered systemic health, neurodegenerative disease, or a history of significant adverse drug reaction such as idiosyncratic or hypersensitivity reactions in the past. Monitoring must be designed based on the specifics of the clinical situation. Patients without an advocate or those unable to communicate require a different strategy. Because of communication difficulties or the nonspecific behavior that may be associated with an adverse effect, these patients may well need testing because of a change of their behavior. Although data are unavailable, blood monitoring should be obtained for patients with multiple disabilities who are institutionalized. Monitoring should include basic studies of hematology and chemistry with additional studies as required by the patient's clinical situation. The exact frequency of this clinical monitoring is undetermined. Both clinical monitoring and blood monitoring must be performed. When a patient is being treated with a newly available drug, detailed information must be provided to the patient or the caregiver, just as with established AEDs. Recommended guidelines for blood or other clinical monitoring should be followed until the numbers of patients increase such that data become available to establish whether a given individual falls within a high-risk group. The sharing of information between patient and medical caregivers and communication regarding possible adverse effect are the most important aspects of monitoring for safety and tolerability during chronic treatment with antiepileptic drugs.

Chapter 120

Rapid Substitution of Antiepileptic Drugs

Blaise F. D. Bourgeois

Introduction

In general, substituting one antiepileptic drug for an other is a relatively slow process that is carried out over several weeks or months. The main reasons for this time frame are the fear of seizure exacerbation resulting from withdrawal of the first drug while the introduced drug is not (or not yet) protective, as well as the fear of side effects associated with rapid introduction of the new drug. However, there are reasons, besides avoidance of unnecessary delays, why it may be desirable to substitute antiepileptic drugs rapidly in some circumstances. One such circumstance is an acute reaction to a drug, such as a severe idiosyncratic adverse effect. In addition, in a patient who is already in the hospital for a seizure exacerbation, it might be desirable to complete a substitution rapidly before discharge and send the patient home on a new drug regimen at therapeutic levels. An additional reason might be the establishment of pharmacoresistance in a potential candidate for epilepsy surgery. The process of establishing pharmacoresistance should be as short as possible for several reasons. First, if the patient's condition is not truly medically intractable, the successful therapeutic step will occur sooner. Second, in a patient who becomes seizure free after surgery, the overall long-term outcome is likely to be better if the surgery is performed earlier. Finally, a patient might already have been referred to a specialized center for epilepsy surgery but not yet meet acceptable criteria of medical intractability, and one additional adequate drug trial needs to be completed as rapidly as pos-sible.

Some clinical experience has been accumulated with the mutual substitutions of several established antiepileptic drugs, mostly in adult patients with focal onset seizures. In many instances, the substitution can be completed within about 5 days. This chapter describes the clinical experience with rapid introduction of carbamazepine, phenytoin, phenobarbital, and primidone, along with the concomitant rapid discontinuation of another drug within this group. Although the rapid replacement of valproate by carbamazepine, phenytoin, phenobarbital, or primidone is easy, the experience with rapid changes from one of these drugs to valproate monotherapy has not been favorable in patients with focal-onset seizures. Less experience has been acquired with the corresponding rapid changes in children, and no systematic observations have been reported about rapid changes involving the newer antiepileptic drugs.

When one antiepileptic drug is replaced by another within a short time, two issues require particular attention: (a) A therapeutic level of the drug to be introduced must be achieved as rapidly as possible and must then be maintained so as to allow rapid discontinuation of the previous drug, and (b) it must be anticipated that any pharmacokinetic interaction between the two drugs will be reversed after discontinuation of one drug. Therefore, rapid drug changes require an understanding of how rapidly a given drug can be introduced, as well as a qualitative and quantitative knowledge of the effect the drug being taken by the patient will have on the pharmacokinetics of the drug to be introduced. These rapid drug changes also require a good level of experience with antiepileptic therapy and appropriate supervision of the patient during the process.

Introduction of Carbamazepine

When carbamazepine is to be introduced rapidly to replace another antiepileptic drug, three points need to be considered: (a) the fact that levels of carbamazepine in the usual therapeutic range are not tolerated during the first days of treatment, (b) the autoinduction of carbamazepine metabolism, and (c) the potential for induction of carbamazepine metabolism by other drugs. For example, if carbamazepine is to be introduced to replace phenytoin, which markedly accelerates the elimination of carbamazepine, the initial dose requirement of carbamazepine will be higher. However, after phenytoin has been discontinued, the dose requirements of carbamazepine decrease within 2 to 4 weeks, and toxic carbamazepine levels will occur if the dose is not reduced. The effects of existing antiepileptic drug regimens on carbamazepine dosage requirements are summarized in Table 1. The processes of heteroinduction and autoinduction of carbamazepine metabolism are all reversible, and the half-life of the induction and deinduction processes is about 4 to 6 days.[8,9] The initial dose for the introduction of carbamazepine is determined on the basis of the preexisting drug regimen.

Patients Taking Phenytoin, Phenobarbital, or Primidone

An initial carbamazepine dose of approximately 25 to 30 mg/kg daily is necessary to achieve carbamazepine levels of about 10 mg/L. However, this dose cannot be administered on the first day because it causes significant neurologic toxicity.[4] The following daily incremental dosage regimen is usually well tolerated: 5 to 7.5 mg/kg on day 1; 10 to 15 mg/kg on day 2; 15 to 22.5 mg/kg on day 3; and 25 to 30 mg/kg each day thereafter. Phenytoin, phenobarbital, or primidone can be discontinued at the time of the introduction of carbamazepine. In my experience, this is generally well tolerated and not associated with significant seizure exacerbation or status epilepticus. However, the abrupt discontinuation of phenytoin, phenobarbital, or primidone is not recommended unless the patient is under close supervision. Discontinuing the previous antiepileptic drug rapidly has the potential advantage of reducing cumulative toxicity during the rapid introduction of carbamazepine. Once phenytoin, phenobarbital, or primidone has been

discontinued, the elimination rate of carbamazepine decreases and the dose has to be readjusted. The dose of carbamazepine should be reduced to 20 mg/kg daily approximately 5 days after the discontinuation of phenytoin, phenobarbital, or primidone, and to 15 mg/kg daily about 3 weeks after these drugs have been discontinued.

Table 1 Dose of carbamazepine required to achieve and average steady-state concentration of 10 mg/L

Drug regimen	Daily dose
Long-term carbamazepine monotherapy	~15 mg/kg
Phenytoin, phenobarbital, or primidone	~20–40 mg/kg
Valproate, benzodiazepine, or no medication	~5 mg/kg[a]

[a]Dose requirements increase during the first month of treatment because of autoinduction of carbamazepine metabolism (see text.)

The validity of this approach has been confirmed in a prospective study in 25 adult patients who were on phenytoin, phenobarbital, or primidone.[6] Following a single-dose pharmacokinetic study of carbamazepine for prediction of the maintenance dose, patients were all switched over to carbamazepine monotherapy successfully within a mean of 6 days. None of the patients experienced an increase in seizure frequency relative to baseline. Twenty of the 25 patients experienced no or only mild adverse effects. Four experienced adverse effects rated as moderate, and only 1 patient with a static encephalopathy experienced severe adverse effects.

Patients Taking Valproate or Another Noninducing Drug

If carbamazepine elimination is not induced, carbamazepine must be started at a low dose. The initial dose should be 3 to 5 mg/kg each day, administered on a twice-daily schedule. The dose can be advanced to 10 mg/kg daily after 5 to 7 days, to 12.5 mg/kg daily after 2 weeks, and to 15 mg/kg daily after 3 weeks. The latter dose is the average carbamazepine dose for long-term monotherapy after full autoinduction of carbamazepine metabolism (Table 1). If the patient is taking valproate, the dose of valproate can be decreased by one third at the time of initiation of carbamazepine and by a second third after 2 to 3 days. The valproate can be discontinued after 5 to 7 days.

Reintroduction of Carbamazepine

When carbamazepine is discontinued temporarily by a patient who is taking carbamazepine alone or in combination with a noninducing drug, a rapid reversibility of the autoinduction of carbamazepine is observed.[9] This process has a half-life of about 4 days only, which means that one-half of the autoinduction of carbamazepine metabolism is lost 4 days after the carbamazepine has been discontinued. Temporary discontinuation of antiepileptic therapy is a common practice during monitoring for epilepsy surgery. If the full previous maintenance dose of carbamazepine is resumed after monitoring, the patient's carbamazepine levels can reach the toxic range within 2 days. If a patient resumes carbamazepine therapy after not taking medication for 5 to 7 days, the following dosage regimen is suggested: 75% of the patient's previous daily maintenance dose of carbamazepine during 10 days, with an increase to the full previous maintenance dose on day 11.

Introduction of Phenytoin

In contrast to carbamazepine levels, phenytoin levels can be brought into the therapeutic range rapidly with little clinical evidence of neurologic toxicity. Therefore, the introduction of phenytoin can be initiated with an oral loading dose, which is then followed by the full maintenance dose. Assuming that a steady-state level of 15 mg/L is desired, one can calculate the loading dose by multiplying the desired concentration by the volume of distribution of phenytoin (approximately 0.75 L/kg). The loading dose is then 11 to 12 mg/kg. The maintenance dose of phenytoin for a desired steady-state level of 15 mg/L can be calculated using the Michaelis-Menten equation and population values for the Michaelis-Menten parameters of phenytoin, V_{max} and K_m.[2] For an average steady-state level of 15 mg/L, the dose is 5 to 6 mg/kg daily. During the first 24 hours, the patient should receive the loading dose plus the maintenance dose, or about 17 mg/kg, in two or three divided doses. Thereafter, the daily maintenance dose can be prescribed. The antiepileptic drugs to be replaced by phenytoin can be tapered or discontinued when phenytoin is introduced. Phenobarbital and pri-midone can be discontinued at the time of the introduction of phenytoin. The doses of carbamazepine or valproate can be decreased by one third daily until the drug is discontinued.

Introduction of Phenobarbital and Primidone

Phenobarbital

The serum levels of phenobarbital cannot be advanced to the therapeutic range as rapidly as phenytoin levels if significant neurologic toxicity is to be avoided. As with carbamazepine, tolerance to phenobarbital develops within the first few days of exposure. Therefore, loading as described for phenytoin is not possible with phenobarbital or carbamazepine. However, if phenobarbital is introduced by administering only a maintenance dose, a steady-state therapeutic level will be reached after 2 to 3 weeks only, because of the long elimination half-life of phenobarbital. As outlined in the chapter on primidone (see Chapter 156), experimentation with various schedules of phenobarbital titration revealed that the following increases in levels are tolerated with minimal or no sedation by most patients: 5 mg/L after 24 hours, 10 mg/L after 48 hours, 15 mg/L after 72 hours, and 20 mg/L after 96 hours (end of day 4). These levels can be quite accurately achieved by giving 3 mg/kg of phenobarbital orally on day 1 (two doses of 1.5 mg/kg each, 12 hours apart); 3.5 mg/kg on day 2; 4 mg/kg on day 3; and 5 mg/kg on day 4. On day 5, the maintenance dose of phenobarbital can be started. In adults, a maintenance dose of about 2 mg/kg daily results in a steady-state phenobarbital level of approximately 20 mg/L, and a dose of about 3 mg/kg daily results in a level of approximately 30 mg/L. If phenobarbital is introduced to replace phenytoin, the phenytoin can be discontinued during the loading with phenobarbital. If carbamazepine or valproate is being replaced, doses of either can be decreased by one third every 1 to 2 days.

Primidone

Primidone must be introduced slowly; otherwise it produces severe side effects. Based on observations in patients and

experimental animals that phenobarbital produces cross-tolerance to the effects of primidone,[1,3] a schedule was developed that allows rapid advancement to the full maintenance dose of primidone[3,5] (see Chapter 158). The principle is based on giving phenobarbital initially, titrating the serum level as described earlier, and then switching abruptly to the full maintenance dose of primidone. On the fifth day, the patient can be given a full daily maintenance dose of primidone of 12.5 to 20 mg/kg, with no significant new toxicity. Other antiepileptic drugs can be discontinued as described earlier for phenobarbital. In patients taking drugs such as carbamazepine or phenytoin concomitantly, a phenobarbital level of about 30 mg/L will be achieved with an average primidone dose of 10 to 15 mg/kg daily. Kanner et al.[7] confirmed the feasibility of rapid introduction of primidone following prior loading or exposure to phenobarbital in 30 patients. With the foregoing schedule of phenobarbital introduction, or if they were already taking phenobarbital, 2 of 30 patients tolerated the introduction of primidone at 500 mg/day with minimal or no adverse events.

In patients who are taking primidone with a noninducing drug or who are on primidone monotherapy, a phenobarbital level of about 30 mg/L will be reached at a daily dose of approximately 20 mg/kg. Therefore, when carbamazepine or phenytoin is replaced by primidone monotherapy, the dose of primidone might have to be increased 2 to 3 weeks after the discontinuation of phenytoin or carbamazepine to maintain the phenobarbital level. This is caused by deinduction of the enzymatic conversion of primidone to phenobarbital.

Summary and Conclusions

In conclusion, there are certain circumstances under which it may be desirable to substitute antiepileptic drugs within a relatively short time, for example, the need for rapid establishment of pharmacoresistance in a patient undergoing evaluation for epilepsy surgery and the need for rapid substitution in a patient hospitalized with frequent seizures or experiencing an acute reaction to a drug, such as a severe idiosyncratic adverse effect. The main risks of rapid substitution are seizure exacerbation resulting from withdrawal of the one drug while levels of the introduced drug are not yet protective and acute side effects associated with rapid introduction of the new drug. With adequate knowledge of certain pharmacokinetic and pharmacodynamic parameters, however, complete substitutions can be carried out safely within about 5 days. Substitutions between certain pairs of drugs are easier and safer than those between others. Regardless of the antiepileptic drugs involved, rapid drug changes require a good understanding of the potential pharmacokinetic and pharmacodynamic pitfalls, an adequate level of experience with antiepileptic therapy, and appropriate supervision of the patient during the process, preferably in the hospital. Systematic observations on rapid switchover involving any of the newer antiepileptic drugs have not been reported. In addition, some of the newer antiepileptic drugs, such as lamotrigine, just cannot be introduced rapidly. Whenever one drug must be discontinued rapidly but experience with rapid introduction of the chosen replacement drug is lacking, a benzodiazepine can be used temporarily while the new drug is introduced gradually.

