Chapter 29

Neocortical Anatomy and Physiology

Kristen A. Richardson

Erika E. Fanselow

Barry W. Connors

Introduction

The neocortex in humans is a sheet of gray matter, 2 to 3 mm thick, with a surface area of about 2,400 cm^2, the size of a chess board. Like crumpled paper, the neocortex is folded into multiple gyri and sulci, and so fits compactly into the cranium. Gyri and sulci may be more than a solution to a packaging problem; by one view, they may also serve to compartmentalize neocortical functions.[192] Neocortex, together with the white matter that makes up its axonal connections, comprises about 80% of human brain volume.[137] Not necessary for life itself, the neocortex is essential for proper perception, motor control, memory, and cognition. Its neural circuits can adapt to a wide variety of functions, and the behavioral characteristics that define humanity can undoubtedly be ascribed to the unique expanse of neocortex enjoyed by our species. Unfortunately, possession of a neocortex comes with significant risk. The neurons and circuits that are fundamental to its normal operations can, with little provocation, produce the spectacularly disruptive activity of a seizure.

The mechanisms of clinical seizures in the neocortex are only poorly understood. However, knowledge of the basic anatomy and physiology of the neocortex is essential even to frame the questions about seizure mechanisms. Indeed, an interest in seizures has inspired many basic studies of the neocortex. The literature on neocortical biology is appropriately immense and eclectic, and numerous reviews are available.[1,25,50,57,77,125,128,129,141,194] This chapter briefly describes the structure and function of the neocortex, emphasizing those features that may contribute to its epileptic tendencies.

Basic Anatomy and Physiology of the Neocortex

The intricate structure of the neocortex has resisted explanation for at least 150 years.[95] On the one hand, all neocortexâ€"from mouse to manâ€"shares a set of common properties: The histologic appearance is comparable, the classes of neurons and the gross pattern of their connections are very similar, and the same transmitters are in use. Nevertheless, the neocortex is subdivided into many distinct areas, perhaps 50 to 100 in humans, and the number and types of areas vary widely among species. The important distinguishing features of each area include variations in cell lamination (useful for identification of the area), the patterns of axonal connections (hinting at the function of the area), and the details of neuronal structure, local interconnections, and biochemistry and gene expression (fodder for mechanistic speculations). Areas may also differ in the physiologic properties of their neurons and synapses. Nevertheless, despite knowing a tremendous amount about the general and specific structure and function of the neocortex, it is still fair to say that we cannot describe with confidence what the fundamental task of any one area of neocortex is.

Lamination as a Structural Principle

Anatomists have settled on a general six-layer nomenclature for the neocortex, although some layers can be further subdivided in many cortical areas and species.[24,104] Layering is easy to see, so the different lamination patterns of neurons, myelin, or various other structural features (glia, blood vessels, biochemical markers) have served as the basis for many schemes for neocortical parcellation. The most common approach to neocortical cytoarchitecture is Nissl staining, which highlights the cell nuclei and darkly staining clumps of material around the nuclei of neurons (Fig. 1). The Nissl-stained neocortical layers are distinguished by the density and size of their constituent neurons. In general, layer I (the â€œmolecularâ€ layer) is just below the pia and is thin and virtually neuron free. Layers II and III are hard to separate in many areas and contain medium-sized neurons in moderate density. Layer IV is the â€œgranularâ€ layer because of its densely packed, small neurons. Layer V contains the largest neurons of the neocortex and includes the output cells. Layer VI (the â€œmultiformâ€ layer) has a wide range of neuronal sizes and shapes. This general scheme has myriad variations that early anatomists, notably Brodmann, used to distinguish and define the areas of the neocortex. For example, Brodmann's area 17 (primary visual cortex) has a thick layer IV with a â€œstriatedâ€ appearance, whereas area 4 (primary motor cortex) lacks an obvious layer IV, but has exceptionally large, pyramidal-shaped neurons in layer V.

Modern anatomic methods show that the axonal connections of the neocortex are also distinctively laminated (Fig. 2). As a rule, specific neural information enters an area of the neocortex only via axons from the thalamus or other areas of cerebral cortex. Additional sources of extrinsic input include a variety of nuclei in the brainstem that project diffusely across the neocortex and deliver modulatory substances, such as norepinephrine, serotonin, acetylcholine, and dopamine.[121] Thalamic afferents from specific nuclei terminate primarily within layers III, VI, and (especially) IV. However, all other cortical layers may also receive thalamic input, depending on the area and thalamic nucleus in question.[81] Although thalamic axons are the source of input to the neocortex from the external world, they provide only a minority of all cortical synapses; even in layer IV, only 5% to 20% of synapses are from the thalamus.[142,194] Most of the rest of neocortical synapses are from the neocortex itself. Neurons in layers II and III project densely upon layers III and IV (primarily) in other areas, whereas cells in layers V and VI project to distant areas and terminate above and below layer IV.

P.324

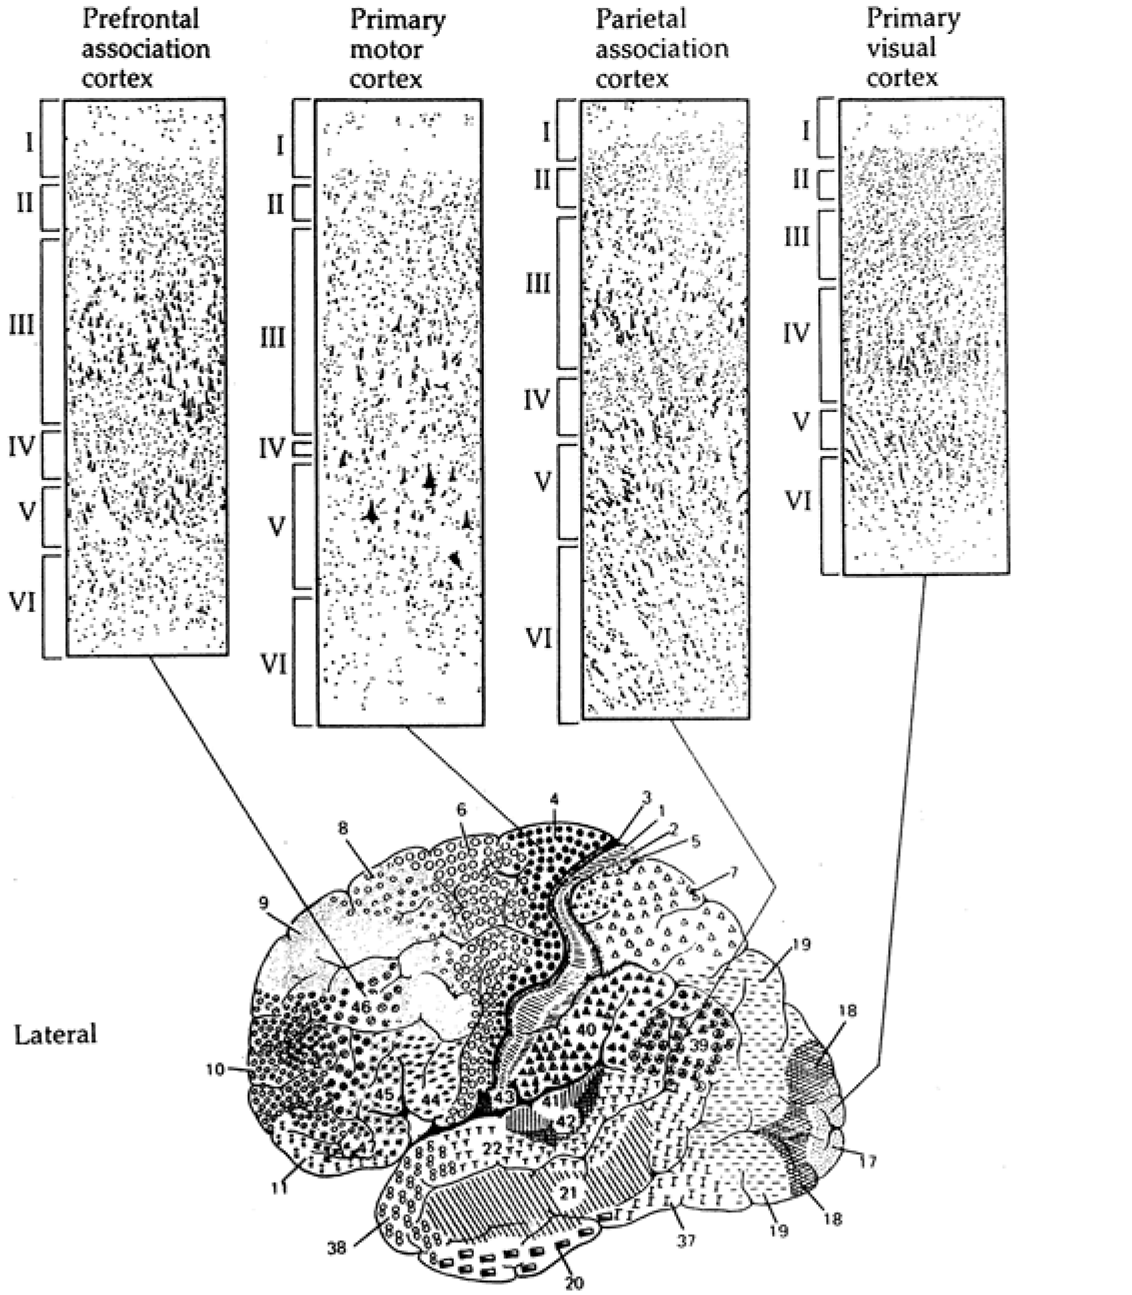

FIGURE 1. Variations in laminar structure of neocortex. *Top:* Nissl-stained sections, with layers indicated. *Bottom:* Brodmann's cytoarchitectonic regions of the human cerebral cortex (lateral aspect). (From Martin JH. *Neuroanatomy: Text and Atlas*. New York: Elsevier; 1989, with permission.)

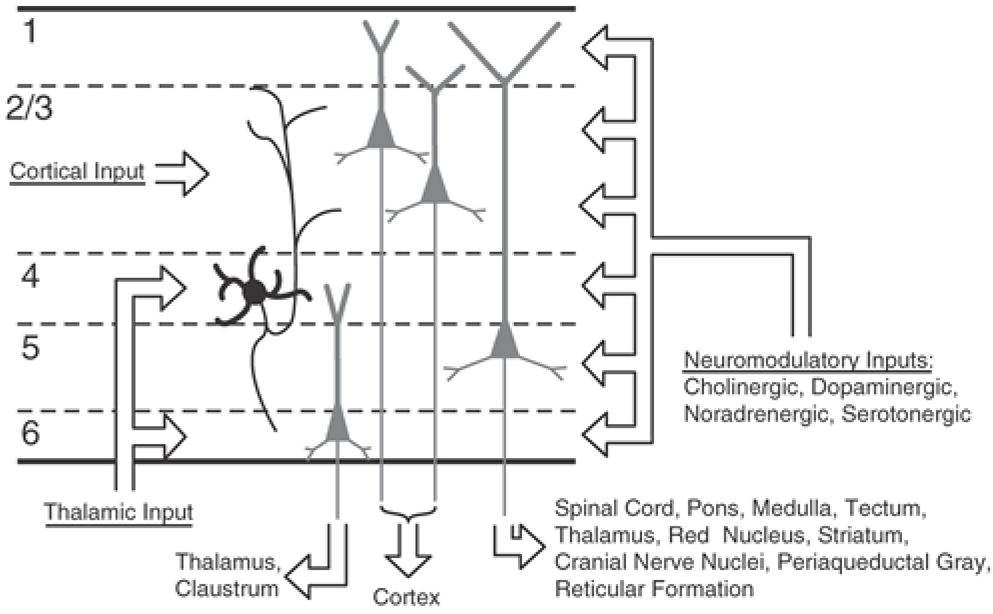

FIGURE 2. Summary of the major connections to and from a generic neocortical area.

Vertical Organization of Neocortex

Nissl stains give the illusion that the neurons of the neocortex are like so many stratified grains of sand and gravel. Despite variable lamination, there is surprising uniformity of dimension. Across cortical areas and even across species, the number of neurons within a vertical column of gray matter with a surface area of 1 mm^2 is nearly identical.[148] Although some variations exist among areas,[13] the only major exception to this rule of uniformity is the primary visual cortex of primates, which has twice the neuron density of most other areas.

Nissl stains illuminate only somata, but the vast majority of each neuron's volume and surface area is in its dendrites and axons, which may stretch across layers and between areas. In the neocortex, a tendency exists for these cellular processes to extend strongly in the vertical dimension and for cells in vertical arrays to be densely interconnected. Pyramidal cells, in particular, seem to have evolved an efficient shape to collect synaptic input from a vertically oriented zone of tissue that may span several layers.[56,174] Physiologic studies show that the sensory or motor response properties of neurons in vertical â€œcolumnsâ€ of neocortex are often quite similar, whereas neighboring neurons along the horizontal dimension are relatively more different.[9,86,127,128] The widespread tendency for neocortical neurons to organize into vertical groups has prompted speculations that the neocortex is basically modular[128]; small columns form the irreducible units of neocortical organization, and new areas and functions are built up by simply adding more columnar modules. This scheme is appealing but unproven.

Systematic anatomic and physiologic measurements have suggested a basic vertical circuit for neocortex.[7,8,72] It begins in layers III and IV, where the main thalamic input arrives. Local axons of the spiny stellate cells in layer IV then excite pyramidal neurons in the upper layers, which in turn strongly excite neurons of layer V. Layer V cells synapse upon cells of layer VI, and these return excitation both to the thalamus and to layer IV. The neocortex is primarily feeding information back upon itself, which may be the single most important thing we can say about its susceptibility to seizures. If excitation were the only story, however, the cortex would seize interminably. In parallel with the loops of excitatory circuitry, Î³-aminobutyric acid (GABA)-releasing neurons also receive excitation and, in turn, inhibit pyramidal neurons, both ahead of and behind them in the circuit flow.[42,96,162]

Topologic maps of the vertical organization of neocortex have been described for many different areas and species; these reveal that, in many cases, â€œcolumnsâ€ have been misnamed. For example, in visual cortex, the zones specific for ocular dominance look, from the surface, like alternating bands or slabs, whereas the organization of neurons with similar stimulus orientation preferences resembles radiating pinwheels.[11,21] Furthermore, these two maps of visual function are coextensiveâ€”they use the same sheet of cortex simultaneously but divide it quite differently. For the most part, the anatomic underpinnings of functional columns have not yet been demonstrated in detail.[28,83] In a general way, vertical connectivity must link neurons across layers, but with a high degree of specificity.

Horizontal Organization of Neocortex

Although vertical connections received early[114] and sustained publicity, the horizontal connections of the neocortex are also widespread, complex, and essential. Their existence provides a ready set of pathways for the rampant propagation of seizures. A few generalizations about horizontal connections can be made: They vary from very short to very long, they are reciprocal, and they tend to terminate in discontinuous, patchy patterns.

In a single brain, the neocortex consists of two continuous sheets, one in each hemisphere. Horizontal connections exist between points on this sheet at very local scales (within single microcolumns), at intermediate scales between columns, within areas, between adjacent areas, and at long distances between far-flung ipsilateral areas, as well as between homologous contralateral areas via connections through the corpus callosum. In most cases, the horizontal interconnections at all scales are reciprocal; a set of connections from cell group A to cell group B is matched by a set of connections from B to A. The patchiness of interconnections is nearly ubiquitous, although there are exceptions,[185] and both the regular patterns of connections and the scale of their periodicities tend to be strikingly similar across cortical areas.[73,97,110,111]

Horizontal interconnections, especially over intermediate and long distances, are overwhelmingly excitatory, reinforcing their relevance for the spread of seizure activity. Experimental work has shown that local variations of horizontal excitatory connectivity are an important determinant of the speed and route of seizure propagation.[35,143,183] At shorter distances, on the order of adjacent intercolumn distances within one area, there may be a liberal mix of horizontal inhibitory and excitatory connections. The spatial details and relative strengths of these connections are variable with area and are probably critical in helping to determine the unique functions of each area.

Growing evidence also suggests that horizontal connections mediate some forms of experience-dependent plasticity in sensory and motor areas of the neocortex.[71,153] Cortical synapses can either strengthen or weaken, depending on their recent history of activity,[12] axons and synapses remodel dynamically[165] and, over weeks and months, cortical axons can also sprout new branches in response to chronic alterations of thalamic input.[53] It seems very likely that the grossly abnormal activity of chronic seizures could induce significant physical and physiologic changes in cortical circuitry.

Diverse Neurons of Neocortex: Morphology

At first glance, the neurons of the neocortex are dazzling in their diversity. By examining cellular morphology, connections, biochemistry, and physiology, however, order emerges.[4,195] The neurons can be divided into two major groups based on structureâ€”spiny neurons (about 70%â€“85% of the total cells) and aspiny (â€œsparsely spinyâ€ or â€œsmoothâ€) nonpyramidal neurons.[56,141,162] Spines are small (about 1â€“0.2 Âµm on average), membranous excrescences along the shafts of dendrites.

Within the cortex, spines are notable as the major site of excitatory synaptic input onto spiny cells. The spiny and aspiny morphologic categories also correspond to basic cellular functions. Spiny cells make excitatory synapses that use the excitatory amino acid glutamate; aspiny nonpyramidal neurons make inhibitory GABA-utilizing synapses. Neurotransmitters of the neocortex will not be specifically covered in this chapter, but numerous reviews are available (see Chapters 22 and 23).

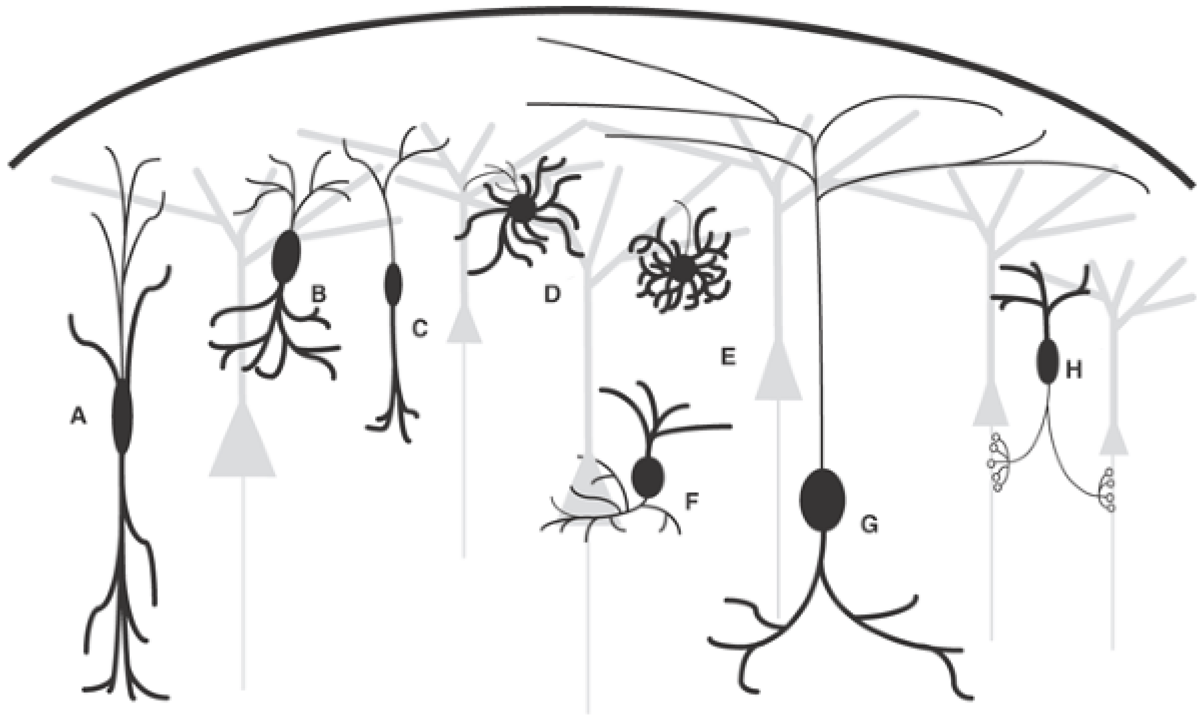

FIGURE 3. Inhibitory interneuron subtypes. **A:** Double bouquet cell. **B:** Bitufted cell. **C:** Bipolar cell. **D:** Multipolar cell. **E:** Neurogliaform cell. **F:** Basket cell. **G:** Martinotti cell. **H:** Axo-axonic/(chandelier cell). Bold lines represent dendrites, fine lines represent axons. Gray cells represent excitatory neurons.

The two major classes of cortical neurons, in turn, are subdivided. The excitatory, spiny cells include pyramidal cells and spiny nonpyramidal cells (often called *spiny stellate cells*). Pyramidal cells are the majority class of neurons in the neocortex. They have a high density of dendritic spines (rare exceptions to this rule exist), prominent apical dendrites, and an axon that projects out of the cortex, as well as locally. Pyramidal cells vary widely in size, shape, axonal structure, and their somata appear in all layers except layer I.[56] Spiny stellate (nonpyramidal) cells are relatively small neurons of layer IV, with high spine density and axons that terminate in excitatory synapses. Spiny stellate cells are distinguished from pyramidal cells by the

P.326

absence of an obvious apical dendrite, and their axons usually do not leave the cortex (although a minority may send axons out of the cortex).[188] Because of their excitatory function and spiny dendritic structure, spiny stellate cells may be considered a simple variant of the pyramidal cells. This view is supported by the development of spiny stellate cells; apparently, they begin life as pyramidal neurons, and during postnatal maturation, they gradually retract their apical dendrites.[187]

The inhibitory, sparsely spiny, nonpyramidal neurons are a very diverse group.[102,118,195] Whereas their dendritic patterns vary systematically,[37] a more useful characteristic is the pattern of their axon arbors, which do not leave the local area of cortex but which may be distinctive and specific.[61] As schematized in FIGURE 3, common morphologies for inhibitory interneurons include *double bouquet cells*, whose axons and dendrites project within a long, narrow, vertical column; *bitufted cells*, whose collaterals form two highly branched protrusions from the soma; *bipolar cells*, which have long collaterals projecting vertically above and below the soma; *multipolar cells*, which have round somata with multiple dendrites projecting radially; *neurogliaform cells*, whose dendrites form relatively tight, symmetrical spheres around their somas; *basket cells*, whose axons tend to form basket-like shapes around the somata of their target cells; *Martinotti cells*, which can have their soma in layers II to V and project their axon up to layer I, where they ramify up to several millimeters; and *axo-axonic cells*, whose dendrites terminate on the axon initial segments of target pyramidal cells, forming structures that resemble candlesticks (thus the alternative name, *chandelier cells*). Note that this is not an exhaustive list of inhibitory neuron morphologies, nor do neurons always fit clearly into one morphologic subtype.

It has been shown that somatic and perisomatic targeting cells can readily suppress action potentials,[124] suggesting that these inhibitory neurons could closely control the output of their target neurons. Because of their potentially strong control over pyramidal cell output, loss of axo-axonic cells has been implicated in epilepsy.[55] It has also been proposed, paradoxically, that axo-axonic cells actually excite pyramidal neurons because of a relatively high internal chloride ions [Cl^-] in axon initial segments.[173]

Other inhibitory neurons terminate on the dendrites of their target cells. Examples include double bouquet cells, bitufted cells, bipolar cells, neurogliaform cells, and Martinotti cells (Fig. 3Aâ€"C, E, G). The nature of the inhibition from these cells probably differs from interneurons that synapse in somatic or perisomatic regions. Dendrite-targeting inhibitory cells can alter the way their target cell integrates synaptic input within the dendrites, and it is thought that these cells can suppress dendritic calcium ion (Ca^{2+}) spikes,[106,124] decreasing the ability of excitatory inputs to propagate along the dendrites.

Classes of inhibitory cells may also be defined by interesting variations in peptide cotransmitters (in addition to the GABA that they all contain),[80] by different types of Ca^{2+} binding proteins they express,[100,184] and by their expression patterns of a wide variety of genes.[22,131,170] Three main Ca-binding proteins have been useful as markers of interneuron types: Calbindin (CB), calretinin (CR), and parvalbumin (PV). The most common neuropeptides used to identify inhibitory interneuron subtypes include cholecystokinin (CCK), somatostatin (SOM), and vasoactive intestinal peptide (VIP). Double labeling studies have shown that several of these markers tend to co-exist within cells (e.g., CR and VIP), but others never or very rarely co-exist (e.g., PV and SOM). Kawaguchi and Kubota[103] divided prefrontal neocortical inhibitory neurons in layers II through VI into four main groups based on these markers. Group I contains PV; group II contains SOM and neuropeptide Y (NPY); group III contains CR, VIP, and CCK; and group IV contains large CCK cells. However, it is not clear that these groups correlate well with specific morphologic or physiologic subcategories of inhibitory neurons. One pattern that does emerge is that PV

appears to be associated with somatic/perisomatic or axo-axonic targeting cells, whereas CR is largely associated with dendritic targeting cells (reviewed in[118]).

Diverse Neurons of Neocortex: Physiology

Just as neurons vary in their shape, transmitter, and synaptic connections, they may also differ in their intrinsic physiologic properties.[46,49,112] â€œIntrinsic physiologyâ€ is defined as a neuron's inherent ability to respond to stimuli, apart from the effects of the neural network surrounding it; intrinsic physiologic properties derive from the cell's membrane (and its ion channels, primarily) and metabolic properties (such as ion pumps and control systems, second-messenger systems, and energy management). Takahashi[176] was the first to show that the intrinsic properties of neocortical cells had diverse properties. Recording from the pyramidal tract neurons of the cat, he found that axonal conduction velocities correlated with somatic spike duration, time constant, input resistance, and duration of the afterhyperpolarization. Since then, numerous studies have used methods of intracellular recording, single-cell staining, and isolated brain slices in vitro to demonstrate that the intrinsic physiology and morphology of neurons in the neocortex are related. The impact of a neuron's intrinsic properties can be appreciated from its response to simple injected current stimuli, as shown in FIGURE 4. Some cells produce a tonic, uniform spike frequency; others display strong adaptation; and still others generate periodic bursts. Clearly, when faced with the same input, each of these neurons provides a very different message to its postsynaptic targets. Myriad variations on these basic themes exist in the neocortex and in the rest of the brain.

Regular-Spiking Pyramidal Cells

The â€œregularâ€ intrinsic firing pattern[130] (regular implying most common) is that of most pyramidal cells from layers II to VI.[47,122,164] Regular-spiking (RS) cells usually fire a single spike to a threshold current pulse. Their action potentials rise at a higher rate than the rate at which they fall. These may display a combination of fast, medium, and slow afterhyperpolarizations, as well as a brief afterdepolarization.[29,47,115,155]

Repetitive firing has an initially high frequency that subsequently shows strong adaptation; that is, spike frequency declines during a sustained stimulus. Most RS cells adapt from a beginning rate of several hundred hertz to a relatively stable, but much lower, rate within about 200 msec. The adapted rates are rarely higher than 50 to 100 Hz. Some RS cells adapt steeply and often stop altogether, even as stimulus current is maintained.[2,33] One subclass of nonbursting pyramidal cell displays no frequency adaptation but generates a very rhythmic pattern of single spikes instead.[158] Near threshold, at about â€“65 to â€“60 mV, these cells can be bistable, shifting from silence to repetitive firing at low (5â€“12 Hz) rates when triggered by brief stimuli.

Intrinsically Bursting Pyramidal Cells

A particularly interesting type of cortical neuron, especially in the context of seizure generation, is the intrinsically bursting (IB) cell. Although RS cells generate a single spike to a just-threshold stimulus, the minimal response of the IB subgroup of pyramidal cells is usually a high-frequency cluster of action potentials or â€œburst.â€[47,109,122] Each burst consists of 3 to 5 spikes firing at about 150 to 300 Hz. Bursts occur either singly or in repeating patterns of bursts at 5 to 15 Hz.[2,34,158] Near firing threshold, repetitively bursting neurons of layer V can also exhibit a bistable state similar to the single-spiking cells described in the previous section. Small triggering stimuli generate long-lasting responses consisting of rhythmic bursts or burst-single spike complexes. These IB cells have been implicated in the initiation of epileptiform activity in experimental studies of neocortex in vitro.[44]

Although most physiologic studies of neurons have actually been studies of their somata, this misses most of the point for pyramidal cells; as much as 97% of their membrane area is actually dendritic,[109] and 1 mm^3 of neocortical gray matter contains a total dendritic length of about 450 m.[25] The patch-clamp method has allowed direct recordings from cortical dendrites. These have shown that the dendrites of pyramidal cells are quite excitable and express sodium (Na),[88,168] Ca,[5,106,116] and potassium (K)[94] currents that can powerfully affect the cells' ability to transform synaptic inputs. Indeed, electrically excitable dendrites are probably essential for the efficacy of many distal synaptic inputs onto the longest dendrites of neocortexâ€"synapses in layer I onto the dendrites of cells with their somata in layer V, for example.[31] In addition, just as the intrinsic physiology of neuronal somata can vary in neocortex, the physiology of long dendrites can also vary systematically from one cell type to another.[106] The properties and significance of electrically excitable dendrites are being intensively investigated.[167,191]

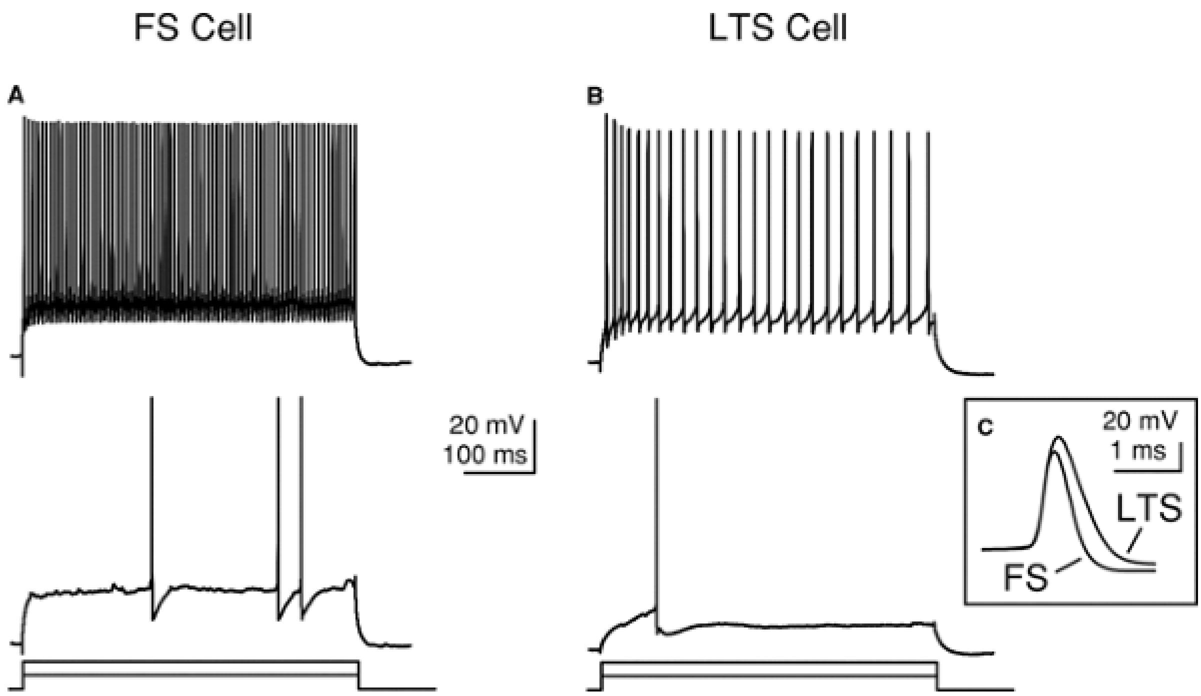

FIGURE 5. The differential responses of inhibitory neurons to pulses of injected current can be used to identify different neuronal types. **A:** Response of an FS neuron to just-threshold (*bottom*) and suprathreshold (*top*) current pulses. **B:** Response an LTS neuron to just-threshold (*bottom*) and suprathreshold current pulses. **C:** Action potentials of FS neurons are narrower than those of LTS neurons.

The density of IB cells is strikingly dependent on the cortical layer. In rodent sensorimotor cortex, their somata are most frequently observed in layer Vâ€"its deeper aspects in particular.[34,122] However, they are also seen in layer IV in some species and cortical areas.[34,47] Most or all of the layer V IB cells are subcortical projection neurons.[98,190]

P.328

Diverse Physiology of Inhibitory Interneurons

Many of the GABA-utilizing, inhibitory interneurons of the neocortex have a distinctive intrinsic physiology earning them the name fast-spiking (FS) cells. Their action potentials are exceptionally brief (<0.5 msec).[130,160,172] Intracellularly recorded, the FS cell spike has a rate of fall almost as fast as its rate of rise and a deep but brief afterhyperpolarization.[122] The inhibitory synaptic effect of FS cells has been confirmed by directly demonstrating that they make gabaergic synapses in tissue culture[87] and by showing their immunoreactivity for GABA and glutamic acid decarboxylase (GAD), the synthesizing enzyme for GABA.[99]

The most distinctive physiologic property of FS neurons is that they can fire at very high rates with little or no adaptation. When activated by coherent synaptic excitation following a single shock, FS cells are impressively responsive. They will often generate a train of spikes at relatively high frequency,[33,99,122] whereas RS cells usually fire one or two spikes. When a just-suprathreshold current step is injected into an FS cell with an intracellular electrode, the cell will often pause prior to firing, then produce the first spike after a considerable delay (Fig. 5A, *bottom*). Firing becomes repetitive with increasing stimulus amplitude, and rates can reach to >300 Hz (Fig 5A, *top*).[15,122] FS cells show little or no spike-frequency adaptation. FS cells include basket cells and chandelier cells. They often express PV.

Not all GABAergic neurons in the neocortex are FS cells. Some aspiny nonpyramidal cells in early studies of rat motor cortex[99] and human neocortex[63] described interneurons with â€œlow-threshold spikesâ€ (LTSs)â€"slow, depolarizing waves produced by low-threshold Ca^{2+} currents that can trigger one or more fast Na^{+}-dependent spikes at high frequency. They also show marked adaptation of firing frequency (Fig. 5B, *top*), and have wider action potentials than do FS cells (Fig. 5C). These cells often express SOM, but rarely PV, and include Martinotti cells, double bouquet cells, and bitufted cells. Similar neurons have also been referred to as regular-spiking nonpyramidal (RSNP) cells.[101]

Neocortical interneurons include cell classes with a variety of other intrinsic spiking patterns, such as bursts or irregular Spike (Is or â€œstutteringâ€) patterns. The intrinsic spiking patterns of interneurons often correlate closely with cell morphology, synaptic properties, and gene expression.[75,170]

Synaptic Physiology of Neocortical Neurons

Excitatory and Inhibitory Chemical Synapses

The functional properties of glutamatergic and GABAergic synapses in the cerebral cortex are complex and reasonably well understood (Chapters 22, 23). Within the neocortex, the strength and dynamics of chemical synaptic connections vary widely and tend to correlate with the types of neurons involved on both the presynaptic and postsynaptic sides. Thalamocortical synapses, which are the neocortex's most important source of specific information, are exceptionally strong and reliable compared to excitatory synapses that interconnect neocortical neurons.[15,68,70] Thalamocortical connections are also subject to unusually strong short-term depression when activated at high frequencies. The strength and dynamics of the synapses that interconnect different types of pyramidal cells in the neocortex also vary, although most display short-term depression.[180]

Inhibitory interneurons, befitting their diverse morphology and physiology, have input and output synapses with a wide variety of functional properties.[118,181] The FS and LTS cells illustrate this particularly well.[15,68,146] When a presynaptic excitatory neuron fires at high frequencies (>10 Hz), the EPSPs recorded in the two types of inhibitory interneurons differ in several ways. The amplitude of the initial EPSPs is relatively large and reliable in FS cells, and substantially smaller and less

P.329

reliable in LTS cells. Subsequent EPSPs are strongly depressed in FS cells but they facilitate powerfully in LTS neurons, particularly above about 20 Hz. This suggests that FS cells are ideal for responding precisely and reliably to transient neural activity. In contrast, LTS cells are not particularly responsive to brief increases in excitatory activity, but they would become strongly engaged by the sort of rapid, ongoing excitatory drive that might occur during seizure activity.