Chapter 121

Adjunctive and Combination Therapy

Blaise F.D. Bourgeois

Frank Gilliam

Introduction

A historical review of the practices of predominant combination therapy versus predominant monotherapy in the medical treatment of epilepsy reveals three sequential currents. After the introduction of phenytoin in 1938, as more antiepileptic drugs (AEDs) became available, it became common practice to prescribe multiple drugs for patients who were not controlled by one. If there was a rationale for this approach, it was mainly based on the assumption that AEDs interact synergistically and can provide more seizure protection together than alone. Even if this was true, the main limitation of this reasoning was that it did not factor in the consequences of combined side effects. Indeed, because of the increasing recognition of the frequent negative impact of polytherapy on the number and intensity of side effects, the concept of monotherapy and sequential monotherapy gained wide acceptance in the late 1970s and early 1980s. The proponents of monotherapy based their recommendations on repeated observations that the severity or number of side effects often diminished following a reduction in the number of AEDs, in most cases without appreciable loss in seizure control.[1,3,10,22,27,28,33] In addition, the beneficial effect of adding a second drug after the failure of a first drug was found to be modest.[27] When patients who had undergone a temporal lobe resection were randomized to ongoing polytherapy or to reduction to carbamazepine monotherapy, both groups experienced the same seizure recurrence rate.[14] However, drug-related side effects were less common in the monotherapy group (10%) than in the polytherapy group (30%). The concept of monotherapy was extended to the practice of "high-dose monotherapy."[15] Two main factors prompted the transition to the third era: (a) The realization that about one third of patients remained refractory even to high-dose monotherapy and (b) the release of many new AEDs after 1993. These newer AEDs have fewer or no pharmacokinetic interactions. Beginning in the 1990s, the concept of "rational polytherapy" was debated and became the object of intense discussion and speculation but of few rigorous clinical studies. The temptation to combine AEDs when single-drug therapy fails to render patients seizure free will endure. Therefore, the advantages and disadvantages of AED combinations must be assessed carefully, and it will always be important to evaluate and identify potentially beneficial specific drug combinations.

Potential Disadvantages of Combination Therapy

Table 1 lists some of the potential disadvantages and advantages of combination therapy. It seems that the disadvantages are more obvious and easier to document, and they will be discussed first.

Increased Number or Intensity of Side Effects

Based on experimental data on pharmacodynamic interactions between AEDs, it appears that the neurologic toxicity of various drug combination is mostly additive, although it can be at times infraadditive or supraadditive (see Chapter 110, Table 1). The consequence of this observation is that two drugs whose concentration is in the usual therapeutic range are more likely to cause dose-related neurologic side effects than either one of the two drugs at the same concentration. This interpretation has been supported by several clinical observations that a reduction in polypharmacy is associated with a reduction in side effects, in particular diminished sedation.[1,3,10,28] Although the drugs involved were often barbiturates that are used less commonly now,[33] subtle toxicity that can occur with any of the other AEDs is more likely to be missed and can include chronic impairment of cognitive function.

Increased side effects during combination therapy can be related not only to cumulative toxicity, but also to the increased statistical probability that the level of at least one drug will be in the toxic range. This might be due also to the fact that patients on combination therapy tend to have more-refractory seizures, and so it is more likely that the dose of their medication will be increased more aggressively. It was found in a prospective study of intelligence in children with epilepsy that the number of children with one or more drug levels in the toxic range increased with the number of drugs prescribed.[7] Toxic levels were recorded in 14% of those taking one drug, whereas they were found in 50% of those taking two drugs and 100% of those taking three or more drugs. Based on a review of the literature, Deckers et al.[9] reassessed the relationship between AED polytherapy and adverse effects; it appears that toxicity during polytherapy is related to the total drug load (i.e., the sum of the relative doses of all AEDs taken by a patient) rather than to the number of drugs. This observation has implications for the concept of rational polytherapy because it implies that a single drug at the maximal tolerated dose can cause more toxicity than two drugs at low doses.

Table 1. Potential advantages and disadvantages of combination therapy

Disadvantages
Increased number or intensity of side effects
Potentiation of dose-related or idiosyncratic side effects
Pharmacokinetic interactions
Difficulty of attributing the response to a given drug
Possible change in the therapeutic range of plasma levels
Cost and complexity of drug regimen
Advantages
Better effectiveness
Milder side effects
Broader spectrum of seizure protection

Cumulative toxicity can also mean that combination therapy will result not only in stronger side effects, but also in more different side effects. Different drugs have different side effects, and combining them will multiply the number of possible side effects, such as thrombocytopenia from valproate, nephrolithiasis from topiramate, and gingival hyperplasia from phenytoin. Conversely, side effects of different drugs might improve when they are combined, such as weight gain or weight loss with valproate and topiramate.

P.1322

Potentiation of Idiosyncratic or Dose-related Side Effects

The likelihood of some idiosyncratic side effects that are not dose related can be increased by the combined administration of two drugs. The incidence of severe rashes with lamotrigine was found to be higher in the presence of valproate, which is likely to be due to a pharmacokinetic interaction.[4] Treatment with valproate can result in an encephalopathic state, which is usually not associated with toxic drug levels.[17,25] There is a marked slowing of the electroencephalographic (EEG) background activity in the context of significant mental status changes, usually a stuporous state. This condition seems to occur more often when valproate is taken with another AED, and it is fully reversible within a few days on discontinuation of either valproate or the other AED.[17]

It appears that dose-related adverse effects of one drug can also be exacerbated by another AED. When lamotrigine was prescribed in combination with valproate, an increase in tremor was observed in two studies.[13,21] When levetiracetam was added to carbamazepine in polytherapy, an increase in side effects characteristic of carbamazepine was noted in four patients.[29] After the addition of lamotrigine, an exacerbation of carbamazepine toxicity has also been noted, and this could not be attributed to a pharmacokinetic interaction.[5] In three patients, chorea occurred on phenytoin and lamotrigine only when they were combined, and it resolved when one medication was tapered.[35]

Pharmacokinetic Interactions

The pharmacokinetic interactions are reviewed in detail in Chapter 110. Adding as well as removing an AED can alter the dose-to-level relationship of other AEDs and also of other drugs. These changes not only make the medical treatment of a patient more complex, but they also can require more frequent drug level monitoring and dosage readjustments, and they are more likely to result at some point in drug levels that are either too low or too high. Interactions are more likely to be overlooked when a drug causing an interaction is removed than when it is added. In addition, interactions due to an enzyme-inducing drug display their full impact after days to week and are equally slowly reversible, whereas interactions due to an enzyme-inhibiting drug usually occur within hours to days and are rapidly reversible due to the competitive nature of the interaction. Overall, the newer AEDs are less likely to cause interactions, although many of them are susceptible to the effect of enzyme induction by the older drugs. Pharmacokinetic interactions are rarely beneficial, and they are at best not detrimental when they are anticipated or recognized early. An inhibitory interaction, such as the effect of valproate on lamotrigine kinetics, can have the theoretical advantages of decreasing the fluctuation of the levels of lamotrigine by prolonging its elimination half-life and of reducing the dose requirements of lamotrigine for the same average plasma levels. This in itself would rarely be a reason for combining two AEDs. Conversely, enzyme induction will result in a shorter half-life of the affected drug and also in wider fluctuation in plasma levels between doses. Such enhanced fluctuations can increase the risk of a seizure before a dose (lower trough levels) or the risk of toxicity at the time of the peak level. In addition, enzymatic induction can make it difficult to achieve good therapeutic levels of the affected drug, even at very high doses, as has been shown for valproate in children.[12] Finally, the inhibition of lamotrigine metabolism by valproate raises the level-to-dose ratio of lamotrigine. This is considered to be a likely explanation for the higher incidence of rashes associated with lamotrigine in patients taking valproate,[4] and this led to a downward readjustment of the titration rate of lamotrigine dose in these patients.

Difficulty of Attributing a Response to a Given Drug

In clinical practice, when a patient is taking two or more AEDs, it is often difficult to determine which one of the drugs is causing a side effect, unless it is a very specific adverse reaction. This is particularly bothersome when a patient develops a rash and was started within a relatively short time interval on two drugs that are known to have a potential for allergic skin reactions. Idiosyncratic toxic reactions do not always appear soon after the introduction of a drug; therefore, they cannot necessarily be attributed to the last drug added to the patient's regimen. Another common dilemma is to determine, in a patient on two or more drugs, which one is more likely to be contributing to seizure control. Frequent dose changes and short periods of observation can confound these problems.

Possible Change in the Therapeutic Range of Plasma Levels

The therapeutic range provides loose guidelines with regard to the minimal effective concentration and the concentration at which side effects become frequent, and it is a statistical compromise based on previous observations in groups of patients. Given the experimental evidence for additive interactions between AEDs, it is unlikely that the therapeutic range of a drug is the same when it is taken alone as when it is taken in combination with other drugs. When drug levels are within the therapeutic range, polytherapy is more likely to be associated with toxicity. Conversely, it has been suggested that toxicity from valproate[25] and from carbamazepine or phenytoin[15] appears at higher levels when these drugs are taken alone. Therefore, when side effects occur at a certain level of a drug during combination therapy, this does not necessarily imply that a given drug with a therapeutic level is not responsible for the toxicity

or that the side effects will recur at similar levels in monotherapy in the same patient.

Potential Advantages of Combination Therapy

The two main advantages that combination drug therapy can have over single-drug therapy are better overall seizure control and a similar degree of seizure control with fewer or less-pronounced side effects. To fulfill these criteria, a combination of two or more AEDs must either have a better therapeutic index (ratio of seizure protection to toxicity) than either drug alone or a wider spectrum of activity against different seizure types. For example, consider a patient whose partial seizures were not controlled by the maximal tolerated doses of either phenytoin alone or carbamazepine alone, leading to both drugs being prescribed together. If the seizures can be controlled by the combination of phenytoin and carbamazepine at doses tolerated by the patient, a superior therapeutic index for the combination of phenytoin and carbamazepine would have been demonstrated. In another hypothetical case, a patient with both primarily generalized tonic–clonic seizures and myo-clonic seizures in whom clonazepam controlled only the myo-clonic seizures and valproate controlled only the tonic–clonic seizures might do well on both drugs. Although neither drug alone controlled both seizure types, together they might be effective and have a wider antiepileptic spectrum than either one alone. Although the clinical literature provides very few data demonstrating a better therapeutic index for any combination of AEDs, increasing attention is being paid to the theoretical, experimental, and clinical background for the practice of combining AEDs. It is difficult to quantify pharmacodynamic interactions between AEDs in a clinical setting because both seizure protection and neurotoxic side effects of single drugs and of combinations of drugs must be assessed quantitatively in a homogeneous population of patients. Therefore, most of the information on the pharmacodynamic effect of combining AEDs has been obtained from animal experiments (see Chapter 110). Although a supraadditive pharmacodynamic interaction (potentiation or synergism) between two drugs with regard to their protective effect against seizures has often been interpreted as supportive evidence in favor of the combination, this in itself has little meaning unless the neurotoxic effects are also evaluated. If toxicity is also supraadditive to the same or greater extent, the therapeutic index of the combination is equal to or inferior to the therapeutic index of each drug alone. In other words, at the same level of neurotoxicity, the drug combination does not provide more seizure protection than either of the two drugs alone. As shown in Chapter 110, Table 1, there can be many different combinations of antiepileptic and neurotoxic pharmacodynamic interactions between various pairs of AEDs.

Clinical Studies

Only few clinical reports of AED combinations have been based on systematic comparisons between the effects of two drugs administered each in monotherapy and then together. To demonstrate the superiority of a combination, it is not sufficient to compare the effect of adding a second drug with the result of monotherapy with the first drug. It is important to keep in mind that success with add-on therapy should be considered as success of alternative therapy until proven otherwise.

A second drug (carbamazepine, phenytoin, phenobarbital, primidone, valproic acid, clonazepam, or clobazam) was added, if necessary up to the maximal tolerated dose, in 30 adult patients who had failed to respond to the maximal tolerated dose of carbamazepine, phenytoin, phenobarbital, or primidone.[27] In 4 patients (13%), there was a reduction in seizure frequency by 75% or more, but no patient became seizure free, and there was an increase in seizure frequency by more than 100% in 3 patients (10%). When 157 patients who were not controlled on AED monotherapy were randomized to alternative monotherapy or to adjunctive therapy, there was no difference in outcome between the two groups in relation to seizure outcome and to adverse effects.[2]

One clinical study suggested that the combination of valproate and ethosuximide is possibly beneficial in the treatment of absence seizures. Five patients with absence seizures became seizure free when ethosuximide and valproate were combined after they had failed to respond fully to ethosuximide or to valproate alone (or to both).[23] This observation is in agreement with experimental evidence cited in Chapter 110. A frequently quoted study of the combination of carbamazepine and phenytoin was only published as an abstract.[11] One hundred newly diagnosed patients were randomized to monotherapy with carbamazepine or phenytoin. After 1 year, 50 patients were uncontrolled, and they were switched to the other medication. Of those, 17 (34%) became seizure free. The 33 remaining patients, whose seizures had not been controlled by carbamazepine and phenytoin monotherapy, received both medications, and only 5 of them (15%) became seizure free. In a sequential study by Walker and Koon[34] some patients who had failed to respond to valproate alone and to carbamazepine alone became seizure free on the com-bination.

The combination of vigabatrin with lamotrigine was evaluated in 42 patients with intractable epilepsy.[26] The median seizure frequency was reduced by 18% when vigabatrin was added to lamotrigine and by 24% when lamotrigine was added to vigabatrin. However, because patients did not receive both drugs in monotherapy first, the results might just reflect the effect of the second drug added, not of the combination. Tanganelli and Regesta[31] made encouraging observations supporting the combination of vigabatrin and carbamazepine in newly diagnosed patients randomized to monotherapy to either one of the two drugs. The 25 patients whose seizures were not controlled were switched to monotherapy with the other drug, and 11 patients (44%) were controlled by alternative monotherapy. The remaining 14 refractory patients received the two drugs in combination, and 5 (36%) became seizure free.

Evidence suggestive of a synergism between lamotrigine and valproate was found in at least two studies. Lamotrigine was added in 347 patients that were not controlled on monotherapy with valproate, carbamazepine, phenytoin, or phenobarbital.[8] In patients with a 50% or greater seizure reduction, an attempt was made to withdraw the first drug. On the basis of two observations, a synergism between lamotrigine and valproate was suggested: (a) There was a significantly better response after adding lamotrigine to valproate than to carbamazepine or phenytoin (p <.001), both for partial seizures (p <.02) and for generalized tonic–clonic seizures (not statistically significant), and (b) there was worsening of seizure control after valproate was withdrawn. Pisani et al.[21] carried out a small but very systematic study that added evidence in favor of the potential benefit of the combination of valproate and lamotrigine. Twenty patients with resistant complex partial seizures received valproate as add-on medication. Three of them had a >50% seizure reduction. In the remaining 17 patients, valproate was replaced by lamotrigine added to the same baseline medications. Four of the 17 had a >50% seizure reduction. In the remaining 13 patients, when valproate was reintroduced while

P.1324

lamotrigine was continued, 4 had a >50% seizure reduction and 4 became seizure free.

Clinical Approach to Selection of Antiepileptic Drug Combinations

At present, there can be no firm guidelines for selecting a combination of two AEDs because there are no definitive clinical studies documenting the superiority of any specific drug combination. In 1995, Meinardi[18] stated that "at present, however, there are too many gaps in our knowledge to make theoretical planning of [combination] drug therapy more promising than an empirical approach." In the absence of unusual circumstances, there is no reason to consider a combination of two AEDs unless at least two sequential monotherapy treatments have failed. When trying to select a meaningful combination of AEDs, one can consider the mechanisms of action, the clinical spectrum of activity, and pharmacokinetic interactions of the drugs. Some have suggested the mechanism of action of AEDs as a criterion for rational combinations, hypothesizing that drugs with different mechanisms of action are more likely be complementary.[16,20] At times, a valuable combination can be found by chance observation in a given patient. A real-life example is the case of a nearly 7-year-old boy with about 30 absence seizures per day and generalized spike-and-waves on the EEG. After about 10 days on ethosuximide, he had about six absence seizures per day but had developed some sudden falls. Valproate was added, and all seizures subsided within days. Two months later, the ethosuximide was tapered and discontinued. Within about 10 days, the absence seizures recurred and then were gradually controlled again when ethosuximide was reintroduced. Clearly, this patient was never seizure free on ethosuximide or valproate alone, only on the combination.

Two drugs can be selected according to their spectrum of efficacy for patients with two or more seizure types that cannot be controlled by one drug alone. The drug likely to be most effective and best tolerated should be selected for each seizure type. The Lennox-Gastaut syndrome is another example of epilepsy with multiple seizure types, and valproate has long been the drug of choice in this syndrome. However, three drugs have now been shown to be effective in double-blind studies—felbamate,[32] lamotrigine,[19] and topiramate.[24] Combinations between these drugs might be more effective in reducing drop attacks as well as atypical absences and tonic seizures than only one drug alone. Conversely, phenytoin and carbamazepine should not be used in any combination because they can exacerbate certain seizures in these patients.[30]

Combinations that should be considered only with caution are those between drugs with similar side effects. Examples are barbiturates and benzodiazepines, or barbiturates and topiramate (sedation, cognitive effects); acetazolamide, topiramate, and zonisamide (nephrolithiasis, acidosis); carbamazepine and oxcarbazepine (hyponatremia); valproate and gabapentin (weight gain); and topiramate, zonisamide, and felbamate (weight loss). In addition, as discussed earlier, combining certain drugs can increase the risk of idiosyncratic reactions. Overall, the need to reduce overtreatment can be as common a clinical situation as the need to find an appropriate duotherapy.[6]

It certainly makes it easier to use two drugs together that have no pharmacokinetic interactions between them. However, it is the physician's responsibility to make appropriate dose adjustments, either as a corrective measure or preferably as a preventive measure, because most pharmacokinetic interactions are known and predictable. Therefore, if a drug combination is of potential benefit to a patient, pharmacokinetic interactions should not be a reason to avoid it.

Finally, a concept of “low-dose polytherapy” could be opposed to the classic concept of “high-dose monotherapy.” All AEDs have in common their antiepileptic effect, but they do not all have the same adverse effects. Accordingly, if a patient had a good seizure response to two drugs in monotherapy but only in the presence of side effects, the two drugs together at lower doses that could be below the clinical threshold for each one's side effects might provide the same seizure control. For example, a child with absence seizures who has thrombocytopenia or tremor at effective doses of valproate and persistent gastrointestinal side effects at effective doses of ethosuximide might have equal seizure control without the side effects while taking the two drugs at lower doses. According to this concept, any two drugs with different side effects but efficacy against the same seizure type could be combined.

Summary and Conclusions

Various clinical problems are associated with antiepileptic drug combinations—pharmacokinetic interactions, cumulative toxicity, a more complicated drug regimen, difficulty in assessing individual drug efficacy and toxicity, and, finally, higher costs. Therefore, two or more antiepileptic drugs should not be prescribed concomitantly unless it can be demonstrated that, compared with either drug used alone in a given patient, that patient derives better seizure protection from the combination with no additional side effects or that the same seizure protection is achieved with fewer side effects. If this is not the case, the patient will be better off on monotherapy with the drug that had previously displayed the best efficacy/toxicity ratio. Rational AED combinations are identified when individual patients do better in terms of seizure control and side effects while taking drugs A and B together (at any dose) than while taking drug A or drug B alone at their respective optimal doses. Under certain circumstances, it could be appropriate to maintain a drug combination even when the foregoing definition is not met. A patient may respond partially to a first drug and experience further improvement after addition of the second drug. In such a case, it is understandable that one might be reluctant to make any change.

Chapter 122

Treatment of Single and Infrequent Seizures

Ettore Beghi

Anne T. Berg

Shlomo Shinnar

W. Allen Hauser

Introduction

Epilepsy is a treatable condition characterized by the occurrence of repeated unprovoked seizures. Thus, the patient who presents with an isolated first unprovoked seizure (or cluster of seizures within 24 hours) does not yet qualify for the diagnosis of epilepsy. In the past, it was believed that almost all individuals coming to medical attention for a first seizure would inevitably have additional episodes; such individuals were usually treated with antiepileptic drugs (AEDs).[22,52] In addition, based on studies from tertiary referral centers, there was the perception that epilepsy was a chronic, progressive, unremitting disease.[30,54] Thus, early aggressive treatment with antiepileptic drugs was presumed to be beneficial through suppression or control of the evolving process of the disorder. The results of recent epidemiologic studies and randomized clinical trials have greatly changed our understanding of the nature and natural history of seizures and of epilepsy. For the most part, it is clear that epilepsy is a relatively benign condition with an excellent prognosis for seizure control and, ultimately, discontinuation of AEDs. In light of these changes, the clinical management of a single seizure has to be reconsidered. In this chapter, we will address several issues pertaining to the diagnosis and management of the patient who presents with a single unprovoked seizure, including (a) the diagnosis of epileptic seizures, first unprovoked seizures, and epilepsy; (b) the influence of seizure recurrence and early treatment on the prognosis of epilepsy, based on earlier and present views; (c) the risk of recurrence of a given seizure; (d) the impact of treatment on that risk and on the long-term prognosis of epilepsy; (e) the risk:benefit ratio of pharmacologic treatment; and (f) the sociocultural and legal implications of seizure recurrence compared with the tolerability and acceptance of chronic therapy.

Diagnosis of Epileptic Seizures, First Unprovoked Seizures, and Epilepsy

The diagnosis of epileptic seizures and epilepsy is beyond the scope of this chapter and is being covered elsewhere in this book. Briefly, in any newly presenting patient a series of questions must be addressed: (a) did the individual have an epileptic seizure? (b) Is there an acute cause for the seizure, perhaps one requiring immediate treatment itself? (c) If this is an unprovoked seizure, is it the first ever this person has had or, upon history, is there convincing evidence of previous events?

According to the International League Against Epilepsy and the International Bureau for Epilepsy, an epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.[25] Although the occurrence of at least one epileptic seizure as a prerequisite for the diagnosis of epilepsy is still a matter of debate,[6] a first epileptic seizure has an inherent susceptibility to relapse. A first seizure may present as status epilepticus. Status epilepticus is a seizure showing no clinical signs of arresting after a duration encompassing the great majority of seizures of that type in most patients or recurrent seizures without interictal resumption of baseline central nervous system function.[11]

Seizures should also be characterized as *acute symptomatic* or *unprovoked*, with reference to the presence or absence of known precipitants.[19] Seizure definitions are discussed more extensively in Chapter 67. Although acute symptomatic seizures are a risk factor for unprovoked seizures and epilepsy, they may not necessarily recur, provided that the underlying epileptogenic condition is properly diagnosed and treated.

Another aspect of diagnosis that can be particularly difficult in an individual with a history of nonconvulsive ictal events is the determination of whether the event is really the first seizure. Not all forms of epilepsy are equally likely to present with a single seizure.[3] This is frequently an issue in syndromes such as juvenile myoclonic epilepsy, where the patient may come to medical attention for a generalized tonic–clonic seizure but, upon careful questioning, is found to have a history of myo-clonic events that were never recognized as seizures. Similar scenarios are often seen with patients who are found to have a history consistent with complex partial seizures, or absence seizures. Some patients may have had one or more nocturnal episodes that are recognized only in retrospect. Such patients may present with a first seizure requiring medical attention; however, they already have epilepsy.[36] The issue of the diagnosis of the first seizure is further complicated by the high variability of clinical interpretation among neurologists. This variability seems to be reduced only by the use of simple diagnostic criteria and a discussion among the treating physicians.[65]

Changing Views on the Early Prognosis of Epilepsy and the Effects of Early Treatment

Views on the prognosis of epilepsy have changed in the last 40 years. Until the late 1960s it was believed that less than a third of patients with epilepsy would achieve a complete remission from seizures, and the majority (up to 85%) would be likely to have a chronic seizure disorder.[54] Further, it was believed that seizures beget seizures. As Gowers wrote[30]:

> "When one attack has occurred, whether in apparent consequence of an immediate excitant or not, others usually follow without any immediate traceable cause. The effect of a convulsion on the nerve centres is such as to render the occurrence of another more easy, to intensify the predisposition that already exists. Thus, every fit may be said to be, in part, the result of those that have preceded it, the cause of those which follow it."

P.1328

In contrast to previous studies, community surveys and prospective studies on referral patients done in the last 30 years have reported that up to 90% of newly diagnosed patients with epilepsy tend to achieve prolonged seizure remission, and about 40% to 60% of these enter remission as soon as treatment is initiated.[39] Likewise, well-conducted, unbiased studies of prognosis following a first unprovoked seizure have also demonstrated that a significant percentage of patients do not have further seizures.[2,31] Although it has been maintained that the better prognoses observed in more recent studies can be attributed to improved treatment,[52] epidemiologic evidence indicates that the poor prognoses observed in earlier studies were largely the result of selection bias: Patients in these studies were from tertiary referral centers where those with poor outcomes are overrepresented.[7] In contrast, recent studies have been conducted on newly diagnosed patients. Given the changes in our understanding of the nature of seizures and epilepsy and the prognosis following a first unprovoked seizure, there are now many considerations that must be made in approaching the management and treatment of the patient who presents with a first unprovoked seizure.

It has been suggested in the past that AEDs should be initiated promptly in newly diagnosed patients under the assumption that epilepsy is an evolving process that, if left untreated, tends to be accompanied by reduced drug response.[52] This assumption was supported by experimental findings in kindled animals.[53] However, the concept that early AED treatment can influence the prognosis of epilepsy is not unanimously accepted. An alternative view is that the outcome of epilepsy is determined largely by the underlying substratum upon which the epilepsy is superimposed and that treatment does not influence the course of the disease.[37,55,61] Epilepsy is a heterogeneous clinical condition and many different forms have been recognized. The outcome to some extent is determined by the type of epilepsy. These contrasting opinions may still greatly affect the decision to treat a patient at the time of his or her first medical contact for unprovoked seizures, which for some individuals may be the first epileptic seizure.

Treatment of a single epileptic seizure is a therapeutic option. Knowledge of the clinical pharmacology of AEDs has led to a more precise outline of the efficacy and tolerability of the available drugs (see Chapter 109). Consequences of recurrence of epileptic seizures must be balanced against the consequences of treatment (Chapters 95 and 108). This chapter will mostly focus on prophylaxis following a single unprovoked seizure. Although a more detailed overview of the epidemiology of isolated seizures has been provided elsewhere in this book (see Chapters 5 and 7), this issue will be summarized briefly here.

Risk of Recurrence of a First Seizure

In patients coming to medical attention with a first unprovoked seizure, the risk of recurrence has been reported to range from 23% to 71%.[4,8] This large range reflects considerable differences among studies with respect to length of follow-up, target population, definition of first seizure, and study design.[7,8] Population-based studies[2,31] provide more homogeneous relapse rates at 1 (36% to 37%) and 2 years (43% to 45%). In a systematic review of 16 reports,[8] the average recurrence risk was 51% (95% confidence interval [CI], 49% to 53%). The risk of recurrence of a first seizure at 2 years ranged from 25% to 52%, with a median of 38%. Numerous prognostic factors have been examined in the literature. These can be divided into three groups: (a) those clearly identifying patients at high and low risk, (b) those clearly considered of no prognostic significance, and (c) those for which available data are insufficient or conflicting.

The two most consistent predictors of recurrence are an abnormal electroencephalogram (EEG) and the presence of an underlying etiology.[8] The EEG is a useful predictor of relapse of a first unprovoked seizure in both children and adults.[8] Children with a cryptogenic first seizure and EEG epileptiform abnormalities have recurrence rates doubling those with nonepileptiform abnormalities. The results are less conclusive in adults, but also suggest that an EEG with epileptiform abnormalities is associated with a significantly increased risk of relapse.[8,57,67] When a first seizure is associated with an underlying neurologic condition or event to which the occurrence of the seizure can be attributed, the risk of recurrence is roughly double that of an idiopathic or cryptogenic first seizure.[8] The 2-year risk of recurrence seems to vary significantly according to the presence of a recognized etiology of the seizure and of an abnormal (not necessarily epileptiform) EEG. The risk is lowest (24%) in patients with idiopathic or cryptogenic seizures and normal EEGs, intermediate (48%) in those with symptomatic seizures or abnormal EEGs, and highest (65%) in those with symptomatic seizures and abnormal EEGs.[8] In three of the four studies that examined the sleep state at the time of the first seizure,[14,38,59,66] the risk of recurrence was doubled in patients who were asleep at the time of the index event compared with those who were awake. In one study,[59] sleep state was a strong predictor of recurrence, even among lowest-risk patients (i.e., those with cryptogenic first seizures and normal EEGs).

Most studies find a small to moderate increase in risk of recurrence associated with a family history of unprovoked seizures. This association appears to be greater among patients with cryptogenic first seizures than among those with a first remote symptomatic seizure. Partial-onset seizures are associated with remote symptomatic etiology and an abnormal EEG. This is particularly the case in patients with remote symptomatic first seizures but less so in those with cryptogenic first seizures. However, in studies controlling for etiology and EEG,[2,14] partial seizures still may be associated with a higher recurrence risk than are generalized-onset seizures.

Some factors were fairly consistently found not to be predictive of recurrence after a first unprovoked seizure. These include gender and status epilepticus. Although the evidence is still limited, the risk of recurrence does not appear to be greater in patients whose first unprovoked seizure was an episode of cryptogenic status epilepticus.[33,60,63] whereas an increased risk of recurrence has been observed in those with a first episode of remote symptomatic status epilepticus.

Factors for which the evidence of seizure recurrence is inconclusive include age and a history of prior provoked seizures. Although developmental factors associated with age play an important role in the occurrence and prognosis of epilepsy, it is not clear whether they play a role in predicting recurrence in patients with a first unprovoked seizure.