Electrical Synapses

In addition to chemical synapses, which communicate via diffusible neurotransmitters, neurons can also be connected by electrical synapses, which allow the direct flow of ionic current from one cell to the next. The substrates for electrical synapses are gap junctions: tight clusters of transcellular channels that are permeable to most physiologically relevant inorganic ions as well as to many small organic molecules (generally â‰¤1 kDa).[18]

Communication across gap junctions differs from chemical transmission in several ways. First, electrical synapses tend to be faster than chemical synapses. However, because of the capacitance of surrounding membranes, gap junctions act as low-pass filters and limit the rate at which signals can be transmitted.[67,68] Second, electrical synapses are bidirectional. The gap junction channels that interconnect neurons in the mammalian brain are essentially linear conductors, so current can flow between cells in either direction in response to voltage gradients across the gap junction.[48,69] Thus, electrical synapses can communicate signals that either depolarize or hyperpolarize neurons. Third, unlike chemical synapses in the neocortex, electrical synapses can transmit subthreshold voltage changes; electrically coupled cells can influence one another without firing action potentials.

In the relatively mature neocortex, the vast majority of electrical synapses interconnect inhibitory interneurons.[51,67,68] Remarkably, most electrical synapses appear to form selectively between interneurons of the same subtype, and only rarely between interneurons of different subtypes. This specificity of gap junctional connections reinforces the notion that there are functionally distinct subclasses of interneurons in the neocortex.[48,82] The subtypes of interneurons that form electrical synapses primarily with homologous inhibitory cells include FS cells,[67,68] LTS cells,[15,68] cannabinoid receptor subtype 1 (CB_1-IS-CCK) neurons,[66] multipolar bursting cells,[23] and late-spiking cells of layer I.[36] The specificity of interneuron gap junctions is not perfect; some electrical synapses have been described between heterologous types of inhibitory interneu-rons.[68,159] Electrical synapses are strongest between cells whose somata are within 75 to 100 Âµm of one another,[6,14,67] although dendritic gap junctions may be several hundred Âµm from a cell's soma.[64] It is estimated that one inhibitory interneuron is electrically connected to 20 to 50 others via gap junctions.[6]

Electrical synapses have not been observed between pyramidal neurons of the mature neocortex, although there is strong evidence that gap junctions interconnect pyramidal cells of the embryonic and early postnatal neocortex.[45,113,139] The functions of neuronal gap junctions during early development are unknown, although they may help to coordinate neurogenesis, differentiation, and the specification of chemical synaptic connections.[126]

Most gap junction channels in vertebrates are comprised of two hexameric hemichannels made of subunits called connexins. There are about 20 connexin isoforms. Although about half of them are expressed in the mammalian brain, only connexin36 (Cx36) has been consistently demonstrated to be an essential component of neuron-to-neuron gap junctions.[16,54,85,186] Additional gap junction proteins, in particular connexin45 and pannexins1 and 2, may also be expressed by central neurons,[26,136] but so far, no evidence suggests that they are important for electrical synapses.

Seizures of Neocortex: neurons, circuits, and architecture

Studies of seizures informed some of the earliest speculations about the functions of the neocortex. The insights of John Hughlings Jackson[177] were particularly notable. Jackson used astute clinical observations of seizures, postmortem examination of epileptic brains, and imaginative deduction to infer the locale of some motor and sensory functions in the cerebral cortex. Seizures have continued to tell us about the cortex, but there is also an urgent need to use knowledge about the cortex to enlighten our understanding of seizures. What follows is a brief survey of experimental and clinical findings that highlight links between neocortical biology and the pathology of epilepsy.

Neuronal Triggers of Seizures

Ironically, some of the characteristics of neocortical seizures that make them so devastating clinically have also made them a popular subject of experiments: Seizures are readily induced by various means, their electrical correlates are large and easily measured, and neocortical activity during seizures is very simple, compared to activity during normal functions. Detailed studies of experimental animal models of partial seizures have suggested numerous hypotheses of neocortical seizure generation.[10,58,92,144] This section focuses on one explicit proposal for the cellular origins of seizure initiation and propagation.[43]

During a seizure, the neocortex generates hypersynchronous activity that may encompass almost every neuron across a wide area. Where does the trigger for these synchronous events arise? How does that trigger spread to engulf the activity of other neurons? How does a very localized seizure propagate into adjacent areas and beyond? One simple way to induce seizures is to reduce the level of synaptic inhibition. Experiments on slices of rodent neocortex in vitro have provided a variety of evidence that certain pyramidal neurons in layer V may act as both the initiators and propagators of hypersynchronous activity. Seizure-like activity is readily induced when synaptic inhibition is depressed by applying antagonists of $GABA_A$ receptors. Even a modest reduction of inhibition, perhaps by 20%, leads to sharply synchronized, often rhythmic activity that can propagate for many millimeters across a cortical slice.[33] Under these conditions, synchronized activity is labile, changing its shape from trial to trial. When $GABA_A$ receptors are more strongly blocked, synchronized events are more stereotyped, often spontaneous, and propagate unimpeded across the cortex.[35,41,74,76,78,143] In each case, layer V is implicated as the initiation site for synchronized activity. If inhibition is eliminated, it is in layer V that epileptiform currents first appear during each event. Layers IV and V are the most sensitive to $GABA_A$ antagonistsâ€"they have the lowest threshold for event initiation, and synchronous events can be most easily blocked there by applying GABA itself.[41] With GABAergic inhibition only slightly reduced, the IB neurons of layer V are the only class of pyramidal cells that consistently generate synchronized excitatory events and spike firing; other pyramidal cells tend to be synchronously inhibited and only weakly excited.[33]

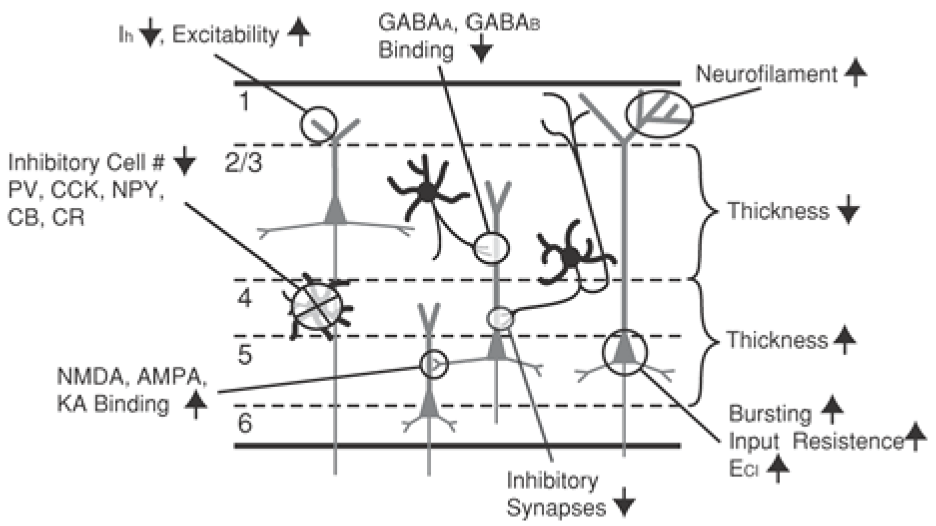

FIGURE 6. Seizure activity has been associated with a wide variety of changes in cortical cells and circuits. A summary of many of these changes are shown here. There is a general increase in excitatory tone due to increases in glutamatergic connections or due to increases in excitability of some pyramidal cells. Also observed is a decrease in inhibitory tone from cell and synapse loss as well as from changes in GABAergic function related to an increase in E_{Cl^-}. Each of these changes may or may not occur in seizing tissue depending on the epilepsy model, as described in detail in the main text.

Moreover, when slices are further dissected with horizontal cuts and bathed in low doses of $GABA_A$ antagonists, those microslices containing layer V (but not other layers) are able to support both the initiation and propagation of

synchrony.[178,179] Small injections of convulsant drugs into neocortex in vivo are most effective at producing epileptiform activity when they are placed in the vicinity of layer IV.[60,84]

Synchronous activity can also be generated by boosting synaptic excitation. For example, the function of one type of glutamate receptor, the *N*-methyl-D-aspartate (NMDA) receptor, is facilitated by lowering the magnesium ion [Mg^{2+}] in the bathing solution. This reduces the voltage dependence of the NMDA receptorâ€"operated channel[134] and, in the neocortex, leads to spontaneous, highly synchronous events that occur in rhythmic epochs with 4- to 7-Hz discharges.[158,171] In horizontally dissected slices in low [Mg^{2+}], a small fragment of layer V is all that is necessary to generate the same type of rhythmic synchrony as the intact slice.[62,158] Microslices without layer V resemble intact control slices and are incapable of supporting rhythmic, synchronous activity.

Once synchronous events are initiated locally by neurons of layer V, they may propagate both vertically into other layers and horizontally into adjacent cortex.[32,35] During moderate disinhibition, the pathway of preference for horizontal movement is within layer V.[178] When inhibition is strongly suppressed, alternative pathways can be found either above or below layer V after removal of layer V. However, it is likely that the pathway through layer V remains the primary mediator of horizontal movement when the cortex is intact.[179] Layer V is also implicated in other forms of cortical synchrony, including chronic models of epilepsy (see later discussion).

Novel electrical stimulationâ€"based techniques that target the excitation thresholds of layer V pyramidal cells may prove to be an effective method of seizure control. Electric field modulation of neuronal excitability has been shown to successfully slow and even halt propagating neocortical epileptiform activity in acute preparations.[147]

In summary, layer V has neurons with the appropriate intrinsic membrane properties, intralaminar connections, neurotransmitter systems, and axonal outputs to generate highly synchronized activity and to impose it on the other neurons of the cortex. It may not be the sole synchronizing network in the cortex, but it is a major one. We do not know which properties of layer V are most responsible for its capabilities. A case can be made that intrinsically bursting neurons are likely instigators of synchrony: They are prevalent in layer V, they are exceptionally excitable, and they have the requisite local connections.[32,41,76,158] However, bursting may be only part of the answer or none of it. Unusually strong or dense interconnections between bursting cells, relatively weak inhibition, a unique complement of neurotransmitter receptors, or especially excitable dendrites could be more important. It is likely that several characteristics conspire to make layer V a uniquely excitable network in neocortex.

Seizure-Related Alterations of Neocortical Circuits

Seizure disorders have many causes. Sometimes a clear genetic basis is present (see Chapters 17, 18 and 37). Many developmental anomalies are accompanied by severe epilepsy (see Chapters 14 and 259).[3,189] Neocortical insults from tumors, trauma, stroke, and infection are also common instigators (see Section X, Epilepsy Syndromes). The origins of most seizure disorders undoubtedly lie in abnormalities of the basic biology of the cerebral cortex. Unfortunately, the large majority of human seizure syndromes cannot yet be described in cellular or molecular terms, and many cannot be described in any terms beyond their signs and symptoms.

While it has been possible to examine epileptogenic tissue resected from epileptic human patients, recording from normal, relevant control tissue for comparison is rarely feasible. Various chronic animal models of different epilepsies have therefore been developed to examine the differences between normal and epileptogenic tissue (Chapters 36,37,38,39). In general, hyperexcitable or epileptogenic neural tissue from both animal models and human epilepsy patients have demonstrable abnormalities of structure and function. These involve growth of dendritic or axonal arbors, changes in synaptic densities or transmitter receptor numbers, and either increases or decreases in specific types of neurons (Fig. 6). We highlight here a few studies of the changes in anatomy and physiology that are associated with seizure-like activity and hyperexcitability in neocortex.

Network Changes After Status Epilepticus

Malformations of cortical architecture following seizures tend to be layer-specific. For example, in the pilocarpine model of human temporal lobe epilepsy (TLE) a severe episode of status epilepticus (SE) is induced through the systemic injection of the acetylcholenergic agonist pilocarpine. Weeks after this major seizure event, spontaneous seizures begin to occur. In adult rats subjected to this protocol, the thickness of cortical layers II and III decreases, whereas the thickness of layers V and VI increases, resulting in overall neocortical atrophy.[152] More specifically, neurofilament protein increases, indicating especially increased dendritic arborization of layer V pyramidal cells into layer I. Studies of postseizure sensorimotor cortex show an overall reduction of both PV-type inhibitory interneurons specifically, and GABAergic neurons (indicated by GAD65 staining) in general.[157]

When SE is induced in relatively young animals, the resulting architectural alterations are surprisingly different from those that occur in more mature brains. PV and GAD65 immunoreactivity actually increase in layer IV of young brains, in contrast to mature brains, whereas neurofilament protein increases in tissue of both ages. Calbindin staining (which was not investigated in the adult study) is reduced after seizures, whereas calretinin staining is similar to that of control tissue.[52] These results suggest that specific subtypes of interneurons are differentially affected by seizure activity. Considering the inherent differences in the inhibitory functions of interneuron subtypes (see earlier discussion), this implies that the dynamic balance of inhibition may be altered by prior seizure experience.

Circuit Modifications in Cortical Dysplasia

Experimental models that mimic human developmental anomalies display changes in neocortical architecture and connectivity in and around the focal lesion. The agent methyl-azoxymethanol (MAM) damages dividing and migrating cells. When injected into a pregnant rat, MAM affects the neural development of gestating pups. Results from studies of MAM-induced epilepsy reveal that different types of neocortical interneurons, expressing different neuropeptide markers, are differentially affected. Neurons that express the neuropeptides SOM and VIP are apparently spared, whereas neurons that express CCK and NPY are decreased in cortical regions.[30,197] It is apparent, as in the SE, that subtypes of interneurons are differentially sensitive to MAM treatment. The exact impact of these changes on seizure dynamics is, however, unknown.

Layered microgyria can be created in rodents by inducing focal cell death with a freeze lesion during early development and neural migration.[89] In this model of cortical dysplasia, the density of inhibitory $GABA_B$ receptors is reduced in the lesioned region only, whereas excitatory NMDA receptors increase in the lesioned area and Î±-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and kainate receptors increase within the lesion and in surrounding cortex as well[196] Jacobs et al.[89] found that PV-expressing interneurons are reduced in lesioned cortex and in layers IV and V of neighboring cortex. The levels of PV-expressing cells eventually return to control levels within the lesion, but in the paramicrogyrial region, these cells are permanently deficient.[149] Somatostatin-expressing interneurons are also reduced around the lesioned area.[138] Electrophysiologic studies indicate that epileptiform activity is more likely to be generated from cells in the paramicrogyrial region than within the lesion focus.[89] The enhanced excitability of the surrounding region may be due to an increased density of functional synapses, both inhibitory and excitatory, on layer V pyramidal cells.[90]

Intrinsic Excitability in Neocortical Epilepsies

Alterations of the intrinsic excitability of neurons can be both a cause and a consequence of seizures. Layer V pyramidal neurons from rats that have experienced chronic pilocarpine seizures show increased excitability.[152] In neocortex that has been chronically isolated from surrounding tissue, the excitability of axotomized layer V pyramidal cells is also enhanced compared to controls.[145] The mechanisms controlling the intrinsic properties of neurons after seizures are poorly understood. Neuronal excitability depends on a large variety of membrane mechanisms. One of them is the ion channel that mediates the hyperpolarization-activated cation current (I_h), which is carried by Na^+ and K^+. When activated, I_h tends to depolarize a neuron and reduce input resistance. The strength of I_h changes in several chronic seizure models. In the kainate model of TLE (which resembles the pilocarpine model), pyramidal cells in layer III of entorhinal cortex show strong and persistently reduced I_h after a single seizure. The resulting increase of dendritic input resistance leads to enhanced sensitivity to synaptic inputs.[156]

The WAG/Rij rat is genetically predisposed to absence epilepsy. Pyramidal neurons in layer II/III of these animals have abnormally low HCN1 protein, one type of I_h channel subunit.[166] This apparently leads to higher input resistances, longer-lasting EPSPs, and increased summation of synaptic inputs. Neurons also tend to show more intrinsic bursting behavior. It is possible that a deficit in I_h is responsible for seizure generation in these rats. Chronic imbalances of I_h in other parts of the brain, including the thalamus,[27,108] hippocampus, and subiculum, may also contribute to seizure-related activity.[19]

A variety of other types of ion channels has been associated with changes in intrinsic excitability following seizures,[123] including A-type K^+ channels,[19] and Ni^{2+} sensitive T-type Ca^{2+} channels.[169,193] Mutations of genes encoding voltage-gated Na^+ and other channels are the basis for several forms of epileptic phenotypes.[133]

GABA as an Excitatory Neurotransmitter

The inhibitory action of GABA is crucial for maintaining the balance of excitation and inhibition in the brain. A primary mechanism of GABAergic function is the opening of Cl^- channels following activation of $GABA_A$ receptors. The reversal potential of Cl^- is generally at or negative to resting membrane potential, so that activation of $GABA_A$ receptors usually results in an outward current that opposes excitatory influences. Shifting E_{Cl} positively can, however, render GABA excitatory, as it sometimes is early in normal brain development.[17] One of the important regulators of intracellular $[Cl^-]$ is the potassium-chloride cotransporter, KCC2, which is impaired in some animal models of epilepsy. For example, excitatory actions of GABA in the secondary focus of a unilateral pilocarpine-induced epileptic hippocampus may be related to progressive KCC2 malfunction.[105] In the chronically isolated neocortex, E_{Cl} of resting neurons is not affected, however a deficiency in the KCC2 transporter slows the extrusion of Cl^- following prolonged GABAergic activation.[93]

Studies of human epileptic hippocampus also indicate that Cl^- regulation is disrupted. In a subset of pyramidal neurons in the subiculum, E_{Cl} appears to be more positive than the resting potential, and synchronous epileptiform discharges can be blocked with the $GABA_A$ antagonists bicuculline and picrotoxin.[38]

Do Gap Junctions Play a Role in Neocortical Seizures?

Electrical synapses are a particularly effective mechanism for synchronizing neurons.[48] As described earlier, electrical synapses extensively interconnect the inhibitory interneurons of the neocortex. It stands to reason that the hypersynchronization associated with seizure activity might be facilitated by interneuronal gap junctions. It is also plausible to suggest that gap junctionâ€“mediated synchronization of inhibition would actually tend to suppress seizures.[132] Recent human genetic evidence suggests that mutations of the Cx36 gene are associated with a form of juvenile myoclonic epilepsy.[79,120] A variety of experimental studies have addressed the potential role of gap junctions in epilepsy; however, it is still unclear whether electrical synapses help or hinder seizures.

Dye-coupling is used as an indirect assay of gap junction connections. Increases in neuronal dye-coupling have been

P.332

observed in both acute (zero extracellular $[Ca^{2+}]$) and chronic (tetanus toxin injections) models of hippocampal seizures.[39,140] The interpretation of these studies is problematic because of the capricious nature of the dye-coupling technique when applied to brain slices.[48] Gap junction-blocking drugs such as heptanol, octanol, halothane, and carbenoxolone,[20,59,65,107,135,175] and manipulations of intracellular pH,[150,163] influence epileptiform bursting in both acute and chronic seizure models.[91,154,182] Unfortunately, both the drugs and pH manipulations are nonspecific,[151] so that it is not clear whether their effects on seizures were mediated by changes in gap junction function.

Mice with a null mutation for the neuronal gap junction protein Cx36 lack electrical synapses between interneurons in neocortex and hippocampus.[54,85] These animals do not have an obvious seizure disorder, although their susceptibility to seizure-inducing stimuli has not been tested. Application of the convulsant drug fampridine (4-AP) to hippocampal slices of Cx36 knockout mice yields fewer long-duration epileptiform discharges but more occasions of burst-like activity compared with wild-type mice.[117]

Chronic seizures induced by kainate treatment or kindling of the hippocampus lead to downregulation of Cx36 mRNA, although there are no clear changes in Cx36 protein levels.[40,161] In the 4-AP seizure model, however, Cx36 mRNA is upregulated along with Cx32 and Cx43, two glial gap junction proteins.[65]

Unfortunately, the importance of electrical synapses for epilepsy remains ambiguous.

Summary and Conclusions

Although the neocortex is responsible for the most complex of animal behaviors, its cellular and molecular composition is not remarkable. The enzymes, neurotransmitters, and ion channels of the neocortex are widely expressed elsewhere in the brain, and neocortical neurons and synapses are modest variations on common structures. The uniqueness of the neocortex probably derives from its elaborate interconnections and their capacity to dynamically organize, associate, and modify myriad streams of neural information.

Interconnectedness may also explain why the neocortex so readily becomes epileptogenic. Reciprocal excitatory connections, normally essential to link widely dispersed but interrelated neurons, can also mediate abnormally synchronous and spatially rampant seizure activity. Many forces goad the cortex from normal to epileptiform activity. At a broad level, these include alterations in neural and synaptic excitability, metabolic aberrations, reduced synaptic inhibition, and reordering of interconnections themselves. At a more detailed level, there may be abnormalities of the modulation or expression of channels, receptors, and enzymes.

It is clear that seizure disorders have many root causes. Determining causality for clinical seizures is complicated by the intertwined and nested nature of cortical networks and their strongly interdependent structural, electrical, and biochemical components. A deep understanding of human seizures will require a comprehensive understanding of basic neocortical biology.

Chapter 30

Limbic Anatomy and Physiology

Dan C. McIntyre

Philip A. Schwartzkroin

Introduction

The concept of a â€œlimbic lobeâ€ was first put forth by Broca[27] as a means of labeling the various structures that surround the brainstem and form the border of the ventricular system. Broca was responsible also for the view of these structures as primarily olfactory in function (a major input from olfactory lobes)â€”i.e., as a â€œsmell brainâ€ (rhinencephalon). Based on anatomic grounds, Papez[182] proposed the existence of a network of limbic structuresâ€”including the hypothalamus, anterior thalamus, cingulate cortex, and hippocampusâ€”that was responsible for emotional behavior. The amygdala was not included in the initial description of the Papez circuit, but Maclean[139] subsequently expanded Papez's view of the anatomy of emotion to include the amygdala and several parahippocampal structures; he called this expanded network the *limbic system*. Although both Papez and Maclean viewed the hippocampus as central to the limbic system concept of emotion, we now know that emotional behavior is more strongly supported by the amygdala.[151,201,271] In contrast, the central position of the hippocampus in the limbic system has more recently focused on its role in memory[61,228,229,247] and its contributions to temporal lobe epilepsy (TLE).[74]

Of the various epileptic disorders seen in humans, the most frequently observed are those of temporal-lobe origin.[62] Considering the pathogenesis of the temporal lobe seizures, one often (but not always) finds a sclerotic lesion in one or more of the limbic or mesial temporal structures (see Chapter 13). These mesial structures form part of an olfactoryâ€“neocortical network that involves the hippocampus; the entorhinal, perirhinal, and piriform cortices; and the amygdala. The cells contained within these structures have both intrinsic properties and local connections that, when sufficiently provoked, can provide strong recurrent excitation that leads to robust seizure activity. The strong communication between these structures can amplify the seizure event and recruit cells with efferent connections that distribute widely throughout the brain. It is of little surprise, therefore, that discrete electrical stimulation in several of these same mesial structures can reproduce, in an epileptic patient, many of the features of the patient's automatism,[259] and that surgical resection of the structures can provide relief from the seizures.[63] With this evidence in mind, we briefly review both anatomic and physiologic features of the hippocampus, entorhinal cortex, perirhinal and piriform cortices, and amygdala. A description of the normal structure and function of these â€œlimbicâ€/mesial temporal structures is critical for our understanding of their roles in the development, study,[126] and expression of TLE.[73]

The Hippocampal Formation

The hippocampal formation has attracted considerable attention during the recent explosion of interest in cellular and synaptic neuroscience.[215,218] Its attraction as a focus for research stems from several considerations: (a) It is a region of the brain implicated in a number of important (and interesting) â€œnormalâ€ behaviors, such as learning and memory; (b) both functionally and structurally, the hippocampus shows an unusual degree of neuronal â€œplasticityâ€[129,172,214]; (c) it has been implicated as a focus of pathology in a number of neurologic disorders ranging from epilepsy to global ischemia,[24] Alzheimer disease,[161] traumatic head injury,[261] to psychiatric disorders[38]; (d) its unique, laminated structure has made it particularly conducive to study using in vitro brain slice preparations, an approach that has been adopted by many laboratories; (e) it can be viewed as a somewhat simplified cortex; and (f) it is richly connected to other parts of the limbic system (Fig. 1). The archicortical hippocampal circuitry has served as a â€œmodelâ€ for the more complex neocortex, and the hippocampal pyramidal cell has been studied and characterized as a model central nervous system (CNS) neuron. Given the interest and activity of so many investigators, a large store of information is available about hippocampal cell properties, structure, afferents and efferents, receptors and transmitters, and local circuits. This chapter deals primarily with major points of organization and function that have potential implications for our understanding of epilepsy-related phenomena.

Regional Connectivity

The hippocampal formation is conventionally divided into four major cell regions: Subiculum, cornu ammonis regio superior (CA1), cornu ammonis regio inferior (CA3), and the dentate gyrus (Fig. 1). Each region is defined, at least in part, by its unique patterns of input and output, as well as by the features of its principal cell population. Part of the beauty and simplicity of the hippocampus is in the early established finding that each region projects to the next through an excitatory â€œtrisynapticâ€ pathway[7] (see Fig. 1). Thus, the granule cells of the dentate gyrus send their mossy fiber axons to the CA3 region (the CA2 transition zone, by definition, receives no mossy fiber input); axon branches of the CA3 pyramidal cellsâ€”the Schaffer collateralsâ€”project to CA1; the CA1 pyramidal cells send axons to the subiculum; and the subiculum projects out of the hippocampal formation (back to entorhinal cortex as well as other cortical targets). Recent studies have suggested that this simple view of an intrahippocampal organization is unrealistic[7] and perhaps even misleading in our efforts to learn how information is processed through the hippocampus. We now know, for example, (a) that the mossy fibers also make numerous contacts within the dentate hilus and that they colocalize opioid peptides[152] and zinc,[68] along with glutamate; (b) that the CA3 cells project to contralateral hippocampus, as well as back into the ipsilateral dentate hilus, where they excite mossy cells and interneurons[65,127]; (c) that activity in the CA1 pyramidal region can influence activity in the CA3

pyramidal cells, perhaps through antidromic mechanisms[233]; (d) and that hilar neurons interconnect ipsilateral and contralateral dentate regions.[200] Further, although it appears that each of the major associational connections uses the excitatory neurotransmitter, glutamate, the nature of the evoked post-synaptic potentials in each region may be rather different. For example, the mossy fiber unitary excitatory postsynaptic potential (EPSP) onto CA3 pyramidal cells is very large (millivolts) and mediated primarily by non-*N*-methyl-D-aspartate (NMDA) glutamate receptors[270]; in contrast, the unitary EPSP produced by Schaffer collateral synapses onto CA1 pyramidal cells is more typical in size (about 100 ÂµV) and involves both non-NMDA and NMDA receptor components.[204] Finally, hippocampal â€œinterneuronsâ€ contribute a Î³-aminobutyric acid (GABA)ergic component to interregional, as well as local intraregional, information relay.[219] Thus, what was once thought to be a simple, serial, feed-forward intrahippocampal pathway is now known to be an elaborate series of interacting and parallel feed-forward and feedback circuits, involving not only principal cell axons but also specialized interneuronal interactions (Fig. 2).

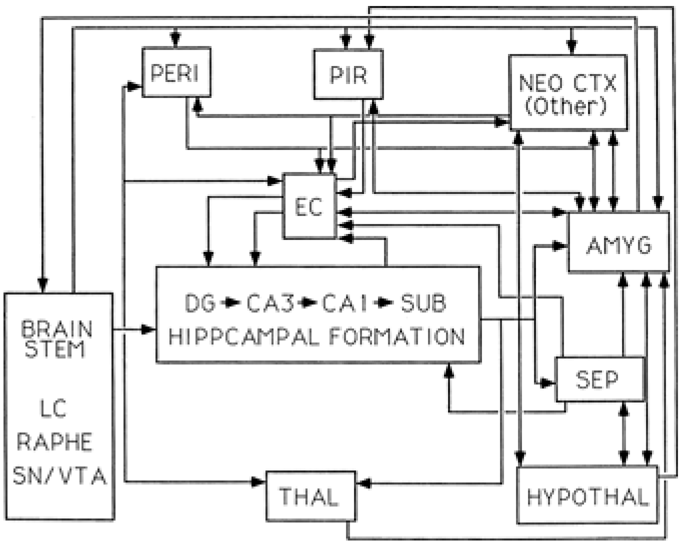

FIGURE 1. Major connections of the limbic system. Diagram of the major interconnections among principal limbic system structures, in particular, those regions described in the current review. EC, hippocampal formation, entorhinal cortex; PERI, perirhinal cortex; PIR, piriform cortex; AMYG, amygdala. Their connections are shown with: NEO CTX, neocortex (with no specification of cortical region); SEP, septum; HYPOTHAL, hypothalamus; THAL, thalamus; and brainstem structures LC, locus ceruleus; raphe; and SN/VTA, substantia nigra/ventral tegmental area.

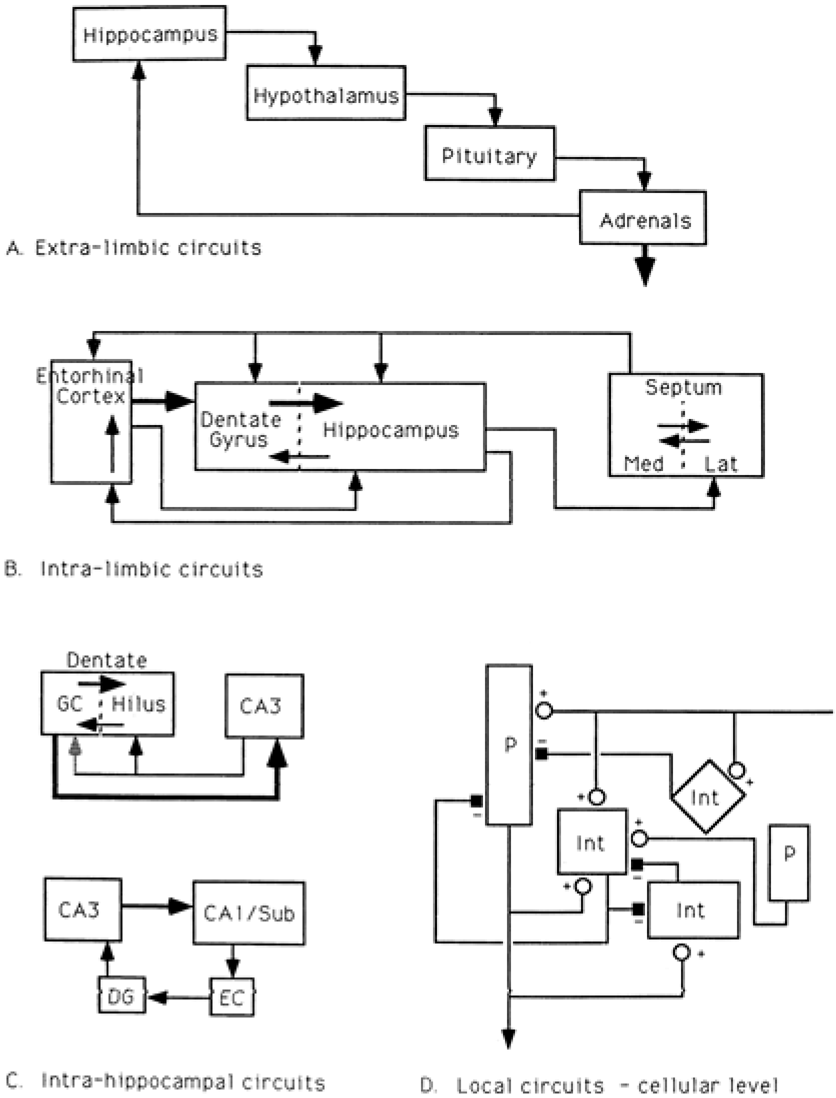

FIGURE 2. Feed-forward and feedback circuits. The limbic system (and its components) is entwined in a large number of feedback control circuits from interregional to local cellular levels. **A:** Hippocampal modulation of the hypothalamic-pituitary-adrenal (HPA) axis via adrenal steroid influences on hippocampal neurons. Hippocampal projections to hypothalamus help to regulate release of corticotropin-releasing hormone (CRH); hypothalamic release of CRH controls pituitary output of adrenocorticotropic hormone (ACTH); ACTH acts on the adrenal glands to stimulate secretion of cortisol. Because hippocampus has a high density of adrenal steroid receptors, the level of circulating cortisol modulates hippocampal output. **B:** Feed-forward and feedback circuits among limbic system regions. The well-studied feed-forward circuit from entorhinal cortex to dentate gyrus (DG), from DG to hippocampus proper and from hippocampus to septum is regulated by a number of feedback steps, including: (a) hippocampal projections â€œbackâ€ to the dentate gyrus; (b) septal projections to the hippocampus, dentate gyrus, and entorhinal cortex; and (c) hippocampal projections to the entorhinal cortex. **C:** Feedback circuits that modulate â€œserialâ€ processing within the hippocampus. Granule cell output to the hilus and CA3 is modulated by CA3 feedback to hilar neurons (and perhaps directly to the granule cells) and by hilar feedback from mossy cells and interneurons to the granule cells. **D:** Local feedback control within a given area of hippocampus. The principal cell (*P*) (e.g., the granule cell or the pyramidal cell) receives excitatory afferent input and sends an excitatory output, not only to the next principal cell region, but also to local inhibitory cells (*Int*). Local interneurons provide inhibitory feedback onto the principal cell and onto other inhibitory interneurons in the region.