Contrary to other reports, two studies[24,66] have found substantial differences in recurrence risk across age groups. In both studies, children and adolescents had higher recurrence risks than did adults. The results for older adults were contradictory in these studies, one reporting a further decrease in risk[66] and the other reporting an increase.[24] Most studies have focused on a history of prior febrile seizures, primarily in patients with cryptogenic first seizures. In studies of children,[14,58] a prior history of febrile seizures does not appear to be associated with the risk of recurrent febrile seizures. In a study primarily of adults,[32] a history of prior provoked seizures (most of which were febrile) was associated with recurrence. Information is insufficient regarding the prognostic significance of neonatal or other prior provoked seizures.

In summary, the overall risk of recurrence after a recognized first unprovoked seizure is about 38% after 2 years. Factors increasing risk of recurrence by 2 years include an antecedent condition associated with an increased risk for epilepsy, an

abnormal EEG (particularly one with epileptiform abnormalities), and, probably, sleep state. In addition, most evidence suggests that family history of epilepsy and partial seizures are associated with a somewhat higher recurrence risk. Either such factors as sex, age at first seizure, status epilepticus, and history of prior provoked seizures were not associated with higher recurrence risk or the available information was inconclusive.

The Impact of Treatment on the Recurrence after a First Seizure and on the Long-term Prognosis of Epilepsy

Observations from clinical trials demonstrate that AEDs are effective in preventing seizures in patients with epilepsy; their role in individuals with a first unprovoked seizure is less defined. Because patients with a recognized etiology and/or an abnormal EEG are considered at higher risk of recurrence, it is conceivable that these subjects are more likely to be treated after the first seizure. However, the proportion of patients treated after the first seizure ranges from 5% to 80% in different published series.[2,12,31,33,38,58] Part of the differences are attributable to the differences in treatment approaches to children and adults. This range can only partly be explained by the different target populations. In fact, the tendency to treat the first seizure may vary across countries, due largely to significant differences in the sociocultural environments (including different legislation and different attitudes of physicians and patients toward treatment).

Several observational studies have assessed the impact of treatment on the risk of further seizures following a first unprovoked seizure.[2,14,33,38] Although some reports documented a striking correlation between the number of seizures prior to initiating treatment and the chance of prolonged seizure remission on follow-up,[18,21,35] with few exceptions,[31,62] these studies reported no significant difference in the risk of recurrence between treated and untreated subjects. However, these findings are most likely confounded by selection bias, as patients considered at higher risk of relapse were most likely to be treated.[62] In addition, some authors[2,12] found recurrences occurring later in treated patients, suggesting that treatment had an effect on the risk of relapse of a first epileptic seizure.

To date, a number of randomized studies have been conducted to assess the effects of treatment of the first unprovoked seizure on the risk of recurrence. In a small Canadian trial[13] of 31 children with a first unprovoked partial or generalized tonic–clonic seizure, patients were randomized to receive carbamazepine or no medication for 1 year or until the time of a second seizure. Overall, 2 of 14 treated and 9 of 17 untreated children had a recurrent afebrile seizure. Four patients discontinued treatment because of adverse reactions, leaving six cases completely seizure free with no unacceptable adverse effects of treatment. Ninety-one patients aged 18 to 50 years with a single generalized tonic–clonic seizure were randomized to treatment (45) or to remain untreated (46) and followed until recurrence or 36 months, whichever first.[27] There were significantly more seizure-free patients in the treated (10) compared to the untreated group (29) (p <0.005). A large multicenter trial (the FIRST study)[24] of 397 children and adults (age range 2 to 70 years of age) was conducted to assess the effectiveness of treatment of the first seizure on the risk of relapse and the long-term prognosis of epilepsy. Patients seen within 7 days after a first witnessed unprovoked tonic–clonic seizure with or without partial onset were randomized to be treated with carbamazepine, phenytoin, phenobarbital, or valproate, or to be left untreated until the time of a second seizure. The mean period of observation was 274 days among patients given immediate treatment and 309 days among patients who did not receive treatment.

Overall, 36 of 204 treated patients and 75 of 193 untreated patients were referred for seizure relapse. The hazard ratio of relapse for untreated patients was 2.8 (95% CI, 1.9 to 4.2). The efficacy of treatment was maintained despite the fact that 41 (20%) of the treated patients discontinued the AED at some point. The results of this study were confirmed by an even larger pragmatic randomized trial (the MESS study) comparing immediate and deferred treatment for early epilepsy and single seizures.[44] Patients aged at least 1 month were randomized if both the clinician and the patient were uncertain whether to proceed with treatment. In this open multicenter trial, 722 patients were randomized to immediate treatment and 721 to deferred treatment. Of these, 404 and 408 had a single seizure at randomization, respectively. Immediate treatment prolonged the time to the first relapse (risk ratio [RR] 1.5; 95% CI, 1.2 to 1.8) and increased the proportion of patients achieving immediate 2-year remission (64% vs. 52%) ($p = 0.023$). These data are consistent with other reports[16,20] and support the assumption that treatment of the first unprovoked epileptic seizure significantly affects the short-term prognosis of a first seizure by reducing the risk of further seizure relapse—regardless of age, presumed etiology of seizures, and EEG abnormalities. However, the FIRST and MESS studies showed that the long-term prognosis of epilepsy (assessed by the chance of achieving 2-year remission after randomization) is virtually unaffected by the treatment of the first seizure[44,47] (Table 1). The long-term outcome of epilepsy was also unchanged by treatment of the first seizures in children enrolled in the small Canadian randomized trial and followed for 15 years.[15] These findings seem confirmed by studies conducted in developing countries, where most—if not all—patients are left untreated or receive drugs only after a prolonged disease course and repeated seizures. In these studies, untreated patients tend to achieve seizure remission in proportions similar to those of patients under treatment,[68] and the start of treatment leads to a proportion of successes and failures similar to that of early treated individuals from the developed countries.[23] In addition, population-based studies in developing countries show high spontaneous remission rates, even without AEDs.[48,50,51]

In summary, treatment of the first unprovoked epileptic seizure seems to reduce the risk of recurrence during the active phase of the disease but does not influence the long-term prognosis of epilepsy. In other words, AEDs exert a symptomatic action but not a curative effect on the course of epilepsy that might be most convincingly related to the underlying epileptic syndrome. It is commonly accepted that the different epileptic syndromes have a different severity and course that might or might not be influenced by AED treatment. A clear demonstration of the symptomatic rather than curative role of AEDs also comes from the results of meta-analyses of studies on their prophylactic use following head trauma,[56] brain tumor,[28] craniotomy,[40] and other clinical conditions.[64] The results of the clinical investigations lend support to the concept that none of the drugs currently in use for the treatment of epilepsy has been clearly shown to be antiepileptogenic in the sense of preventing the establishment of a chronic seizure disorder.[49]

Adverse Effects of Antiepileptic Drugs, Quality of Life, and Patients' Preference

Adverse drug reactions are reported in about a third of ambulatory patients receiving chronic AED therapy, 22% of

P.1330

whom receive monotherapy[17] (see also Chapter 101). Adverse treatment effects may lead to treatment failure in up to 36% of previously untreated or undertreated patients.[45] In the FIRST study,[24] adverse events were reasons for drug withdrawal in 7% of cases (14 of 204). In the MESS study,[44] patients in the immediate treatment group were more likely to report at least one adverse event than those in the deferred group (difference 8.6%; 95% CI, 3.6 to 13.6).

Table 1 Actuarial Cumulative Percentage Achieving 2-Year Remission at Various Time Intervals from Randomization in Patients Receiving Immediate or Deferred Treatment after a First Seizure

Study	Follow-up				
	2 yr	4 yr	5 yr	8 yr	15 yr
FIRST					
Immediate treatment	68	72	NA	NA	
Deferred treatment	60	67	NA	NA	
MESS					
Immediate treatment	69	NA	92	95	
Deferred treatment	61	NA	92	96	
CANADA					
Immediate treatment					80%
Deferred treatment					88%

NA, not available.
Comparative findings from the FIRST study (Musicco M, Beghi E, Solari A, et al., and the First Seizure Trial Group. Treatment of first tonic–clonic seizure does not improve the prognosis of epilepsy. *Neurology.* 1997;49:991–998), the MESS study (Marson A, Jacoby A, Johnson A, et al. Immediate versus deferred antiepileptic drug treatment for early epilepsy and single seizures: a randomised controlled trial. *Lancet.* 2005;365:2007–2013), and the Canadian study (Camfield P, Camfield C, Smith S, et al. Long-term outcome is unchanged by antiepileptic drug treatment after a first seizure: a 15-year follow-up from a randomized trial in childhood. *Epilepsia.* 2002;43:662–663).

The incidence of adverse drug reactions tends to increase with increasing dosage, even when plasma levels are maintained within the so-called therapeutic range.[45,46] The prevalence of any adverse drug effect may be even higher when specific screening procedures are adopted. This is particularly important when behavioral and cognitive functions are being assessed. It is commonly accepted that the currently available AEDs have an adverse influence on mental and behavioral functions, which are increased by higher plasma levels and polypharmacy (see Chapter 114).[29,43]

There are some patients who might have greater susceptibility to the adverse effects of drugs. These include infants (see Chapter 105) and the elderly (see Chapter 106), in whom drug metabolism might be inefficient because of the presence of immature or aging metabolic pathways; pregnant women, who are exposed to the teratogenic effects of AEDs and have an increased liver metabolic capacity and the development of drug-metabolizing capacity in the fetal liver; and patients with hematologic, hepatic, and renal disturbances, in whom drug metabolism may be defective.[42] The risk:benefit ratio of the anticonvulsant drug treatment must be carefully assessed in patients at their first epileptic seizure, as even a modest risk might not be accepted and might affect compliance with the proposed therapeutic regimens (see below).

The impact of treatment of the first seizure on the patient's quality of life and preference is still a controversial issue. In the MESS study,[44] immediate treatment was not followed by a significant change in the scores for anxiety, depression, and mastery. Patients randomized to immediate treatment were then more likely to express a preference for the alternative treatment than were those randomized to deferred treatment.

Other Factors

The decision to treat a first epileptic seizure must be based on factors that are pertinent to the individual patient's situation.[9] A practical factor that might influence the decision to treat a first epileptic seizure is the need for the patient to drive and pertinent licensing regulations regarding patients with seizures.[5] Another factor that may encourage treatment after a first seizure is the local health insurance system. In countries with public health insurance coverage, no pressures are made on the therapeutic decisions by the practicing physicians; however, in countries such as the United States, the risk of recurrence must be minimized to prevent financial complications to the patient. Compliance is also extremely influential in deciding whether to treat a patient after a first seizure. Although it may be difficult to assess compliance in a newly diagnosed patient, it is important to identify poor compliers, as failure to adhere to the proposed treatment regimen is one of the most common causes of treatment failure.[41] In the FIRST trial,[24] poor compliance was among the most likely causes of recurrence in treated patients. In patients with poor compliance, anticonvulsant therapy might be withheld until seizure recurrence, in which case the greater risk for further relapse may change the attitude of the patient toward medication. There are also sociocultural factors for each patient that must be considered when deciding whether the complications of a recurrence outweigh the risk of acute or chronic drug toxicity. These factors must be

P.1331

carefully evaluated on an individual basis, regardless of any general recommendation.

Starting or Withholding Treatment after a First Seizure

Even in the presence of multiple risk factors for seizure recurrence, the first unprovoked seizure may still remain an isolated episode. In addition, given the high potential for misdiagnosis among epileptic seizures, pseudoseizures, and nonepileptic events, treatment should be generally deferred in most patients with a first seizure. This is also the case for individuals in whom the recurrence of the seizure does not pose significant physical and psychological problems or who might be unduly exposed to the adverse effects of the AEDs (Table 2). Included are children, pregnant women, elderly subjects, and individuals with hematologic, liver, and kidney disorders. In children, for whom the consequences associated with a seizure are generally low because they are usually in a supervised environment and who are particularly susceptible to adverse effects from medications, the decision should usually be not to treat, even if they fall into categories with a high risk of recurrence. Likewise, in women of childbearing age, the recurrence of a first seizure must be balanced with the potential for adverse effects and teratogenic potential of AEDs. The elderly also might be left untreated after a first seizure because they may be less disadvantaged by the consequences of a relapse, their susceptibility to the adverse drug reactions is greater (see above), and the possibility exists that the first seizure is the hallmark of an underlying central nervous system disorder (i.e., progressive, symptomatic seizure). Patients with metabolic disorders will benefit from alternative treatments and may be at greater risk of experiencing drug toxicity. Even in the presence of an apparently unprovoked seizure, the acute manifestation of the disease must be considered.

As about 60% to 70% of recurrences are within 6 months of the first seizure,[2,31,60] patients withholding treatment should consider restriction of dangerous jobs, noncommercial driving, and recreational activities during this period. Commercial and professional drivers with a first unprovoked seizure should be subject to more restrictive rules. Patients at higher risk of recurrence might be considered for treatment after a single unprovoked seizure (Table 3). These include patients with single seizures and EEG epileptiform abnormalities or an associated medical or neurologic condition possibly increasing the risk of further seizures. In adults who depend on driving, the risk–benefit analysis is a matter of personal judgment and must be individualized. Any treatable epileptogenic condition must be identified and given specific therapy. Medical management of first seizures is beyond the scope of this chapter. The treatment of the first unprovoked seizure might be indicated in patients with a documented etiology or an abnormal EEG. Individuals with a first seizure associated with a neurologic deficit present from birth, progressive neurologic disease, or gross structural lesion also might be candidates of immediate treatment. Status epilepticus as the first seizure is a special case that merits careful assessment of the risks and benefits of treatment including prescribing abortive therapy. Those who present with a cryptogenic status as their first unprovoked seizure do not have an increased risk of recurrence.[33,60,63] However, should a recurrence occur, it is likely to be prolonged and the risk of recurrent status is increased.[10,63] However, the treating physician must also balance all the factors that play a role in the outcome of a first seizure, the personal characteristics of the patient, and the advantages and limitations of treatment. In that sense, the social complications (e.g., loss of employment) and the emotional reflections of a relapse should be strongly considered. If treatment is considered, the choice of the AED should be individualized and factors should be considered including teratogenicity, patient's cognitive abilities, drug interactions, physician's familiarity with the drug, and cost. The starting dose should be in the lower range and the maintenance dose should be increased only at the presence of a relapse. In the absence of published guidelines, the duration of treatment should be driven by common sense. In children, there is little justification for continuing treatment beyond 1-year seizure freedom. For adults, at least 1 year of treatment should be recommended and an individual decision is required for drug discontinuation and should consider the medical and social consequences of a recurrence. Where possible, all these data should be communicated to the patient and the relatives or caretakers, who must be as knowledgeable as possible about the issues so that an informed decision can be made.

Table 2 Suggested Treatment Plan in Patients with a First Unprovoked Epileptic Seizure

Favors withholding treatment	Favors considering treatment
Normal EEG	Abnormal (epileptiform) EEG
Cryptogenic/idiopathic etiology	Symptomatic etiology
Blood, liver, kidney disease	Risky occupation
Pregnancy	No disease interfering with drug metabolism Need to drive

EEG, electroencephalogram.