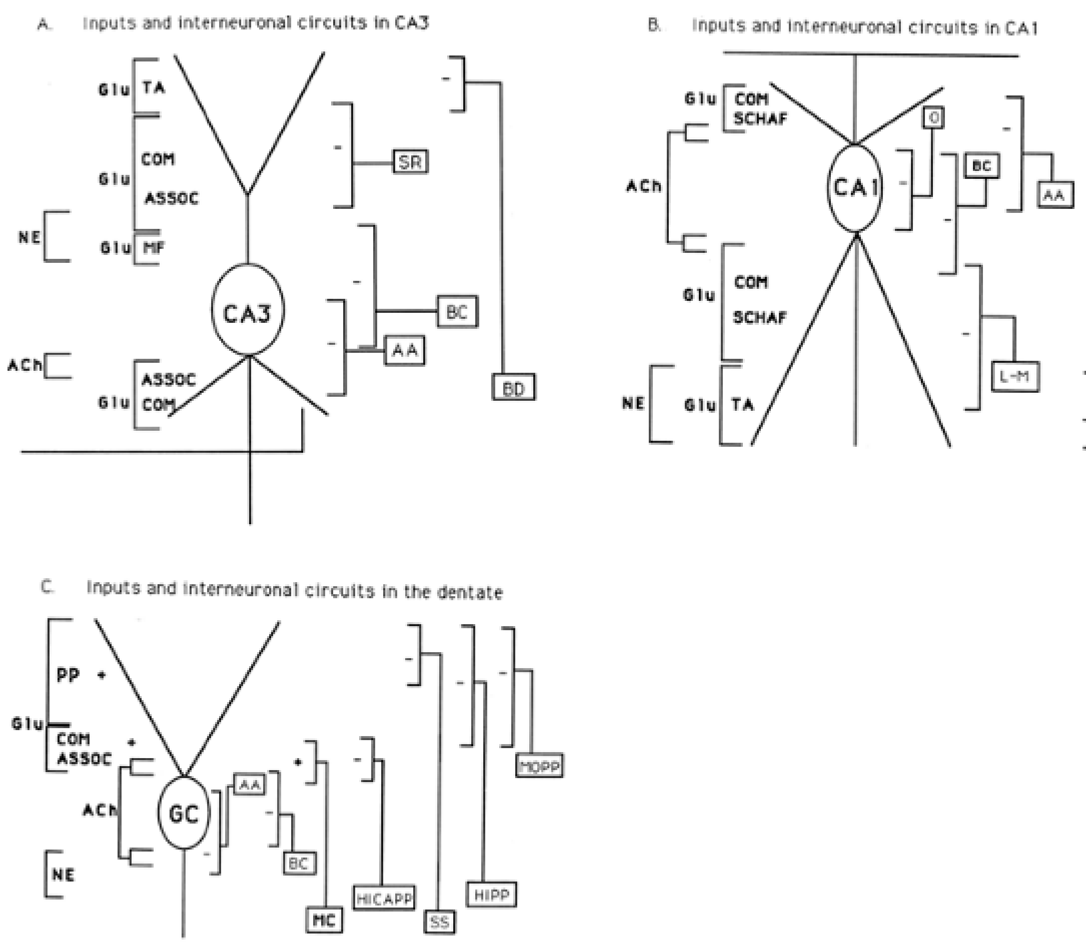

FIGURE 3. Laminar organization of hippocampal subregions. Schematic diagrams on local inhibitory interneurons and various afferent inputs (with associated transmitter type) in the CA3 region (**A**), the CA1 region (**B**), and the dentate/granule cell region (**C**). **A:** In CA3, the temporal ammonic (*TA*), commissural (*COM*), associational (*ASSOC*), and mossy fiber (*MF*) afferents all make excitatory glutamatergic (*Glu*) synapses on pyramidal cell dendrites (both apical and basal). Other inputs (e.g., from the septum and locus ceruleus) use other neurotransmitters (acetylcholine [*Ach*] and norepinephrine [NE]). Locally, inhibitory interneurons (stratum radiatum [SR] cells, basal dendritic [BD] cells, basket cells [BC], and axo-axonic [AA] cells) elaborate axons targeted to particular layers. **B:** A similar organization can be seen in CA1 with respect to both afferent inputs and to local inhibitory cell types (oriens alveus [A], oriens [O], basket cells [BC], axo-axonic [AA], and lacunosum-moleculare [L-M]); as seen in the CA3, these interneurons send axon terminals to different layers of CA1, where they make inhibitory (GABAergic) synaptic contacts. **C:** In the dentate, the perforant path (PP) input from entorhinal cortex contributes excitatory glutamatergic drive onto the granule cells. The local inhibitory cell types in the dentate include axo-axonics (AA), basket cells (BC), hilar cells of different types (HICAP, hilar cell with axon in the commissural/associational pathway; HIPP, hilar cell with axon in the perforant pathway; and SS, hilar somatostatin cell with axon in the distal dendritic layer), as well as interneurons with both soma and axon in stratum moleculare (e.g., MOPP, moleculare cell with axon in the perforant pathway). In addition, mossy cells (MC) of the hilus constitute the excitatory commissural/associational input to the dentate granule cells.

Afferents (Inputs)

Cortical Afferents

The major cortical input to the hippocampal formation arises in layer II pyramidal cells of the entorhinal cortex (EC), projects

through the angular bundle pathway, and enters the ipsilateral dentate gyrus via the perforant pathway.[94,235] This excitatory input terminates largely on spines on the distal dendrites of granule cells (and on interneurons) in the outer two thirds of the dentate molecular layer (Fig. 3). The entorhinal input has been subdivided into two divisions, with fibers originating in the medial EC synapsing in the middle third of the molecular layer and fibers from the lateral EC synapsing in the outer third. Investigators continue to explore differential features of these subdivisions, some of which may be relevant to dentate seizure susceptibility. For example, the medial division is glutamatergic and evokes EPSPs with both NMDA and non-NMDA components; in the lateral division, opioid-dependent long-term potentiation[26] is supported by anatomically defined colocalization of glutamate and enkephalin, with the latter â€œtransmitterâ€ affecting regional interneurons (inhibition via Âµ- and Î´-receptors) to mediate disinhibition of granule cells[269]â€"a perhaps critical step in dentate seizure genesis.

Anatomic studies of the EC projection to the hippocampal formation have also identified an input to hippocampus proper.

This temporoammonic pathway arises in layer III cells of EC but separates from the perforant pathway to contact the most distal branches of pyramidal cells in the stratum lacunosum-moleculare of CA1 to CA3.[264] Although clearly excitatory (i.e., glutamatergic), the functional nature of this pathway has been questioned because its influence on pyramidal cell discharge has been difficult to demonstrate.[225] Recent experiments suggest that temporoammonic modulation of pyramidal cells is significant, and that this input may also differentially activate an interneuron subpopulation located in these distal reaches of the apical dendritic region (see Fig. 3).[123] It is worthwhile to note that the direction of input to cornu ammonis via this entorhinal input is opposite to that of the associational input via the major trisynaptic pathways; thus, pyramidal cell excitation and processing cannot be viewed as a one-way serial influence. The function of this pathway remains unclear but appears to provide a frequency-dependent modulatory action from the entorhinal cortex directly onto hippocampal pyramidal cells.[107]

Subcortical Afferents

A variety of subcortical fiber inputs innervate the hippocampal formation, some in very specific laminar patterns and others in a more diffuse pattern (see Fig. 3). The major subcortical projections include:

The *septohippocampal* input arises in the medial septal nucleus and diagonal band of Broca and enters the hippocampus via the fimbria/fornix.[268] This input provides the hippocampal formation with the vast majority of its acetylcholine (ACh)[131] and comprises a subcomponent of the basal forebrain cholinergic projection to cortex that has been implicated in learning and cognitive function. However, it is now very clear that this input consists of both cholinergic and GABAergic components[6]; septohippocampal lesion experiments, designed to deprive hippocampus of its ACh supply, must be carefully interpreted in light of damage to both GABAergic *and* cholinergic inputs. Acetylcholinesterase staining, which disappears almost entirely with septal lesions or with fimbria/fornix transection, shows a discrete pattern of staining in all regions of hippocampus, with a concentration in thin supra- and subcellular regions (Fig. 3). Interestingly, recent studies suggest that some interneuron subpopulations are extremely sensitive to ACh[197] and may be excited at much lower thresholds than are the principal cells. This possibility is intriguing, inasmuch as at least one form of hippocampal Î¸-activityâ€"the slow, rhythmic EEG activity that is associated with restful alertnessâ€"is mediated via cholinergic mechanisms[128] and may well depend on excitation of interneurons for synchronization of the hippocampal projection cell populations.[237] The cholinergic synaptic action in hippocampus is primarily muscarinic (blocked by atropine). The GABAergic projection from septum to hippocampus appears to have a slightly different set of targets. Although it is difficult to identify the general pattern of septal GABA fiber ramification in hippocampus (because of the large intrinsic GABA network), tracing studies have shown that septohippocampal GABA fibers preferentially synapse on GABAergic basket cells in the dentate gyrus,[69] forming a pathway for hippocampal/dentate disinhibition.

The *brainstem monoamine* pathways also provide an important, presumably modulatory, influence on hippocampal neurons. Noradrenergic fibers arising from the locus coeruleus,[135] serotonergic fibers arising from the raphe nuclei,[170] and dopaminergic fibers (although very sparse) from brainstem nuclei have been shown to ramify diffusely within all regions of hippocampus. The noradrenergic input, although generally diffuse, is most obvious in the CA3 and dentate hilar regions. However, cells in all parts of hippocampus have been shown to be sensitive to norepinephrine (NE), primarily (but not exclusively) via a Î²-adrenergic receptor mechanism[217] that leads (via cyclic adenosine monophosphate [cAMP] production) to a blockade of a hyperpolarizing potential (with loss of spike-firing adaptation) and net cell excitation.[140] Norepinephrine has been implicated in a form of long-term potentiation (LTP) in the CA3 pyramidal cell region,[97] as well as in the dentate.[232] How these noradrenergic effects on hippocampal cells are related to whole-brain hyperexcitability is unclear because lesions of the ascending noradrenergic system yield a nervous system with heightened seizure susceptibility.[153] A mouse â€œknockoutâ€ of the norepinephrine-synthesizing enzyme (dopamine Î²-hydroxylase) also shows increased seizure susceptibility.[244] In contrast to this net excitatory effect of NE in hippocampus, both serotonin 5-hydroxytryptamine (5-HT) and dopamine (DA) produce hyperpolarizing (inhibitory) responses in hippocampal pyramidal cells, mediated by G-proteinâ€“coupled mechanisms.[9,22] The role played by these potent modulators of cell excitability is yet to be well characterized. However, serotonergic fiber input, like the septal GABAergic input, has been recently traced to a specific contact with interneurons within the dentate hilus[87]; specific serotonergic effects on interneurons may well be critical in the net influence of this pathway in hippocampus. Clearly, the effects of these monoaminergic afferents in hippocampus depend on the postsynaptic receptor subtypes upon which they synapse.[10] Interneurons exhibit 5-HT3 receptors, which are colocalized with CB1 cannabinoid receptors, thus suggesting not only a specific serotonin modulation of interneurons, but also a complex interaction between 5-HT and the endocannabinoid system.[171]

Efferents (Outputs)

Cortical Projections.

The major hippocampal cortical efferents arise in the subiculum and CA1 regions and project to the lower layers of entorhinal cortex.[265] This system completes a feedback loop to the EC (through hippocampus) (see Fig. 2), because the deep cortical layers of EC then influence the output of layers II and III projection cells.[5] In addition, subicular fibers project to the perirhinal cortex, another component of the â€œparahippocampalâ€ complex. Anatomic and electrophysiologic studies show that CA1 and subiculum send axons to widespread prefrontal cortices, including the prelimbic area, cingulate cortex, medial orbital cortex, and the infralimbic areas.[102,180,258] Although the roles of these efferent projections have not yet been clearly understood, these connections are consistent with a role for parahippocampal and prefrontal cortices in cognitive processes. Further, because medial/orbital prefrontal regions have brainstem connections that modulate autonomic function, these hippocampal connections to prefrontal cortex may endow the hippocampus with a role in emotional and visceral aspects of behavior long associated with the limbic region.

Subcortical Projections.

The best studied of the subcortical hippocampal projections are the â€œreciprocalâ€ connections from CA1 and subiculum back to the septumâ€"but to the lateral, rather than medial, septal nucleus.[265] Again, because the lateral septal nucleus connects closely with the medial septal nucleus (from which hippocampal afferents arise), this projection constitutes part of still another feedback loop between the hippocampus and a related structure (see Fig. 2). The nucleus accumbens of the basal forebrain is a related projection from the same general subregions of subiculum. This structure is associated with the â€œlimbicâ€ component of the ventral basal ganglia. The subiculum also provides important connections from the hippocampal formation to the thalamus (midline nuclei), amygdala, and hypothalamus (ventromedial nucleus and mamillary body).[37,93] Although these projections â€œmake senseâ€ in terms of the old Papez circuit view of limbic system involvement in emotional and visceral behaviors, the actual role of these efferents (and of the reciprocal connections

P.341

to hippocampus, largely through septum) are still to be determined. One additional circuit of note includes the hippocampus as the component of the hypothalamic-pituitary-adrenal (HPA) axis.[76] Adrenal steroid receptor (glucocorticoid and, especially, mineralocorticoid) concentration is high in the hippocampus, and its modulation of hippocampal output may play a key role in controlling the release of corticotropin-releasing hormone (CRH) and in corticotropin release from hypothalamus (i.e., in feedback control of adrenal steroid secretion). The hippocampal efferents to hypothalamus may thus be critically involved in adrenal stress responses.[253]

Regional Characteristics

Dentate Gyrus.

The dentate gyrus is the primary target of cortical input to the hippocampal formation and consists of the granule cell region and the related dentate hilus. The granule cell region is neatly laminated,[23] with the granule cell bodies densely packed in stratum granulosum (SG) and their dendrites reaching through the stratum moleculare (SM) (see Fig. 3). The stratum moleculare is conventionally divided into thirds: The inner third is the focus of associational, commissural, and septal input; the middle third receives input from the medial EC; and the outer third receives input from the lateral EC. Partially surrounded by stratum granulosum is the hilus, home to a variety of polymorphic cells that include the excitatory (glutamatergic) mossy cells (primary source of the dentate commissural and associational connections) and inhibitory interneurons.[4] Until recently, the dentate region of hippocampus was relatively neglected by epileptologists because it appeared to have a very high threshold for seizure activity.[138] Recent studies, however, have focused more closely on this region because (a) the granule cells are relatively resistant to seizure-associated damage[224]; (b) granule cell axons show a high degree of plasticity (sprouting) in epileptic brain[42]; (c) changes in synaptic currents and voltage-dependent channels have been demonstrated in granule cells following kindling[165]; and (d) maximal activation of this region is associated with the generalization of seizure activity through the limbic system and beyond.[138] Indeed, the dentate is now sometimes considered the gatekeeper of hippocampal excitability.[91]

Granule cells are unusual because they show constant turnover throughout life, regulated in part by adrenal steroids and stress,[75] exercise,[112] and even seizures.[183] The role of newborn granule cells has been discussed with respect to behavioral function,[132] hippocampal repair,[117] and development of the epileptic state.[209] Electrical propertiesâ€”intrinsic and synapticâ€”have been extensively studied,[211,227,252] and granule cells have been found to be rather unexcitable because they maintain a very negative resting potential. Prolonged depolarization also fails to evoke rapid, repetitive firing for long periods because these cells exhibit pronounced spike firing adaptation; bursts of action potentials are followed by a large after-hyperpolarization. Activation of EC afferents to the dentate evokes a monosynaptic EPSP in granule cells; it is unclear how much of this synaptic excitation in normal hippocampus is mediated by NMDA receptors.[165] In addition, this afferent input activates a powerful inhibitory local circuit that rapidly curtails granule cell firing.[138] As elsewhere in hippocampus, at least some of the dentate interneurons are activated at a much lower threshold than are the granule cells[30]; activation of inhibitory interneurons dampens the granule cell discharge so that â€œphysiologicâ€ levels of EC input are likely to result in rather discrete and restricted dentate (i.e., granule cell spiking) output to the hilus and CA3. The granule cell axons (mossy fibers) excite hilar and CA3 neurons (both principal cells and interneurons) via glutamatergic mechanisms.[206] These cells colocalize the opioid peptide dynorphin[255] and contain a high concentration of zinc[68] in their terminals. Although the role of these colocalized substances remains controversial, evidence suggests that zinc may modulate synaptic plasticity (long-term potentiation [LTP]) at the postsynaptic cell[133]; decrease glutamate release from the presynaptic terminal,[12] and even affect GABA receptors in epileptogenic circuits.[49,169] Further, it has recently been shown that granule cells/mossy fibers also contain and release GABAâ€”an observation that has obvious implications for â€œexcitatoryâ€ neurotransmission in the adult hippocampus and also for hippocampal development in the immature brain.[80]

In addition to the granule cells, the other â€œprojectionâ€ cell type in the dentate is the hilar mossy cell, which sends its axons into the inner SM, both ipsi- and contralaterally, to make excitatory connections on granule cell dendrites. These cells receive their primary input from granule cells (another feedback circuit) (see Fig. 2), although some mossy cells have dendrites that reach into the SM to receive EC input directly.[205]

Interestingly, mossy cells are among the most vulnerable cell types in the hippocampal formation, and their death is thought to trigger the granule cell axon sprouting response into the inner SM, often seen in epileptic hippocampus.[42] It has also been hypothesized that mossy cell damage, by removing a tonic source of excitation to inhibitory interneurons, gives rise to disinhibition of the granule cells.[222] Recordings from mossy cells show them to receive a constant â€œspontaneousâ€ stream of large, non-NMDA EPSPs[206] from granule cell mossy fiber terminals that require minimal summation to trigger action potential discharge; thus, it is not surprising that mossy cells have a very low threshold for discharge and may fire in bursts of action potentials when the summed EPSP is very large.[32] Recent studies have shown that mossy cells also receive input from CA3 projecting back into the hilus.[207] Finally, it is of interest that these cells have none of the calcium binding proteins common in other hippocampal cell types (granule cells contain calbindin). It is thought that inadequate intracellular calcium buffering may contribute to mossy cell vulnerability, a possibility supported by the finding that the injection of an intracellular chelator will save these neurons from potentially toxic levels of excitation[210] and the apparent resistance to injury of calretinin-containing mossy cells in the mouse and the gerbil.[71,118]

Local circuits in the dentate, once thought to be restricted to the relatively simple feedback loop between inhibitory basket cells and granule cells, are shown to be very complex (see Fig. 3). In addition to five subtypes of dentate basket cells,[199] the dentate contains a myriad of other GABAergic interneurons. Each subpopulation appears to have a specific dendritic and axonal arborization pattern,[89] and some colocalize (with GABA) peptide neurotransmitters. For example, the somatostatin-containing interneurons in the hilus send their axons into the outer molecular layer to interact with distal granule cell dendrites and with the incoming lateral perforant path fibers.[130] Although the role played by these interneurons is not yet clear, their mode of termination (and data regarding mechanism of action of somatostatin) suggests that they may have a presynaptic inhibitory function in relation to the perforant path input. Chandelier cells, a unique interneuron cell type, make exclusiveâ€”and apparently powerfulâ€”inhibitory synapses on the axon hillock and initial segment of hippocampal cells.[33,226] Other inhibitory cell types have been described with specific axon terminal fields in the middle or inner SM,[89] and one interneuron cell type has now been found that projects to CA3 and CA1.[31] Interestingly, all these interneurons appear to contain GABA; no excitatory â€œinterneuronsâ€ have been described in the dentate (or anywhere else in hippocampus).

It is clear that each cell type has a special function, as determined by the arborization pattern of its dendritic tree, the localization of its axon terminals, and its colocalized transmitter content. However, because most interneurons synapse with each other, it is often difficult to predict what the net effect of activation of a given subpopulation might be; interneuron

P.342

synapses directly onto granule cells may have a clear inhibitory outcome, but interneuron inhibition of interneurons may result in granule cell disinhibition or net excitation. Recent studies have revealed that at least one interneuron population in the dentate appears to be particularly sensitive to $GABA_B$ receptor-mediated inhibition[164]; it has been hypothesized that $GABA_B$ receptors on the terminals of GABA interneurons may, in fact, regulate the cell's release of GABA through a direct inhibitory effect by GABA on its own terminal.[173] Different interneurons, too, are differentially sensitive to excitotoxic damage; basket cells (at least those types that contain the calcium-binding protein parvalbumin) are resistant to damage,[223] and are well preserved in epileptic hippocampus (even hippocampi showing severe mesial temporal sclerosis), whereas hilar somatostatin-containing interneurons are quite vulnerable (they lack calcium-binding proteins), and their loss may contribute to the hyperexcitability of dentate exposed to high levels of prolonged stimulation.[52] Not surprisingly, the different subpopulations of interneurons express different receptor and channel combinations.[41] Finally, in interneurons, as in other cells of hippocampus, activity-dependent (seizure-inducing) changes occur in cell properties (e.g., receptor complement, channels.[186] For example, neuropeptide Y (NPY) and associated receptors are dramatically regulated by seizure activity[46,254]; these changes, plus the observation that exogenously modified NPY expression may modify seizure activity, has led to the view that the NPY system constitutes an adaptive feedback system for regulating excitability.[254]

CA3.

The CA3 region is composed of large pyramidal cells (and associated interneurons) and is the recipient of mossy-fiber input from the granule cells. The region is conventionally divided into at least three divisions: CA3a (which we shall consider together with CA2 for the purposes of this discussion) is that part of the cell band most distal from the dentate (and closest to CA1); CA3b comprises the middle part of the band, nearest the fimbria/fornix connection; and CA3c is most proximal to the dentate, inserting into the hilus.[5] Although each of these divisions may have slightly different characteristics, the region as a whole (including CA2) has been considered to be the â€œpacemakerâ€ area of the hippocampus.[267] In CA3 much of the rhythmic, synchronous bursting activity associated with interictal epileptiform activity appears to be generated. This population property is a product of the intrinsic properties of CA3 pyramidal cells and their high degree of excitatory collateral connectivity.[249] Unlike other regions of the hippocampus, CA3 pyramidal cell axon collaterals ramify extensively within the local region and make excitatory contacts with their neighbors. The unique properties of CA3 local circuitry have been implicated in a number of hypotheses regarding learning and memory processes in the hippocampus,[81] and also appear to provide a basis for oscillatory rhythms that are characteristic of hippocampus. The CA3 region (as well as entorhinal cortex) constitutes a generator of Î³-frequency (10â€“30 Hz) oscillations, a cholinergically driven pattern that depends on coupling of interneurons (and pyramidal cell axons) via gap junctions, as well as via more conventional chemical excitatory (glutamatergic) and inhibitory (GABAergic) synapses.[146,250] The CA3 region also generates sharp waves and high-frequency oscillationsâ€”EEG patterns implicated in memory consolidation.[142]

Although the excitatory output of CA3 is often damped by strong inhibitory interneuronal influences, even minor reductions in inhibitory efficacy in CA3 can result in significant synchronized bursting, due to interaction among CA3 pyramidal cells. This bursting (or oscillatory drive) is relayed to the CA1 region ipsilaterally (via Schaffer collaterals) and to CA1 and CA3 regions contralaterally (the commissural fibers of hippocampus proper). Although this output is effective in driving postsynaptic targets, it also appears to be important in inhibiting the generation of ictal activities, particularly in entorhinal cortex.[14] Because of the very extensive nature of the CA3 axon collateralization over the longitudinal extent of hippocampus,[134] there is significant divergence of this CA3 output (it is *not* laminar). Perhaps curiously, this same CA3 region is only reluctantly recruited into ictal-like seizure activityâ€”perhaps because of the strength of its inhibitory circuitry or perhaps because the mechanism of the interictal-like bursts directly antagonizes seizure genesis.[104]

The intrinsic and synaptic properties of CA3 pyramidal cells determine this unique set of epilepsy-related characteristics. Individual pyramidal cells in this region have an intrinsic burst propensity, apparently based on a relatively high density of calcium channels in their proximal dendrites.[66,266] Membrane depolarization (e.g., from incoming synaptic activity) not only may trigger conventional sodium action potentials, but also may open these calcium channels; the calcium influx causes a more prolonged depolarization of the cell, driving additional action potentials in a â€œburst.â€ Because afferent input often involves activation of both excitatory and inhibitory influences onto CA3 cells, this burst propensity is generally curtailed by the hyperpolarizing effect of the inhibition.[163] When these bursts occur, however, they provide a potent drive, not only to CA1 targets, but also to neighboring CA3 cells (via the excitatory collateral system); a gradual recruitment of CA3 neuron activity can thus lead to synchronized burst discharge. Importantly, there also appears to be a very effective mechanism for turning off these burstsâ€”the after-hyperpolarization generated by a calcium-dependent potassium conductance.[98] Thus, the very mechanism of burst generationâ€”calcium influxâ€”also involves a self-limiting process (the calcium-activated hyperpolarization). These processes presumably contribute to the reluctance of CA3 to participate in ictal-like activity, which requires prolonged depolarization and repetitive action potential discharge.

Presumably, the major trigger for CA3 discharge is afferent input from the dentate granule cells. Large mossy fiber terminals engage in very complex synapses on the proximal part of the CA3 apical dendrite in the stratum lucidum, where they contact complex dendritic spines; glutamate release from a single terminal evokes a large nonâ€“NMDA-mediated EPSP.[28] Fortunately, the baseline â€œspontaneousâ€ level of granule cell activity is relatively low, so that CA3 cells are not constantly driven at high rates. The unique features of mossy fiber input appear to account for many of the region-specific properties of CA3. Mossy fibers colocalize glutamate with high concentrations of zinc (see earlier discussion), dynorphin, and GABA. Further, the mossy fiber terminals appear to have receptors for kainate (see next section), as well as for BDNF. BDNF application to the CA3 region results in synchronized burst discharge activity.[208]

Fortunately, the same mossy fiber input that activates CA3 pyramidal cells also drives local interneurons very effectively, so that CA3 cells are tonically inhibited by a variety of interneuron subtypes[79] (see Fig. 3). The subpopulations of interneurons in CA3 overlaps with, but is not exactly the same as, those in the dentate; basket cells provide potent inhibition to the level of the cell soma, and other cell types show unique dendritic arborization patterns and region-specific targeting by axon collateral. Investigators have shown that different morphologically defined interneurons also show different electrophysiologic properties; the interneurons include both fast-spiking cellsâ€"whose inhibitory postsynaptic potentials (IPSPs) summate to produce small, smooth IPSPs in pyramidal cellsâ€"and slow-spiking cells, which produce large, fast-rising IPSPs in the pyramidal cell target.[162] As in the dentate, the dendritic region of CA3 is laminated; the most proximal apical dendrite receives mossy fibers exclusively, the mid-dendritic regions (strata radiatum on the apical side and oriens on the basal side) receive primarily associational and commissural fibers (i.e., from other CA3 cells),

and the distal apical dendrites (stratum lacunosum-moleculare) receive input from the temporoammonic afferents (from EC) (Fig. 3). All these excitatory glutamatergic inputs are modulated not only by the local GABAergic circuits but also by the subcortical afferent systems. Interestingly, the mossy fiber input to CA3, because it is mediated by non-NMDA glutamate receptors, exhibits a different form of synaptic plasticity[256] from the typical LTP (or long-term depression [LTD]) so intensively studied as a cellular model of learning (and a possible contributor to kindling). The plasticity of this synapse, in contrast to the LTP produced in stratum radiatum of the same region, appears to be particularly dependent on (sensitive to) monoaminergic activation of a cAMP second-messenger system.[97] Recent studies suggest that interneurons specific to the stratum lucidum are key participants in mossy fiberâ€"induced synaptic plasticity.[184]

Seizure-related pathology in the CA3 region tends to be rather varied.[224] The neighboring CA2 transition zone, which does not receive mossy fiber input (and differs from CA3 in a few other subtle ways) is commonly identified as the â€œresistant sectorâ€ because these cells are sometimes the only CA pyramidal cells to survive in human TLE. Temporal lobe epilepsy-related â€œend-folium sclerosis,â€[147] a variation on the mesial temporal sclerosis pattern, is a pathology that primarily affects the CA3 and hilar regions, leaving surviving neurons in the surrounding granule cell layer. The kainic acid [KA] model of TLE has been used to study this pattern of cell loss because intraventricular injection of KA produces excitotoxicity, primarily among CA3 pyramidal cells.[178] Studies have suggested that the KA receptors that mediate this damage are located on mossy fiber terminals; the excitotoxic effect of KA on CA3 cells is mediated indirectly by the KA-induced release of glutamate from these terminals. Indeed, if the granule cell input to CA3 is blocked (lesioned), the CA3 population is protected from KA damage.[177]

CA1.

The CA1 pyramidal cells make up an apparently homogeneous population[103] which, together with their relatives in subiculum, comprise the primary output cells of the hippocampal formation. Their primary excitatory inputs are via the glutamatergic CA3 Schaffer collaterals (both ipsi- and contralateral), which contact spines on apical and basal dendrites in strata radiatum and oriens. An additional excitatory input (the strength of which is still unclear) is via the EC-originating temporoammonic system, which synapses in the distal apical dendrites in stratum lacunosum-moleculare.[225] Although these CA1 pyramidal cells also receive inhibitory input from a variety of interneuronal influences,[122] the strength of inhibition in CA1 seems lesser than that in dentate and CA3, and the cells, therefore, are more vulnerable to recruitment into seizurelike activity and to excitotoxic damage. This relatively low level of inhibition may also help explain why LTP is so easily induced in this region, compared with other brain regions.[110,141] Interestingly, unlike CA3, CA1 pyramidal cells appear to have relatively little excitatory interaction with each other,[248] so the basis of their synchronization rests with CA3. In general, the cell properties and circuits intrinsic to CA1 are not themselves epileptogenic (i.e., these cells are not intrinsic â€œburstersâ€); however, once provoked or recruited (e.g., by excitatory drive from CA3), their control mechanisms are insufficient to prevent seizure activity from taking over the region. In mesial temporal sclerosis, CA1 (Sommer sector) is, next to the dentate hilus, the region showing most damage[260]â€"perhaps reflecting the inadequacy of CA1 control mechanisms to reduce cell excitation. Although it is clear that CA1 can easily be driven to seizure activity, it remains unclear what role this region plays in TLEâ€"either its generation or maintenanceâ€"because these cells are often entirely absent from a hippocampus thought to be the source of seizure activity in TLE.

CA1 cell properties have been so intensively studied that CA1 cells are now often referred to as the â€œmodelâ€ CNS neuron. A variety of voltage-dependent ion channels have been characterized in the CA1 pyramidal cell membrane, including high-threshold calcium currents[227] (which are blocked by such drugs as nimodipine and nifedipine), a large number of potassium currents (delayed rectifier, calcium-activated, etc.), and even noninactivating sodium currents. These cells do not normally discharge in a burst pattern, but recent studies have shown that a subpopulation of CA1 cells tend to burst,[103] and that this proportion of cells increases as the extracellular potassium concentration increasesâ€”as might occur in epileptic tissue. Further, perhaps because of the relatively small extracellular space in CA1,[251] these pyramidal cells may be particularly sensitive to the effects of extracellular current flow as a source of ephaptic interaction and synchronization.[246] A large number of recent studies have focused on the plasticity of receptors and channels in hippocampal CA1 pyramidal cells as a function of activityâ€”both normal and pathologic.[21,48,105] Such studies have illustrated the potential for epileptogenic stimuli to induce â€œchannelopathies.â€

The major basis for local circuit communication with the CA1 region lies in the interneuronal circuitry. In CA1, a number of different inhibitory (GABAergic) interneuronal cell types have been characterized, based on (a) the laminar location of the cell body (oriens, pyramidale, radiatum, lacunosum-moleculare); (b) the shape of the soma and the pattern of the dendritic ramification (which should provide some information about the source of inputs to these cells); (c) the â€œspininessâ€ of the dendrites (many are aspinous); (d) the colocalization of transmitters/peptides with GABA (e.g., somatostatin, parvalbumin); and (e) regional specificity of its axon projection (basket cell specificity for CA1 somata, oriens/alveus cell projections to distal apical dendrites, etc.).[122] Studies have suggested that a subpopulation of GABA neurons mediates $GABA_B$ inhibitory effects[263] and that different interneuron populations are differentially sensitive to ACh[197] and norepinephrine.[56] Of particular interest is the hypothesized role played by interneurons in the generation of the rhythmic activity that is so prominent in CA1 (e.g., Î¸-rhythm), especially within the context of theories in which these rhythms provide a framework for cognitive functions.[237] Interneurons also appear to be the source (or target) of various modulatory substances that control hippocampal excitability, including opioids and endocannabinoids.[44,86,160] And recent studies implicate metabotropic glutamate receptor effects within the interneuronal circuitry as a particularly important new focus for understanding control of synaptic excitation and plasticity.[99,121,124]

This pattern of synaptic activities in CA1 has generated the most intense analysis, driven in large part by interest in the mechanisms of synaptic plasticity (LTP/LTD).[145] These studies have revealed that the EPSP in CA1 pyramidal cells has both NMDA and non-NMDA components; activation of the NMDA receptors is normally crucial for initiation of LTP-like events, but high levels of input, which activate high-threshold calcium currents, may also produce a form of LTP.[78] Studies have also confirmed the major role of intracellular calcium changes during synaptic plasticity, an issue that has been pursued with imaging techniques to follow localized changes in cellular calcium levels resulting from discrete synaptic inputs.[198] Also of considerable interest have been the studies of the various forms of inhibition in CA1 and their roles, not only in synaptic plasticity, but also in epileptogenicity. Investigators disagree about how activity-dependent changes in synaptic inhibition might occur but concur that plasticity is enhanced when inhibition is reduced. This finding is significant for epilepsy because reductions in inhibitory efficacy are clearly associated with the generation of seizure-like activity. The concept of the â€œdormantâ€ or â€œdisconnectedâ€ interneuron, originally developed within the context of epileptogenicity in the dentate gyrus, has also been found appropriate for the CA1

P.344

region.[20] For example, in the KA model, CA1 becomes hyperexcitable when the CA3 region is damaged, and a reduction of both $GABA_A$ and $GABA_B$ IPSPs occurs; curiously, the GABA interneurons (and their connections) are still intact in this model, but appear to be more difficult to activate than in the normal brain (i.e., they act as though they are functionally â€œdisconnectedâ€ from the target CA1 pyramidal cells).[67]

Subiculum.

The subiculum has been studied primarily as the major output station for the hippocampal formation. As discussed above, it receives information from the CA1 region and relays the hippocampal output to cortical and subcortical sites. Despite this apparently pivotal role in the function of the hippocampal formation, the cellular and synaptic properties of subiculum have only recently received attention. This relative neglect is even more surprising within the context of TLE; in typical mesial temporal sclerosis (MTS), the greater portion of the CA1 region is damaged (leaving few viable CA1 cells) but the subiculum remains generally intact.[11,224] Given the hypothesis that epileptic activity is generated within sclerotic hippocampus in TLE, and the knowledge that in typical MTS the CA1 region is damaged (or even absent), it may be that the subiculum is uniquely responsible for â€œprojectingâ€ the abnormal hippocampal output to other parts of the brain. How subiculum receives this abnormal hippocampal input in the face of CA1 destruction, and how it processes/modulates such excitability before sending it on to EC, prefrontal cortex, midline and anterior thalamus, amygdala, and hypothalamus remains unexplored. A number of relatively recent studies have begun to fill in the void on subiculum function, both within the context of normal â€œhippocampalâ€ function,[176] and as seen within the epileptic brain.[119,230]

What little we do know about subiculum comes from recent studies of the intrinsic and synaptic properties of subicular neurons.[148,240,245] These investigations suggest that subicular projection cells are similar to hippocampal pyramidal cells in CA1 (and CA3). Subicular pyramidal cells appear to be grouped into two categories; one category comprises cells that normally produce burst discharges (similar to CA3), and the other category consists of â€œregularâ€ firing cells (like most CA1 cells). Both types receive input from CA1 and project to EC. EPSPs with both NMDA and non-NMDA components, and complex GABAergic IPSPs, can be recorded in these cells. The mechanism of discharge in the bursting neurons appears to involve a calcium current (as in CA3 pyramidal cells); however, there is also a tendency toward burst discharge when the cell recovers from a hyperpolarizing drive (similar to the low-threshold burst seen in thalamic neurons), and the underlying basis for that burst may be activation of a low-threshold sodium current. Finally, these cells show a pronounced inward rectifier current (even more so than that in CA1) that provides a depolarizing influence on the cell when it is hyperpolarized. These characteristics would, in theory, endow the subicular neuron with the ability to support hyperexcitable, burst-like discharge generated within an abnormal hippocampus. Because so little is known about the local circuitry of the region, it remains unclear to what extent subiculum might be capable of independent epileptogenesis (e.g., when deafferentated from CA1 and CA3 in MTS).

Entorhinal Cortex

The entorhinal cortex is a relatively large area that interfaces anatomically with the hippocampus so strongly that Ramon y Cajal[196] suggested a functional solidarity between the two structures. Even today, much effort is focused on dissociating the functions of the two structures, compared with the surrounding (parahippocampal) cortical tissues. It is clear that both the hippocampus and entorhinal cortex provide modulation of many functions, particularly those associated with the declarative forms of memory.[272]

Anatomically, large portions of the neocortex project directly to the entorhinal cortex[100] and to its dorsally adjacent neighbor, the perirhinal cortex.[36,37,51] The hippocampus receives most of its cortical information from these two structures. The anterior cortical projections to the entorhinal cortex are particularly dense from the infralimbic and the orbitofrontal cortices, areas that are prominent in stimulusâ€"reward associations and other goal-directed responses.[40] Posteriorly, the orbitofrontal cortex blends first into the insular cortex, where gustatory information is processed, then into the perirhinal cortex, the functions of which are currently under study because of its role in temporal lobe amnesia[273] and its ability to propagate convulsive seizures.[95] Both of these two cortical areas, in turn, densely innervate the entorhinal cortex.[37] The cingulate cortex also innervates the entorhinal cortex,[113] and its loss significantly affects memory, especially in delayed response tasks.[60] Lastly, the subiculum interfaces between the hippocampus and the entorhinal cortex[175] and provides dense projections to both the medial entorhinal area and the perirhinal cortex.[114,265] Based on the intrinsic â€œburst firingâ€ properties of many of these subicular cells,[240] it is presumed that they provide a strong amplifying function for information to and from the hippocampus and entorhinal cortex.

The subcortical inputs to the entorhinal cortex are numerous. Prominent in this regard are several olfactory structures, including a massive input from the olfactory bulbs, which innervates the superficial layers of the entorhinal cortex, along with dense projections from all the olfactory or piriform cortex.[82] Clearly, the entorhinal cortex is privy to considerable olfactory information. Also, projecting strongly to the entorhinal cortex are the cholinergic fibers from the medial septum. It is presumed that, because these same cholinergic cells drive the rhythmic Î¸-activity pattern in the hippocampus associated with memory storage, the entorhinal activity contributes importantly to this process.[3] Emotionally colored information readily arises from the amygdala, where projections are derived from the cortical nucleus to both the medial and lateral entorhinal cortex, and the basolateral and lateral amygdala nuclei to the lateral entorhinal cortex.[18,187] From the brainstem, serotonergic afferents originate in the raphe nuclei, and noradrenergic inputs arrive from the locus coeruleus and the reticular tegmental area. Additionally, thalamic afferents to the entorhinal cortex originate in the reuniens nuclei and in the anterior thalamic nuclei.[16] Thus, the entorhinal area is broadly innervated by both cortical and subcortical structures, and clearly participates in a variety of behaviors, particularly those involving learning and memory.

Like other periallocortical and isocortical structures, the entorhinal cortex is composed of six layers, including a superficial layer I, which is comprised largely of afferents onto the apical dendrites of the cells in layers IIâ€"VI.[54,265] Its intrinsic organization is realized by prominent longitudinal pathways, much like the association pathways in the piriform cortex, with caudal levels projecting most strongly to rostral levels. Within each entorhinal area (medial and lateral), the deeper layers innervate the more superficial layers, and the superficial layers innervate other superficial layers in adjacent areas. In this regard, the entorhinal pyramidal cells of layer V receive strong input from the perirhinal cortex and the sensory cortices[25] and, in turn, project to the superficial entorhinal layer II and III cells.[58] In addition, the layer V entorhinal cells show strong interconnections via recurrent excitatory synapses, much like the CA3 cells in the hippocampus and, when appropriately provoked, are capable of firing in burst patterns.[236] This disposition clearly is important for epilepsy. Connections between the medial and lateral entorhinal areas are more sparse than their longitudinal associations and largely involve diffuse projections that arise

from the medial entorhinal cortex and project to the lateral entorhinal cortex.[54] These medial-to-lateral projections are not reciprocal.[265]

The output of the entorhinal cortex to other cortical and subcortical structures is largely reciprocal with the inputs described. However, the outputs generally arise from the deeper layers (IVâ€"VI), whereas inputs are received in the superficial layers (Iâ€"III). Thus, the entorhinal cortex innervates the olfactory and visual cortices, as well as the amygdala, septum, and thalamus, including the anterior, reuniens, pulvinar, and several â€œauditoryâ€ thalamic nuclei. The other major output of the entorhinal cortex is to the hippocampal formation. Here, the layer II entorhinal cells project to the dentate gyrus and to the CA3 cell field, constituting the well-known â€œperforant pathway,â€ whereas the layer III cells give rise to fibers that innervate the CA1 field. These two entorhinal outputs provide the hippocampus with much of its cortical information.[55]

In comparative studies, clear species differences are apparent in cortical connections with the entorhinal cortex. In the rat and cat, a very large reciprocal connection exists between the entorhinal cortex and the olfactory system, a connection that is much reduced in the primate. By contrast, the primate shows highly differentiated connections between multimodal parasensory and paralimbic cortices and the entorhinal cortex, which are not so evident in the rat and cat.[202] Also, the subiculum in both humans and other primates is considerably larger than that of other species. Perhaps, with such an increase in the size of the primate subiculum, its effect on the entorhinal cortex is enhanced proportionately.

Although the cells that comprise the entorhinal cortex are of mixed types, the majority are pyramidal in shape. Based on their intrinsic properties, most (>90%) of the layer V cells are â€œregular spiking,â€ like most other neocortical neurons,[47] with only a few â€œburst-firingâ€ cells and a few â€œfast-spikingâ€ or presumed inhibitory interneurons.[88,108] Although many of these layer V cells provide important communication routes outside the entorhinal area, the best known entorhinal output, as described earlier, is the perforant pathway. The latter originates in both the medial and lateral entorhinal areas from either â€œstellateâ€ (layer II) or small pyramidal (layer III) cells. Both of these pathways stain intensely for heavy metals using the Timm method, and they appear to use glutamate as their principal excitatory transmitter.[241] Indeed, both the superficial layers and the deep layers of the entorhinal cortex have many cells that possess glutamate receptors of both the NMDA and non-NMDA types, and repetitive stimulation at higher frequencies (as in kindling) appears to unmask depolarizing NMDA receptor-dependent responses easily, particularly in the superficial layers.[92] With this in mind, in temporal lobe tissue excised from TLE patients, an *increase* in excitatory amino acid receptors in the parahippocampal gyrus has been reported.[72] This increased expression of excitatory receptors could easily reflect much of the hyperexcitability characteristic of that TLE tissue.

Also prominent in the entorhinal cortex is the inhibitory transmitter GABA. Although the deep entorhinal cells show little evidence of slow GABAergic IPSPs, and their fast IPSPs are weak,[92] GABA is strong in superficial layers.[106] In addition, GABA antagonists applied to slices of the entorhinal cortex result in large paroxysmal depolarizations, often lasting hundreds of milliseconds; in contrast, the same treatment of the hippocampus produces a disinhibited response of only 100 msec or less. Importantly, the disinhibited entorhinal cortex response in the presence of GABA antagonists is much smaller than that arising during exposure to low extracellular Mg^{2+}.

In a horizontal slice preparation containing both entorhinal cortex and hippocampus, tissue exposure to low Mg^{2+} results in the development of protracted seizure-like events that share ionic properties with in vivo preparations. For example, the increases in $[K^+]_O$ in the slices during â€œseizuresâ€ are similar in intact animals,[231] with the larger increases occurring in the deeper layers. This large response in deep layers likely results from the seizure activity induced in the highly interconnected layer V pyramidal cells. During the seizure, much smaller increases in $[K^+]_O$ are associated with the superficial layers of the entorhinal cortex. In a similar manner, the seizure-inducing effects of low Mg^{2+} can be duplicated in the slice preparation by experimental elevation of $[K^+]_O$. This manipulation results in low-threshold burst responses in the entorhinal cortex, which are often independent of the hippocampal burst response.[17]

In the low-Mg^{2+} slice preparation, after about an hour of large-amplitude and long-duration depolarizations, the discharges change quite suddenly into shorter events. At this time, the events become synchronized throughout the various cortical structures in the slice and exhibit features similar to the late stages of status epilepticus in humans.[57] This change in recurrent discharges from an early to a late form can be blocked by increases in GABAergic activity or can be hastened by GABA antagonists. This finding suggests that reduced efficiency in GABAergic communication may underwrite the transition in the seizure discharges from an early to a late form.

It is important to note that, in low Mg^{2+} conditions, the early form of the entorhinal seizures responds well to therapeutically relevant doses of several different anticonvulsants. However, the late form of the entorhinal discharge is unresponsive to any of the clinically used anticonvulsants, similar to status epilepticus in humans; this property of the entorhinal model system may provide a means of testing agents for their therapeutic efficacy against drug-resistant seizures.[92] It is also apparent that the intrinsic and synaptic properties of the entorhinal cortex significantly contribute to the development of these drug-resistant epileptiform responses. For example, in this model system, the synaptic activation of the dentate gyrus is quite weak and rarely produces action potentials. Thus, it appears that the dentate gyrus filters both epileptic activity[109] and normal information,[77] while the CA3 cells impose an interictal profile on the network that suppresses ictal events.[13] However, with sufficient alterations to the entorhinal/hippocampal network, the dentate gyrus loses some of its filter function and begins to augment synchronized discharges, reinforcing rather than dampening abnormal activity in the entorhinal/hippocampal loop.[138] Such alterations in function would surely be associated with impairments in the normal behavior supported by this network.

Perirhinal Cortex

Lately, there has been considerable interest in the perirhinal cortex. This interest arises largely from the finding in the monkey that many of the symptoms of human temporal lobe amnesia are duplicated by perirhinal cortex lesions.[274] Spontaneous activity in the perirhinal cortex also is uniquely tied to the entorhinal cortex, which suggests a close relationship between it and the entorhinalâ€"hippocampal system that is not evident in other neocortical systems.[45] This relationship also exists at the behavioral level, at which spatial learning can be impacted in perirhinal lesions much like that seen after hippocampal lesions.[2] In addition, in the context of epilepsy, it has been shown recently that kindling of the perirhinal cortex provides the fastest rates of epileptogenesis in the forebrain, accompanied by extremely fast convulsion onset latencies (usually <1 sec). Both the rapid genesis of these kindled seizures and their brief latencies to motor expression suggest that the perirhinal cortex[154,203] and the adjacent insular cortex[168] must be intimately connected with motor areas that support convulsive expression.

Positioned laterally adjacent to the entorhinal cortex, the perirhinal cortex extends from the posterior margin of the

entorhinal area forward to the insular cortex.[36,37] Throughout its course, it forms the banks of the rhinal sulcus. The perirhinal cortex is richly innervated by cortical afferents that arise from the frontal, temporal, parietal, occipital, and piriform cortices.[51,242] Further, the subcortical afferents include the thalamus (reuniens, posterior and â€œacoustic thalamusâ€), lateral nucleus of the amygdala, claustrum, endopiriform nucleus, and dorsal raphe nuclei.[187] Although less is known about the projections of the perirhinal cortex, its efferents to the cortex tend to be reciprocal with the afferents indicated above.[265] In considering its rapid kindling rates, the dense projection from the anterior perirhinal area to the frontal motor cortex is particularly intriguing.[155] Subcortical efferents of importance include the thalamus (nucleus reuniens, posterior and acoustic thalamus), basolateral and lateral amygdala, and nucleus accumbens.[70,155,220,265]

There has been little study of the intrinsic organization of the perirhinal cortex. Cytoarchitectonically, it is agranular cortex, largely devoid of layer IV. The general excitability of the perirhinal cortex appears to parallel that of the entorhinal cortex, and indeed, there exist strong anatomical and physiological (excitatory) interactions between them.[53] With depolarizing current injection into perirhinal cells at their resting potential, most layer III pyramidal cells show regular spiking features. However, like the cells of the somatosensory and visual cortices,[43] intracellular depolarizing current into resting layer V pyramidal cells provokes burst discharges, which transform into a single-spiking profile when their membrane is held at more depolarized values.[65,174] Importantly, these bursting layer V perirhinal cells project densely to the frontal motor cortex.[156] By contrast, layer VI cells are mostly late-spiking in character, including both pyramidal and nonpyramidal cells, and are unlike any other cortical region studied to date. Recently, it has been shown that loss of the perirhinal cortex (in combination with the piriform cortex) prevents the normal development of clonic motor seizures during dorsal hippocampal kindling.[111] Similarly, extensive perirhinal/insular lesions[35] or chemical insular suppression alone,[116] but not discrete perirhinal cortex lesions alone,[212] significantly delays amygdala kindling. Thus, perhaps it is recruitment of the perirhinal/insular efferents during kindling or other forms of epileptogenesis that carries focal, mesial-limbic seizures into their generalized convulsive form. This result is clearly suggested by the recent studies of Harvey and Sloviter,[90] in which the electrographic activity and c-fos expression associated with the spontaneous seizures that occur weeks after exposure to pilocarpine-induced status epilepticus begins outside the hippocampus in parahippocampal structures like the perirhinal cortex.

Piriform or Olfactory Cortex

The piriform cortex is continuous with the entorhinal cortex anteriorly and with the perirhinal cortex ventrally (rat) or medially (cat, primate). The critical importance of the piriform cortex and the other olfactory structures for survival and reproduction in macrosomatic animals is reflected by their relatively large size. By comparison, in humans, dependency on olfactory information has been reduced considerably, along with the size of the olfactory structures, including the piriform cortex. Yet, despite its relative diminution in humans, activation of the olfactory system creates memories that are vivid and enduring, and likely provide the distinct olfactory auras experienced by some TLE patients.

The intrinsic organization of the piriform cortex involves three basic layers: The superficial plexiform layer (layer I), the cell-dense somatic or pyramidal cell layer (layer II), and the deep, diffuse polymorphic cell layer (layer III). As with the entorhinal and perirhinal cortices, layer I consists primarily of afferent inputs to the apical dendrites of deeper cells. In addition, layer I has been subdivided into layers Ia and Ib, each containing its own afferents. Layer II is densely packed with pyramidal and semilunar cells, whereas layer III contains mostly pyramidal cells in its superficial part and nonpyramidal cells in the deeper part. Many of these deep, nonpyramidal cells are presumed inhibitory interneurons and likely provide the strong recurrent inhibition shown by the piriform cortex.[82]

Fibers arising from the olfactory bulbs comprise the primary input to the piriform cortex, where they heavily innervate distal dendrites in layer Ia. Other important inputs to the piriform cortex include the anterior olfactory nucleus (to layer Ib), ventral tenia tecta (to layers II and Ib), nucleus of the lateral olfactory tract (to layer II), cortical nucleus of the amygdala (to all layers), and the insular cortex (to layer III).[19,85] Deep to layer III of the piriform cortex and laterally adjacent to the amygdala is the endopiriform nucleus. This relatively long and highly excitable structure provides dense innervation to layer Ib of the piriform cortex throughout its anterior-posterior extent.[82]

Subcortical inputs to the piriform cortex include the anterior amygdala area, substantia innominata, midline thalamus, and most of the hypothalamus. The brainstem afferents come from the dopaminergic cells in the ventral tegmental area and substantia nigra, the noradrenergic cells from the locus coeruleus, and the serotonergic cells from the raphe nuclei.[243] These brainstem afferents tend to distribute broadly in all three cell layers.

The network organization of the piriform cortex involves both vertical and horizontal dimensions. In the vertical domain, a precise ordering of fibers is present, best characterized by the segregation of afferents to the superficial layer Ia and the association fiber system to layer Ib. There is further segregation of the association fibers, in that those arising in the anterior piriform, usually from layer II, innervate the more superficial parts of the posterior piriform Ib, whereas the association fibers arising from the posterior piriform cortex do so from layer III alone and innervate the deeper part of anterior Ib.

In addition, the organization of the olfactory system is both divergent and convergent, so that activation of restricted parts of the olfactory bulb will broadly innervate the entire superficial piriform cortex, whereas inputs from all parts of the olfactory bulb will converge on discrete areas in the piriform cortex. To achieve the divergent innervation, it has been shown that a single piriform association fiber will course longitudinally for a considerable distance, making only a few contacts but with many neurons.[84] The epileptic disposition of this network of cells has been studied extensively by Haberly and colleagues, particularly with current source density analysis, and presently is a favorite structure for network modelers interested in learning and memory.[15,83]

In interfacing with several other olfactory structures, the output of the piriform cortex remains relatively restricted to much of its own association network. However, it does project densely to adjacent cortical structures, including the insular, perirhinal, and entorhinal cortices, as well as to a few subcortical structures, such as the lateral hypothalamus, ventral striatum, and dorsal medial thalamic nucleus.[85]

The importance of the piriform cortex as a seizure generator is evident in a variety of whole-animal experiments. Until superseded recently by the perirhinal and insular cortices,[154,168] the piriform cortex was thought to develop kindled seizures faster than any other structure in the forebrain.[136,156]

During kindling, the piriform cortex develops interictal spikes before all other limbic structures; when the interictal spikes are present concurrently in several structures, spikes in the piriform cortex anticipate spikes in the other structures.[191]

In the deep layers of the anterior piriform cortex, in or near the endopiriform nucleus, picomolar amounts of several convulsants (including GABA antagonists and cholinergic and

P.347

glutamate agonists) have been reported to induce the rapid development of convulsive seizures.[188] Such pharmacologic sensitivity has not been observed elsewhere in the brain. A second, central area in the piriform cortex, transitional between anterior and posterior regions, provides dense expression of GABAergic neurons that are believed to broadly modulate excitability of this entire area.[137] When damaged, this expression results in facilitated kindling from the adjacent amygdala.[213]

The sensitivity of the piriform cortex to seizure activity is highlighted by its extreme vulnerability to protracted seizures. In several models of status epilepticus, the piriform cortex is the first structure to experience damage, an effect that is massive.[179]

The plasticity of the piriform cortex also has been demonstrated using in vitro experiments. In tissue slices taken from previously amygdala-kindled rats, excitability in the piriform cortex is clearly enhanced.[158] A parallel enhancement in piriform excitability is observed in control tissue when it was returned to normal Mg^{2+} perfusate after previous exposure to the seizure-inducing effects of low Mg^{2+}. The earlier exposure to low Mg^{2+} irreversibly increases piriform excitability for synaptically triggered network events mediated by changes in the deep layer III cells,[96] as well as for spontaneous events.[157] Such changes in the piriform cortex could provide the basis for alterations in olfactory experience and memories. Clearly, the powerful association system in the piriform cortex, coupled with its rich interconnections to the entorhinal and perirhinal cortices, provides it with the capability to trigger and amplify epileptic events.

Amygdala

The amygdala complex plays an important role in a variety of behaviors, including fear, aggression, learning, reproduction, and epilepsy.[1,74] Until recently, its connections with the hypothalamus were considered to be central to the expression of most of these behaviors, but it is now believed that many are realized through its connections with the sensory systems, cortex, striatum, and brainstem.[50]

The amygdala is a heterogeneous collection of nuclear groups,[150] often divided simplistically into the following divisions: The olfactory group, including the anterior area, nucleus of the lateral olfactory tract, and the cortical nucleus; the central-medial group, including the central and medial amygdala nuclei; and the basolateral group, including the lateral, basolateral, and basomedial nuclei. Not surprising, such a heterogeneous structure is matched equally by a diversity of connections.

The afferents to the olfactory group include both the olfactory bulbs and a third-order olfactory input via the piriform cortex.[85] The hippocampus provides some direct input to this group from CA1 but has more indirect influences through the subiculum and tenia tecta.[181] Important innervation also comes from the lateral entorhinal and agranular insular cortices. Subcortical afferents include cholinergic projections from the diagonal band, noradrenergic fibers from the locus coeruleus, and serotonergic fibers from the raphe nuclei.[64] Other important afferents involve the highly excitable endopiriform nucleus and several hypothalamic and thalamic nuclei.

The efferents of the olfactory group are largely reciprocal with their afferents. However, other important targets include the ventral striatum, which gives strong motor representation to the olfactory group output, and the nucleus accumbens, where reward mechanisms are influenced. This group also is well connected with the other amygdala nuclei, particularly the medial, central, and basolateral nuclei, but not with the lateral nucleus.[50]

In the medial-central group, the medial nucleus is reached by several cortical afferents, including those from piriform, agranular insular, retrosplenial, and entorhinal cortices, as well as by fibers from the subiculum and hippocampus.[149,181] Subcortical afferents arise from the hypothalamus and several midline thalamic nuclei, as well as from the brainstem structures described for the olfactory group. Efferents of the medial nucleus that might be important for epilepsy project to the entorhinal cortex and ventral striatum.[18] The hypothalamus and the brainstem also receive many efferents from the medial nucleus.[50] Although cells in the medial nucleus express many peptides such as cholecystokinin (CCK), vasoactive intestinal polypeptide (VIP), enkephalin, somatostatin, thyrotropin releasing hormone, and others, GABA is the transmitter that is particularly well represented. Perhaps this is why the medial nucleus is the slowest of the amygdala nuclei to develop kindled convulsions.[127]

By contrast, the central nucleus is the fastest nucleus to kindle.[127,167] This nucleus receives afferents from the piriform, agranular insular, entorhinal, perirhinal, and other cortices.[50] Hypothalamic afferents innervate the central nucleus, as do extensive inputs from a variety of thalamic nuclei. As with the other amygdala groups, brainstem afferents contain nor-adrenergic and serotonergic fibers. The cortical efferents from this group are Spartan, except for those to the perirhinal cortex.[51] This projection may have important implications for the generation of convulsive seizures, because the fast-kindling central nucleus is second only to the faster-kindling perirhinal cortex.[154] Important subcortical efferents include projections to the medial dorsal striatum, fundus striati, and hypothalamus.[50] Brainstem communication involves the central gray, pedunculopontine nucleus, parabrachial nucleus, nucleus of the solitary tract, dorsal motor nucleus of the vagus, and others. These brainstem structures provide considerable motor and autonomic nervous system expression for the central nucleus. Although the number of neuropeptides observed in this nucleus exceeds all others, the manner in which they contribute to the excitability of the central nucleus has not been determined.

Simplistically, the basolateral group comprises the basolateral, basomedial, and lateral amygdala nuclei. This group is distinguished by its dense connections with the neocortex, originating in the piriform, entorhinal, agranular insular, infralimbic, cingulate, orbitofrontal, and perirhinal cortices.[143,144,189,190,234] Subcortical afferents of importance include the dense cholinergic projections from the diagonal band, ventral pallidum, and substantia innominata. Further afferents reach the basolateral group from the hypothalamus and several midline thalamic structures, as well as from dopaminergic, noradrenergic, and serotonergic fibers from the brainstem.

The cortical outputs of the basolateral group are largely reciprocal with the inputs described, with the addition of a dense projection to both the somatosensory and motor cortices. The subcortical efferents of this group include projections to the dorsal and ventral striatum, as well as the nucleus accumbens and olfactory tubercle. Whereas much of the hypothalamus receives efferents from the basolateral group, projections to the thalamus are restricted to the dorsomedial nucleus.[120] Unlike the central nucleus, the basolateral group also shows limited innervation of the brainstem.

The diversity of transmitters seen in the other amygdala groups is not evident in the basolateral complex. Of course, the basolateral complex still exhibits many peptides and is highly sensitive to the classic transmitters. Indeed, most of the in vitro electrophysiologic studies of the amygdala have involved the basolateral nucleus. In this regard, it has been shown by Rainnie and colleagues[192,193,194,195] that: (a) low Mg^{2+} perfusion of the amygdala-piriform slice preparation readily results in spontaneous interictal and ictal burst discharges in the basolateral amygdala that are both NMDA- and nonâ€"NMDA-sensitive; (b) GABAergic inhibition is feed-forward to this group via the stria terminalis and direct via the lateral amygdala; and (c) previous

kindling of the amygdala results in a loss of only the stria-mediated GABAergic inhibition and is accompanied by the development of NMDA-sensitive, spontaneous burst discharges. Many of these changes in kindled tissue are evident similarly in the adjacent piriform cortex.[95,158] Thus, it appears that the development of epileptiform discharges in the amygdala-piriform area is associated with an increased sensitivity of both NMDA and non-NMDA glutamate receptors and with the loss of some GABAergic inhibition. Finally, although the basolateral nucleus is undistinguished in its kindling profile, developing convulsions at a rate intermediate between the fast-kindling central nucleus and the slow-kindling medial nucleus, it plays a critical role in the development and maintenance of limbic-based status epilepticus.[257]

When examining the amygdala in an interactive context, by comparing its kindling progression against other limbic or cortical structures concurrently stimulated by alternating between the amygdala and those other sites, an antagonism between the sites in their kindling progression becomes evident.[34,59] The amygdala kindling dominates in paired encounters with the septum, ventral hippocampus, piriform or posterior perirhinal cortices, but loses and remains undeveloped in the presence of concurrent stimulation applied to either the anterior perirhinal, insular or anterior cingulate cortices.[34,166] Clearly many dynamic interactions can be provoked in the limbic system, which can favor or disfavor epileptogenesis, depending upon their origins and timing.

Summary and Conclusions

Although Broca's[27] first description of the â€œlimbic brainâ€ was based on strictly anatomic contiguity, the idea of a limbic â€œsystemâ€ has proved very resilient, even in an age of functional emphasis. Papez[182] painted a picture of strong connectivity among various elements of the limbic brain, giving rise to a system in which sensory, endocrine, and autonomic functions were integrated to produce complex emotional behaviors. In Maclean's[139] reinterpretation of the field, the limbic brain stood interposed between the older parts of the CNS (dealing with sensing of the â€œinner worldâ€) and the newer parts of the CNS (providing sensory experience of the external world). Behavioral studies on monkeys[116] and on epilepsy patients with bilateral temporal lobe removals[216] showed this integrative system to be important in memory, as well as in emotional behaviors. These views have continued to receive support from recent studies. Many modern investigators have taken issue with the concept of a single limbic system involved in so many different (and such diverse) functions. Yet the richness of anatomic connectivity among many of these limbic brain regions and the relatedness of many of the implicated behaviors argue for some significant level of interaction among putative limbic structures.

This chapter has concentrated on a few of the most salient â€œstationsâ€ in the limbic complexâ€”salient, at least, with respect to what we know about epileptogenesis. Our omission of the hypothalamus, limbic aspects of the basal ganglia/thalamic complex, limbic (cingulate) cortex, and septal and olfactory regions from this discussion says less about their involvement in epileptogenesis than about our lack of understanding of their structure and function. Without question, however, the hippocampus, entorhinal cortex, amygdala, parahippocampal/piriform cortex, and perirhinal cortex are major players in complex partial or temporal lobe seizure syndromes. These regions display relatively low thresholds for seizure induction, tend to show some degree of damage associated with long-term (continuous) seizure activity, and are intimately connected. Seizure initiation at one site may spread rapidly to related structures. Disruption of one (or more) regionâ€”e.g., in temporal lobectomyâ€”will inevitably have consequences for function and excitability in the remaining cortices. The view of each region as an isolated entity was initially useful in attempts to characterize these structures but must be ultimately misleading with respect to both normal function and generation (initiation, maintenance) of epileptic activities. Despite the difficulties in defining a â€œlimbic system,â€ it is perhaps our inability to view these structures within the context of an interactive â€œsystemâ€ that has made it so difficult to identify the epileptogenic keys to limbic structure and function.

Chapter 31

Thalamocortical Anatomy and Physiology

Hal Blumenfeld

Douglas A. Coulter

Introduction

The thalamus and the thalamocortical system participate intimately in the generation of generalized seizures and probably are involved in the synchronization and propagation of localization-related seizures as well.[11,13,14,108] This is due to a combination of factors that will be discussed in this chapter, including chiefly the intimate reciprocal excitatory synaptic relationship between the thalamus and cerebral cortex, and the intrinsic properties of the thalamus and associated structures that predisposes the system to generate synchronized rhythms. We will emphasize the role of the thalamocortical system in generating the spike-and-wave discharges (SWDs) seen in generalized seizures, since most work has been done with this seizure type. Continued investigations may allow similar concepts to be applied in localized epilepsy as well.

The importance of the thalamus in generation of seizures has been a subject of active experimentation for at least the past 60 years. In the 1940s, the fact that generalized spike-and-wave seizure discharges appeared virtually simultaneously throughout large areas of neocortex led investigators of the time to hypothesize that there was a â€œcentrencephalicâ€ pacemaker structure synchronizing and driving these rhythms.[112,114] Studies by Jasper and colleagues[65] and by Dempsey and Morison[39] demonstrated that low-frequency stimulation to midline thalamic structures elicited electroencephalographic responses in cortex very similar to generalized SWDs of generalized absence epilepsy. Depth recordings in patients established that the SWDs of generalized absence epilepsy were generated by an underlying thalamocortical oscillation.[5,13,52,106,113,122,126,146,147] Detailed studies of anatomic and physiologic mechanisms underlying generation of normal rhythms in the thalamocortical system have clearly delineated the underlying structures critical to the generation of synchronized rhythms in this system: the thalamic relay nuclei, the surrounding Î³-aminobutyric acid (GABA)ergic nucleus reticularis, and the neocortex. Recent work suggests that epileptic activity and altered excitability occurs in selective regions of the thalamocortical network and spares others. This selective involvement may provide more specific targets for therapeutic interventions.

Anatomy of the Thalamus

Gross Structure

The thalamus can be subdivided, based on its gross anatomy, into three main nuclear masses: anterior, medial, and lateral. They are separated by a white-matter tract called the *internal medullary lamina*. In addition, a fourth group consists of several small nuclei found within the internal medullary lamina, termed the *intralaminar nuclei,* and extends to the midline, forming the *midline thalamic nuclei*. These four groups of nuclear masses share a common embryologic origin and have collectively been termed the *dorsal thalamus*. An important functional partner of the thalamus is the nucleus reticularis thalami (NRT), which in coronal sections is a shell-shaped, thin layer of cells surrounding the thalamus on its lateral and rostral extentâ€"separated from the thalamus proper along most of its extent by the external medullary lamina. The NRT has a distinct embryologic origin from the remainder of the thalamus and has been grouped within the ventral thalamus (also comprised of the ventral lateral geniculate nucleus and zona incerta), which, unlike the thalamus proper, does not send axonal fibers to the cerebral cortex. Within each nuclear group in the dorsal thalamus, it is possible to distinguish subnuclei based on their appearance in Nissl-stained sections.

Different Nuclei

Thalamic nuclei can also be classified based on their main input and output connections (Table 1). Thalamocortical cells in the thalamic relay nuclei convey nearly all information en route to the cerebral cortex. Projections from some relay nuclei to thalamus are localized to specific cortical regions, whereas projections from other nuclei are more diffuse (Table 1). In addition, the relay nuclei receive massive reciprocal connections returning from the cortical areas to which they project. The intralaminar nuclei are distinguished by their major reciprocal connections with the basal ganglia, in addition to widespread reciprocal connections with the cerebral cortex. The NRT is unique in that it receives inputs, but sends no outputs to the cerebral cortex, and also has reciprocal connections with all thalamic nuclei.

Thalamocortical Circuits and Other External Connections

The basic synaptic circuit comprising the thalamocortical system is repeated with only modest modifications in most of the primary sensory relay nuclei. This simplified functional circuit will be employed to develop the concept and discuss the rhythm-generating functions of the thalamocortical system, the main focus of this chapter. This basic synaptic circuit is discussed in the next section and schematically depicted in FIGURE 1.

Reciprocal Connections Between Thalamus and Cortex

The principal sensory relay nuclei within the thalamus send an ordered projection to layers III and IV and to the Vâ€“VI border of cortex (synapse 1 and 2, Fig. 1) and receive a feedback

P.354

P.355

projection from the layer VI pyramidal neurons of the same area of cortex (synapse 3, Fig. 1). Both the thalamocortical and corticothalamic projections also send axon collaterals to the surrounding NRT (synapses 4 and 5), which, in turn, provides inhibitory feedback onto the thalamus (synapse 6, Fig. 1). Both the corticothalamic and thalamocortical projections are excitatory and use glutamate or aspartate as a neurotransmitter, whereas NRT uses GABA as a neurotransmitter (Fig. 1).

Table 1 Major Thalamic Nuclei

Nuclei[â€]	Main input[â€¡]	Main outputs	Diffuseness of projections to cortex*	Proposed functions
RELAY NUCLEI **Lateral nuclear group**				
Ventral posterior lateral nucleus (VPL)	Medial lemniscus, spinothalamic tract	Somatosensory cortex	+	Relays somatosensory spinal inputs to cortex
Ventral	Trigeminal	Somatosensory and taste	+	Relays

posteromedial nucleus (VPM)	lemniscus, trigeminothalamic tract, taste inputs	cortex		somatosensory cranial nerve inputs and taste to cortex
Lateral geniculate nucleus (LGN)	Retina	Primary visual cortex	+	Relays visual inputs to cortex
Medial geniculate nucleus (MGN)	Inferior colliculus	Primary auditory cortex	+	Relays auditory inputs to cortex
Ventral lateral nucleus (VL)	Internal globus pallidus, deep cerebellar nuclei, substantia nigra pars reticulata	Motor, premotor, and supplementary motor cortex	+	Relays basal ganglia and cerebellar inputs to cortex
Ventral anterior nucleus (VA)	Substantia nigra pars reticulata, internal globus pallidus, deep cerebellar nuclei	Widespread to frontal lobe, including prefrontal, premotor, motor, and supplementary motor cortex	+++	Relays basal ganglia and cerebellar inputs to cortex
Pulvinar	Tectum (extrageniculate visual pathway), other sensory inputs	Parietotemporo-occipital association	++	Behavioral orientation toward relevant visual and other stimuli
Lateral dorsal nucleus	See anterior nucleus	â€”	++	Functions with anterior nuclei
Lateral posterior nucleus	See pulvinar	â€”	++	Functions with pulvinar
Ventral medial nucleus	Midbrain reticular formation	Widespread to cortex	+++	May help maintain alert,

				conscious state
Medial nuclear group				
Mediodorsal nucleus (MD)	Amygdala, olfactory cortex, limbic basal ganglia	Frontal cortex	++	Limbic pathways, major relay to frontal cortex
Anterior nuclear group				
Anterior nucleus	Mammillary body, hippocampal formation	Cingulate gyrus	+	Limbic pathways
Midline thalamic nuclei Paraventricular nucleus Parataenial nucleus Interanteromedial nucleus Intermediodorsal nucleus Rhomboid nucleus Reuniens (medial ventral) nucleus	Hypothalamus, basal forebrain, amygdala, hippocampus	Amygdala, hippocampus, limbic cortex	++	Limbic pathways
INTRALAMINAR NUCLEI				
Rostral intralaminar nuclei Central medial nucleus Paracentral nucleus Central lateral nucleus	Deep cerebellar nuclei, globus pallidus, brainstem, ascending reticular activating systems (ARAS), sensory pathways	Cerebral cortex, striatum	+++	Maintain alert consciousness; motor relay for basal ganglia and cerebellum
Caudal intralaminar nuclei	Globus pallidus, ARAS, sensory pathways	Striatum, cerebral cortex	+++	Motor relay for basal ganglia

Centromedian nucleus Parafascicular nucleus				
RETICULAR NUCLEUS	Cerebral cortex, thalamic relay and intralaminar nuclei, ARAS	Thalamic relay and intralaminar nuclei	None	Regulates state of other thalamic nuclei

â€ Some additional smaller nuclei have not been included.