Table 3 Variables Associated with High and Low Risk of Seizure Recurrence after a First Unprovoked Seizure

	Risk of recurrence
Age	+/-
Sex	0
Family history (first-degree relatives)	+
Seizure type (partial)	+/-
Status epilepticus	+/-
Abnormal (epileptiform) EEG	++
Known etiology	++
Sleep state—sleeping	+
History of prior provoked seizures	+
Time elapsed from seizure	+
Abnormal neurologic examination	NA
Todd paresis	+
Drug treatment	-

-, association with low recurrence risk is weak; +/-, association with recurrence risk is conflicting; 0, no association; +, association with high recurrence risk is weak; ++, association with high recurrence risk is strong and/or consistent; EEG, electroencephalogram; NA, data not available.

P.1332

Treatment of the Patient with Occasional Seizures

In an earlier adult study,[34] the 70% recurrence risk after a second seizure led to the conclusion that treatment with AEDs is appropriate once a second seizure has occurred. In children,[62] the overall recurrence risk of about 70% was higher in those with a remote symptomatic etiology and in those whose second seizure occurred within 6 months of the first. EEG abnormalities and sleep state at the time of the seizure, which helped to distinguish those who had only one seizure from those who experienced a recurrence, were no longer associated with a differential risk of further seizures once a second attack had occurred. Treatment decisions in the child with a second seizure are complex. Many of these children have idiopathic self-limited syndromes such as benign rolandic epilepsy in which the need for treatment has been questioned.[1,26] In addition, only 25% of children who had two seizures experienced 10 or more seizures over a 10-year period.[62] Thus, the decision to treat children with cryptogenic/idiopathic seizures who have a second attack must consider whether a benign self-limited syndrome is present, as well as the frequency of the seizures and the relative risks and benefits of therapy.

More recent studies cast doubt even on the need to treat adults with rare seizures. The MESS study,[44] which randomized subjects to immediate versus deferred therapy, found no differences in outcome between the two groups. Delayed treatment in this study was when the physician and subject agreed to initiate treatment and was not necessarily the second seizure. As noted above, patients randomized to immediate treatment were then more likely to express a preference for the alternative treatment than were those randomized to deferred treatment. As treatment does not influence long-term outcomes, one needs to reassess the risks and benefits of treatment even in adults with two seizures. This is particularly true in young women entering their childbearing years and in patients who live in an urban setting who use public transportation rather than driving.

Summary and Conclusions

In light of the accumulated epidemiologic findings that have changed our understanding of seizures and epilepsy, treatment of a single seizure is no longer automatic. Many factors have to be weighed, including the effect of treatment on seizure recurrence, the effect of treatment on the long-term prognosis of epilepsy, the adverse reactions (including teratogenicity), and the cost of drugs. The diagnosis of the first seizure, the results of an EEG, and the presence or absence of an underlying etiology to which the seizure can be attributed all contribute to the decision of whether to treat. The adverse events of drug treatment, as well as patient lifestyle issues, must also be considered. The decision as to whether or not to treat a first unprovoked seizure must be based on a risk:benefit assessment that weighs the risk of another seizure against the risk of chronic AED therapy. This decision must be individualized and take into account both medical issues and patient and family preference. The Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society have recently developed the following recommendations for children and adolescents[37]: (a) treatment with AED is not indicated for the prevention of the development of epilepsy and (b) treatment with AED may be considered in circumstances where the benefits of reducing the risk of a second seizure outweigh the risk of pharmacologic and psychosocial side effects. In the absence of official guidelines for adults (which are awaited), these recommendations can also be applied to adults.

Chapter 123

Treatment of Neonatal Seizures

Eli M. Mizrahi

Mark S. Scher

Introduction

The overall goal of treatment of neonatal seizures is to minimize brain injury that may be associated with or caused by recurrent seizures. A critical factor in the therapy of neonatal seizures is accurate diagnosis. This requires precise clinical characterization and classification of neonatal seizures and, when the electroencephalogram (EEG) is available, accurate interpretation of the ictal EEG. These will allow for the determination of the presence or absence of behaviors that can be considered neonatal seizures and, importantly, whether these clinical events can be considered epileptic or nonepileptic in origin. Overall, this provides the basis for the determination of the appropriateness of antiepileptic drug (AED) treatment.

Characterization, classification, and determination of pathophysiology have been discussed in detail in Chapter 56 and are summarized in Table 1. In this chapter, the term *seizures* will be utilized to refer to all clinical seizure types; the terms *epileptic* and *nonepileptic* will be used to specifically address the therapy of these types. The discussion below, for the most part, will be directed toward seizures based on their clinical characteristics. However, some aspects of the discussion will consider electrical seizure activity, either alone or in relation to clinical seizures. In these instances, EEG seizure discharges will be referred to specifically. One practical method of classifying seizures is to consider the clinical events in relationship to electrical seizure activity. Thus, *electroclinical seizures* are those during which both clinical and electrical seizure activity occur simultaneously, *electrical-only seizures* are those without clinical events, and *clinical-only seizures* are those that occur with no associated electrical seizure activity.

Principles of Therapy

The goal of treating neonatal seizures is to prevent long-term central nervous system (CNS) dysfunction, which may be associated with or potential sequelae of seizures. The main objectives in the therapy of neonatal seizures are the treatment of the etiologic factors that may be responsible for the seizures and the cessation of seizures of epileptic origin with either AEDs or etiology-specific therapy. These goals may be achieved in the treatment of some, but not all, infants with seizures. Etiologic factors may not be determined in all cases, and when potential causes are discovered, their precise relationship to the seizures may not be known. Some clinical seizures, because of their nonepileptic physiologic origin, may not require AEDs. Importantly, AED administration in the treatment of some epileptic seizures may not be effective in control of either the clinical or the electroencephalographic seizures. Finally, some electroencephalographic seizures may be difficult to control, despite high doses of multiple AEDs. While it is not definitively determined that either recurring seizures or acute or chronic AEDs have an adverse effect on the developing brain, there is recent evidence suggesting that both seizures and AEDs may have unwanted sequelae.

In addition to the characterization and classification of seizure type, the treatment of neonatal seizures, ideally, is based on the consideration of several interrelated factors. These include identification of the etiology of the seizure, recognition of associated risk factors, determination of pathophysiology of the seizures, assessment of the duration and the severity of the seizures, understanding the natural history of the specific seizure disorder, and assessment of the expected effects that the seizures and the AEDs may have on the developing brain. Unfortunately, information concerning all of these factors may not be complete. Despite limitations imposed by incomplete data, some rational decisions for therapy can be made by understanding these constraints and the information that is known about neonatal seizures.

Phases of Acute Therapy

Three phases of acute therapy for neonates with seizures are initial medical management, etiology-specific therapy, and AED therapy. These phases are typically individualized to each infant.

Initial Medical Management

The usual principles of general medical management, which are important in the care of older children and adults with acute seizures, also apply to neonates with seizures: maintenance of airway, adequate ventilation, and cardiovascular circulation. Neonates with seizures may be critically ill, and the frequency or duration of epileptic seizures may be consistent with the diagnosis of status epilepticus. Changes in respirations, heart rate, and blood pressure may occur (a) in association with clinical seizures, (b) as a consequence of the seizures themselves, (c) as a consequence of the etiologic or risk factors, or (d) in association with vigorous AED therapy. Thus, measures must be taken to ensure adequate ventilatory support and circulatory perfusion of neonates with seizures during initial evaluation and therapy. The anticipation that these potential autonomic changes may occur will increase the likelihood of their successful treatment.

Table 1 Classification of Neonatal Seizures Based on Electroclinical Findings

Clinical seizures with a consistent electrocortical signature (pathophysiology: epileptic)
Focal clonic
- Unifocal
- Multifocal
- Hemiconvulsive
- Axial

Focal tonic
- Asymmetric truncal posturing
- Limb posturing
- Sustained eye deviation

Myoclonic
- Generalized
- Focal

Spasms
- Flexor
- Extensor
- Mixed extensor/flexor

Clinical seizures without a consistent electrocortical signature (pathophysiology: presumed nonepileptic)
Myoclonic
- Generalized
- Focal
- Fragmentary

Generalized tonic
- Flexor
- Extensor
- Mixed extensor/flexor

Motor automatisms
  Oral-buccal-lingual movements
  Ocular signs
  Progression movements
  Complex purposeless movements
Electrical seizures without clinical seizure activity

From Mizrahi EM, Kellaway P. Characterization and classification of neonatal seizures. *Neurology.* 1987;37:1837–1844; and Mizrahi EM, Kellaway P. The response of electroclinical neonatal seizures to antiepileptic drug therapy. *Epilepsia.* 1992;33(Suppl 3):114.

Table 2 Etiology-specific Therapy for Neonatal Seizures of Metabolic Origin

	Acute therapy	Maintenance therapy
Glucose, 10% solution	2 mL/kg IV	Up to 8 mg/kg/min IV
Calcium gluconate, 10% solution (9.4 mg of elemental Ca/mL)	2 mL/kg IV over 10 min (18 mg of elemental Ca/kg)	8 mL/kg/day IV[a] (75 mg of elemental Ca/kg/day)
Magnesium sulfate, 50% solution (50 mg of elemental mg/mL)	0.25 mL/kg IM	0.25 mL/kg IM repeated every 12 h until normomagnesemia
Pyridoxine	100 mg IV	

[a]After restoration of normocalcemia, tapering dosage may help in preventing rebound hypocalcemia.
Diagnosis of hypoglycemia, hypocalcemia, and hypomagnesia may vary between laboratories and is dependent on neonate's gestational age (with preterm infants tending to tolerate lower physiologic levels). Administration of metabolic correcting solutions requires careful monitoring of infant's systemic homeostasis, including electrocardiogram monitoring during administration of calcium.[33,34] Table from Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures.* Philadelphia: Lippincott-Raven; 1998:181.

Etiology-specific Therapy

When specific causes of seizures are identified and are potentially treatable, etiology-specific therapy is initiated. The therapy of specific etiologic factors is critical as the seizures may not be responsive to standard AED therapy unless the underlying causes are successfully treated. In some cases, etiology-specific therapy may be the only treatment needed. In other cases, AEDs must be administered because of secondary brain injury caused by the primary process. For example, metabolic etiologies such as hypocalcemia, hypomagnesemia, and hypoglycemia may be corrected, resulting in cessation of seizures and obviating the need for AEDs. On the other hand, these or other etiologies may be associated with additional underlying brain disorders; though therapies must be directed toward central nervous system (CNS) and systemic infections, AEDs may still be required for complete management.

Treatments of metabolic etiologies are listed in Table 2, including therapies for the relatively common conditions of hypocalcemia, hypomagnesemia, and hypoglycemia. For completeness, it also includes the therapy for pyridoxine deficiency. However, while pyridoxine deficiency is often cited as a treatable cause of medically refractory neonatal seizures, it is exceedingly rare and may not warrant the wide consideration it has received as an important cause of neonatal seizures. Other metabolic disorders can masquerade as hypoxic-ischemic encephalopathy with seizures and should be considered in the differential diagnosis, depending on historical, clinical examination, and laboratory findings; glycine encephalopathy, sulfite oxidase deficiency/molybdenum cofactor deficiency, glucose transporter defect deficiency syndrome, mitochondrial disorders, and folinic acid–responsive seizures are a partial listing.[18]

Table 3 Dosages of First-line, Second-line AEDs in the Treatment of Neonatal Seizures

Drug	Dose		Average therapeutic range	Apparent half-life
	Loading	Maintenance		
Diazepam	0.25 mg/IV (bolus) 0.5 mg/kg (rectal)	May be repeated one to two times		31–54 h
Lorazepam	0.05 mg/kg (IV) (over 2–5 min)	May be repeated		31–54 h
Phenobarbital	20 mg/kg IV (up to 40 mg)	3-4 mg/kg in two doses	20–40 μg/L	100 h after days 5–7
Phenytoin	20 mg/kg IV (over 30–45 min)	3-4 mg/kg in two to four doses	15–25 μg/L	100 h (40–200)

Acute Antiepileptic Drug Therapy

First-line Antiepileptic Drug Therapy

The AEDs traditionally utilized in the acute treatment of neonatal seizures are phenobarbital, phenytoin, and a benzodiazepine (diazepam and, more recently, lorazepam) given intravenously (Table 3). The dosages utilized in the United States are phenobarbital, 20 mg/kg as a loading dose, followed by additional dosages of 10 mg/kg to achieve serum levels between 20 and 40 μg/mL; phenytoin, 20 mg/kg as a loading dose to achieve serum levels between 15 and 20 μg/mL; diazepam, 0.1–0.3 mg/kg in repeated dosages; and lorazepam, 0.05 mg/kg.[4,13,39,40] Acute administration of each of these AEDs may carry some risk of adverse reactions and, therefore, treated infants should be monitored closely. These adverse events may include CNS depression, hypotension, bradycardia, and respiratory depression (phenobarbital, diazepam, lorazepam), and cardiac arrhythmia (phenytoin).

Traditionally, initial dosing has been determined only by body weight of the infant. However, Painter et al.[51] stressed the importance of serum protein characteristics of phenobarbital and phenytoin in initial dosing. The unbound (free) fraction of each of these drugs is pharmacologically active, and the protein-binding characteristics in neonates may vary to an extent that a uniform dosing schedule by weight only may not provide the same efficacy and safety to all infants. Thus, Painter et al. suggested that the use of in vitro binding profiles, calculated for individual neonates at risk for seizures, will allow the establishment of appropriate loading dosages of each drug and will avoid potential toxicity in individual neonates. This technique is not universally available. However, the findings do underscore the potential variability among neonates in the utilization of these drugs.

There is relative consensus of selection of specific AEDs as first- and second-line drugs: Phenobarbital is almost universally accepted as the first-line AED and phenytoin as the second-line AED.[4] However, there is less consensus as to the use of additional AEDs if the initial drugs fail to control the seizures. Most often, a benzodiazepine (diazepam or lorazepam) may be given in these instances.

Despite the wide acceptance of phenobarbital as the first-line AED, there have been few controlled studies of the relative efficacy of various AEDs in the initial treatment of neonatal seizures. Recently, however, Painter et al.[53] compared the effectiveness of acute administration of phenobarbital and phenytoin in seizure control, found no significant difference, and suggested that neither is as efficacious as originally thought.