â€¡In addition to the inputs listed, all thalamic nuclei receive reciprocal inputs from the cortex and from the thalamic reticular nucleus. Modulatory cholinergic, noradrenergic, serotonergic, and histaminergic inputs also reach most thalamic nuclei.

*+, least diffuse (specific thalamic relay nuclei); ++, moderately diffuse; +++, most diffuse. Reproduced from Blumenfeld H. *Neuroanatomy through Clinical Cases*. Sunderland, MA: Sinauer, 2002, with permission.

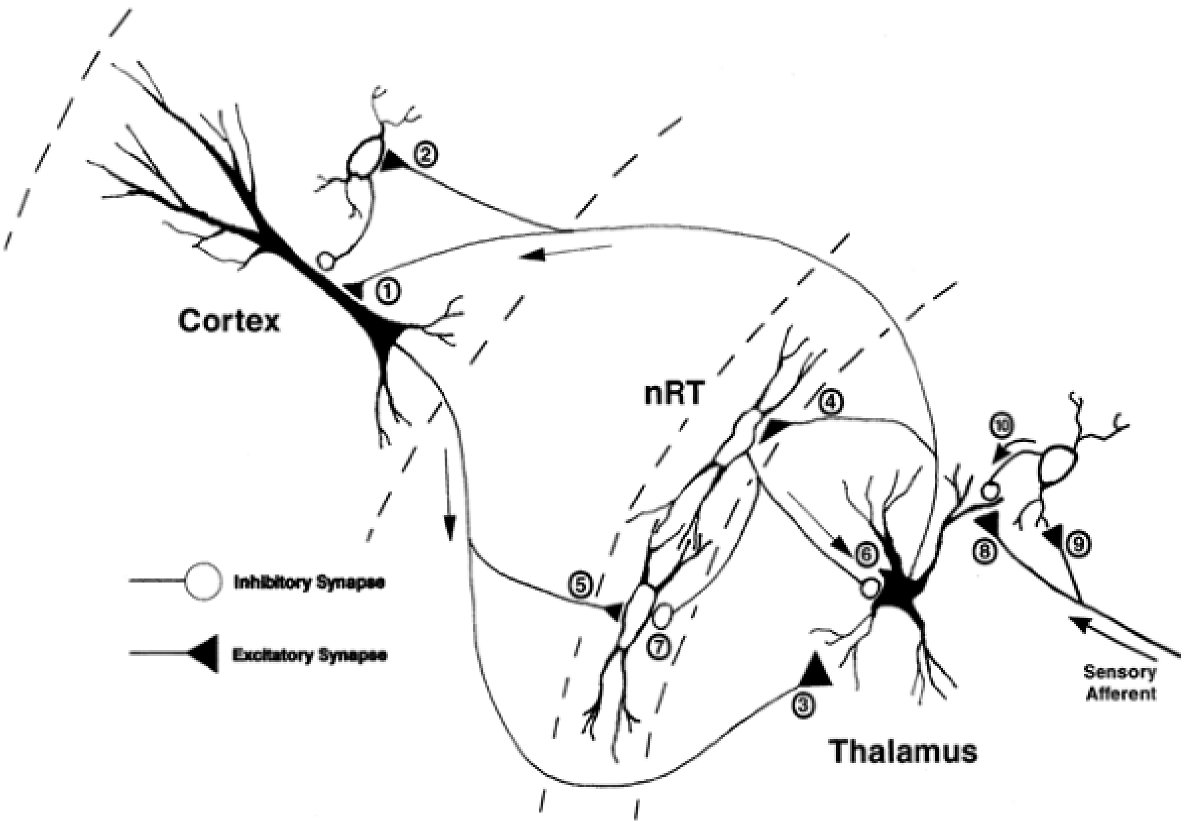

FIGURE 1. The basic thalamocortical circuit. Thalamic neurons in primary sensory relay nuclei project to layers III and IV and V and VI of the cerebral cortex. This projection terminates on both pyramidal neurons (synapse 1) and on inhibitory interneurons (synapse 2) in the cortex. Layer VI pyramidal neurons reciprocally innervate the same area of thalamus from which an ascending afferent is received (synapse 3). Both the thalamocortical and the corticothalamic projections send an axon collateral to nucleus reticularis thalami

(nRT; synapses 4 and 5). Nucleus reticularis thalami provides inhibitory GABAergic innervation to the thalamus (synapse 6) and to other NRT neurons (synapse 7). The major sensory afferents to the thalamus synapse onto the dendrites of both thalamic relay neurons (synapse 8) and inhibitory interneurons (synapse 9). The dendrites of inhibitory interneurons can function as both pre- and postsynaptic elements and can provide inhibitory innervation of thalamic relay neuron dendrites (synapse 10), as well as conventional axonal synaptic connections (synapse 10).

In contrast, the midline (intralaminar) thalamic nuclei also send projections to cortex (with a collateral projection to NRT), but this projection is much more diffuse than is the ordered projection from sensory relay nuclei, and terminates in superficial and deep layers (I and VI). These intralaminar nuclear projections are concentrated in the frontal, medial, and dorsolateral cortex, but intralaminar projections may reach all cortical areas.[56] As with the sensory relay nuclei, the intralaminar nuclei receive feedback projections from the cortex but, unlike the corticothalamic feedback projections onto principal sensory relay nuclei, intralaminar nuclei receive this projection from smaller layer V pyramidal neurons of cortex. In addition, the intralaminar nuclei project to the neostriatum and receive a feedback projection from the globus pallidus, as well as from the NRT.

Local Intrathalamic Circuits

Essentially, there are no local intrathalamic circuits involving interconnections of thalamocortical relay neurons within or between thalamic nuclei. The principal axonal target of these neurons is the ipsilateral cerebral cortex, and this projection was discussed earlier. However, there are significant populations of local circuit neurons within thalamic nuclei, and these neurons usually are GABAergic. In addition, NRT provides an extensive and powerful feedforward and feedback inhibitory projection onto relay neurons of the dorsal thalamus, and this intrathalamic inhibitory connection is of fundamental importance in the rhythm-generation capabilities of the thalamocortical system.

GABAergic local circuit neurons modulate the strength of afferent input into the thalamus. These neurons participate in a distinct form of synaptic arrangement in which dendrites of interneurons act as both pre- and postsynaptic elements in a large, glial-ensheathed synaptic aggregation that also contains the large afferent sensory terminal, dendritic appendages from relay neurons, and conventional inhibitory terminals (synapses 8â€"10, Fig. 1). The interneuron dendrite receives excitatory synaptic input from the sensory afferent terminal (synapse 9, Fig. 1), which also provides excitatory input onto the

P.356

neighboring thalamic relay neuron dendrite (synapse 8, Fig. 1). The interneuron dendrite also forms an inhibitory synaptic connection with the thalamic relay neuron dendrite (synapse 10, Fig. 1).[125] This synaptic arrangement has been termed a *synaptic triad* (Fig. 1). One of the primary functions of these synaptic specializations within the thalamus is to dramatically shorten the duration of afferent excitation of thalamic relay neurons through rapid truncation of the sensory excitatory postsynaptic potential (EPSP) before it can reach the thalamic relay neuron soma and there be transduced into action potential output to the cortex. This may serve a role in more the faithful temporal relay of sensory information to the cerebral cortex.

Brainstem Neuromodulatory Afferents

In addition to the excitatory sensory afferents that innervate the dorsal thalamic relay nuclei, other inputs reach the thalamus and cerebral cortex from various brainstem sources. These afferents release a number of different neurotransmitters. Cholinergic afferents arrive from the basal forebrain, pedunculopontine tegmental and lateral tegmental nucleus; noradrenergic afferents arrive from locus ceruleus; serotonergic afferents originate from the dorsal raphe; and histaminergic afferents originate from the tuberomammillary nucleus of the hypothalamus. Activation of these neuromodulatory afferents serves principally to maintain the thalamus in a â€œrelayâ€ mode (i.e., where afferent sensory activity is faithfully relayed to the cortex). Reduction in the activity in these afferents results, in general, in an enhancement of low-frequency oscillatory activity in the thalamocortical system.[90]

Physiology of Thalamic Neurons

Neurons in virtually all areas of the thalamus are characterized physiologically by the presence of a large-amplitude, low-threshold calcium spike.[63,64] This intrinsic membrane conductance underlies bursts of action potentials generated in thalamic neurons and plays an important amplifying role in thalamic oscillatory behavior, including sleep spindles and the spike-and-wave discharges (SWDs) of generalized absence epilepsy. In contrast to its size in other mammalian neurons, the low-threshold calcium (Ca) current is particularly prominent in thalamic neurons, where its overall peak amplitude is usually equal to or greater in amplitude than the high-threshold (dihydropyridine-sensitive) calcium current in the same cells.[30] This proportionally large low-threshold (â€œTâ€-type) Ca current influences the behavior of thalamic neurons and, in situations in which thalamic neurons are hyperpolarized from their normal waking resting membrane potentials, dominates the cellular properties of these neurons.[63] The anomalous dependence on hyperpolarization for activation of low-threshold Ca current is explained by the underlying characteristics of this current. The biophysical properties of the low-threshold Ca current are similar in many ways to those of the classical sodium (Na) current underlying action potential generation. The T current is activated at potentials very close to the resting potential of neurons, with a threshold for activation around -60 mV (Fig. 2A).[32] However, the T current is also inactivated by potentials near the normal resting potential of thalamic neurons, with virtually all the T channels inactivated at -60 mV (Fig. 2B).[30] For T-type Ca channels to be activated, the neuronal membrane potential must be hyperpolarized below -60 mV for a sufficient time to allow the channels to â€œdeinactivateâ€ or become able to be activated. Once this deinactivation process occurs, a subsequent depolarization will allow these Ca channels to open and generate the regenerative low-threshold Ca spike that is the amplifier underlying and generating oscillatory behavior within the thalamocortical system (Figs. 3 and 4). This deinactivationâ€“activationâ€“inactivation sequence of functional states of the T current underlying low-threshold Ca spikes in thalamic neurons is a fundamental process that is repeated over and over during the generation of low-frequency rhythms within the thalamus and within the thalamocortical system. Neurons within the NRT have a T current with similar voltage dependence and pharmacology but slower kinetics than those seen in thalamic neurons.[60] The genes encoding T-type Ca currents have been cloned, and three T-type Ca channels have been characterized: Cav3.1 (Î±1G), Cav3.2 (Î±1H), and Cav3.3 (Î±1H).[49,115,116] Cav3.1 is predominantly expressed in thalamic relay neurons, and Cav3.3 in NRT neurons,[132] which explains the difference in T-current properties evident in the two populations of neurons.

In addition to the T-type Ca current underlying the low-threshold Ca spike, thalamic neurons are endowed with another variety of intrinsic membrane current that significantly contributes to the propensity of these neurons to generate low-frequency rhythms. This current is a hyperpolarization-activated cationic current, I_h. This current is carried by both Na^+ and potassium (K^+) ions, and is activated by hyperpolarization to potentials more negative than -60 mV (Fig. 2C). I_h activates slowly and results in generation of a depolarizing pacemaking potential (Fig. 3A, B).[92] When the neuron is in a membrane potential range of -70 to -85 mV, this depolarizing pacemaking potential can then activate a low-threshold Ca spike, which will deactivate the h current and, upon repolarization, I_h is reactivated, once again generating a depolarizing pacemaking potential, activating another low-threshold spike, and so on (Fig. 3A, B). The rate at which I_h activates determines the frequency of low-threshold spike firing, and this, in turn, depends on the resting membrane potential of the neuron because the kinetics of I_h are voltage-dependent, with activation occurring more rapidly during greater hyperpolarizations. This combination of the T-type Ca current and the hyperpolarization-activated cationic current I_h will generate spontaneous, low-frequency oscillatory activity in thalamic neurons when in a membrane potential range of -65 to -75 mV, even in the absence of any synaptic input (Fig. 3A, B).[78,92] However, for this activity to become synchronized between cells, the synaptic network of which these thalamic neurons are members must play a critical role.

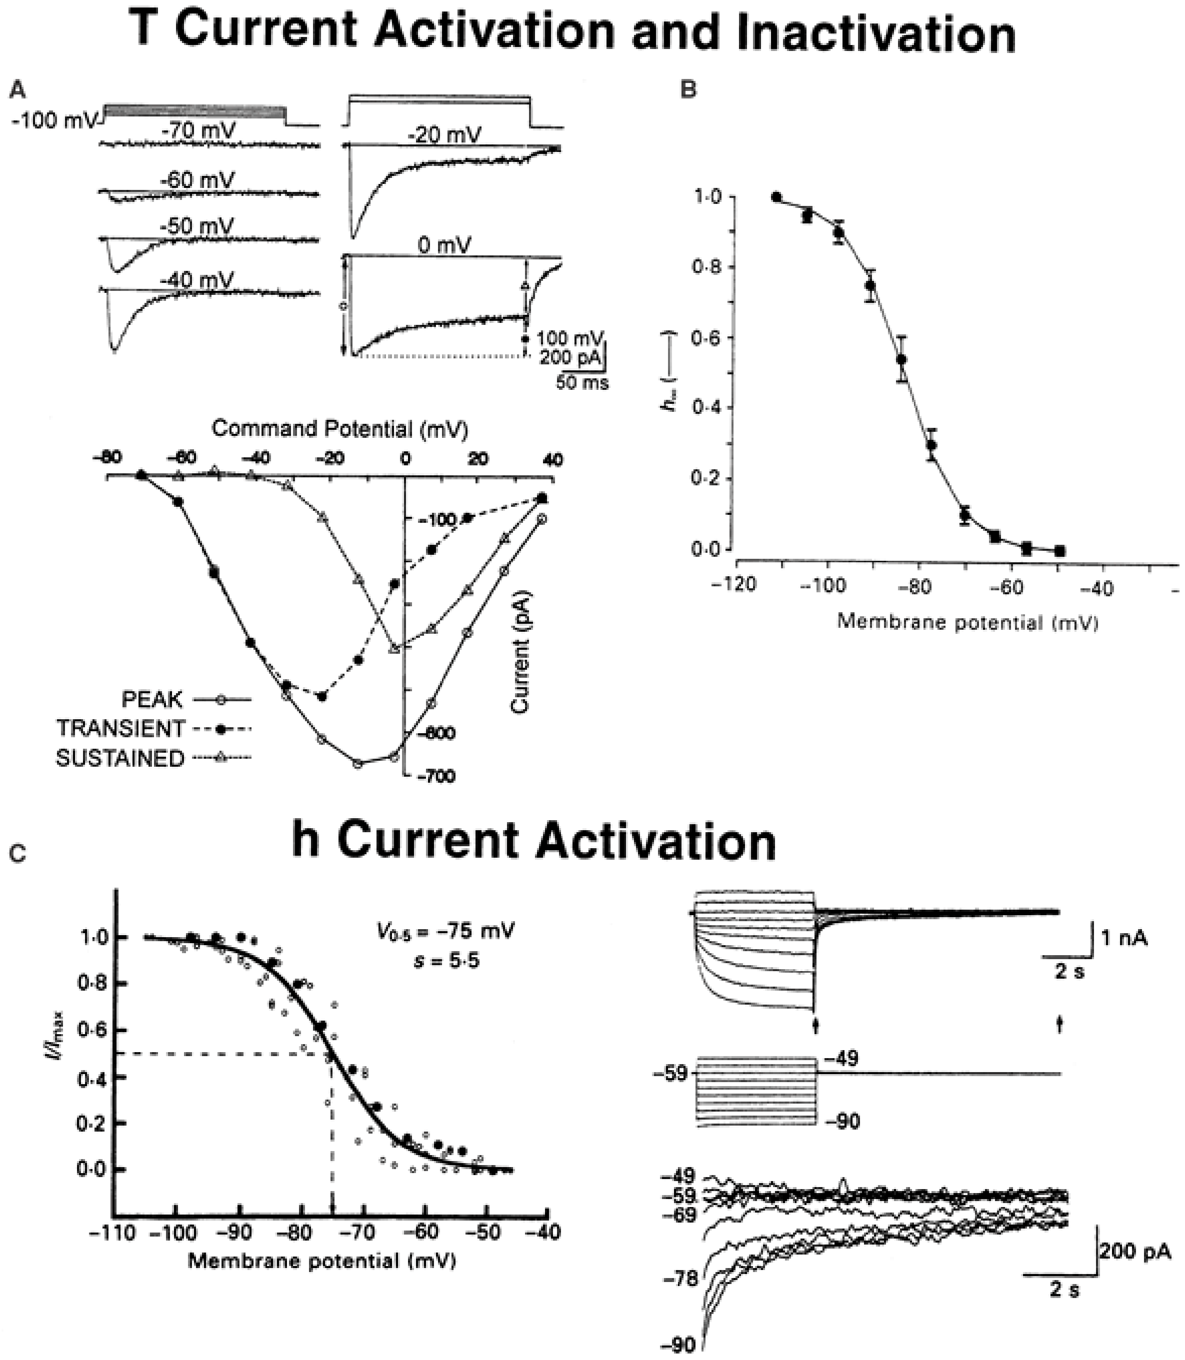

FIGURE 2. Intrinsic membrane properties of thalamic neurons that contribute to their propensity to generate low-frequency rhythms. **A,B:** Biophysical properties of the low-threshold T-type Ca current. **A:** Current voltage plot illustrating activation of the T current by depolarizing steps in an acutely isolated rat thalamic neuron. Note that the T current activates at very hyperpolarized potentials (-60 mV), and that the T current inactivates (i.e., is transient). From Coulter DA, Huguenard JR, Prince DA. Differential effects of petit mal anticonvulsants and convulsants on thalamic neurones: calcium current reduction. *Br J Pharmacol*. 1990;100(4):800â€"806, with permission.[32] **B:** Inactivation of the T current by increasingly depolarized membrane potentials in a rat thalamic neuron. Note that the T current requires the membrane potential to be hyperpolarized below -60 mV for the current to be able to be activated, and that the T current is half-inactivated at -80 mV. Modified from Coulter DA, Huguenard JR, Prince DA. Calcium currents in rat thalamocortical relay neurones: kinetic properties of the transient, low-threshold current. *J Physiol*. 1989;414:587â€"604, with permission.[29] **C:** The hyperpolarization-activated cationic current I_h. Note that

increasing hyperpolarizations activate a greater and greater proportion of the h current, which is half-activated at a membrane potential of -75 mV. From McCormick DA, Pape HC. Properties of a hyperpolarization-activated cation current and its role in rhythmic oscillation in thalamic relay neurones. *J Physiol*. 1990;431:291â€"318, with permission.[93]

Generation of Normal Thalamocortical Rhythms

In the awake animal, thalamic neurons are maintained at a resting potential of -50 to -60 mV by the combined effects of normal afferent activity and by the ascending activating systems of the brainstem (see earlier discussion); the T current is inactivated; and the thalamus serves as a faithful relay of all types of sensory information to the cerebral cortex (Fig. 3, *tonic mode*). In this state, the thalamus transduces incoming synaptic input into a patterned action potential frequency output to cortex, with little or no loss of information content. Loss of conscious perception associated with drowsiness or sleep is associated with a marked alteration in the functional properties of the thalamus. Thalamic neurons hyperpolarize as a period of drowsiness or sleep begins,[70] due to a reduction in the neuromodulatory activity of the ascending activating systems and a decrease in normal afferent activity; the T current deinactivates in thalamic neurons, and the thalamus transitions from a faithful relay mode of firing to an oscillatory or burst mode of firing (Fig. 3, *oscillatory mode*). Because of this change in the â€œstateâ€ of thalamic neuron firing properties, during drowsiness or sleep, the thalamus serves more to disrupt and filter sensory information, and generates low-frequency oscillations during this state of reduced consciousness. Deep stages of sleep are associated with several varieties of rhythmic oscillations in the brain that are generated principally in cortical and thalamic synaptic networks. The early stages of slow-wave sleep are characterized by spindle waves recorded in the electroencephalogram (EEG). These spindle waves consist of 11- to 15-Hz oscillations that wax and wane in amplitude and are usually 2 to 4 seconds in duration, reappearing every 3 to 10 seconds. These events are triggered by an oscillatory interaction between the thalamus and NRT, and can occur spontaneously when these structures are isolated from their cortical connections[17,29,61,101,142]â€"that is, the neocortex is not required for generation of these events. Intracellular recordings in vivo have clearly shown that NRT neurons are firing in a series of bursts during spindle discharges, superimposed on a slow depolarization.[128] Synchronization of NRT may be enhanced by the presence of dendrodendritic,[40] electrical,[76,82] and conventional axonal reciprocal inhibitory interconnections between NRT neurons (synapse 7, Fig. 1). Unlike the very specific reciprocal excitatory connections between thalamus and cortex, NRTâ€"thalamic inhibitory connections tend to be much more divergent, with extensive NRT axonal arbors in the thalamus. Therefore, these bursts in NRT elicit synchronized GABAergic inhibitory postsynaptic potentials (IPSPs) in large populations of thalamic relay neurons, mediated by activation of both $GABA_A$ and $GABA_B$ receptors (Fig. 4).[17,73] Due to deinactivation and subsequent activation of T current in thalamic neurons by the IPSP-induced hyperpolarization, a large Ca-dependent spike with an associated burst of Na-dependent action potentials is generated on the rebound of the NRT-mediated IPSPs (Figs. 3B, 4B). These thalamic bursts then reactivate the NRT and activate the cerebral cortex. The reactivated NRT then rapidly reinitiates a second wave of the spindle by triggering another IPSP in thalamic neurons. In this spindle rhythm, the NRT may serve as the pacemaker because thalamic neurons do not exhibit spindle rhythms when isolated from the NRT, whereas the NRT apparently will spontaneously trigger spindles when isolated from the thalamus.[128,142] The termination of spindle oscillations may depend on progressive intracellular Ca^{2+} accumulation, which leads to persistent activation of I_h, disrupting the pacemaker potential for this rhythm.[8,84,85]

Role of Thalamus and Thalamocortical Circuits in Generating Generalized Epileptiform Discharges

Relationship Between Spindles and Spike-and-Wave Discharges

In addition to the generation of normal rhythms like sleep spindles, the thalamocortical system participates in the generation of pathologic rhythms, as well. Perhaps the best characterized of these rhythms is the 3- to 4-Hz SWD activity of absence epilepsy.[14] Unlike spindles, which can be recorded in the thalamus of decorticated animals,[29,101] intact thalamocortical connections are required for typical SWDs to be generated.[47,97] SWDs are bilaterally synchronous thalamocortical oscillations[106,122,146] and, as the name implies, consist of repetitive cycles of an early sharp spike associated with action potential firing in thalamus and cortex, followed by a slower wave associated with prolonged inhibition in cerebral cortex[118] and probably also in thalamus.[127] Several lines of evidence support the concept that similar mechanisms and

synaptic circuitry may underlie the generation of normal sleep spindle rhythms and the pathologic thalamocortical rhythms of generalized absence epilepsy. In patients with generalized absence epilepsy, Kellaway[71] has demonstrated that the occurrence of SWDs is remarkably correlated with slow-wave sleep stages. In the feline penicillin-generalized epilepsy model of generalized absence epilepsy, SWDs have been shown to evolve from spindle rhythms following intramuscular injection of penicillin. This transition from 7- to 14-Hz spindle rhythms to 3- to 4-Hz SWDs occurs gradually and is accompanied by the behavioral symptoms of absence.[47] Consistent with the hypothesis that the T current amplifies and drives both normal and pathologic thalamocortical oscillations is the finding that specific generalized absence anticonvulsants like ethosuximide (Zarontin) and trimethadione (Tridione) block the T current in thalamic neurons[30,31,32,33] and also block cloned, expressed human T-type Ca channels, including Ca3.1 to Ca3.3, when applied in clinically relevant concentrations.[49] In in vitro studies of spindle rhythms in slices of ferret lateral geniculate nucleus, blocking $GABA_A$-mediated inhibition in these slices is associated with a transition from faster, smaller, spindle-like rhythms to slower, larger, SWD-like rhythms, which are blocked by ethosuximide.[142] Huguenard and Prince[61] have also demonstrated that in vitro stimulation-evoked thalamic oscillations can be blocked by ethosuximide, a generalized absence anticonvulsant, and that this block is associated with the T-current blocking effects of this drug. Extending these studies to include the cerebral cortex in thin slices of rodent brain maintaining reciprocal connections between thalamus, cortex, and NRT, spontaneous thalamocortical oscillations can be recorded.[34] These oscillations are similar in many ways to SWD rhythms and are selectively blocked by drugs effective in the control of generalized absence epilepsy[152,153] but not by other anticonvulsants.[151] This suggests that thalamocortical circuitry is both necessary and sufficient to generate SWD rhythms, although other areas of the brain are certainly involved in the modulation of these events. Human and animal neuroimaging studies also support the role of both cortex and thalamus in spike wave seizures.[2,6,9,10,43,104,123]

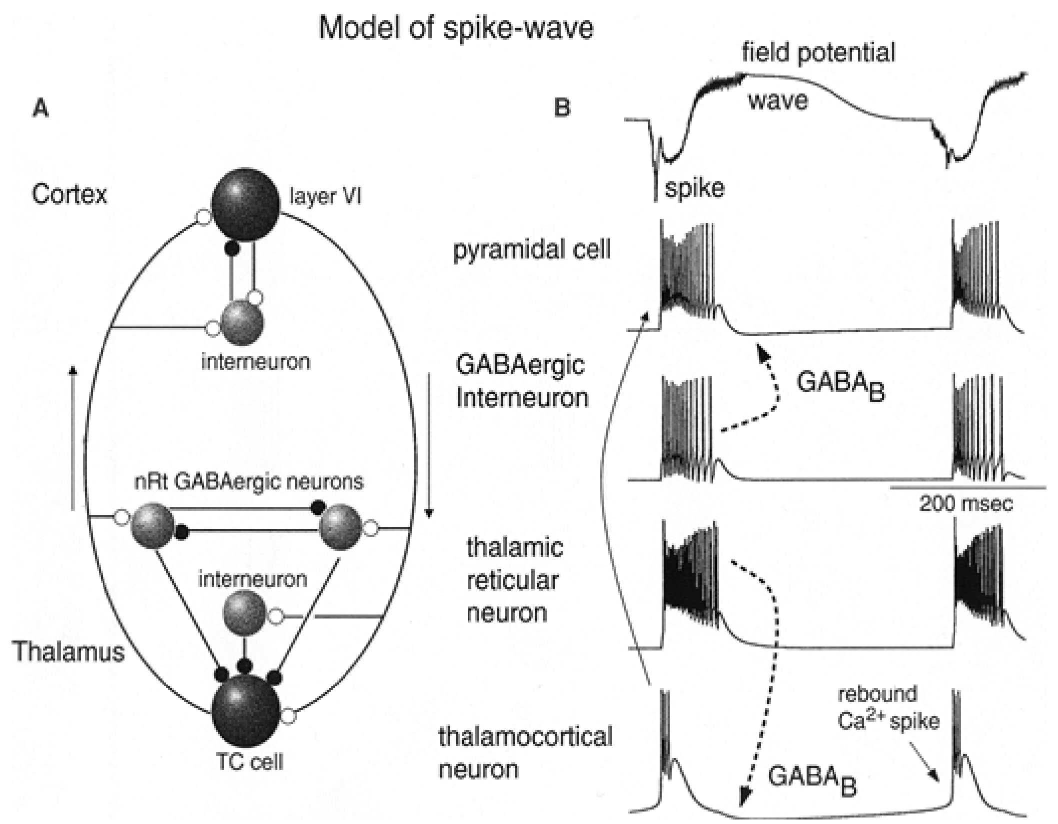

FIGURE 4. Cortical and thalamic cellular networks involved in spike-and-wave seizure generation. **A:** Simplified circuit diagram of cortical and thalamic networks shown in FIGURE 1, involved in both normal spindle wave oscillations, and spike-and-wave seizures. Cortical pyramidal neurons and thalamocortical cells form reciprocal excitatory connections (*open circles*). Inhibitory GABAergic interneurons distributed throughout the cortex and thalamus, as well as in the thalamic reticular nucleus, modulate the excitatory activity (*inhibitory synaptic connections are denoted with filled circles*). **B:** Simulation of one cycle of a SWD in corticothalamic networks. A burst of spikes in a thalamocortical neuron activates the cortical pyramidal cell through excitatory connections. This generates a strong burst of action potentials through intracortical recurrent excitatory connections. This burst strongly activates both local GABAergic neurons and thalamic reticular neurons. Activation of $GABA_B$ receptors produces a slow IPSP, leading to a rebound Ca^{2+} spike in the thalamocortical cell, 300 msec later, and initiates the next cycle of the oscillation. From McCormick DA, Contreras D. On the cellular and network bases of epileptic seizures. *Annu Rev Physiol*. 2001;63:815â€“846, with permission.

Cellular Correlates of Spike Wave Discharges of Generalized Absence Epilepsy

Steriade and Contreras[127] have physiologically characterized the cortical and thalamic cellular events that occur during the transition from spindle to seizure rhythms in anesthetized cats in vivo. In this study, it was found that during 2- to 4-Hz SWD-like activity, thalamic, cortical, and NRT neurons behave very similarly to that expected if SWDs were generated by similar underlying mechanisms to spindles (described earlier). Cortical neurons evidence increased excitatory recurrent

drive during the transition from sleep to paroxysmal activity or, in some cases, a large synchronous inhibitory event could trigger the transition between sleep and epileptic activity. NRT neurons triggered large rhythmic bursts of action potentials riding a slow depolarizing wave during low-frequency thalamocortical rhythms. During 2- to 4-Hz SWD-like activity, thalamic neurons either triggered rhythmic rebound bursts following NRT-mediated IPSPs (similar to that depicted in Figs. 3,4) or exhibited prolonged periods of inhibition with no rebound activity.

Transition From Normal Sleep Spindles to Pathological Spike Wave Rhythms

The above studies, work from the feline penicillin model,[7,48] and rodent studies[96] suggest that enhanced cortical excitability can trigger a change from normal spindle oscillations to SWDs in an intact thalamocortical circuit. Dual intracellular recordings from ferret lateral geniculate nucleus slices demonstrated that brief firing of GABAergic NRT cells produced brief, approximately 0.1-second IPSPs in thalamocortical cells, mediated by $GABA_A$ receptors.[73] In the same preparation, sustained firing of NRT cells produced longer, approximately 0.3-second IPSPs, mediated by $GABA_B$ receptors (Fig. 4B). Under normal conditions, cortical inputs (Fig. 1, synapse 5; Fig. 4A) may produce brief firing of NRT cells, with approximately 0.1-second IPSPs in the thalamus, which sets the oscillation frequency at approximately 10 Hz or higher, as is seen in normal sleep spindles. On the other hand, pathologically enhanced cortical firing may produce sustained NRT firing, with approximately 0.3-second thalamic IPSPs setting the oscillation frequency of the whole system at 3- to 4-Hz, as is seen in typical absence seizures. Thus, the switch from spindles to spike waves may depend on enhanced cortical firing, which causes a transition from fast $GABA_A$ to slow $GABA_B$ receptorâ€"mediated IPSPs in the thalamus (Fig. 4B). Additional support for this mechanism has come from recordings in a stimulated thalamic slice preparation, which simulates corticothalamic and thalamocortical feedback interactions.[17,144] In this preparation, selective $GABA_A$ or $GABA_B$ antagonists were capable of switching the network oscillations from paroxysmal spike-and-wave rhythms to normal spindle oscillations, regardless of cortical inputs.

Phenotypic Basis for Generalized Absence Epilepsy in Animal Models

Generalized absence epilepsy is a disorder with a strong genetic basis. Elucidating the phenotypic basis of absence in rodent genetic models of this disorder has been a focus of much recent research effort. Several mechanisms that may underlie the generation of SWDs have been described in genetic animal models of generalized absence epilepsy. In a pioneering series of studies aimed at elucidating mechanisms underlying SWDs in a single-gene mutant mouse *tottering* that phenotypically expresses absencelike seizures, Noebels et al. reported a gene-linked proliferation of noradrenergic locus coeruleus axon terminals in the brain of epileptic mutants.[80] Furthermore, correction of this inherited hyperinnervation with neonatal 6-OHDA treatment prevented the expression of the absence-like phenotype, implicating noradrenergic mechanisms as being critical for expression of the epilepsy in this model.[107] Subsequent to these studies, the gene responsible for generation of seizures in *tottering* has been determined and found to be a gene encoding a high-threshold Ca-channel subunit, Cav2.1/Î±1A.[45] Similar mutations in high-threshold Ca-channel subunits have been found in several other mouse strains with absence seizures, including *lethargic* (Î²4),[24] and *stargazer* (Î³2).[79] Interestingly, these mutations in high-threshold Ca-channel subunits are all accompanied by an upregulation in low-voltage activated Ca currents in these three strains, perhaps as a compensatory mechanism, and consistent with the probable role of upregulation of T-type Ca currents in the pathophysiology of absence seizures.[25] $GABA_B$ mechanisms have also been implicated as important in the generation of SWDs in various rodent genetic models expressing absence because systemic administration of $GABA_B$ antagonists has a strong anticonvulsant effect, whereas localized perfusion of $GABA_B$ agonists into the thalamus has a marked proconvulsant effect in these animals.[59,81] In addition, Hosford et al.[59] have reported an increase in the density but not the binding properties of $GABA_B$ receptors in the thalamus and cortex of lethargic mice, a mutant strain that evidences SWDs as part of its phenotype. $GABA_A$ receptors are important for damping overexcitation in NRT neurons; and one study found that knocking out the $GABA_A$ receptor's Î²$_3$ subunit, normally expressed selectively in the NRT, caused enhanced paroxysmal oscillations in mouse thalamic slices.[62] In the genetic absence epilepsy rat strain from Strasbourg (GAERS), it has been reported that an increased amplitude of T-type Ca current is evident in the NRT but not in thalamic neurons of GAERS, relative to control strains.[133] WAG/Rij rats, another rodent absence model, show several differences compared with control rats, including increased expression of cortical voltage-gated Na channels Nav1.1 and 1.6; decreased cortical hyperpolarization activated cation channels, HCN1; increased thalamic HCN1; increased expression of the high-voltage activated Ca-channel $Ca_V2.1$ (P/Q) in RTN; and altered cortical dendritic morphology.[23,69,74,129,134] Several other genetic models have known molecular defects associated with spike-and-wave seizures. HCN2 knockout mice and stargazer both have alterations in I_h,[42,83] whereas a variety of Ca-channel mutations produce spike-and-wave in mouse models.[14,36] Mutations in genes associated with other cellular maintenance functions,[68,150] and in the Na/hydrogen exchanger gene, NHE1 can cause spike-and-wave seizures in mice.[35] Given our current understanding of the mechanisms important in rhythm generation within the thalamic synaptic network, this type of phenotypic alteration could certainly contribute to an increased bias of the thalamocortical system toward generation of excessively synchronized oscillations in these epileptic rodent model systems.

The possible involvement of these experimental phenotypic mechanisms in the generation of the human epileptic condition remains to be fully determined, although recent human studies have elucidated mutations in several genes in families or individuals with absence seizures. Amino acid substitution or splice-donorâ€"site mutations in the $GABA_A$ receptor Î³2 subunit (*GABRG2*) have been associated with childhood absence and febrile seizures,[67,143] and a stop mutation in the pore-forming Î±1A subunit of the P/Q Ca^{2+} channel (*CACNA1A*) is associated with childhood absence seizures and ataxia.[66] These early examples are likely to be rare causes of absence seizures, and the search for additional genes continues. However, these findings demonstrate that changes in a number of different single genes important in neuronal signaling and excitability are capable of generating absence seizures.

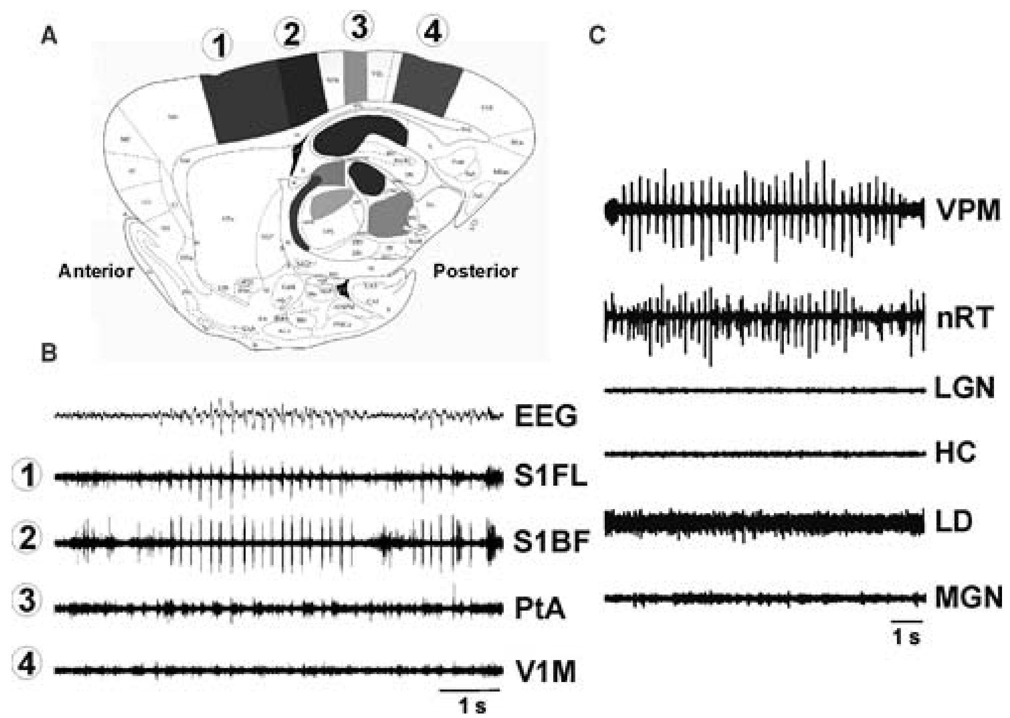

FIGURE 5. Selective cortical and subcortical network involvement in rodent spike-and-wave seizures. **A**: Regions sampled by microelectrodes, displayed on a sagittal section from a stereotactic atlas; Paxinos G, Watson C. *The Rat Brain in Stereotaxic Coordinates*, 4th ed. San Diego: Academic Press; 1998, with permission.[111] **B**: Example of recordings from cortical regions with simultaneous EEG and extracellular

multiunit electrodes during spike-and-wave seizures in the WAG/Rij rat. An array of four microelectrodes was placed along a straight line running from anterior to posterior (*contacts numbered 1 through 4*), 3.6 mm lateral from bregma. Interelectrode spacing was 2 mm. EEG (*upper trace*) was recorded with subcutaneous electrodes. S1FL, forelimb primary somatosensory cortex; S1BF, barrel field primary somatosensory cortex; PtA, parietal association cortex; V1M, primary visual cortex. **C**: Recordings from deep structures during spike-and-wave seizures. Examples are shown of recordings with individual extracellular microelectrodes placed during different experimental runs in the thalamic ventral posterior medial nucleus (VPM). nRT, thalamic reticular nucleus; LGN, lateral geniculate nucleus; HC, hippocampus; LD, lateral dorsal nucleus; MGN, ventral medial geniculate nucleus. Simultaneous recordings from frontal cortex had large amplitude SWD in all cases. Recordings were performed from WAG/Rij rats under fentanyl/haloperidol anesthesia. Modified from Nersesyan H, Herman P, Erdogan E, et al. Relative changes in cerebral blood flow and neuronal activity in local microdomains during generalized seizures. *J Cereb Blood Flow Metab*. 2004;24(9):1057â€“1068, with permission.[103]

Specific Nuclei Considered Especially Important for Generalized Epilepsy

Three main types of dorsal thalamic nuclei have been implicated as especially important in the generation of generalized seizure discharges. These are the lateral sensory relay

nuclei and the midline thalamic (intralaminar) nuclei, which are importantly involved in the generation of SWDs in animal models of absence; and the anterior and mediodorsal thalamic nuclei, which may be involved in the generation of primarily or secondarily generalized convulsive seizures, due to their extensive interconnections with the limbic system.

Lateral Thalamic Relay (Specific) Nuclei

In studies both in humans[5,13,52,106,113,122,126,146,147] and in animal models of generalized absence epilepsy,[47,97,103] the post-erolateral thalamic nuclei appear to be intimately involved in the generation of SWDs (Fig. 5). In cats experiencing feline generalized penicillin epilepsy, extracellular recordings of spike-and-wave activity are much more readily obtained from the specific nuclei than from the nonspecific midline nuclei.[94] Recordings from rodent models have shown that certain specific thalamic relay nuclei and their corresponding cortical regions are preferentially involved, whereas other thalamocortical networks are almost entirely spared[97,103] (Fig. 5).

Midline Thalamic (Intralaminar or Nonspecific) Nuclei

The midline thalamic nuclei have been reported to rarely participate vigorously in SWD generation in rodent genetic models of absence,[97] or in some chemically induced models of absence (e.g., feline penicillin generalized epilepsy).[47,94] On the other hand, more recent recordings from rodent models have shown delayed involvement of intralaminar thalamic nuclei, suggesting a role in synchronization and maintenance of SWDs.[124] In addition, these nuclei do participate in SWDs generated by systemic administration of Î³-hydroxybutyrate, and there is some evidence from depth recordings in humans that midline thalamic nuclei participate in the generation of SWDs accompanying other (nonabsence) epileptic conditions.[122] In early experiments in cats, midline stimulation of the thalamus elicited cortical EEG responses similar to SWDs, as well as some of the behavioral symptoms of absence.[39,65] It was also shown that injection of small amounts of penicillin into the midline thalamic nuclei induced a slowing of cortically recorded barbiturate spindles (8- to 12-Hz) to SWD frequencies (3- to 5-Hz), accompanied by enhanced synchronization of the rhythms,[119]

further suggesting a role for the nonspecific thalamic midline and intralaminar nuclei in the generation of SWDs.

Anterior and Mediodorsal Nuclei and Generalized Convulsive Seizures

The anterior and midline thalamic nuclei have been shown to be involved in the generation of convulsive seizures elicited by systemic pentylenetetrazol (PTZ) or bicuculline administration. In the PTZ model of seizures, EEG recordings cycle through a series of stages prior to the development of convulsive seizures. One of these activity stages appears to be SWDs, suggesting involvement of the thalamocortical system in PTZ-induced electrical activity and convulsions. Injection of $GABA_A$ or $GABA_B$ agonists into the midline thalamus will exacerbate generalized convulsive seizures induced by the systemic administration of either PTZ or bicuculline.[98,99] Furthermore, irreversible inhibition of GABA-transaminase activity with Î³-vinyl-GABA microinjections into midline thalamus elevated PTZ seizure thresholds. These data are consistent with the concept that PTZ-induced electrical and convulsant activity may involve the activation of neuronal circuitry and processes similar to those of generalized absence epilepsy (the thalamocortical system). Also compatible with this idea of PTZ's thalamocortical activation-mediating effects is the ability of generalized absence anticonvulsants to block PTZ-induced seizures. This relationship is so consistent that PTZ-induced seizures are routinely employed as a screen to test drugs for potential activity in absence epilepsy.

Further support for the role of medial thalamic nuclei in generalized convulsions comes from recent neuroimaging studies showing activation of the medial thalamus during human induced or spontaneous secondarily generalized tonic-clonic seizures.[22,137,138]

Localized Thalamocortical Networks in Generalized Seizures

Although considered a form of generalized epilepsy, it has long been recognized (based on EEG recordings) that SWDs do not involve the entire forebrain in a uniform fashion. Based on human scalp EEG, a frontal predominance in the amplitude of SWDs often is seen, maximal in the frontal midline region.[58,121,145] Recent functional magnetic resonance imaging (fMRI) studies in patients during SWDs have also shown focal involvement of bilateral frontal and parietal cortex, as well as the thalamus, with large regions of cortex relatively spared.[2,6,9,10,123] Similarly, neuroimaging of secondarily generalized tonicâ€"clonic seizures has shown focal bilateral involvement of the frontoparietal cortex and medial thalamus, with other regions relatively spared.[18,22,46,95,137,138]

Focal thalamocortical network involvement in generalized seizures has important practical implications. Selective involvement of frontoparietal association cortex may explain why patients with absence seizures often have difficulty with tasks requiring novel information processing, but continue to perform simple motor tasks during seizures.[15,75] Intense, focal involvement of the frontoparietal cortex and medial thalamus during tonicâ€"clonic seizures may explain the profound impairment of consciousness that occurs during and following this seizure type.[22,137,138]

Focal involvement in generalized seizures suggests that altered excitability in specific regions of the thalamocortical network may be crucial for seizure generation. This opens the possibility of developing more selective regional therapies, targeted at controlling altered excitability in specific regions rather than the whole brain. Work in animal models has begun to shed some light on the mechanisms of altered excitability in selective thalamocortical networks during generalized seizures. In vivo recordings from rodent models of spike-and-wave seizures have shown that seizure discharges are largest in amplitude in the more anterior somatosensory and motor cortex and corresponding thalamic nuclei, whereas the occipital cortex and thalamic visual relay areas are almost entirely spared[96,103] (Fig. 5). High-field fMRI studies in rodent models have agreed with this selective thalamocortical network involvement in generalized seizures, and may lead to the identification of other regions important in seizure generation.[104] A recent elegant study found that local delivery of ethosuximide via microinfusion to the region of somatosensory cortex most intensely involved in spike-and-wave seizures led to seizure blockade.[87] In addition, it has been found that altered expression occurs of molecules, such as Na channels, which may contribute to enhanced excitability in focal brain regions[74] (Fig. 6). An increased expression of voltage-gated Na channels Nav1.1 and 1.6 was found selectively in layers II and III of the somatosensory cortex in epileptic rats with spike-and-wave seizures, but not in nonepileptic control rats.

Pharmacologic Control of Spike-and-Wave Discharges

Generalized absence epilepsy has a unique pharmacologic profile with respect to control by antiepileptic drugs (AEDs). The efficacy (or lack thereof) of most of the currently employed AEDs can be explained, at least in part, through an understanding of how the cellular mechanisms of action of the drug interact with our current understanding of the physiologic oscillator generating SWDsâ€" the thalamocortical system. The specific generalized absence drugs ethosuximide and trimethadione, which have little or no efficacy in other forms of epilepsy, both block the T-type Ca current as one cellular mechanism of action.[31,32] Broader-spectrum anticonvulsants with absence efficacy have variable cellular mechanisms, including augmentation of GABAergic inhibition (benzodiazepines, valproate) and T-current block (methsuximide [Celontin]; valproate[72]). Both benzodiazepines and barbiturates augment GABAergic inhibition as a cellular mechanism of action, but only benzodiazepines are effective in the control of absence. This selective efficacy of benzodiazepines in controlling absence is apparently due to the selective augmentation of GABAergic neurotransmission in the cerebral cortex by these drugs, with much reduced efficacy in thalamus.[109] This may be due to regional variation in the structure and function of $GABA_A$ receptors in the brain.[62,110,117,148] Because augmenting inhibition in the thalamus is proconvulsant in absence,[47,97] the selective effects of benzodiazepines in the cortex may be consistent with their clinical utility in this seizure disorder. Barbiturates are equally effective in augmenting inhibition in the thalamus and cortex, and this could reduce their effectiveness in controlling absence seizures. In addition, differential effects on $GABA_A$ versus $GABA_B$ receptors may determine whether a medication reduces or increases absence seizures. For example, vigabatrin, by nonselectively increasing $GABA_A$ and $GABA_B$ neurotransmission, tends to increase SWDs.

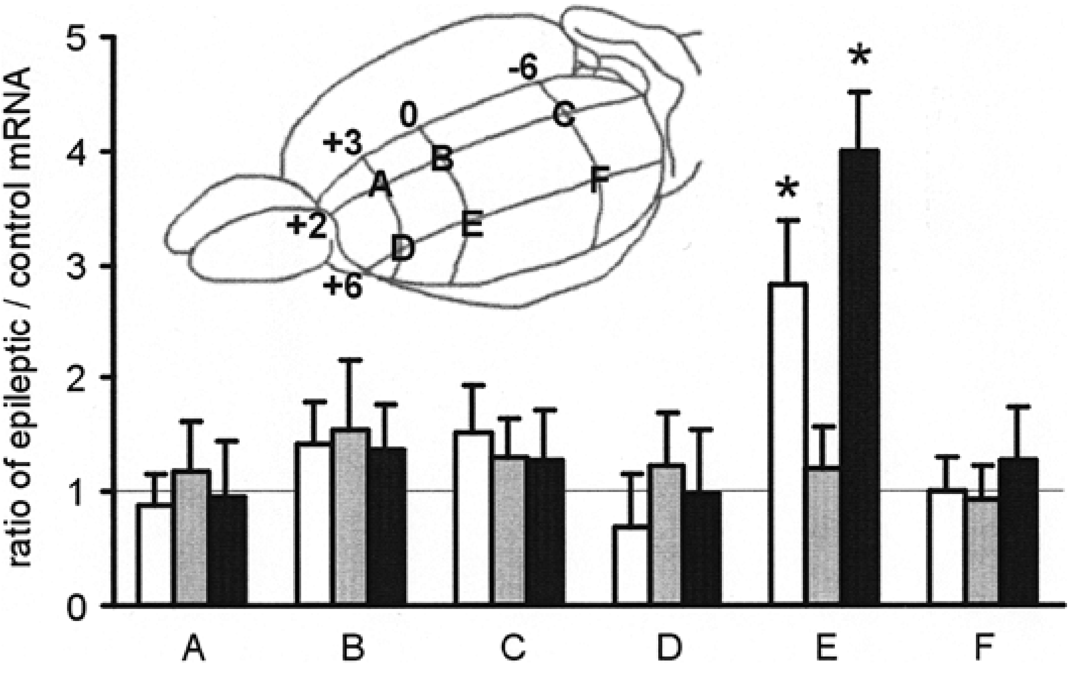

FIGURE 6. Focal increased expression of voltage gated sodium channels in region of most intense cortical spike-and-wave seizures. Na-channel mRNA was analyzed in the cortex of epileptic WAG/Rij rats and compared to nonepileptic and Wistar control rats. Anatomic locations of tissue plugs used for quantitative PCR analysis are indicated on inset drawing of rat brain. The histogram shows the ratio of sodium channel mRNA levels in the neocortex of 6-month-old WAG/Rij (epileptic) rats compared to age-matched Wistar (control) rats. At anatomical location â€œE,â€ which corresponds to the rat facial somatosensory cortex, there is a statistically significant (*$p < 0.05$) increase in the voltage-gated Na channel Nav1.1 (*white bars*) and Nav1.6 mRNA (*black bars*), but not Nav1.2 mRNA (*gray bars*), in the epileptic animals compared with control animals. From Klein JP, Khera DS, Nersesyan H, Kimchi EY, Waxman SG, Blumenfeld H. Dysregulation of sodium channel expression in cortical neurons in a rodent model of absence epilepsy. *Brain Res*. 2004;1000:102â€"109.[75]

Thalamocortical networks in localized epilepsy

The anterior thalamic nuclear group, mediodorsal nucleus, and midline thalamic nuclei have strong reciprocal limbic connections (Table 1). Because limbic cortical structures, most often in the temporal lobe, are commonly involved in localized epilepsy,

interest has been growing in these limbic thalamic regions as possible therapeutic targets for localized epilepsy.

Several lines of evidence demonstrate that the thalamus participates in localized epilepsy and may be important for controlling seizure susceptibility.[108] In patients with mesial temporal lobe epilepsy, the ipsilateral thalamus shows reduced volume on MRI,[26,37,38] atrophy on pathologic study,[88] and hypometabolism on fluorodeoxyglucose positron emission tomography (PET) metabolism.[27,54,105,149] Depth electrode recordings have demonstrated thalamic involvement during seizures in patients and animal models with partial epilepsy.[11,20a,139,140] Rats with chronic spontaneous limbic epilepsy were found to have neuronal loss in the medial dorsal thalamic nucleus.[12] In addition, several 2-deoxyglucose mapping[28,50,51,93,136] and focal drug infusion studies[57,98,100] have identified the mediodorsal thalamus and midline nuclei as important for limbic and other seizure activity in animal models. These findings may reflect the known strong reciprocal connections between limbic mesial temporal structures and the medial thalamic nuclei.[1,25]

Recent fMRI and MR spectroscopy studies also suggest thalamocortical network dysfunction in localized epilepsy.[3,41,144] In addition, during seizures in patients with mesial temporal lobe epilepsy, increased perfusion occurs in the medial thalamus based on single photon emission computed tomography (SPECT),[19,77,89,130] which is highly correlated with decreased perfusion in frontoparietal association cortex.[19] Dysfunction of the frontoparietal association cortex, caused by abnormal thalamocortical network activity, may be crucial for loss of consciousness in temporal lobe seizures.[19,20,21]

Because of its participation in partial seizures, the thalamus has been investigated as a therapeutic target to reduce seizure susceptibility. In animal studies, thalamic lesions or electrical stimulation are associated with a reduction in partial seizures.[108,132] Some studies suggest that the thalamus may participate in the therapeutic modulatory effects of vagus nerve stimulation.[53,55,120,135] Work by Velasco et al. has suggested that stimulation of the centromedian nucleus in humans may reduce seizures,[141] however a trial by Fisher et al. was inconclusive.[44] Initial studies of anterior thalamic stimulation have shown promising results.[4] A large multicenter prospective trial of anterior thalamic stimulation is currently under way, and future prospects for therapeutic brain stimulation are being pursued actively.[102,132]

Summary and Conclusions

The present chapter provides an overview of the anatomy and physiology of the thalamocortical system, with a specific emphasis on how this system functions in the generation of normal and pathologic rhythms. The thalamus and cerebral cortex function in an intimately interconnected manner and, to fully understand their operation, the synaptic and intrinsic properties of both must be considered jointly. The thalamocortical system functions in two main states: a faithful relay mode, in which afferent information is relayed through the thalamus to the cortex, with little loss of information content; and an oscillatory mode, in which the system tends to spontaneously generate normal and pathologic low-frequency rhythms. The transition between these states is mediated by the degree of activity in both sensory and brainstem neuromodulatory afferents. The main oscillator driving and maintaining the rhythmic properties of this system resides in the thalamus/NRT synaptic network. In this circuit, GABAergic inhibition impinging onto thalamic neurons originating from the NRT serves as a synchronizing mechanism, and the low-threshold T-type Ca

current in thalamic neurons serves as an amplifying factor. With this oscillator positioned in a tightly interconnected thalamocorticothalamic loop, the thalamocortical system is in an optimum situation to generate reverberating generalized rhythms that can be recorded in the cortical EEG. In normal situations, rhythms generated by this system include the spindle discharges encountered during drowsiness and sleep. The thalamocortical system is also critically involved in generating pathologic rhythms, including the SWDs of generalized absence epilepsy. Although little is known as yet about the etiology of absence in humans, recent studies in rodent genetic models of absence have demonstrated several candidate phenotypic mechanisms that may contribute to the generation of SWDs. Growing evidence suggests an important role for thalamocortical networks in localized epilepsy as well, with important therapeutic implications. These types of studies, coupled with our current knowledge of mechanisms involved in the generation of synchronized rhythms within the thalamocortical system, afford promise for a better understanding of the epileptogenic mechanisms underlying generalized seizures and may also have applications to understanding localized epilepsy.

Introduction

Seizure activity does not spread diffusely throughout the brain, but propagates along specific anatomic pathways. The particular pathways responsible for triggering and propagating a seizure determine the nature of the seizure and the pattern of the motor manifestations that accompany it. Although seizures may result from any of a broad array of brain insults, the motor concomitants of the seizures fall into only a few categories of remarkably stereotyped behaviors. This suggests that the anatomic substrates of propagated convulsive seizures in the intact organism may likewise fall into a few major categories or systems. In this chapter, some of the subcortical anatomic substrates of seizure propagation are reviewed. In addition, we identify certain anatomic circuits that are responsible for regulating seizure susceptibility and act as common modulators for multiple seizure-generating circuits. The pathways within the basal ganglia and brainstem will be the main focus of this chapter, with passing reference to other subcortical structures with which these systems interconnect.

Before considering particular anatomic substrates, it is important to recognize that brain regions and pathways may participate in the seizure process in distinctive respects. Some of the roles that a brain area or pathway may play include:

- *Epileptogenic â€œtriggerâ€ area*. A site in the brain that is capable of evoking propagated seizure activity upon focal electrical or chemical stimulation. The trigger area is analogous to a â€œswitch.â€ It sets in motion the events that result in a seizure, but it is not necessarily one of the first areas to exhibit ictal activity during seizure development.
- *Epileptogenic â€œtargetâ€ area*. A site in the brain that is especially vulnerable to the development of ictal activity, either by virtue of its anatomic inputs (e.g., from a â€œtriggerâ€ area) or by virtue of its intrinsic circuitry. This area would be one of the first areas to exhibit a pattern of ictal discharge during the initial development of a seizure, but it is not necessarily a source for seizure propagation.
- *Pathways involved in propagation of the seizure.* These include pathways connecting â€œtriggerâ€ areas and â€œtargetâ€ areas, pathways creating positive or negative feedback circuits, pathways allowing the seizure to spread to additional brain loci, and commissural pathways allowing bilateral spread.
- *Gating inputs*. Neural inputs to â€œtriggerâ€ or â€œtargetâ€ areas that modulate the excitability of these regions. Changes in the activity of the gating inputs alter seizure threshold in a predictable fashion. These inputs alone are not necessarily capable of inducing seizures.

The first three of these categories are generally specific to seizure type. Gating inputs, on the other hand, exert a common influence on many different seizure types. Brainstem circuitry is most often associated with gating functions, whereas forebrain circuitry has typically been studied for trigger and target components.[101,102,104]

Overview of Anatomy

Basal Ganglia Circuits

The basal ganglia are a collection of nuclei situated in the forebrain and midbrain that include the caudate nucleus and putamen (together referred to as â€œstriatumâ€), globus pallidus, entopeduncular nucleus (equivalent to the internal segment of the globus pallidus), subthalamic nucleus, and substantia nigra. The striatum represents the â€œreceivingâ€ end of the system, and the internal segment of the globus pallidus (entopeduncular nucleus in rat) and substantia nigra represent the output end of the system. Three major relays mediate the impact of the basal ganglia on behavior: thalamus, intermediate and deep layers of superior colliculus, and the pedunculopontine area of the caudal mesencephalic tegmentum. Some of the circuitry that interconnects these regions is illustrated in FIGURE 1.

Brainstem Projections

The midbrain and pontine regions of the brainstem contain the cell groups from which the ascending serotonin-containing pathways originate (dorsal and median raphe nuclei) and from which the noradrenergic pathways originate (locus ceruleus and nearby cell groups). Important cholinergic projections also derive from specific cell groups in the caudal midbrain and rostral pons. These monoaminergic and cholinergic projections reach widespread regions of the diencephalon and telencephalon in the forebrain (see Fig. 2). These projections play a critical role in the regulation of sleepâ€“waking states, arousal, and attention, in addition to influencing seizure susceptibility.

Independence of Seizure Generating Mechanisms in Forebrain and Brainstem

Forebrain Mechanisms

It has been demonstrated in the cat that complete transections disconnecting the forebrain from the brainstem do not interfere with the electroencephalographic seizure discharge recorded from the forebrain in response to pentylenetetrazol.[173] More recently, in the rat, Browning et al. found that electroencephalographic seizure activity evoked focally from the area tempestas, an epileptogenic site in the deep anterior piriform cortex, was not impaired by complete transections of the brainstem at the pre-, mid- or postcollicular level.[24] These observations indicate

P.368

that circuitry within the forebrain is sufficient to initiate, propagate, and sustain bilateral seizures in the absence of neural connections with the midbrain or hindbrain.

Brainstem Seizures That Do Not Depend on Connections with Forebrain

Although forebrain regions are crucial in many forms of epilepsy, the brainstem has multiple roles in both the triggering and propagation of certain types of seizures. A â€œbrainstemâ€ seizure model has been suggested by Gioanni et al. with regard to the quaking mutant mouse. They found that focal stimulation of multiple brainstem regions can induce tonicâ€“clonic seizures in these animals.[121] Likewise, brainstem substrates are critical in the induction of audiogenic seizures in susceptible animals, and massive ablation of forebrain structures does not prevent these convulsions.[117] Brainstem structures are also sufficient for tonic convulsions evoked by maximal electroshock or chemoconvulsants.[28] These observations indicate that, for certain seizure types, the brainstem contains the trigger areas and target areas as well as the pathways required for the full expression of the seizures.

Several animal models of convulsive seizures frequently include explosive running and bouncing characterized by vigorous clonic movements of all four limbs; a tonic component involving the flexion/extension of all limbs, and loss of righting reflex often follows. This convulsive pattern is produced by systemic administration of chemoconvulsant drugs such as pentylenetetrazol, picrotoxin, and bicuculline, as well as by acoustic stimulation of animals that are prone to audiogenic seizures.[25,103] These types of seizures have been shown to depend on neural substrates in the brainstem, and do not require the integrity of the forebrain for either their initiation, development, or expression.[25,28]

Inferior Colliculus as a Site of Seizure Initiation

Stimulation of Inferior Colliculus

The inferior colliculus is a brainstem site from which running/ bouncing clonic seizures can be triggered in rodents. Electrical stimulation of the inferior colliculus in the rat, as well as focal application of drugs that stimulate excitatory amino acid transmission in this site, elicit sudden, explosive bouts of leaping, running, and bouncing on all four limbs.[82,94,95,187,194] This behavior resembles that associated with sound-induced (audiogenic) seizures in susceptible rodent strains, and although it can also be evoked by disinhibition of periaqueductal gray neurons,[10] it is not dependent on the integrity of the periaqueductal gray for its expression. These inferior colliculus-evoked seizures in rats, which can be induced as early as 3 days of life, have been compared to human neonatal seizures. In fact, McCown and Breese suggest that many neonatal human seizures may actually be initiated in the inferior colliculus.[183]

The electroencephalographic features of seizures electrically evoked from the inferior colliculus have been well characterized by McCown et al.[187] During the wild running behavior, afterdischarges are seen in the region of the inferior colliculus, without abnormalities in the forebrain. Upon repeated stimulation of the inferior colliculus, there is a kindling-like progression to forelimb manifestations (myoclonus or tonic extension); this is associated with both afterdischarges in the region of stimulation and electrical spiking activity in the frontal cortex.

Î³-Aminobutyric Acid and Glutamate in the Inferior Colliculus

Blockade of Î³-aminobutyric acid (GABA) transmission in the inferior colliculus evokes convulsive effects similar to audiogenic seizures,[94,95] increases auditory evoked potentials, and induces susceptibility to audiogenic seizures in otherwise normal rats.[11] Faingold et al. found that infusion of baclofen (a $GABA_B$ agonist) or gabaculine (a GABA transaminase inhibitor) into the inferior colliculus of genetically epilepsy-prone rats (GEPRs) significantly reduced the severity and incidence of audiogenic seizures;[81] muscimol, a $GABA_A$ agonist, was almost twice as potent as baclofen at reducing seizures in this model. Similarly, tiagabine, a GABA uptake inhibitor that increases extracellular GABA levels, significantly reduced seizure severity in the GEPR when given either systemically or focally into the inferior colliculus. This occurred in conjunction with a reduction in neuronal firing in the central nucleus of the inferior colliculus.[85] Taken together, these observations indicate that GABAergic transmission within the inferior colliculus provides a crucial inhibitory influence on susceptibility to sound-induced seizures.

An essential role for *N*-methyl-D-aspartate (NMDA) and non-NMDA glutamate transmission in audiogenic seizure initiation was suggested by Faingold et al.[84] based on evidence that the NMDA and non-NMDA antagonists were able to block audiogenic seizures in GEPRs when focally applied to the inferior colliculus. Focal application of an inhibitor of glutamate synthesis in the inferior colliculus also blocked audiogenic seizures in the GEPR,[86] whereas focal application of glutamate agonists in this region induced runningâ€"bouncing seizures in normal rats.[82,194]

Bicuculline in the inferior colliculus evoked only submaximal seizure activity, whereas NMDA agonists fully reproduced the tonicâ€"clonic seizure seen during audiogenic seizures, suggesting that disinhibition alone, without increased excitation, is not sufficient for full seizure expression in the GEPR.[117] In the aftermath of an audiogenic seizure, depletion of excitatory amino acids in the inferior colliculus may contribute to the postictal refractory period.[243]

Interactions Between Inferior Colliculus and Other Brainstem Structures

Lesions or focal inhibition of inferior colliculus transmission interferes with the generation of sound-evoked seizures not only in the genetically epilepsy-prone rat[26,73,83,149,300] but also in DBA/2 mice[306] and in rats undergoing alcohol withdrawal.[95] Cortical, not central, inferior colliculus nuclei appear to be critical for expression of these seizures.[117]

The inferior colliculus, as part of the auditory sensory system, is probably a crucial afferent relay station for converting acoustic stimulation into convulsive discharge. Consistent with this view is the reciprocal positive transfer between kindling of audiogenic seizures and electrical kindling of the inferior colliculus[140] and the fact that subconvulsant stimulation of this region can render otherwise normal animals susceptible to audiogenic seizures.[82,194] Direct chemical or electrical stimulation of this brain region does not typically evoke *tonic* convulsions in normal rats unless ascending norepinephrine (NE) projections have been compromised by lesions or depletion of NE.[31]

Detelencephalated rats exhibit enhanced susceptibility to audiogenic seizures in the presence of bicuculline in the inferior colliculus. Therefore, the forebrain structures may normally exert some inhibitory control over these seizures.[12] The specific target areas within the brainstem engaged by the inferior colliculusâ€"evoked convulsions have not yet been elucidated, but it is likely that there are critical glutamate-mediated connections in the mesencephalic and pontine tegmentum.[193] Mid-collicular knife cuts decrease the wild running component of audiogenic seizures, indicating that inferior colliculusâ€"superior colliculus interconnections are required for some components of audiogenic seizures.[245,269] Complete blockade of audiogenic seizures has been obtained with knife cuts that separate the central and external nuclei of the inferior colliculus, suggesting that seizure activity triggered in the central nucleus propagates out of the inferior colliculus via the external nucleus.[245,269] Because corticocollicular fibers terminate mainly in the external nucleus, this region may be an important link in a positive feedback loop involving the cortex. In fact, the actual seizure discharge pattern may become organized in the network engaged by the external nucleus, because this nucleus exhibits a low threshold for bursting in disinhibited collicular slices in vitro.[233] Pierson and Snyder-Keller[233] suggest that a bidirectional excitatory loop between superior colliculus and inferior colliculus may provide for an important oscillatory interaction that sets up the seizure discharge. According to their model, an initial depolarization of external nucleus cells contributes to the epileptiform discharge that develops in the deep superior colliculus and dorsal cortex of the inferior colliculus. The bursting in superior colliculus in turn precedes the synchronous repetitive bursting that occurs in the external nucleus. Thus, the deep superior colliculus is a crucial component of this oscillatory pattern. The participation of the external nucleus and dorsal cortex of inferior colliculus, as well as the deep superior colliculus, was also indicated in vivo by the pattern of *c-fos* expression associated with audiogenic seizure development.[233]

A high degree of lateralization is present in the inferior colliculus. Unilateral kindling of the inferior colliculus sufficient to produce runningâ€"bouncing seizures and bilateral electrical afterdischarge in the rat, does not alter the de novo kindling rate of the contralateral inferior colliculus. This lateralization is supported by 2-deoxyglucose studies.[184] Thus, the progression to runningâ€"bouncing seizures is distinct for each side. This contrasts with forebrain seizures in rats; for example, unilateral amygdala kindling facilitates kindling of the contralateral amygdala.[185]

Brainstem Substrates of Tonic Extensor Convulsions

In rodent models involving maximal or supramaximal convulsive stimuli, tonic extension of the forelimbs or hindlimbs is the typical convulsive endpoint. During the tonic extensor phase of a seizure, the forelimbs are rigid and extended caudally against the ventral surface of the body, while the hindlimbs are rigid and extended horizontally and away from the prone or supine body in a caudal direction. This tonic extensor phase is characteristic of seizures evoked by maximal electroshock or high doses of chemoconvulsants and is usually maintained for 3 to 12 seconds. It is also observed in two strains of genetically epilepsy-prone rats (GEPR 9 rats) and Wistar audiogenic sensitive rats (WAS) in response to acoustic stimulation.[220,244,293]

As in the case of runningâ€"bouncing convulsions, tonic extensor convulsions require the integrity of the brainstem but not the forebrain.[28,235] However, the anatomic substrates within the brainstem responsible for generating tonic seizures have not been characterized. Neurons within the reticular formation of the caudal midbrain and pons are likely to be involved, based on the fact that stimulation of this general region triggers tonic extensor convulsions, and lesions within this area can selectively attenuate tonic convulsions.[20,29,30,157] Moreover, sustained multiunit activity in the reticular formation correlates with the tonic extensor component of seizures induced by pentylenetetrazol; this activity is not abolished following transections that disconnect the hindbrain from the forebrain at the precollicular level.[279]

The tonic extensor components of audiogenic and maximal electroshockâ€"induced convulsions are selectively suppressed by lesions of the nucleus reticularis pontis oralis (RPO) without altering clonic seizure activity.[25,30]

Furthermore, focal injections of a local anesthetic (lidocaine) directly into the RPO reversibly blocked the expression of tonic extensor convulsions.[25,30] A similar selectivity for tonic extensor seizure manifestations is seen with lesions of the superior cerebellar peduncles[25,30] or removal of the cerebellum.[237]

Interactions Between Brainstem and Forebrain

Midbrain Regulation of Forebrain Seizure Spread

At the same time that brainstem regions serve to regulate seizure susceptibility in forebrain circuits, they participate in the

development of certain changes that occur in the course of the limbic kindling process. Midsagittal section of the brainstem prior to kindling of the amygdala in rats did not alter the development of kindling at the primary (i.e., first) site but was able to prevent the positive transfer effect at the secondary site (i.e., contralateral amygdala).[137] In all intact animals, kindling of the second amygdala proceeded at a rate several-fold faster than the primary site kindling (two to five vs. nine to fourteen stimulations). In contrast, the majority of bisected rats exhibited no enhancement of the secondary-site kindling rate. These observations confirm that interhemispheric connections within the brainstem are not required for amygdala seizure development and, at the same time, suggest their importance for the *interhemispheric* transfer of susceptibility to kindled seizures. This is supported by studies in feline amygdala kindling, in which bisection of the midline brainstem from the midbrain to pons prevented the positive interhemispheric transfer effect.[130,298] It also appears that the midline brainstem participates in symmetrical patterning and electroclinical tonic expression of the kindled seizure. It is possible that the kindling process removes inhibitory influences of specific (as yet unidentified) brainstem regions and that this removal of inhibition contributes to the progressive enhancement of limbic seizure susceptibility. Presumably, brainstem structures homolateral to the primary kindling site must participate in the progression of kindling at that site via intrahemispheric projections. This notion is supported by the observation that unilateral lesions of the midbrain reticular formation markedly reduce susceptibility to seizures evoked by kindling of the homolateral amygdala in cats.[299] Apparently, the bisection of the brainstem can prevent the kindling-induced changes from occurring in the contralateral hemisphere, rendering that hemisphere â€œnaiveâ€ to the kindling stimulation.