It is helpful to understand aspects of the pharmacology of phenobarbital and phenytoin in the neonate during their use in treatment of seizures. The availability of active drug given at standard doses may be altered by pathologic conditions in the sick neonates. These principles are discussed in detail elsewhere[12,36,37,50] and summarized here. Phenobarbital is a weak acid and is protein bound. Infants with acidosis may have less active phenobarbital available and those with hypoalbuminemia may have greater unbound or active drug available. Both conditions may be found in sick neonates. Phenobarbital is eliminated by the liver and kidney. Thus, infants with impaired hepatic or renal function, which may occur in infants with hypoxic-ischemic encephalopathy, may have a reduced rate of elimination and, therefore, a potential for toxicity with standard dosing. There is a longer half-life of phenobarbital in preterm compared to term infants, and in term infants the half-life is reduced with chronologic age in the first month of life. Thus, in preterm infants there is a potential for higher serum levels with standard doses and the potential for toxicity. As the infant becomes older there is the potential for identical doses to result in lower serum levels, creating the potential for breakthrough seizures with no other change in the infant's clinical condition. Overall, monitoring trends of serum levels rather than day-to-day fluctuations are more useful in management of phenobarbital therapy.[17,21,52,62]

Important pharmacologic characteristics of phenytoin are described in detail elsewhere[10,16] and summarized here. These features include nonlinear pharmacokinetics, a variable rate of hepatic metabolism, a decrease in elimination rates during the first weeks of life, and a variable bioavailability of the drug with various generic preparations. In addition, there is a redistribution of the AED after the initial dose resulting in a drop in brain concentrations after the first dose. These pharmacologic characteristics indicate that phenytoin use requires individualization of dosing after the initiation of therapy.

Acute Therapy for Refractory Seizures

Because neonatal seizures may be resistant to traditionally utilized AEDs, other medications have been tried with varying success.[26,27,49,50] True efficacy of these agents is difficult to assess because their trials have been conducted either in an uncontrolled manner, on few patients, on infants who have already received and failed with other AEDs, on infants with only clinical seizures with electroencephalographic confirmation, or on infants utilizing oral medication (because of availability of the compound), thereby limiting the assessment of efficacy. In addition, because of the preliminary nature of these trials, little safety data are available. These AEDs have been used as alternative acute drugs or as adjuvant therapy.

The AEDs used as alternative acute therapy—and given intravenously—are midazolam,[31,58] lidocaine,[26,27] and paraldehyde (not available in the United States).[35] One recent study reported success with continuous midazolam infusion in the treatment of otherwise uncontrolled neonatal seizures,[31] although infants experienced treatment-related hypotension that was medically managed. Lidocaine has also been utilized, primarily in Europe, as an AED in neonates. It has been administered intravenously at a rate of 4 mg/kg/hr, which achieves serum levels between 3.4 and 10.5 mg/L. This drug has a narrow therapeutic range; at serum levels between 0.5 and 4 mg/L, lidocaine may act as an anticonvulsant, but at levels of

P.1338

7.5 mg/L, it may act as a convulsant.[26,27,48,50,55] Boylan et al.[9] reported limited success with lidocaine in refractory neonatal seizures. Another recent investigation[60] reported that during the use of lidocaine (initial loading dose of 2 mg/kg over 10 minutes followed by a continuous infusion of 6 mg/kg/hr), 4.8% of infants experienced a cardiac arrhythmia (all responding to lidocaine discontinuation).

Some AEDs have been used in attempts to control otherwise medically refractory seizures. Agents in both classes have been utilized either intravenously or orally with variable success. Those given intravenously and primarily as alternatives to acute therapy include clonazepam,[3] lidocaine,[9,26,27,60] midazolam,[58] and paraldehyde.[35] Other agents given orally to control medically refractory seizures include carbamazepine,[38] primidone,[56] valproate,[20] vigabatrin,[2] and lamotrigine.[40] The success of this latter group of AEDs is difficult to assess since they have been used in conjunction with other AEDs and well into the course of illness.

These other medications include carbamazepine, primidone, paraldehyde, clonazepam, valproate, vigabatrin, and lidocaine, Carbamazepine has been utilized in dosages of 10 to 16 mg/kg/day to achieve serum levels between 10 and 40 mg/L approximately 6 hours after its oral administration.[38] Primidone, also given orally to neonates with otherwise refractory seizures, has been administered in loading dosages between 15 and 25 mg/kg.[54,56] Paraldehyde, given intravenously, has been utilized with success (200 mg/kg, followed by 15 mg/kg/hr).[23,35] Clonazepam, intravenously in dosages of 0.1 mg/kg, has been given to infants with seizures refractory to phenobarbital.[3] Valproate has been reportedly used to treat neonatal seizures, with serum levels up to 60 mg/L.[20] There are also anecdotal experiences with the use of vigabatrin and lamotrigine in neonates with medically refractory seizures, although few published data of efficacy and safety are available.

Initiation of Therapy

Not all neonatal seizures require acute AED therapy. Some examples include seizures that may be nonepileptic in origin; seizures that may be epileptic in origin but that are adequately treated by etiology-specific therapy; or epileptic seizures that may be considered so brief, infrequent, and short lived as to not warrant AED treatment. Thus, the decision to initiate AED therapy for neonatal seizures should not be automatic after the reporting or recognition of the seizures. Rather, initiation of AED therapy requires the consideration of seizure type, pathophysiology, duration and severity of seizures, natural history of the seizure disorder, and anticipated effects of both the seizures and the selected AEDs on the infant. Though comprehensive data on these factors may not be available, it is essential that these factors be considered at the onset of therapy.

Most often, clinicians consider beginning AED therapy without the benefit of EEG or bedside EEG/video monitoring. Under these circumstances, the clinician must first decide whether the clinical seizures are of epileptic or nonepileptic origin (Table 1) (see Chapter 56). If the seizures are of epileptic origin, they must be assessed for duration and severity.

Antiepileptic Drug Therapy Based on Features of the Clinical Seizure

The clinician may encounter four specific situations in which AED use may be considered based solely on the clinical features of the seizures (Table 1)[43]:

1. **Focal clonic or focal tonic seizures may be prolonged and recurrent**. The clinical features of focal clonic or focal tonic seizures help to designate them as epileptic in origin. Focal clonic seizures are repetitive and rhythmic muscle contractions that cannot be arrested by restraint or repositioning. Similarly, focal tonic seizures, such as sustained posturing of a limb, cannot be altered by these maneuvers. The focal tonic seizures that are characterized by eye deviation can be differentiated from the random eye movements of nonepileptic motor automatisms, as the epileptic tonic eye deviation is sustained and cannot be evoked by stimulation. Once the clinical focal clonic or focal tonic seizures are considered epileptic in origin, duration and severity must be considered. When they are thought to be sustained and prolonged, they are treated vigorously with AEDs.
2. **Focal clonic or focal tonic seizures may be brief and infrequent.** The specific features of these seizures of epileptic origin are the same as those just described, also providing the basis for their designation as epileptic in origin. As such, AEDs may be utilized in attempts to control the seizures. However, because these seizures may be brief, occur infrequently, and have a short natural history with relatively rapid spontaneous resolution, the use of AEDs for these seizures may not be required and is being reconsidered. This re-evaluation is based on the following considerations: epileptic seizures may be reactive, or secondary, to an acute underlying brain disorder; for some infants following the acute injury, seizures may resolve spontaneously as the acute period passes; and, in these instances, the potential adverse effects of AEDs may outweigh the potential risks of these brief and infrequent seizures on the developing brain.[46] Unfortunately, specific criteria for the differentiation of "brief" and "infrequent" seizures from "prolonged" and "recurrent" seizures have not been established. In addition, the issues of whether AEDs or seizures adversely affect the immature brain have not yet been completely resolved.
3. **Generalized tonic posturing and motor automatisms may be responsive to stimulation and may be suppressed by restraint.** Some seizure types may be presumed to be of nonepileptic origin based on their clinical features and their response to stimulation and restraint (see Chapter 56). These include generalized tonic posturing and motor automatisms (including ocular signs, oral-buccal-lingual movements, and movements of progression, and are more traditionally referred to as *subtle seizures*). This determination can be made at the bedside based on the characterization of the events and their response to clinical maneuvers: The spontaneous events can be suppressed by restraint or repositioning of the limbs or trunk, and events similar to spontaneous events can be evoked by tactile stimulation. Traditionally, these clinical events have been treated with AEDs, and in some instances, their frequency and severity have diminished. Whereas this finding has been utilized to support the notion that these events may be epileptic seizures, this effect of AEDs is most likely not the result of specific antiepileptic properties, but rather because some of these drugs are also CNS depressants. Overall, if generalized tonic posturing and motor automatisms demonstrate characteristic clinical features, they can be presumed to be of nonepileptic origin and do not require AED therapy.[41,43] Although the clinical events may be initially quite dramatic, their natural course is one of gradual and spontaneous resolution without AED therapy.
4. **Generalized tonic posturing and motor automatisms may not be responsive to stimulation or may not be**

   P.1339

   suppressed by restraint. For some infants, the clinical features of spontaneous generalized tonic posturing and motor automatisms may be typical of nonepileptic events, but they may not respond in a characteristic way to the clinical maneuvers of restraint, repositioning, or stimulation. In these instances, the decision to initiate AED treatment is more difficult. Some clinicians may withhold AEDs with the understanding that the clinical features of the spontaneous events are evidence enough of the nonepileptic origin of the events. However, others may initiate AED treatment with the belief that clinical observation and maneuvers alone cannot provide data to indicate underlying pathophysiology.

Antiepileptic Drug Therapy Based on Electroencephalographic or

Electroencephalographic/Video Monitoring

Bedside EEG and EEG/video monitoring are powerful diagnostic tools in the diagnosis of neonatal seizures, and they complement clinical assessment to a considerable degree.[30,42] When these techniques are available and appropriately utilized, additional clinical circumstances may be encountered that determine whether AED therapy should be initiated in the treatment of neonatal seizures.

1. **Clinical seizures may be present in the absence of EEG seizure activity**. These clinical seizure types include generalized tonic posturing and motor automatisms (or some "subtle seizures"). As discussed above, the clinical features of the spontaneous events and the response of the events to clinical maneuvers suggest that they are of nonepileptic origin. The lack of EEG seizure activity at the time of the clinical seizures provides further support for this determination. These clinical events, particularly when they occur in the absence of electrical seizure activity, are not treated with AEDs.
2. **Electroencephalographic seizure activity may occur in the absence of any clinical seizures**. This may occur in neonates who are pharmacologically paralyzed for respiratory care; in neonates with seizure discharges of the depressed brain type (see Chapter 56); or in neonates with epileptic seizures already treated with AEDs. Electrical seizure activity occurring in the absence of any clinical seizure activity is treated with AEDs. However, these electrical seizures may be highly resistant to therapy, despite high dosages of several AEDs, and the degree to which high-dose polypharmacy should be utilized in attempts to abolish EEG seizure activity is controversial (see below).

Response of Seizures to Acute Antiepileptic Drug Therapy

Although AED therapy is initiated to stop epileptic seizures, prevent seizure recurrence, and minimize any adverse consequences of the seizures to the infant, not all of these goals may be easily accomplished. Not all electrical seizure discharges can be eliminated; when some are eliminated, their recurrence can be unpredictable, and it is not clear what, if any, adverse effects seizures may have on the infant.

The response of epileptic seizures to AEDs has been described in investigations utilizing EEG/video monitoring. In an infant not treated with AEDs, clinical epileptic seizures occur in a time-locked relationship to EEG seizure activity. The initial response to AED administration is the cessation of clinical seizures; however, the EEG seizure activity may persist. This initial response to AED treatment has been referred to as decoupling[43,44] or uncoupling[57] of the clinical from the electrical seizure (Figs. 1 and 2). The response of the EEG to additional therapy consisting of increasing dosages or with additional AEDs is variable and not always successful. The electrical seizure activity may prove to be highly resistant to additional AED therapy.

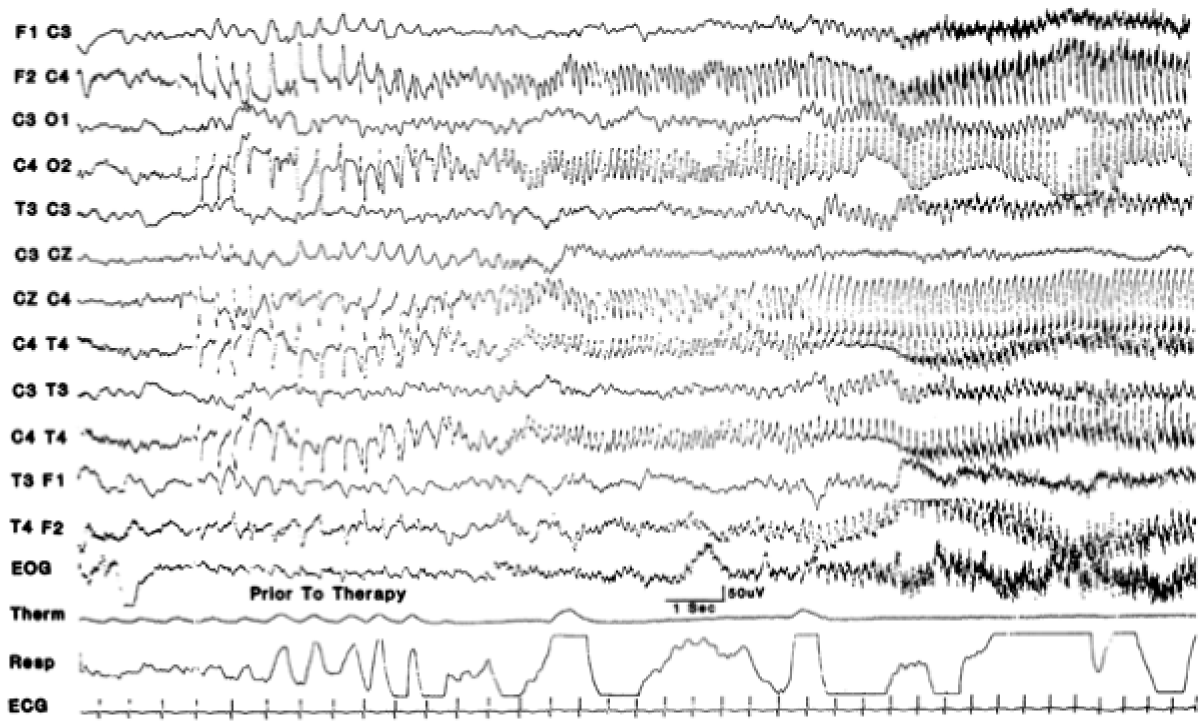

FIGURE 1. Prior to treatment with phenobarbital, this electrical seizure discharge arising from the right central region is associated with focal clonic seizures involving the left arm and leg. (From Mizrahi EM. Consensus and controversy in the clinical management of neonatal seizures. In: Volpe JJ, ed. *Clinics in Perinatology. Vol 16, No 2: Neonatal Neurology*. Philadelphia: WB Saunders; 1989:485–500, with permission.)