Kindling of Brainstem Regions

The anatomic separation between forebrain and hindbrain seizures that has been repeatedly documented in experimental models is largely derived from the study of acute seizures in otherwise normal animals. Under conditions in which repeated seizure activity or *kindling* has occurred over prolonged periods, an erosion of this anatomic separation may take place. For example, repeated audiogenic seizures (daily for 2â€“3 weeks) give rise to seizures that resemble forebrain seizures, based on behavioral and electrographic characteristics. Moreover, audiogenic kindling in susceptible animals markedly accelerated hippocampal and amygdala kindling.[138,139] Data from 2-deoxyglucose, c-Fos protein expression, and functional disconnection by local lidocaine injections, indicated that the amygdala, but not hippocampus, is critical for the spread of audiogenic seizures from brainstem to forebrain.[138]

Similarly, whereas acute electrical stimulation of the inferior colliculus evokes seizures limited to the hindbrain, repeated electrical or acoustical stimulation of this structure eventually recruits forebrain circuits and induces forebrain seizure discharge.[139,140,186] Amygdala spiking has been seen after chronic inferior colliculus stimulation, indicating forebrain recruitment.[116,117] Once forebrain circuits have been recruited by repeated inferior colliculus stimulation, the focal inhibition of area tempestas (an epileptogenic region within the deep rostral piriform cortex) can suppress the limbic motor seizures that occur as a result of seizure spread into the forebrain. This suggests that the kindling-evoked spread of seizure discharge into the forebrain comes under the control of forebrain circuits that do not otherwise influence brainstemâ€“evoked seizures.[182]

Other studies demonstrate that repeated seizures in forebrain circuits can modify susceptibility to brainstem convulsions. For example, amygdala kindling was found to increase susceptibility to electroshock-induced tonic hindlimb extension, even though the kindled seizures themselves never evoked a tonic extensor response.[7]

Apparently, repetitive seizure activity in one circuit may alter the susceptibility of other circuitry to seizure induction, possibly by inducing long-term changes in structures and pathways (e.g., substantia nigra, midline thalamic nuclei, superior colliculus, ascending noradrenergic projections) that serve a general gating function (see later discussion).

Seizure-Gating Mechanisms in Basal Ganglia and Brainstem

Under this category, we describe certain pathways that influence seizure susceptibility by modulating the threshold for seizure initiation or by regulating the sensitivity of the pathways responsible for propagating the seizure activity.

In many cases, the gating substrates are relatively nonselective as to the type of seizure they can influence. Consequently, by manipulating the activity of seizure gating systems, we can exert a broad-spectrum shift in seizure susceptibility. There are, however, circumstances in which a particular pathway exerts divergent or opposing effects on different types of seizures, further reinforcing the independent nature of some of the seizure-generating networks.

Basal Ganglia and Related Structures

The earliest indications that the basal ganglia participated in seizure propagation came from subcortical ablation stu-dies[133,145] that identified the substantia nigra (SN) and the thalamic and lenticular nuclei as crucial for the generalization of chemically evoked cortical seizures. Depth recording experiments[80] showed involvement of the putamen and associated structures in the spread of seizures evoked focally from cortex or amygdala; similarly, seizures evoked from hippocampal stimulation or by systemic chemoconvulsants were observed to propagate through the SN.[134] Metabolic mapping studies reinforced the involvement of the basal ganglia in seizures by demonstrating a profound increase in 2-deoxyglucose accumulation in the SN and globus pallidus after kindled amygdala seizures.[79] More recent studies have suggested that increases in metabolic activity in basal ganglia nuclei may precede the onset of clinical seizures during epileptogenesis: SN and striatum are hypermetabolic in rats that are at the end of the latent period following lithium-pilocarpine status epilepticus (SE); that is, at a time point just prior to the development of spontaneous seizures.[71,72] Likewise in 21-day-old genetically susceptible rats (GAERS) that do not yet exhibit spike-and-wave discharges (SWDs), rates of glucose utilization are increased in the SN, superior colliculus, and globus pallidus.[221] It is possible that these changes reflect ongoing subclinical seizure activity and/or an effort of the network to retard or prevent the occurrence of seizures.

The influence of the basal ganglia on seizure propagation and generalization is not confined to the motor manifestations of the seizures. In instances in which electrographic signs of seizures have been monitored, anticonvulsant manipulations of basal ganglia structures induce a corresponding suppression of electrographic seizure discharge in cortical and subcortical structures.[112,162,192,271,272,275,276] This is consistent with a role of basal ganglia circuits in the control of cortical excitability and the regulation of neuronal discharge synchronization in widespread regions of the forebrain.

Substantia Nigra

Broad-Spectrum Seizure Protection

The caudate-putamen (striatum), globus pallidus (entopeduncular nucleus in particular), and SN are all basal ganglia components that have been demonstrated to influence seizure susceptibility in numerous experimental seizure models. The best studied of these structures is the SN, the only region that has been examined in connection with more than 10 different experimental seizure models.[100,101]

Bilateral treatments that either increase inhibitory transmission (mediated by the neurotransmitter GABA) in SN, or block excitatory transmission (mediated by glutamate or certain neuropeptides such as substance P) in the SN pars reticularis (SNpr) prevent or attenuate convulsive seizures induced by several chemoconvulsants (pilocarpine, kainic acid, bicuculline, and flurothyl, among others), maximal electroshock, kindling of amygdala, drug application into the area tempestas, acoustic stimulation in rats susceptible to audiogenic seizures (the subject of several reviews[60,100,101,105,284,289]), and spontaneously occurring in absence-like seizures in GAERS.[65] These anticonvulsant effects may be mediated largely by the rostral regions of the SNpr, because activation of GABA receptors in the caudal SNpr has been reported to be proconvulsant in the flurothyl model.[214,268,291] VelÃ¡kovÃ¡ and MoshÃ© have reviewed regional differences within the SNpr.[289]

Not only motor manifestations, but also electrographic manifestations of seizures are regulated by SN: Inhibition within the SNpr decreases susceptibility to nonconvulsive electrographic SWD that occur either spontaneously (in genetically predisposed strains of animals such as GAERS) or as a consequence of treatment with drugs such as pentylenetetrazol in low doses.[58,60,61,62] Although the GABA agonist muscimol in SNpr was found not to protect against seizures evoked by high doses of pentylenetetrazol[315] blockade of *glutamate* transmission in SN did protect against these seizures,[310] indicating a role for SNpr in the modulation of seizures in this model. The lack of anticonvulsant effects of intranigral muscimol found in the latter study may be due to the high doses of pentylenetetrazol employed; these doses are likely to interfere with GABA receptor function and the postsynaptic responses to muscimol in the SNpr. In fact, seizures induced by lower doses of pentylenetetrazol are attenuated by SNpr muscimol infusions.[144,222] Other pharmacologic manipulations of SNpr that are anticonvulsant include augmenting serotonergic transmission,[226] stimulating opiate receptors,[110] blocking substance P receptors,[111] and enhancing adenosine transmission.[136] The anticonvulsant effect of adenosine and the proconvulsant effect of adenosine antagonists such as caffeine and theophylline within the SN suggest that the synaptic availability of adenosine may provide a physiologic mechanism whereby seizures can be self-limiting.[136]

The SNpr is probably part of a seizure-suppressing circuit that becomes engaged by seizure discharge. For example, the SNpr of kindled animals becomes recruited into a burst-firing pattern during the afterdischarge.[21] Increased burst firing in SNpr can still be seen 1 day after a fully kindled seizure, with a significant increase in neuronal discharge rate in the posterior, but not anterior, SNpr.[120] Likewise, in GAERS, simultaneously with the occurrence of SWDs at the cortical level, SNpr neurons increase their firing rates, and action potentials become organized in bursts. However, this SN burst-firing pattern stops before or at the end of the nonconvulsive seizure.[62,63] Thus, the SN and associated nuclei of the basal ganglia may act to maintain a homeostatic balance of brain excitability, attempting to resist the development of widespread synchrony.

The SN also may be a substrate for the actions of several antiepileptic drugs. Bilateral injections of midazolam, phenobarbital, or trimethadione into the SN protect against systemic pilocarpine seizures in a rodent model. Not surprisingly, ethosuximide had no effect,[270] because the site of action of ethosuximide has been localized to the hindbrain.[176]

The integrity of the SN is not required for seizure induction, indicating that this structure is not part of a crucial seizure-conducting pathway. Bilateral destruction of the SN has been shown by Garant and Gale[109] and by McNamara et al.[192] to protect against experimentally evoked seizures by *shifting the threshold* for seizure induction. Although a later study[301] reported no effect of bilateral destruction of SN on kindled seizures (in direct contrast to the findings of McNamara et al.), the completeness of nigra damage in that study is uncertain in the absence of histologic documentation of the lesions.

Role in Genetic Predisposition to Epilepsy

The SN may be a site at which genetic abnormalities can determine seizure susceptibility. For example, it has been suggested that abnormal GABA mechanisms in the SN may contribute to the seizure susceptibility in the GEPR. Clobazam, a benzodiazepine, focally administered in the SN blocked audiogenic seizures in normal rats made susceptible to these seizures by administration of bicuculline in the inferior colliculus. However, intranigral clobazam did not block audiogenic seizures in the GEPR. Because clobazam acts by enhancing endogenous GABA transmission, this indicates that endogenous GABA transmission in the nigra of GEPRs may be deficient.[266] Moreover, intranigral injections of muscimol had no effect on audiogenic seizures in a seizure-prone strain of Wistar rat.[57] Franck and Schwartzkroin[92] found a defect in GABA receptor binding in the SN of GEPRs but did not find it in the inferior colliculus. Microdialysis studies have shown that potassium (K^+)-evoked GABA release within the SN is significantly reduced in the GEPR, as compared with controls.[69]

Role of GABA, Glutamate, and Other Neurotransmitters

The fact that GABA agonists in the SNpr reduce seizure susceptibility in seizure models in which depletion or blockade of GABA in the SNpr does not increase seizure susceptibility,[172,225] suggests that GABA release is not the only mechanism by which seizure resistance can be achieved from the SN. Enhancing 5HT transmission in SN also confers seizure resistance.[224,226] GABA and 5HT appear to work in concert with each other in the SN: Under conditions in which GABA transmission is impaired, 5HT release can increase to maintain inhibitory tone.[99] Consequently, when 5HT is depleted, the blockade of GABA receptors in the SNpr becomes proconvulsant.[225] Therefore, a defect in 5HT transmission may compromise the endogenous anticonvulsant mechanisms in the SN and predispose to epilepsy.

Consistent with the role of GABA in the SN serving a seizure gating function and not a seizure triggering function is the observation that seizures are not triggered by the blockade of GABA receptors in the SNpr,[172] even in the presence of 5HT depletion.

The only intranigral treatment that has been documented to trigger clinical seizures is kainic acid (KA). The presence of KA focally in the SN can provoke a long duration state of SE in the Sprague-Dawley rat.[171] The fact that the seizures occur following a considerable latency suggests that the KA-induced stimulation of a subpopulation of SNpr outputs is sufficient to lower seizure threshold in limbic networks to the extent that SE can develop from spontaneous (endogenous) patterns of activity in limbic circuits. Because intranigral GABA agonists are ineffective in blocking the development of seizures following intranigral KA, it appears that the kainate stimulation

overwhelms GABAergic control in this region.[171] This may explain why SE induced by systemic KA is resistant to the anticonvulsant action of intranigral GABA agonists.

Sources of Afferent Control

The activity of SN neurons can be affected by epileptogenic influences through several routes. The major route is via the striatum, which receives information converging from widespread cortical regions and communicates to the SN via the â€œdirectâ€ striatonigral projections, which are largely GABAergic and inhibitory on nigral neurons. In addition, cortico-subthalamic-nigral pathways relay cortical influences to the SN; these tend to be excitatory on SNpr neurons.[179] At the same time, ascending 5HT and noradrenergic projections from the brainstem modulate nigral activity in response to changes in arousal, pain, sleep stages, and associated fluctuations in autonomic and endocrine function.

Stimulation of various cortical regions evokes predominan-tly inhibitory responses in the SNpr, most likely reflecting transmission mediated via the cortico-striatal-nigral pathways.[152] The cells in the SNpr that respond to stimulation of the prefrontal cortex are distinct from those responsive to auditory cortex stimulation, and these populations are differentially localized in SNpr, suggesting a topographic organization and functional compartmentation within the SNpr circuitry.[152]

Striatum

Certain key structures of the forebrain and midbrain work in concert with the SN in a seizure-resisting capacity (see Fig. 1). The striatum is a major source of neural input to the SN, whereas the superior colliculus (deep layers) is an important target of neural projections coming from the nigra. One of the most prominent pathways connecting the striatum to SN is inhibitory and utilizes GABA as its transmitter.[91,132] Likewise, the SN sends an inhibitory GABA-containing projection to the superior colliculus.[67,296] Consequently, it might be expected that the stimulation of the neurons in the striatum that give rise to the GABA inputs to the SN would enhance GABA transmission in the SN and thereby exert an anticonvulsant effect. The experimental evidence supports this proposal: Electrical or drug-induced excitatory stimulation in striatum is anticonvulsant in experimental seizure models.[5,34,159,276] LaGrutta et al.[159] found that a prior conditioning stimulation to the caudate nucleus (30 c/s, 1.5 msec for 5 s, 5 V) caused almost complete inhibition of the afterdischarge in amygdala, hippocampus, and temporal cortex evoked by stimulation of a kindled amygdala.

The anticonvulsant effect of GABA blockade in striatum can be reversed by blocking GABA in the SN or entopeduncular nucleus (see discussion in next section), consistent with the concept that GABAergic efferents from striatum mediate this region's influence on seizure susceptibility.

Entopeduncular Nucleus (Globus Pallidus, Internal Segment)

The entopeduncular nucleus, also known as the internal or medial segment of the globus pallidus, is similar to the SN in function, morphology, and neuroanatomic connections. Together with the SN, this nucleus relays neuronal outputs from the striatum. It is therefore not surprising that the same treatments that suppress seizure propagation when placed in the SN exert a similar action in the entopeduncular nucleus.[51,229] However, unlike the SN, the entopeduncular nucleus does not appear to exert an influence on brainstem seizure substrates. Whereas blockade of glutamate transmission in SN attenuated audiogenic seizures in the GEPR, this manipulation in entopeduncular nucleus did not reduce audiogenic seizure activity[193] under the same conditions in which it blocked pilocarpine-induced limbic motor seizures.[229] Moreover, GABA agonist application in entopeduncular nucleus did not prevent maximal electroshock-induced tonic convulsions under conditions in which it prevented pilocarpine-induced limbic motor seizures.[141] Thus it appears that the influence of the entopeduncular nucleus may be preferentially directed at forebrain seizure circuitry, perhaps via its close connections with the habenula and other limbic structures.

Globus Pallidus: External Segment (GPe)

The indirect pathway of the basal ganglia system is a polysynaptic circuit composed of (a) GABAergic striato-pallidal neurons projecting to the external segment of the globus pallidus, (b) GABAergic neurons projecting from GPe to the subthalamic nucleus (STN)[4] and to SN, and (c) neurons projecting from the STN to SN.[4] Because the GPe sends GABAergic projections into SN, it is expected that the activation of these projections would attenuate seizures. This has shown to be the case in the GAERS model, where the *disinhibition* of GPe by local injection of the $GABA_A$ antagonist, picrotoxin, at doses devoid of behavioral effects, suppressed nonconvulsive absence seizures.[66] The antiepileptic effect obtained at the pallidal level is also linked to a decrease in glutamate levels in the rat SN measured by microdialysis,[66] suggesting that a reduction of activity in STN may also contribute to the seizure attenuation (see discussion in the next section).[66] On the other hand, disinhibition of GPe did not attenuate amygdala kindled seizures,[62] indicating that the role of this structure in seizure control may be more limited than the role of the SN. Interestingly, repeated stimulation of the GPe is effective for generating kindled seizures, suggesting that seizure suppressing actions of acute GPe stimulation are easily overridden in chronic conditions.

In sharp contrast to these results, bilateral GABAergic inhibition within the GPe, using the GABA uptake inhibitor tiagabine or a $GABA_B$ agonist, baclofen, markedly attenuated the tonic convulsions induced by acute pentylenetetrazol treatment.[39] This observation raises the possibility that $GABA_B$ receptors may exert control on a subpopulation of GPe projections that are distinct from those regulated by $GABA_A$ receptors. Thus, the role of GABAergic synapses in GPe on the development of seizures is likely to be varied and highly dependent on the nature of the seizure. The fact that GABAergic synaptic transmission in the GPe is especially sensitive to rapid frequency-dependent depression[238] may account for the conditional nature of the influence of the GPe on seizure activity.

Subthalamic Nucleus

Interactions with the Substantia Nigra

As an important component of the basal ganglia network, the STN represents a source of input into both the SN and the entopeduncular nucleus (GPi). It is therefore well positioned to regulate the outflow from these critical nuclei. Direct afferents to the STN arise from the prefrontal, premotor, and motor cortex; these projections are largely excitatory, mediated by glutamate. Inhibitory projections to STN arise form GPe; these relay the indirect influence of the cortico-striatal system.

Detailed analysis of the nature of STN interactions with the SN have largely been confined to the rat. In the rat, the STN provides a major source of glutamatergic excitatory drive that sustains the firing of nigral neurons.[247,254,256] When

activity in the rat STN is inhibited either by GABA agonists or glutamate antagonists, this results in a decreased activity of SNpr neurons.[87,247] Thus, it stands to reason that lesions or inhibition of STN could mimic the anticonvulsant action of inhibition in the SNpr. Experimental evidence in support of this proposal derives from the studies of Deransart et al. in amygdala kindled rats or GAERS,[64] Dybdal and Gale[77] in rats with seizures evoked focally or systemically with bicuculline, and VelÃÅ¡kovÃ¡ et al.[290] in rats with flurothyl-induced seizures. As in the case of SNpr inhibition, bilateral STN inhibition is required for anticonvulsant effects.[64,77,290]

A similar profile of anticonvulsant effects has been achieved in the rat using high-frequency (130 Hz) electrical stimulation of the STN.[161,277,292] This effect is frequency-dependent,[161] and the frequency-dependency is closely related to the ability of the stimulation to cause a decrease in the activity of STN neurons[263] as well as SN neurons.[180,263] Although â€œdepolarization blockâ€ has been proposed to account for the inhibitory action of the high-frequency stimulation of STN, the fact that the inhibitory action in STN is rarely complete[263] and that it is reversed by iontophoretic application of a GABA receptor antagonist[180] argues against this proposal. Instead, it appears that the stimulation in STN may activate fibers that cause the release of GABA into the SNpr.[180,307,308] These fibers could be striatonigral, pallidonigral, and/or collaterals of the SNpr GABAergic neurons themselves.

Interactions with the Frontal Cortex

An effect on SNpr may not be the only mechanism by which STN stimulation in the rat can suppress seizures. Usui et al.[277] found that *unilateral* stimulation of STN was effective in preventing the recruitment of frontal cortex into the electroencephalographic seizure discharge induced by systemic KA in rats, even though this treatment was ineffective in reducing the total seizure duration or the incidence of seizure discharge recorded from hippocampus (which was actually increased by the STN stimulation). This contrasts sharply with the more robust anticonvulsant effects observed with bilateral STN stimulation.[161,292] Because inhibition of SN must be bilateral to achieve an anticonvulsant action, it is likely that the unilateral stimulation of STN influences the seizure discharge in the frontal cortex through a mechanism not mediated by SN. In fact, in the same study, Usui et al.[277] found unilateral high-frequency stimulation in the SNpr to be ineffective, in agreement with previous observations[281] and in contrast to the anticonvulsant actions of bilateral stimulation in the SNpr.[281]

Antidromic activation of corticosubthalamic axons is one mechanism that can explain a seizure-suppressing effect of unilateral STN stimulation. It is possible that recruitment of the frontal cortex into the seizure discharge pattern was impeded by antidromic activation of STN afferent fibers coming from the frontal cortex.[179] Disruption of the activity pattern in these frontosubthalmic neurons may make it more difficult to generate hypersynchronous discharge in the frontal cortex. In support of a relationship between seizure activity in the frontal cortex and discharge in the ipsilateral STN, Dinner et al.[68] found that the activity recorded from depth electrodes in the STN mirrored both scalp EEG seizures and interictal sharp waves in patients with predominantly frontal-onset refractory epilepsy. The STN activity was consistantly lateralized to the hemisphere with the seizure activity and typically occurred after a short delay.

Deep Brain Stimulation

The success in the application of deep brain stimulation (DBS) for therapy of Parkinson disease (PD) has raised hopes that DBS can also prove effective as a therapy for intractable epilepsy. Knowing that there are endogenous neural network mechanisms for resisting seizures, it makes sense to find ways to use DBS to activate these mechanisms. Conveniently, the same region that is most often the target for DBS in PDâ€"the STN[22,166]â€"is a promising candidate for DBS therapy in patients with epilepsy.[22,35,36,107,131,166,169,297] Although evidence for an anticonvulsant therapeutic benefit is mounting, the mechanisms responsible for DBS therapy remain elusive. Once assumed to act by inactivating the neurons in the location of the high-frequency stimulation, DBS is now recognized to activate fibers of passage and collateral projections, and even to antidromically activate afferent projections.[22,166,168]

Interestingly, inhibitory treatments in the SNpr are able to reverse the akinesia caused by a loss of striatal dopamine transmission,[210,253] much as inhibition in the SNpr is anticonvulsant.[105] Therefore, the use of DBS to directly or indirectly enhance inhibition in SN would be expected to benefit PD patients as well as epilepsy patients. Moreover, the induction of dyskinesias is associated with DBS in the human STN; this is consistent with the dyskinesias that are produced by treatment in nonhuman primates when intranigral muscimol is administered in doses that are anticonvulsant.[74,75,76,107]

The fact that anticonvulsant effects using DBS in humans can be achieved in some cases with unilateral stimulation of the STN, suggests that part of this effect may be mediated by the antidromic activation of corticosubthalamic fibers (see earlier discussion). Because bilateral inhibition of the SN is required to achieve anticonvulsant effects even with seizures evoked by focal unilateral stimulation,[74,76,170] unilateral STN stimulation may depend on direct effects of the STN stimulation on the homolateral cortex, as can be achieved by back-firing cortical afferents to STN.

Evidence in favor of a combination of actions contributing to the seizure attenuation achieved with DBS in the STN comes from studies in which unilateral and bilateral stimulation was examined. Chabardes et al.[35] reported on five patients, three of whom were substantially improved by DBS in the STN. One of these patients had only unilateral stimulation, while the other two had bilateral stimulation. In one of the patients, bilateral stimulation and unilateral stimulation were compared; seizures were attenuated in both conditions, but bilateral was clearly superior to unilateral. These preliminary observations suggest that by altering corticosubthalamic activity, unilateral DBS in STN may exert seizure control; however, this control is likely to be less efficacious than that mediated via the SNpr, as may be achieved by bilateral DBS in the STN. It is also likely that the relative effectiveness of these approaches in a given patient will depend on the nature of the seizure disorder being treated and the extent of frontal cortical involvement.

If an anticonvulsant action of STN stimulation is mediated by increasing inhibitory tone in the SNpr, it remains to be determined how this occurs. As discussed earlier, it is unlikely that the mechanism is via a DBS-induced depolarization block of neuronal activity in the STN. A more likely mechanism is that stimulation in the vicinity of the STN activates GABAergic afferents to the SNpr; these afferents arise from the striatum and external GP and have axons that travel through the vicinity of the STN. It is also conceivable that GABAergic collaterals of SNpr neurons may be activated by DBS in the STN or that there may be GABAergic projections from STN to SNpr (see next section). Evidence that DBS in the STN increases the release of GABA in the SN[180,307,308] supports the possibility that DBS can exert an anticonvulsant effect by enhancing GABA transmission in the SNpr.

By enhancing inhibition in the SNpr, DBS in the STN can cause disinhibition of neurons that are the targets of the GABAergic nigrotectal projections. This has been confirmed in the rat.[23] With acute high-frequency stimulation in the STN, increased firing was observed in the majority of cells in the deep layers of the superior colliculus.[23]

P.374

Superior Colliculus

The connections and functional interactions between the SN and the superior colliculus are particularly relevant to seizure regulation. This was first demonstrated by Garant and Gale,[113] in animals in which the superior colliculus was removed bilaterally. Removal of the intermediate/deep layers of the superior colliculus, which did not impair the expression of seizures induced by electroshock or systemic convulsants, eliminated the anticonvulsant action of GABA transmission in SN.[113] In contrast, the integrity of the nigrothalamic, nigrotegmental, and nigrostriatal pathways was not required for the nigral GABA-mediated anticonvulsant action.[113] The nigrotectal pa-thway was also demonstrated to be required for the control of nonconvulsive absence seizures in GAERS,[59] and lesions of the SC enhanced the response to amygdala-kindled seizures.[216]

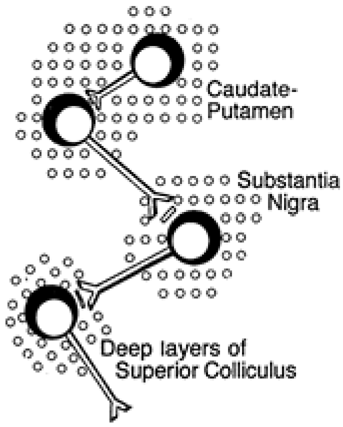

FIGURE 3. Serial inhibitory connections within the basal ganglia. All synapses shown are inhibitory and utilize GABA as their neurotransmitter. Although tonic excitatory inputs are not shown, they are present at each link in the circuit; therefore, the inhibitory terminals act to antagonize the influence of excitatory drive. When the neurons in the deep superior colliculus are *active* (*not* inhibited) enhanced *resistance* to seizure propagation results. Augmentation of GABA transmission in the SN exerts an anticonvulsant action by suppressing activity in the nigrocollicular GABA projections, thereby causing *disinhibition* (activation) of target neurons in the superior colliculus. *Blockade* of GABA transmission in caudate-putamen and superior colliculus has been demonstrated to exert anticonvulsant actions in experimental seizure models, consistent with the serial GABA interactions described.

Within the SN, inhibitory GABAergic transmission acts to suppress the activity of output projections to superior colliculus (Fig. 3). This relationship predicts that blockade of GABA transmission in the nigral projection target area of the superior colliculus should be anticonvulsant. Consistent with this expectation, blockade of GABA receptorâ€"mediated transmission in the intermediate and/or deep layers of superior colliculus is anticonvulsant against focally-evoked limbic motor seizures,[108] clonic and tonic convulsive seizures,[52] as well as against nonconvulsive spike-and-wave electrographic seizure discharge induced by pentylenetetrazol[52,108,241] or spontaneously occurring in GAERS.[56,218] Likewise, stimulation of glutamatergic transmission in the superior colliculus has also found to protect against seizures.[59] This illustrates a fundamental principle of central nervous system (CNS) organization: *disinhibition*. Inhibitory transmission within the SN acts to reduce the activity of the nigral outputs to the colliculus (which are themselves inhibitory), resulting in the withdrawal of inhibition, or disinhibition, of neuronal targets in the superior colliculus (see Fig. 3).

In detailed functional and anatomic mapping studies, Redgrave et al. identified a â€œdorsal midbrain anticonvulsant zoneâ€ (DMAZ), a region including the caudolateral intermediate/deep layers of the superior colliculus, the intercollicular nucleus, and the adjacent midbrain reticular formation. Connections between the substantia nigra pars lateralis and the adjacent peripeduncular area that project directly into this DMAZ suggest that the pars lateralis of the SN may be especially important in seizure regulation.[242]

Presently, it is not fully understood how neuronal activity within the superior colliculus acts to impede seizure progression. Some of the colliculus neurons that are activated by nigral disinhibition may be those that project to the brainstem reticular formation, where they relay with both ascending and descending neural pathways. Stimulation of certain regions of the reticular formation is capable of interfering with the development of a synchronized pattern of neuronal discharge in cortex.[267] By engaging these desynchronizing influences of the reticular formation, the superior colliculus can disrupt the generation of the synchronized neuronal bursting necessary for seizure development.

Pedunculopontine Nucleus

The pedunculopontine nucleus (PPN) is another major target of basal ganglia outflow[249] (see Fig. 1). As in the case of the superior colliculus, the PPN receives direct projections from the SNpr neurons,[249,278] and these projections have been demonstrated to be GABAergic.[41] In addition, the PPN receives direct projections from the entopeduncular nucleus.[249] Therefore, this region, like superior colliculus, may mediate the functional influence of basal ganglia structures.

Evidence for a crucial role of the PPN in the expression of nigra-evoked behavioral responses comes from studies in which the stereotyped sniffing and gnawing behavior evoked by intranigral muscimol was completely prevented by the micro-injection of muscimol into the PPN.[40,113] These observations are consistent with the concept that intranigral muscimol evokes stereotyped behaviors by inhibiting the GABAergic projections from the SN to PPN; maintaining GABA tone in PPN by the focal application of muscimol prevents this disinhibition. However, at the same time that muscimol in the PPN blocked the stereotyped behavior evoked by intranigral muscimol, it did not interfere with the anticonvulsant actions of intranigral muscimol against maximal electroshock tonic seizures.[113] This indicates that, whereas disinhibition of superior collicular neurons is crucial for nigra-evoked anticonvulsant effects, disinhibition of PPN neurons is not necessary for the anticonvulsant actions elicited from the SN.

Interestingly, in the pilocarpine-induced seizure model it appears that inhibition of PPN, by focal application of muscimol or antagonists of glutamate receptors, can exert an anticonvulsant action.[227] At first glance, this seems paradoxical, since GABA in the PPN would be expected to exert effects opposite to GABA in the SN. However, the PPN also sends afferent projections to the SN, and these appear to contain excitatory fibers.[251] Thus, inhibition of PPN neurons may also cause a reduction of excitatory input to the SN and thereby reduce seizure susceptibility. It may be relevant that pilocarpine seizures are especially sensitive to changes in glutamate transmission in the SN, as evidenced by the fact that they can be blocked by intranigral NMDA receptor antagonism and enhanced by intranigral application of NMDA[272] or depletion of GABA.[172]

Inhibition of the PPN does not protect against seizures induced by electroshock or systemic bicuculline, both of which are subject to nigral influence.[113,196] PTZ-induced seizures were unchanged[196] or enhanced by GABA agonists in the PPN and attenuated by bicuculline in the PPN.[222]

Basal Ganglia Species Differences: Rodent to Primate

Much of the functional neuroanatomy of seizure propagation and control in subcortical circuits comes from studies conducted in rat models. Although a few notable laboratories have conducted experimental epilepsy studies in cats and in nonhuman primates, only rarely are direct comparisons made to rats.

Consequently, the information derived from rodent studies cannot easily be compared to primate studies, especially because different questions are often asked. In cases in which comparisons have been made, it is clear that (a) the specific pharmacologic response profile within a given brain region can be strikingly different (and even opposite) between rat and monkey; (b) the anatomic routes via which partial seizures progress to become generalized are distinct for the rodent versus primate brain; and (c) the elaboration and topographic sorting of connections within a single nucleus, such as the SN, in the primate brain allows for rich intranuclear site specificity of far greater complexity than can be achieved (or evaluated) in the rat brain.

The most obvious difference between the progression of seizures in monkey and rat is the ease with which the focally evoked seizures become bilateral. In the rat, focally evoked partial forebrain seizures rapidly engage the hemisphere contralateral to the stimulation, mostly via commissural pathways such as those in the anterior commissure and hippocampus. Thus, in the rat, focally evoked seizures may appear bilaterally symmetrical from time of onset, as evidenced by both behavioral and cortical EEG manifestations. In contrast, in the monkey, seizure manifestations (behavioral and electrographic) stay lateralized (contralateral) longer and remain asymmetrical even as they progress to engage brainstem circuits. In fact, in the monkey, as in the human, the â€œpath of least resistanceâ€ is down the neuraxis rather than across the forebrain commissures. This is probably why the term â€œgeneralizedâ€ is used to describe seizure activity that is manifest bilaterally in the primate brain: By the time the participation of the contralateral hemisphere has been secured, it is well past the point at which the seizure networks in the midbrain and hindbrain have been recruited. In contrast, it is misleading to use bilaterality as a sufficient criterion for generalization in the rat, because partial complex seizures limited to the forebrain limbic networks are often bilateral in the absence of recruitment of brainstem seizure networks. These rat/primate differences have important implications for neural mechanisms of seizure control; compared with the rat, the primate brain may be more responsive to brainstem-evoked mechanisms of seizure protection.

Anatomically, the segregation of afferent/efferent connections according to a topographic scheme is more pronounced in the monkey SN than in the rat. This has implications for the functional impact of focal manipulations in the SN.[107] The reorganization of the functional interconnections within and between basal ganglia regions is a necessary consequence of the phylogenetic expansion and differentiation of the neocortex in the primate brain. As Beckstead and Frankfurter commented: â€œthe spatial relationships and morphological features of SNR's efferent cell populations exhibit a pattern in the monkey that does not compare well with that seen in the rat.â€[15] Thus, for example, in the rat there is great overlap in nigrotectal, nigrotegmental, and nigrothalamic projection cells, with as many as 50% of the cells projecting to both thalamus and tectum.[19,55] In contrast, little overlap in these projection cells exists in the monkey SN,[223] allowing for greater topographic discrimination of distinct outputs.