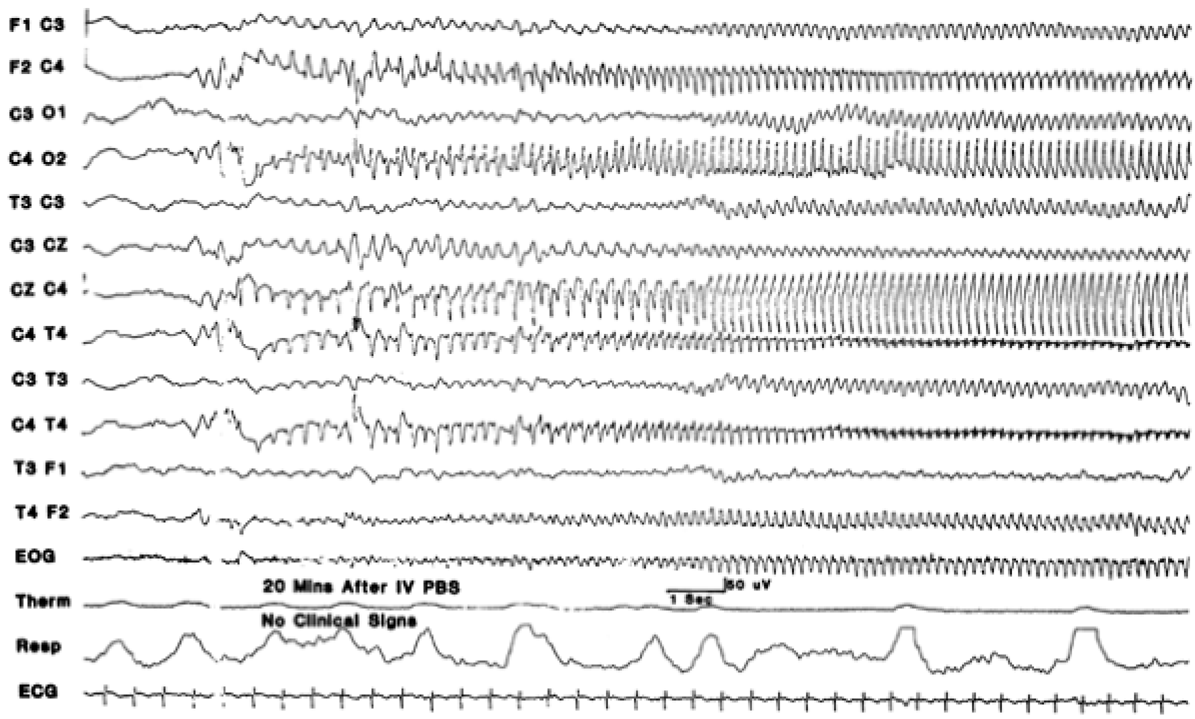

FIGURE 2. Electroencephalogram from the same infant in FIGURE 1, following initiation of therapy with phenobarbital. The clinical seizure resolved, although the electrical seizure discharge recurs without clinical signs. (From Mizrahi EM. Consensus and controversy in the clinical management of neonatal seizures. In: Volpe JJ, ed. *Clinics in Perinatology. Vol 16, No 2: Neonatal Neurology*. Philadelphia: WB Saunders; 1989:485–500, with permission.)

Whereas the clinical seizures of epileptic origin may be controlled with AED therapy, the electrical seizure activity recorded by EEG that accompanies the clinical seizures may persist.[24] This response to AEDs raises the central question: What is the end-point of AED therapy cessation of clinical seizures or cessation of electrical seizure activity?

Vigorous attempts to eliminate electrical seizure activity may lead to the administration of higher dosages and multiple AEDs. In some instances, this management regime can be successful. However, this strategy may also fail to control EEG seizure activity. Regardless of the degree of success in seizure control, high-dose polypharmacy may be associated with the clinical problems of CNS depression, systemic hypotension, and respiratory depression. Here, the clinician must weigh the potential risks of vigorous AED treatment against the potential benefits and likelihood of success of therapy. In these situations, therapeutic strategies may be devised to strike an even balance. One scheme is to attain high therapeutic levels of phenobarbital and phenytoin, and then utilize individual dosages of a benzodiazepine in attempts to reduce or eliminate electrical seizure discharges. Further AED therapy may not be attempted because of the systemic adverse effects that are frequently encountered.

Chronic Therapy

Maintenance Therapy

Not all neonates require chronic therapy after acute seizures have been controlled; however, specific criteria for selection of neonates for maintenance therapy remain controversial. Once a desired therapeutic effect is obtained in the acute setting, infants are typically placed on regimens of maintenance AEDs. Phenobarbital, alone or with phenytoin (if it had been required to control the clinical seizures acutely), is utilized. The maintenance dosage of each is 3 to 4 mg/kg/day. The principles of monitoring serum AED levels, utilized in older children and adults, apply to neonates: Serum levels are most optimally obtained after five half-lives of the drug to be tested. If drug levels are obtained and found to be in a laboratory-designated *toxic range*, it should be considered in relation to the clinical condition of the infant. The presence of clinical toxicity rather than the isolated finding of elevated serum drug levels should determine alteration of dosages.

Maintenance treatment with either phenobarbital or phe-nytoin may pose some difficulties early in the course of therapy. When maintenance dosages of phenobarbital at 5 mg/kg/day are utilized, there may be drug accumulation within 5 to 10 days.[52] This is related to the relatively slow elimination rate of phenobarbital within the initial 2 weeks of treatment. This is particularly true for asphyxiated infants who may have had concomitant hepatic or renal dysfunction.[17,22,62] Eventually,

however, elimination rates increase with duration of therapy. Thus, maintenance dosage requirements may be relatively lower early in the course of therapy and increase later. Similarly, there may be problems in maintenance therapy with phenyt-oin. Stable serum levels may be difficult to maintain because of phenytoin's nonlinear kinetics and the rapid decrease in elimination rates during the first weeks of life.[10,16] The monitoring of serum AED levels periodically or when the clinical state of the infant changes (e.g., depressed state of alertness or breakthrough seizures) will guide the clinician in drug dosing, despite the relatively unpredictable pharmacokinetics of AEDs in the neonatal period.

Discontinuation of Therapy

Discontinuation of AEDs after a period of clinical seizure control is highly individualized as no specific practice guidelines have been established. An important consideration is the probable natural history of the treated disorder. For example, some seizures may represent a short-lived phenomenon produced in reaction to an acute injury. In this instance, then, the traditional practice of long-term AED therapy will extend treatment beyond what is needed for a relatively short-term clinical disorder. No controlled investigations have resolved this issue, and most clinicians individualize chronic AED therapy. Reported maintenance schedules range from 1 week to 12 months after the last seizure.[8] Although specific clinical and EEG predictors of recurrent seizures following AED withdrawal have not been identified,[11,22] there has been increasing clinical interest in short-term therapy, with AED withdrawal 2 weeks following the infant's last clinical seizure. Whereas EEG may be helpful in the neurologic assessment of infants following neonatal seizures, its use as a predictor of seizure recurrence has not been as valuable. This is, in part, related to the fact that there are no reliable interictal EEG signs of epileptogenesis early in life (e.g., spike-and-wave or sharp-wave transients) that can be present in older children. Therefore, the decision to withdraw AEDs is based primarily on the clinical course of individual infants and the report of the presence or absence of seizures.

Risk Versus Benefit of Antiepileptic Drug Therapy

As with all therapy, the decision to treat neonatal seizures with AEDs is based upon the consideration of relative risks versus relative benefits. Current evidence suggests that the treatment of electrical or electroclinical seizures with AEDs outweighs the relative risks of the use of AEDs themselves on the developing brain. This is particularly true if first-line AEDs at standard doses control the seizures. As increasing doses and AEDs are required, the risk:benefit ratio may change.

Risk of Recurrent Seizures

Primary Risks

For many years it was believed that even though the immature brain was more likely to develop seizures in response to injury than the more mature brain, the immature brain was either more resistant to seizure-induced injury or that any seizure-related alterations were not clinically significant. However, there is no clear consensus as to what, if any, sequelae may be associated with the occurrence of epileptic seizures in the developing brain.[28] Though some investigators suggest that, in animals, there are important changes in the CNS at a cellular or molecular level or involving brain circuitry, these may be transient, or their influence may not be detectable when performance is tested. These issues are the subject of continuing investigations. Various research strategies have been undertaken to further understand this problem with variable results. Overall, emerging evidence suggests that seizures early in life can result in permanent behavior and enhanced epileptogenicity although the mechanisms of some seizure-induced dysfunction have not been clearly delineated.[29,59] A number of mechanisms of seizure-induced injury have been investigated to determine whether seizures cause direct neuronal injury, whether seizures impair brain growth, whether seizures enhance epileptogenesis by altering hippocampal development, and whether seizures alter animal learning and behavior or the development of normal brain pathways.[5,59,61] These are discussed in detail in Chapter 56.

Secondary Risks

In addition, there are few conclusive clinical investigations of the adverse systemic effects of seizures. However, infants with prolonged seizures may experience changes in respiration, heart rate, or blood pressure and may have increased levels of energy utilization. In an infant who may already be medically compromised, these may be unwelcome clinical findings.

Risk of Antiepileptic Therapy

Primary Risks

There is also an equal lack of consensus concerning the possible adverse effects of AEDs on the developing brain. Early experimental data suggest alteration in cell growth and energy substrate utilization.[6,14,15,47]

However, the applicability of these findings to human neonates has been called into question, and the relative risks have been considered small when compared with the overall potential gain.[62] More recently, Ikonomidou et al.[7] assessed the effect of phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, and valproate on apoptotic neurodegeneration in the developing rat brain in plasma concentrations relevant for seizure control in humans. The basis of their study was the consideration that AEDs work via three mechanisms: limitation of sustained repetitive neuronal firing via blockade of voltage-dependent sodium channels; enhancement of γ-aminobutyric acid (GABA)–mediated inhibition; and blockade of glutamatergic excitatory neurotransmission. However, they hypothesized that these mechanisms that are blocked are also features of an endogenous neuroprotective system in the brain that is crucial for neuronal survival during development. They concluded that AEDs may impair survival-promoting signals and an imbalance between neuroprotective and neurodestructive mechanisms in the brain, which, during a developmental period of ongoing programmed neuronal death, will promote apoptotic neurodegeneration. However, it is unclear if these results can be extrapolated to the human. In addition, recent data from the same group show that another AED, topiramate, lacks the toxicity seen with some of the other drugs mentioned above.[24]

Secondary Risks

There have also been few studies of adverse effects of acute AED therapy. However, vigorous treatment may result in CNS depression, hypotension, bradycardia, and respiratory depression,[25] and may create the potential for secondary CNS hypoxia or ischemia.

Balanced Treatment Regimen

Overall, a regimen that may minimize perceived risks and maximize therapeutic benefit is as follows: (a) initiate acute therapy to eliminate clinical seizures with the first-line AED of phenobarbital; (b) if clinical or EEG seizures persist, increase phenobarbital dosage, add another first-line AED, phenytoin, and, if needed, a benzodiazepine; (c) if clinical seizures are controlled but electrical seizures persist, increase first-line AEDs to obtain high-therapeutic serum levels; (d) after seizure control is attained or is determined to be acceptable based on trials of initial therapy, establish maintenance therapy; (e) withdraw

P.1342

AEDs 2 weeks following the last clinical seizure; and (f) carry out clinical follow-up.

Summary and Conclusions

Treatment and Long-term Outcome

Though it is hoped that successful AED treatment of neonatal seizures will either prevent adverse sequelae or improve long-term outcome of affected neonates, there are few comprehensive studies that provide conclusive data concerning the relationship of cessation of seizures and prognosis. It may be assumed, however, that easily controlled seizures are the result of transient, successfully treated, or benign CNS disorders of neonates. On the other hand, medically refractory neonatal seizures may be the result of more sustained, less treatable, or more severe brain injury. Based on these assumptions, the primary factor that predicts outcome is the underlying cause of the seizures rather than specific characteristics of the epileptic events themselves.

Quality of Life Following Neonatal Seizures

Quality-of-life issues for patients who have experienced seizures have been almost exclusively discussed in relation to older children and adults. However, there are relevant points to be made for the neonate. Discharge from the hospital following the diagnosis and therapy of neonatal seizures is a period of both relief and increased anxiety for parents, other family members, and caregivers of affected infants. Some infants may have multisystem disorders requiring significant medical follow-up; others leave the hospital without any further problems. Despite these differences, discharge planning should include the discussion of seizure recognition; the potential, if any, of seizure recurrence; medication administration; and the course of action if seizures do recur.

Because the long-term outcome for most neonates with seizures is generally good, it is important to stress the fact that individual infants can be expected to have few, if any, problems that could be related to the neonatal seizures (beyond those dictated by the underlying etiology). For those infants with a good prognosis, efforts should be made to help family members look past the neonatal seizures and view their newborns as "healthy" rather than as "ill" children. For those infants whose neurologic outcome will clearly not be normal, clinicians should stress the needs of the potentially multiply handicapped child.

The occurrence of seizures in the newborn could be limiting to infants and children who may eventually be seizure free if parents view them as "at risk." Ample opportunity should be given to families to fully discuss their apprehensions and concerns. The clinician can take the lead in providing a forum for this discussion and, in turn, a basis for the normalization of the lives of infants and children who may have had seizures as neonates.

Chapter 124

Treatment of Febrile Seizures

Peter R. Camfield

Carol S. Camfield

Kai J. Eriksson

Introduction

From a biologic perspective, febrile seizures are virtually always benign. However, they are frightening for parents and disruptive to family life. Therefore, the primary goal for treatment for febrile seizures should be to provide information and reassurance for parents. Aspects of febrile seizures other than treatment are considered in Chapter 57.

Evidence for the Benign Nature of Febrile Seizures Epilepsy

Epilepsy subsequently develops in only 2% to 4% of children with a first febrile seizure.[1,54,73] When it does, the seizures can be of virtually any type, although the highest association is with generalized rather than partial seizures.[14,61,62] Approximately 15% of children with epilepsy have one or more preceding febrile seizures, regardless of the cause of the epilepsy.[14] This observation suggests that the tendency to have febrile seizures plays an important role in a person's seizure threshold; however, there is no evidence that one or multiple febrile seizures cause epilepsy.[1,54,57] The febrile seizure tendency is likely inherited, possibly as an autosomal dominant trait with variable penetrance (see Chapter 57).

Intractable Complex Partial Seizures (the Mesial Temporal Sclerosis Connection)

For a further discussion of this issue, see Chapter 13. Unquestionably, intractable temporal lobe epilepsy with mesial temporal sclerosis, identified by pathologic studies or magnetic resonance imaging (MRI), has later developed in some children with prolonged febrile seizures.[20,26] These patients are rare,[14] and fortunately febrile status epilepticus is a benign phenomenon in most cases.[48] The cause-and-effect relationship between prolonged febrile seizures and mesial temporal sclerosis in humans is still debated, and the minimum length of febrile seizure that might cause mesial temporal sclerosis is unknown. Some animal experiments suggest that status epilepticus can damage mesial temporal structures in the immature brain,[51,53] but other studies do not.[76] Nevertheless, it seems prudent to stop prolonged febrile seizures promptly. It is important to keep in mind that an estimated 75% of prolonged febrile seizures are the first febrile seizure.[54] Therefore, the effort to eliminate febrile status should not determine the treatment for the vast majority of children with febrile seizures who have an excellent outcome.

Brain Damage

Short febrile seizures do not appear to damage the brain. The National Institute of Neurological Disorders and Stroke (NINDS) Collaborative Perinatal Project included 431 sibling pairs in which only one child had febrile seizures.[24] Testing included the Wechsler Intelligence Scale for Children (WISC) as a measure of overall intelligence and the Wide Range Achievement Test (WRAT) as a measure of academic achievement. No difference was found between children with and without febrile seizures in psychometric test scores at the age of 7 years. Even those 27 children with a febrile seizure lasting 30 minutes or more had a mean full-scale IQ no different from that of their siblings. The only exceptions occurred in sibling pairs in which the child with the febrile seizures was known to be neurologically abnormal before the first febrile seizure.

The British febrile seizure study documented intellectual, behavioral, and achievement function in a national sample of children followed to age 10 years.[74] There was no penalty for having one or more febrile seizures.

In the opinion of these authors, these studies are so robust that the issue of short febrile seizures and brain damage can be put to rest.

Recurrent Febrile Seizures

About 40% of children with a first febrile seizure have at least one recurrence.[1,54] Multiple recurrences are rare, with fewer than 10% having more than three recurrences.[54] There are several statistically valid predictors of recurrent febrile seizures, although for the individual child in a clinical setting, these predictors are often not very powerful.

Age is the most powerful predictor of a febrile seizure recurrence. If a child has a first febrile seizure at an age of <1 year,[54] <15 months,[7] or <18 months,[40] the risk for recurrence is increased severalfold. The risk for recurrence is also increased if the first seizure occurred at a low body temperature or after a short illness, or if there is a close family history of epilepsy.[7] Some authors have noted that atypical features of the first febrile seizure (focal, clustered, or prolonged) may predict recurrence,[57] although the largest studies did not find such a relationship.[1,7] One experienced investigator noted that increased exposure to infectious illness by attendance at a daycare facility increased recurrences.[40]

A typical child with a first febrile seizure who has the highest risk for recurrence (>60%) would be <14 months of age, have a marginally elevated temperature within the first day of being ill, and have a close family relative with febrile seizures. A typical child with a minimal risk for recurrence (<15%) would be >3 years at the first febrile seizure, have a temperature above 39°C at the time of the seizure after an illness of several days, and have no family history of febrile seizures.

P.1346

If treatment for prevention of recurrent febrile seizures is contemplated, these two extremes of risk should be taken into account. However, the ability to predict recurrence does not mean that preventive treatment is indicated.

Approaches to Treatment

Antipyretic Measures to Prevent Febrile Seizures

Because fever (usually a high fever) is an essential element in the genesis of febrile seizures, it would seem intuitively correct that antipyretics would prevent febrile seizures. Empiric studies suggest the opposite. A meta-analysis concluded that there is no evidence that antipyretic medications reduce the risk of febrile seizure recurrence.[25] A British study found that many children with an initial febrile seizure had received an appropriate dose of antipyretics within an hour or two of a febrile seizure.[65] A Canadian study found no clear benefit in regard to recurrence risk from intensive antipyretic instructions to parents.[17]

A Finnish study randomized children to receive placebo or acetaminophen (10 mg/kg) at the time of illness for 2 years following a febrile seizure.[70] Again, there was no effect on febrile seizure recurrences. Those receiving placebo had recurrent febrile seizures during 8.2% of febrile illnesses, compared with 5.2% for those receiving acetaminophen.

A Dutch study randomized 230 children with at least one risk factor for a recurrent febrile seizure to either receive ibuprofen or placebo during subsequent febrile illnesses. The recurrence risk was identical in treatment and placebo groups.[71]

At present, the only apparent effect of antipyretics on febrile seizure treatment may be to increase “fever phobia."[67] This may be contrasted with the increasing evidence of the beneficial effects of fever during recovery from infections.[66] The compulsive use of antipyretic drugs cannot be recommended, other than to make the child more comfortable. Because sponging the child is ineffective in reducing body temperature and is uncomfortable, it should be abandoned.[55] Despite the strong evidence that antipyretics are ineffective, many health care providers remain attached to their use; more education is needed.[75]

Another obvious approach to reducing febrile seizures would be to reduce the frequency of febrile illness in childhood. Vaccination against common childhood infectious illness is to be supported. Whole-cell pertussis vaccines frequently cause fever, which in turn may provoke a febrile seizure.[34] Acellular pertussis vaccine causes fewer febrile reactions, and now is in widespread use for routine immunization. In Canada and Japan there is good evidence that acellular pertussis vaccine is associated with many fewer febrile seizures.[42,44]

Day care attendance appears to increase the number of febrile illnesses in children in the febrile seizure age range[22] and is associated with first febrile seizures[9] and recurrences.[40] The effect of the size of the day care on rates of febrile illness has not been reported. As the risks associated with a febrile seizure are exceedingly low and the benefits of day care may be large, the issue of febrile seizures should rarely have an effect on the choice of setting for a child's daily care.

Dealing with Febrile Status Epilepticus

Physicians and emergency department personnel should promptly treat any child admitted with an ongoing febrile seizure. Intravenous or rectal liquid diazepam is well studied and demonstrated to be effective.[39] Intranasal midazolam was found equally effective to intravenous diazepam to stop seizures in a randomized study of 47 children presenting to an emergency room with a febrile seizure of at least 10 minutes' duration.[43] From the time of administration, intravenous diazepam had a shorter response time; however, it takes time to achieve intravenous access. The time from arrival in the emergency room to seizure cessation averaged 2 minutes less for the midazolam group. A larger study is needed to confirm these results before intranasal midazolam can be recommended to replace diazepam.[41]

Buccal midazolam was recently shown in a randomized study in the United Kingdom to be statistically more effective and as safe as rectal diazepam in 219 separate febrile or afebrile seizure episodes in 177 children over the age of 6 months.[49] Limitations for the use of intranasal or buccal midazolam are a suboptimal drug formulation (intravenous liquid may not have the optimal pH for this purpose) and absence of licensure for midazolam for this use.

It is likely that other intravenous drugs (lorazepam, phenobarbital, phenytoin) are effective to stop ongoing febrile seizures; however, there are no systematic studies of these agents in febrile status.

Failure to recognize a febrile seizure at home is occasionally a problem. No studies have explored this issue and its possible solution. Anticipatory guidance might be offered to parents during visits for well-baby care if their child is at particular risk for an initial febrile seizure.[9] A child has a high risk for an initial febrile seizure (about 30%) if two or more of the following factors are present: First-degree relative with febrile seizures, second-degree relative with febrile seizures, delayed neonatal discharge, developmental delay, and attendance at day care. Only about 3% to 4% of the overall population of children has this increased risk.[9]

Emergency Room Management and Counseling Families

After a febrile seizure, it would seem prudent to keep the child under medical observation for several hours or longer. Once the child is alert and active and the fever has been adequately diagnosed and treated, the child may be discharged with proper follow-up care arranged. Hospital admission normally does not seem warranted, although no studies have addressed this issue. Families should know that about 15% of children experience another febrile seizure within 24 hours, but it is not possible to predict these recurrences.

Several studies have documented that the majority of parents believe that their child is dying during a first febrile seizure.[5,6] Few studies have addressed the value of strategies to deal with this extraordinary anxiety. Information in the form of audiovisual material and handouts appears to ensure that parents learn the facts about febrile seizures; however, it is the experience of these authors that family routines are still disrupted several weeks after a febrile seizure.[8] The family's management of recurrent febrile seizures seems to be more appropriate following detailed instructions.[36]

Many emergency departments have found written handouts useful. In our opinion, handouts should stress the following points[12,16,68]:

1. Febrile seizures are frightening to watch, but benign. They do not cause brain damage, and the likelihood of epilepsy developing later is small.
2. There is a substantial risk for further febrile seizures during this or subsequent illnesses.
3. Antipyretic medications provide comfort for the child but do not influence the chance of recurrence.
4. If another seizure occurs, stay calm, observe, place the child on the side or stomach; do not force anything

between the teeth; and clear the mouth of food or vomitus if necessary. If the seizure does not stop by itself after 5 to 10 minutes, the child should be brought to the nearest medical facility by car or ambulance.

The only serious sequela of most febrile seizures appears to be parental anxiety and subsequent labeling of the child as "vulnerable." To date, no "treatment" study has addressed this critical question. Nonetheless, two studies have noted that over the next 7 to 10 years children with a first febrile do not consume excessive health care resources, suggesting that parents eventually cope with the emotional upset of a febrile seizure.[28,31]

Drugs to Prevent Recurrent Febrile Seizures

Daily Treatment

Phenobarbital.

There is controversy about the value of daily phenobarbital to prevent recurrent febrile seizures.[47] Some studies have found the drug to be very efficacious provided that compliance is excellent.[17,77] Other studies have noted no effect.[27,32,56] A meta-analysis including all randomized, controlled studies published until the end of 1996 concluded that phenobarbital with a daily oral dose of 3 to 5 mg/kg reduced the risk of recurrence of febrile seizures by 13% (95% confidence interval [CI], 4% to 22%) compared to placebo in follow-up periods ranging from 12 months to 3 years.[59] However, issues of length of treatment, patient characteristics, and compliance have varied across studies making direct comparison difficult.

There is reasonable consensus that phenobarbital has important side effects for many children. Major behavioral changes (catastrophic behavioral disintegration) occur in 5% to 15%.[13,78] One large study noted a modest decrement in IQ in children with febrile seizures treated with daily phenobarbital compared with children receiving placebo[21] and the effect seemed to persist long after the drug was discontinued.[69] Therefore, a price is paid for treatment with phenobarbital, a price that is likely excessive given the benign nature of the disorder. In our opinion, daily phenobarbital should not be a recommended treatment for most children with febrile seizures. Its continued routine use in the United States is of concern.[52]

Phenytoin.

A single randomized trial failed to find phenyt-oin effective to prevent recurrent febrile seizures.[4] Two open trials also found it ineffective.[29,50]

Carbamazepine.

One open study of children with recurrent febrile seizures who had failed with phenobarbital (side effects or efficacy) found daily carbamazepine of little value.[18] A randomized trial comparing carbamazepine with phenobarbital also failed to find it effective.[2]

Valproic Acid.

Several studies have suggested that daily oral valproic acid reduces the rate of recurrent febrile seizures, although there are opposing studies.[19,33,56] The only placebo-controlled, randomized study compared valproate (30 to 40 mg/kg/day), phenobarbital, and placebo to reduce the recurrence risk of febrile seizures during a 21-month follow-up period in 48 children.[45] The risk of recurrence was 30% lower (95% CI 10% to 50%) in the valproate group compared to placebo. However, concerns about reports of fatal hepatitis in this age range[23] or pancreatitis,[15] although rare, make valproate an inadvisable choice.

Intermittent Treatment

To prevent recurrent febrile seizures, a variety of drugs given only at the time of illness have been studied. Intermittent use of drugs has two important limitations. First, one large American study noted that about 30% of children with a febrile seizure are not recognized by parents as being febrile before the convulsion; in these cases, seizures cannot be prevented by intermittent prophylactic drug treatment.[64] Second, the child must be consistently supervised by a small number of trained caregivers if the drug is to be administered promptly and correctly.

Nitrazepam.

One study found nitrazepam to be effective in preventing recurrent febrile seizures when given at the time of illness.[72] Children in the study were considered to be at high risk for recurrence after a first febrile seizure. The study design was "open label" and used historical controls. The authors noted that the drug was well tolerated. The design of this study was not sufficiently rigorous to recommend the use of nitrazepam.

Oral Diazepam.

A French randomized study of oral diazepam at the time of illness after a first febrile seizure found the drug ineffective.[3] The authors felt the result reflected a lack of efficacy of intermittent drug administration rather than of diazepam itself. A larger study found a modest reduction in recurrent febrile seizures with intermittent oral diazepam at doses of 0.33 mg/kg every 8 hours during illness (recurrence rate for treated patients 21% compared with 31% for placebo).[64] Based on the data from this study, we calculated that to prevent one febrile seizure, 14 children would need to be treated.[10] Forty percent of children experienced significant side effects, which included lethargy, ataxia, and irritability. The author's assertion that similar or better results can be obtained in a routine clinical situation seems at odds with a large literature on compliance with complex medical regimes with a low frequency of adverse outcomes.[30,60]

A Finnish study found no benefit from intermittent oral diazepam at doses of 0.2 mg/kg during the 2 years after a first febrile seizure.[70] The drug was given every 8 hours when the child was febrile. Side effects were infrequent with this dose but as noted above, higher doses cause a high rate of significant side effects.[64]

There is no evidence that intermittent oral diazepam alters parental anxiety about febrile seizures. It is possible that the anxiety is increased because of the need to monitor the child's health and temperature frequently and administer for several days a drug that frequently has side effects. This issue requires more study before treatment with oral diazepam should be offered to many children.

Oral Clobazam.

Clobazam is a benzodiazepine that appears to be less sedating than diazepam and is licensed in many countries, although not presently in the United States. An Indian study randomized 39 children with at least one febrile seizure to intermittent clobazam at the time of subsequent fever or placebo.[63] The recurrence risk was markedly reduced in the clobazam group with few side effects except ataxia. An open-label study of intermittent clobazam in 50 children with febrile seizures also found the drug to be very efficacious but 35% had some degree of side effects—vomiting, somnolence, and hyperactivity were most common.[46] It is unclear how oral intermittent clobazam compares with oral intermittent diazepam.

Rectal Diazepam

At the time of illness.

A Danish study found that rectal liquid diazepam given every 12 hours at the time of illness had efficacy similar to that of daily phenobarbital in reducing febrile seizure recurrences.[37] The same criticisms as of intermittent oral diazepam might be directed to rectal administration, except that the reduction in recurrence rate appears to be greater with the rectal than the oral route.

At the time of a recurrent seizure.

Rectal liquid diazepam is rapidly absorbed, with high serum levels achieved within 4 to 5 minutes of administration.[38] In one study,[39] 85% of ongoing febrile seizures stopped promptly after the administration of rectal liquid diazepam. This approach can be used by parents at home to limit the length of febrile seizure recurrences.[11,35]

The child must have only a few caregivers, and families must be warned not to teach others to give the drug. Although this approach keeps drug exposure at a low level and likely prevents prolonged recurrent febrile seizures, it has not been studied with a randomized trial. It will not prevent the majority of prolonged febrile seizures, as most of these occur as the first febrile seizure.[54] In addition, the effect of this approach on parental anxiety is unknown.

Summary and Conclusions