Important functional differences between the rat and the primate must also be considered when extrapolating between species. For example, the response to stimulation and blockade of GABA receptors in the monkey STN is not predicted by the neural circuitry model derived from studies in the rat. In the monkey, inhibition of the STN (using focal muscimol) was without effect,[75] whereas *blockade* of GABA inhibition in the STN by the focal application of bicuculline evoked dyskinetic and postural responses similar to those evoked by inhibition of the SN,[46,74,76] suggesting that unlike the rat STN, the monkey STN (or particular populations of neurons within the STN) may exert a net *inhibitory* influence on the SN (either directly or via projections to globus pallidus or pedunculopontine nucleus). In contrast, when applied to the SN, the same dose of bicuculline caused no dyskinetic movements but instead caused a *hypo*activity of the contralateral limb.[74,76] Thus, there is need for caution when attempting to generalize findings from the rat to the primate circuitry.

Ascending Monoaminergic Projections

Specific ascending projections from brainstem cell groups have been implicated in the regulation of seizure threshold. Best characterized in this regard are the noradrenergic projections arising from the locus coeruleus and the lateral tegmental area of the pontine tegmentum. Depletion of norepinephrine (NE) or lesions of the locus coeruleus usually causes a reduction in seizure threshold.[43,44,88,146,191] Most evidence suggests that a *deficiency* of NE increases susceptibility to a variety of seizure types. Accordingly, drugs that block CNS receptors for NE (Î±-receptors in particular) lower seizure threshold.[18,118,163] This is likely to account for the increased seizure susceptibility associated with the use of antipsychotic phenothiazines and related compounds. Depletion of NE does not in and of itself evoke seizures without a seizure-inducing stimulus; this is consistent with a modulatory or gating role of this system.

The increase in seizure susceptibility observed in animals with impaired NE transmission is not specific for seizure type. Potentiation of limbic motor seizures evoked by kindling[43] and exacerbation of explosive runningâ€"bouncing clonic and tonic convulsions evoked by focal or systemic chemoconvulsants[88,146] have been observed. Lesions of the locus coeruleus convert sporadic limbic seizures induced by bicuculline into limbic SE, suggesting that noradrenergic projections may serve to limit seizure duration.[128] Conversely, stimulation of the locus coeruleus can delay the onset of generalized seizures during kindling, an effect that is reversed by lesions of the dorsal NE bundle.[303] In addition, the suppression of kindling at one site by concurrent kindling of another site (kindling antagonism) may be mediated by release of NE.[6] Lesions of the locus coeruleus potentiated seizures evoked by kindling and maximal electroshock seizures, consistent with the NE modulation of both forebrain and brainstem seizures.[208,215] In fact, seizures evoked by acute stimulation of the inferior colliculus do not lead to tonic limb extension unless the NE projections originating in the locus coeruleus have been compromised.[31]

A genetically determined deficiency in NE contributes to the seizure susceptibility of GEPRs, and the degree of NE deficiency correlates with the severity of the audiogenic seizure response observed in different subsets of

GEPRs.[146] Conversely, drug-induced enhancement of NE transmission can protect the GEPR, as well as epileptic gerbils and seizure-susceptible mice, from seizures.[45,47,126,151] Paradoxically, the quaking mouse, which also has increased seizure susceptibility, appears to have an excess of NE neurons, and lesions that destroy NE neurons can reverse the seizure-prone phenotype of these mice.[181] Thus, the influence of the NE projections from the locus coeruleus may depend on the constellation of other neural abnormalities that coexist in the CNS of mutant strains.

Numerous brain regions may mediate the anticonvulsant influence of NE. Because the NE projections arising from the locus coeruleus diffusely innervate widespread regions of the telencephalon, multiple target regions are simultaneously regulated by this system; these targets include the entire limbic system circuitry as well as the thalamus and neocortex. In animals with lesions of the ascending NE projections, grafts of fetal NE neurons that innervate hippocampus reverse the increased susceptibility to limbic seizures caused by the lesions.[14] This effect is dependent on NE mechanisms,[163] and microdialysis studies have shown that hippocampal locus coeruleus grafts restore both basal and postconvulsive levels of NE to prelesional levels.[18] Thus, the hippocampus may be one site at which the ascending NE system may act to regulate seizure threshold (see Fig. 2A).

In addition to NE, 5HT-containing projections arise from brainstem cell groups and innervate virtually the entire central neuraxis. A defect in 5HT has been implicated in the seizure susceptibility of the GEPR, and pharmacologic evidence supports a role of 5HT in regulating seizure threshold. In particular, it has been observed that enhancement of 5HT transmission by inhibition of 5HT uptake (with fluoxetine) exerts anticonvulsant actions against explosive runningâ€"bouncing clonic convulsions and tonic convulsions[48] as well as limbic motor seizures.[236] One site of action of fluoxetine for exerting anticonvulsant effects appears to be the SN,[224,226] but in view of the extensive network of 5HT terminals throughout the brain, it is likely that additional sites of action will be identified in future studies.

In the SN, bilateral infusion of the dopamine D_1 agonist SKF-38393 potentiated pilocarpine seizures.[276] In specific subregions of striatum, the D_1/D_2 receptor agonist apomorphine was found to have anticonvulsant effects.[276] More detailed investigation suggested that D_2 agonists are anticonvulsant, whereas D_1 agonists are proconvulsant for pilocarpine seizures.[2] Lesions of ascending dopaminergic projections have been found not to significantly alter seizure threshold or severity.[44]

Cholinergic Pathways: Reticular Formation and Thalamus

The lateral dorsal tegmental nucleus of the reticular formation appears to modulate seizures via two pathways (see Fig. 2B). The cholinergic projection from lateral dorsal tegmental nucleus to the central median nucleus of the thalamus inhibits myoclonic and tonic convulsions, whereas a second ill-defined pathway may facilitate tonic seizures.[201] Substrates within the reticular formation may also explain the association between seizures and levels of arousal, because certain seizures will only occur during sleep,[195] whereas others occur during quiet wakefulness or drowsiness.[49,262] The role of the midbrain reticular formation as a crucial structure for driving the secondary generalization of seizures has been confirmed for seizures evoked unilaterally from the amygdala, hippocampus, thalamus, and visual cortex.[96,265]

Pharmacologic manipulations of the central median nucleus of the thalamus produce coupled changes in arousal states and seizure threshold, with increased arousal occurring in association with decreased seizure susceptibility.[195,196,197,198,199] Injection of either muscarinic cholinergic antagonists or GABA agonists directly into the central median thalamus depressed arousal and facilitated limbic motor seizure responses (myoclonus, facial, and forelimb clonus). This inhibition in the central median thalamus was accompanied by local suppression of neuronal activity and low-amplitude slow activity on the cortical EEG. Injections of GABA agonists into the lateral dorsal tegmental nucleus also produced a suppression of arousal and facilitated limbic motor seizure responses elicited by bicuculline or PTZ.[196] These studies suggest that a cholinergic projection from the lateral dorsal tegmental nucleus regulates both arousal and seizure susceptibility via muscarinic receptors in the central median thalamus, and that this projection and its targets are under the inhibitory control of GABA. Interestingly, the effects of inhibition of this pathway on forebrain (limbic) clonic seizure manifestations were separable from and often opposed to the effects on tonic convulsions.[196,197,199,200]

Vagal Pathways

Vagal nerve stimulation (VNS) was first used in animal models of seizures, such as those induced by electroshock,[309] and was then applied to refractory epilepsy and psychiatric depression in humans.[17,119,178] To date, VNS has been used safely for prolonged periods in over 15,000 patients worldwide.[119] VNS is indicated in the treatment of Lennox-Gastaut syndrome,[93,119,175,252] and its antiepileptic efficacy may persist for several months.[54] The effectiveness of VNS therapy increases over time of chronic treatment, and in some patients the response to VNS therapy may not appear until after a delay.[257] VNS has been shown to attenuate seizures in a variety of animal models, with the notable exception of absence seizures: VNS has no seizure-suppressing effect on nonconvulsive SWDs in GAERS and even prolongs the duration of absence seizures when applied shortly after the onset of the SWD.[53]

The fact that stimulation of the afferent vagus has been found to have therapeutic impact in treating seizures in patients with epilepsy argues that brainstem circuits (which are the direct targets of afferent vagal nerve fibers) can regulate forebrain seizure susceptibility in the human brain. The influence of VNS on epileptic seizure generation is mediated via important relays within the brainstem. Stimulation of vagal afferents generates evoked potentials in the cerebral cortex, hippocampus, thalamus, and cerebellum, and modulates EEG activity and sleep states. According to the frequency of stimulation, afferent VNS can either synchronize [weak stimulation recruiting A (0.02â€“0.2 mA) and B fibers (0.04â€“0.6 mA)],[13] or desynchronize [high stimulation recruiting C fibers (0.4â€“1.2 mA)] in the EEG.[37,38] The latter pattern can suppress strychnine-induced EEG spikes.[248] High-frequency (50 Hz) VNS has also been found to block sleep spindle occurrence during slow-wave sleep in cats.[314] Stimulation of vagal C fibers at frequencies over 4 Hz attenuated both electroshock- and chemoconvulsant-induced seizures in rodents,[309] PTZ-induced seizures in dogs,[313] and focal motor seizures in monkeys.[165] However, activation of C fibers does not appear to be necessary for an anticonvulsant action, because seizures were still suppressed in rats in which C fibers were selectively destroyed,[156] and stimulation parameters that do not recruit C fibers are clinically effective for seizure suppression.[154]

VNS is currently used to treat medically intractable complex partial seizures. The effects of ascending VNS are relayed primarily via the nucleus of the solitary tract (NTS) and its broad connections to the mesencephalic and diencephalic reticular formation, as shown by c-Fos mapping[219] and pharmacologic[302] and lesion experiments.[155] Inhibition within the NTS[302] and NTS-inhibition during VNS may be the first step in conferring seizure resistance. This inhibition, along with that of other interconnected brainstem nuclei,[219] confirms their role as a gating mechanism to impede seizure organization.[105,302] The major ascending targets of the NTS projections are the parabrachial nucleus and the locus coeruleus, from which numerous pathways project into midbrain and forebrain structures. Lesions of the locus coeruleus nullify the anticonvulsant action of VNS, suggesting that this

P.377

structure is a key relay in the seizure gating network.[155] In addition, NTS raphe-mediated activation of 5HT transmission may contribute to the anticonvulsant effects of VNS.[27,147] Within the brainstem, vagal afferents terminate in the cuneate nucleus, dorsal motor nucleus of the vagus nerve, and area postrema, in addition to the NTS.

Among the forebrain regions that receive NTS projections, either directly or indirectly via brainstem or thalamic relays, are the insular cortex, lateral hypothalamic nucleus, diagonal band nucleus, medial septum, amygdala, and hippocampus.[33] Data from imaging studies using positron emission tomography (PET) and single photon emission computed tomography (SPECT) in human subjects demonstrated VNS-induced increases in synaptic activity in structures directly innervated by central vagal structures and areas that process somatosensory information. VNS also modulates synaptic activity in multiple limbic system structures bilaterally.[13,135] VNS-induced activation of the thalamus is correlated with a favorable clinical outcome,[164] consistent with the role of the thalamus as a generator and modulator of cerebral activity.[150,246]

Most recent studies seem to agree on the primary role of the locus coeruleus and noradrenergic transmission in the effects of VNS.[122] The inhibition of the NTS triggered by VNS leads to increased activity of locus coeruleus neurons. Acute VNS at low intensities that recruit A and B fibers results in a significant increase in the discharge rate of locus coeruleus neurons,[127] causing an efflux of noradrenaline in target regions such as the amygdala.[42,155] The efficacy of VNS requires the integrity of noradrenergic neurons in the locus coeruleus, but the integrity of the latter nucleus in just one hemisphere is sufficient to maintain the anticonvulsant activity of VNS.[155] In addition to enhancing noradrenergic transmission, VNS has been shown to increase GABA levels in the cerebrospinal fluid.[17] Moreover, $GABA_A$ receptor density in the hippocampus was found to be increased in epileptic patients treated chronically with VNS, and this change was preferentially observed in responsive patients as compared with controls and nonresponders.[177] Thus, changes in $GABA_A$ receptor density may also contribute to the seizure attenuating effects of VNS; this topic has been reviewed.[128]

Cerebellum

Neurophysiological and 2-deoxyglucose studies have shown the cerebellum to be electrically and metabolically active during experimental seizure models, including focal and systemic penicillin, PTZ, and maximal electroshock seizures.[9,143,203] The cerebellum appears to have opposing effects on forebrain versus brainstem seizures. Lesions of the cerebellum *facilitate* seizures evoked focally from forebrain regions, including neocortex, and *inhibit* tonic convulsive seizures.[230,237] However, because lesions are accompanied by retrograde neuronal damage, the effects of these cerebellar lesions cannot be assumed to be due to the removal of cerebellum alone. Cooling of the cerebellum has also been shown to reversibly enhance spontaneous and sensory-evoked epileptic discharge.[70,174]

Stimulation of the cerebellum inhibits forebrain seizures while potentiating brainstem convulsions. Microinjection of high doses of picrotoxin (2 mg), a GABA antagonist, into the fastigial nucleus of the cerebellum has been reported to induce brainstem-related wild running and tonic convulsions.[50] On the other hand, electrical stimulation of the cerebellar cortex or deep cerebellar nuclei inhibits forebrain-evoked seizure induction.[9,70,143] This is consistent with the facilitatory effects of cerebellectomy on seizures evoked from the forebrain. Thus it appears that activity in cerebellar circuitry can dampen seizure susceptibility in the forebrain; this control may be mediated via relays in thalamus or via an influence on the monoaminergic projections ascending from the pontine tegmentum.

Thalamus

The thalamic nuclei are principal relay sites for both subcortical and cortical projection systems. Within the thalamus, ascending projections from the reticular formation and other brainstem cell groups impinge on pathways radiating to numerous forebrain structures, including those of the neocortex, basal ganglia, and limbic system. The role of the brainstem lateral dorsal tegmental nucleus and its projections to the thalamus was discussed in the section on cholinergic projections. At the same time, neural inputs from diverse telencephalic regions converge on thalamic nuclei from which projections descend onto brainstem neurons.[148] Accordingly, the thalamus represents a critical link in the transfer of information between cortical and subcortical structures, and between the periphery and the cortex. It is therefore reasonable to expect thalamic nuclei to be capable of regulating seizure susceptibility and influencing seizure propagation.[195]

The mediodorsal nucleus (MD) of the thalamus is a central component of the network supporting limbic seizure propagation. Blockade of excitatory transmission mediated by glutamate in the MD has been found to block systemically and focally evoked limbic motor seizures.[32,228] Moreover, MD exhibits marked increases in glucose utilization during limbic motor seizures[101,190,304] and undergoes degenerative changes following limbic SE in experimental animals[78,255,264,273] and in humans with prolonged hemiconvulsions.[211] The prominent connectivity between the MD and major limbic system regions including amygdala, hippocampus, and piriform and perirhinal cortex, as well as its connections to/from prefrontal cortex is likely to account for the pivotal position of the MD in the limbic seizure network.

Over the last several decades, the thalamus has figured prominently in the investigation of neural substrates for generating the bilaterally synchronous spike-and-wave rhythmic discharge characteristic of petit mal, nonconvulsive epileptic seizures.[89,90,123,294,305] These studies have generally provided convincing support for a crucial role of thalamic nuclei in the genesis of the 3-Hz SWD. Unilateral chemical stimulation of the ventral posterior lateral nucleus of the thalamus with kainate caused bilateral electrical disturbances within 2 hours, followed by the onset of nonconvulsive seizures at 3 to 4 hours. Interestingly, in this model, the convulsions spread bilaterally by passing via the midbrain reticular formation.[8] Glutamatergic projections from the superior colliculus to the parafascicular thalamic nucleus may be responsible for the control of absence seizures in GAERS. Disinhibition of these neurons could lead to seizure suppression and may be involved in the nigral control of this type of epilepsy.[217] Please refer to Chapter 31 for a more detailed discussion of thalamocortical substrates associated with nonconvulsive spike-and-wave seizure activity.[124,295]

The convulsive seizure paradigm used most extensively for examining thalamic involvement is the PTZ-induced model in rats. Metabolic mapping studies have shown that the neural projections from the mammillary bodies of the hypothalamus to the anterior thalamus exhibit especially pronounced increases in activity during the PTZ-induced seizures.[204] Lesions of this mammillothalamic pathway abolished both behavioral and electrographic expression of pentylene tetrazol seizures, as did focal microinjection of drugs that enhanced GABA transmission in the anterior thalamus.[204,205,207]

Studies using drug application to restricted regions of the thalamus indicated that direct stimulation of GABA receptors (using muscimol) in the dorsal midline thalamus (central median in particular) facilitated the clonic, but not the tonic, seizures induced by systemic administration of PTZ[202] and bicuculline.[198] Conversely, blockade of GABA receptors

in the central medial nucleus appeared to suppress the clonic seizures induced by pentylene tetrazol while at the same time facilitating the tonic convulsions.[197] These observations suggest that ascending influences from the central medial thalamic neurons exert a seizure-suppressing action in the forebrain, whereas descending projections from this region promote susceptibility to the tonic convulsions evoked from the brainstem. On the other hand in the ventromedial thalamus, enhancement or blockade of GABA-mediated neurotransmission was without an effect on either clonic or tonic seizures.[115]

Developmental Considerations

The immature brain has been shown to be more susceptible to seizures than the mature brain, so it is not surprising that human seizure disorders often begin during childhood.[213] In the juvenile preweaning rat, tonicâ€"clonic brainstem seizures are the hallmark manifestation in many experimental seizure models, such as those induced by chemoconvulsants.[283] It appears that the brainstem seizure circuitry matures earlier or has a lower threshold than the forebrain circuitry in young rat pups. In part, this may reflect the underdevelopment of substrates for suppression of seizure propagation in these animals. Accordingly, progression of seizure generalization during forebrain kindling is especially rapid in developing animals, and the seizures readily progress into the tonicâ€"clonic seizures of brainstem origin.[129] This is in marked contrast to adult rats, in which brainstem seizures are atypical, occurring only after hundreds of forebrain kindling stimulations.[234]

As a reflection of the reorganization of networks during development, the pattern of seizure-induced metabolic activation of the basal ganglia is age-dependent.[232] In adult rats, the SNpr consistently shows striking hypermetabolic activity during a variety of seizures.[3,16,167,221,231,287] On the other hand, during early postnatal development in the rat, the SN shows no changes in glucose metabolism regardless of seizure severity.[1,3,258] This suggests that the immature SN is not engaged by the seizure network and therefore may be less effective for seizure control as compared with its role in the mature brain. Before the third postnatal week, NMDA application into the striatum does not exert an anticonvulsant effect, despite robust NMDA receptor activation in the striatum during the early developmental period.[188] This may reflect an inability of the striatonigral pathways to recruit seizure-protective mechanisms in the SN. Thus, the gating role of the SN may not come into full swing before 21 days of age in the rat.[288]

Microinfusion studies of drugs in the SNpr have revealed an age-dependent pharmacologic profile.[259,260,311,312] For example, in the developing SNpr, instead of having anticonvulsant effects, $GABA_A$ activation by intranigral muscimol has proconvulsant effects.[260,288] This may be a result of one or more immature features of SN neurons in the pups: $GABA_A$ receptor subunit composition,[286] amount of GABA in the nigral neurons,[239] expression of the neuronal specific potassium chloride cotransporter KCC2,[97] electrophysiological properties of the SNpr GABAergic neurons,[158] or neuronal network connectivity.[214,282] However, the elevation of endogenous GABA in the SNpr protects against seizures in rat pups as it does in adults, indicating that altered receptor-specific mechanisms are responsible for the lack of muscimol-induced seizure protection in the immature SN. In fact it appears that $GABA_B$-mediated transmission in the SNpr control seizure during development, whereas $GABA_A$ â€“mediated transmission serves this purpose in the mature SN.[261,285] In 2-week-old rat pups, intra-nigral baclofen, a $GABA_B$ receptor agonist, is anticonvulsant, whereas this effect is not evident in the adult SN.[261] The relatively greater expression of $GABA_B$ receptor binding in the immature SNpr as compared to adults[114] may explain the shift in sensitivity to specific agonists. Because brain development is markedly influenced by sex hormones,[125,189] it is not surprising that the development of the seizure-controlling network in the SNpr is also influenced by exposure to testosterone and its metabolites.[98,239,240,280,282,288] The hormonal regulation of the development of this system may contribute to sex-specific differences in seizure susceptibility.

Disruption of NE innervation in immature rats has been associated with an increased rate of kindling, as has been seen in adults.[153] However, after forebrain NE lesions, the immature brain is prone to exhibit a reactive sprouting of NE innervation into the cerebellum and pons in the rat pups. When this occurs, a marked depletion of forebrain NE may have little or no impact on kindling rate.[153]

Age-specific expression of some epileptic syndromes, such as infantile spasms, probably reflects unique features of the networks in the immature brain. The possibility that the spasms may represent motor manifestations of basal ganglia outputs associated with attempts of the nigral circuitry to contain the seizure propagation, is worthy of consideration. A strong expression of a tonic phase during infantile spasms suggests involvement of brainstem in this devastating epileptic disorder.[142] Indeed, a variety of brainstem abnormalities has been found in patients with infantile spasms.[209,212,250] Maturational delays of cortico-subcortical circuits resulting in a failure of cortical regulation of the brainstem structures has been suggested as a possible pathologic substrate for infantile spasms.[160]

Summary and Conclusions

Preclinical and clinical experience dictates that the efficacy of a given therapeutic intervention depends on the type of seizure being treated. As additional therapeutic strategies develop, further refinements in distinctions between seizure types are likely to emerge. Because distinct neural circuitry underlies the epileptogenesis of different seizure types, it stands to reason that therapeutic interventions directed at specific circuitry can selectively affect the particular types of seizures that depend on that circuitry. On the other hand, therapeutic interventions directed at neural circuitry involved in â€œgatingâ€ mechanisms, such as those found in the basal ganglia, can modify susceptibility to multiple types of seizures. Thus, for example, inhibition of substantia nigra outputs can suppress tonicâ€“clonic as well as limbic motor seizures, whereas activation of cerebellar circuits reduces susceptibility to forebrain-evoked clonic seizures but enhances susceptibility to tonic extensor seizures. Vagal stimulation may represent one way of diffusely activating multiple brainstem seizureâ€“gating circuits.

Genetic or acquired predispositions to epilepsy may involve abnormalities that compromise the endogenous seizure-gating mechanisms. A better understanding of which mechanisms are compromised and which remain intact in a given seizure disorder will allow more precise and efficacious therapeutic interventions.

Systemically administered anticonvulsant drugs are likely to act on a series of mechanisms involved in the seizure-generating process. In recent years, GABAergic and glutamatergic mechanisms of seizure control have received the greatest focus. Considerations of the seizure-modulating influence of NE and serotonin projections may provide additional avenues for reducing seizure susceptibility. Multiple levels of drug action may be advantageous insofar as various anticonvulsant mechanisms may be additive or even synergistic. On the other hand, therapy that is â€œtargetedâ€ to modify a specific neural circuit may avoid many of the unwanted side effects associated with more widespread drug actions. Emerging advances in pharmacology, functional neuroanatomy, and DBS offer significant promise for such targeted approaches.

Chapter 33

Development of Cortical Excitability

Peter B. Crino

Introduction

In the human brain, cerebral cortical development spans approximately weeks 7 to 24 of gestation and proceeds from a primordial neural tube structure containing a seemingly unspecified pseudostratified ventricular zone (VZ) epithelium to a mature layered cortex containing virtually all of the necessary cellular elements required for a functional cortex in the behaving animal. The assembly of each cortical layer is a spatiotemporally regulated process in which a series of well-orchestrated molecular events culminate in the formation of a six-layered cytoarchitecture. During this time, many early structural connections will herald functional capabilities such as the formation of synaptic connections, expression of neurotransmitter receptor subunits or ion channels, generation of axon potentials, and, ultimately, electrical activity. Indeed, it is virtually axiomatic that the development of functional electrical excitability in the cortex is necessary for virtually all cortical activity in the mature animal. One consequence of the disruption of these functional attributes is altered cellular excitability and, potentially, epileptogenesis. Thus, understanding the developmental assembly of structural elements that result in normal cortical excitability can highlight possible mechanisms leading to seizures and epilepsy. Indeed, several well-defined epilepsy syndromes result from single gene defects that alter the appropriate temporal expression of a single neurotransmitter receptor subunit or ion channel. This chapter will address the development of cortical excitability as a function of structural alterations such as neuronal cytoarchitecture and pharmacologic changes including neurotransmitter receptor and ion channel expression.

Cortical Development: Structural Changes

Early Cortical Development: Overview

At each cortical developmental epoch, there is progressive assembly of cellular, subcellular, and pharmacologic machinery necessary for mature cortical function.[37] Thus, while cells in the VZ and early cortical plate are linked by nonsynaptic electrotonic coupling (e.g., gap junctions), following the establishment of cortical laminae, the formation of axodendritic synaptic connections and transcriptional expression of many neurotransmitter receptor subunits and voltage-gated ion channels permits synaptic transmission (Fig. 1). Concurrent with this process, additional cell types such as astrocytes and oligodendrocytes appear in the cortex and refine synaptic transmission. The ingrowth of afferent fibers from brainstem monoaminergic nuclei (e.g., the locus coeruleus and raphe complexes) as well as cholinergic input from the basal forebrain contribute to modulation of synaptic function. Perhaps most interesting is that the establishment of synaptic machinery does not end with birth but continues into postnatal periods. Thus, the development of normal cortical excitability spans embryonic and postnatal periods. The implications of this time course for epileptogenesis are profound since subtle or overt disruptions in either structural assembly or pharmacologic regulation can in theory lead to epileptogenesis.

Assembly of the Cerebral Cortex

Cortical development occurs in three broad stages: Proliferation, migration, and organization. Proliferation of progenitor cells that will populate the cortex occurs in two primary sources: (a) a single layer of mitotic progenitor cells in the VZ gives rise to most excitatory projection neurons (pyramidal cells[19]) and (b) progenitor cells in the ganglionic eminence give rise to most local circuit, inhibitory interneurons.[26,34] During the proliferative phases, radial glial cells serve as progenitor cells in the VZ of the neural tube and undergo active mitosis, giving rise to daughter progeny.[19] Cells destined for a specific cortical layer are born during similar and restricted developmental epochs. Mitotic progenitors express select genes such as intermediate filaments (nestin, vimentin), transcription factors (OTX-1, Emx1, Pax6, BF1/BF2, HES-1), and markers of active cell cycle phases such as proliferating cell nuclear antigen (PCNA) and cyclins (cyclin A, D1). Daughter progeny of progenitor cells either continue to divide or exit the cell cycle (become postmitotic) and differentiate into mature neurons. At this point, cell cycle G0, expression of many â€œembryonicâ€ genes is down-regulated and a new set of â€œmatureâ€ cellular genes are turned on as cells initiate migration and lamination.

The evolving cortical plate is formed between the marginal zone (the future layer I) above and subplate below.[34,35] During the migratory phase, differentiated daughter cells exit the VZ and move radially into the cortical plate along radial glial fibers in an inside-out gradient (i.e., neurons destined for deeper cortical layers [VI] exit the VZ first, followed in succession by waves of neurons destined for more superficial laminae [V to II[26]]). Progenitor cells deriving from the ganglionic eminences follow nonradial (tangential) paths to the cortex using trophic and other guidance signals.[42] Select genes are turned on (e.g., doublecortin) that regulate physical migration of individual cells.

During the organizational phases of cortical development, upon arrival into the appropriate cortical layer, neurons extend dendrites and axons and receive a variety of afferent inputs. At this time, synaptic connectivity is initiated. At the molecular level, new expression of many distinct genes including structural proteins necessary for dendrite and axon outgrowth and synapse formation permits the generation of nascent synapses in the late embryonic and early postnatal cortex. Finally, a substantial proportion of neurons within both the cortical plate and subplate undergo apoptosis.

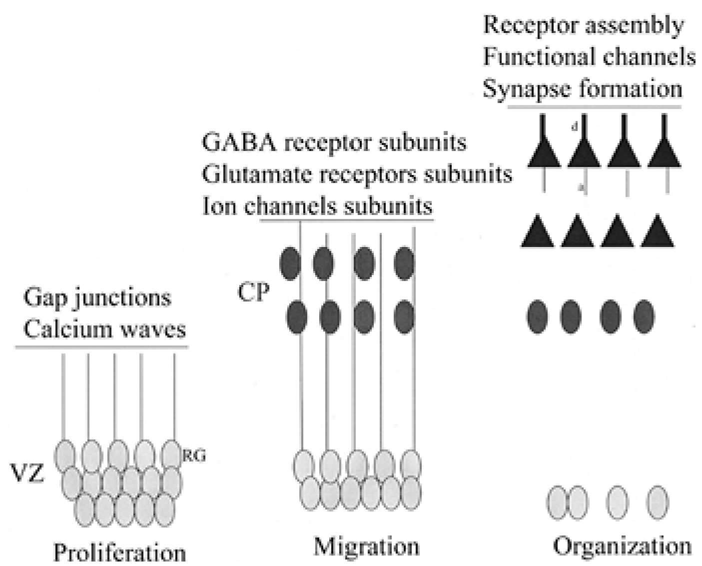

FIGURE 1. The structural assembly of the cerebral cortex during development leads to the establishment of cellular machinery necessary for normal cortical excitability. In early stages of cortical development (**left**), when cells are proliferating in the ventricular zone (VZ), electrical activity is mediated via gap junctions and through calcium waves that spread through the VZ. These electrotonic waves may be mediated largely by radial glial (RG) cells. During migratory phases (**middle**), the cortical plate is formed and there is early transcriptional expression of neurotransmitter receptor subunits and ion channels. At this stage, the establishment of resting membrane potential is a pivotal event that

heralds subsequent action potential generation. During organizational stages of development (**right**), migrating neurons have arrived in their appropriate laminar destination and have begun to extend axons (*a*) and dendrites (*d*). At this point synapses are formed, and there is coordinated expression and assembly of functional neurotransmitter receptor and ion channel subtypes. From this time forward, there are alterations in receptor subunit expression and composition as the brain moves from the late embryonic to early postnatal phases. GABA, Î³-aminobutyric acid.

In the earliest phases of cortical development, there is little spontaneous electrical activity and, in fact, the formation of synapses with subsequent synaptic transmitter release does not occur until later developmental epochs.[30,31] During migratory and early organizational phases of development, much of the structural machinery necessary for synaptic connections have not yet formed and other important components of synaptic function (i.e., glia) have not yet arrived in the cortical plate. In the VZ, there is electrotonic coupling between cells mediated largely by gap junctions.[28] Calcium waves spread selectively through the VZ, a region rich in radial glial cell bodies, and the majority of participating cells are radial glia.[40] Several investigators have demonstrated that calcium waves propagate through the proliferative zone of the embryonic cortex mediated via gap junction proteins (connexins) and intracellular calcium release.[40] In the rodent, VZ calcium waves become more robust from embryonic day 12 (E12) to E16 and coincide with increasing levels of neurogenesis. In addition to setting the stage for early electrical activity in cortex, calcium waves may be involved in modulating neurogenesis during embryonic cortical development. Thereafter, calcium waves abate in the postnatal brain and are replaced by synaptically mediated potentials in the nascent cortex.

Cajal-Retzius Cells

One exception to migratory schema of the embryonic cortex are Cajal-Retzius (CR) cells, which are present in the marginal zone before other neurons initiate migration from either the VZ or ganglionic eminences. CR cells represent a transient population of layer I cells present at early stages of cortical development that diminish during postnatal development.[24] The secreted protein reelin is released by CR cells and plays a pivotal role in permitting appropriate lamination. Layer I in the developing neocortex consists of CR and non-CR cells. Most non-CR cells are Î³-aminobutyric acid (GABA)-ergic, whereas CR cells are glutamate immunoreactive but not GABA immunoreactive.[24] CR cells also express parvalbumin and calbindin. CR cells are first observed in the preplate and later in the marginal zone. CR cells respond to various neurotransmitters and contribute to the synchronized network activity in layer I of the neocortex in which the apical dendrites of many deep and superficial layer pyramidal cells will arborize.[33] CR cells receive dense GABAergic and non-GABAergic input on cell body and dendrites.[20] CR cells express $GABA_A$ receptors and NR1/NR2B subunit-containing receptors.[33] Corticogenesis may depend on the early electrical activity of CR cells and, in fact, CR cells express functional Ca^{2+} channels. Recent calcium imaging analysis has shown that the developing layer I neurons exhibit correlated neuronal activity that could serve as the scaffold for the activity-dependent development of intracortical connections.[20]

Dendritic Development

Dendrites play a crucial role in synaptic signal integration, synaptic plasticity, and network connectivity.[32] Dendritic arborization on pyramidal and local circuit neurons occurs progressively beginning in late embryonic stages of development and extending well into the postnatal periods. Extension of dendritic arbors is a pivotal process for subsequent connectivity since synaptic connections between dendrites and incoming axonal afferents drives many of the functional properties of the mature cortex. Many dendrites of pyramidal neurons in deep layers arborize in layer IV, while some extend to more superficial layers. Pyramidal cell dendrites in layer III arborize in layer I. Thalamocortical afferents will make synaptic contact with dendrites in layer IV, while myriad other inputs will meet dendrites in layer I. The establishment of synaptic structure (see below) is in part driven by signals from incoming afferent fibers, and throughout life there is a high degree of structural and functional plasticity in axodendritic synapses. Several factors, both extrinsic and intrinsic to the neuron, are involved in the regulation of dendritic size. These factors include genetic control, electrochemical signals from incoming axons, and release of growth or trophic factors.

Synapse Formation

The generation of functional synapses in the cortex is critical for the development of cortical excitability, and a complete review of this topic is beyond the scope of any single chapter. In rodents, neocortical inhibitory synaptogenesis is a protracted process that begins in late embryonic life and matures through the first postnatal month. In man, synaptogenesis begins early prenatally and peaks a few months after birth. Perhaps the most striking physical feature of the developing cortex is the precision of its synaptic connections since these specifications herald cortical excitability.[17] In rodent, nascent synapses first appear in the late embryonic periods, but the numbers dramatically increase over early postnatal periods, coincident with the overwhelming flood of activity generated by activity and experience in the postnatal period. From a molecular perspective, the molecules governing synapse formation can be classified into at least two types: Synaptic recognition molecules that mediate

choices of appropriate synaptic partners and synaptic organizing molecules that regulate maturation and differentiation of the synapse. Thus, synapse formation is driven by internal cellular programs but also in response to activity-dependent cues from incoming axons.

As axons and dendrites meet, a complex set of mechanisms set the stage for functional connectivity.[32] From a structural perspective, the pre- and postsynaptic elements fuse to form the synaptic cleft. There is rapid expression of cytoskeletal and structural proteins (e.g., cadherins, neuroligins, and GAP-43) to solidify the axodendritic contact. Subsequent expression of synaptic vesicle proteins such as syaptophsyin, synaptotagmin, and synaptobrevin permits formation of presynaptic vesicles for neurotransmitter release, whereas expression of postsynaptic proteins such as dendritic postsynaptic protein 95 (PSD95) or gephyrin are necessary for neurotransmitter receptor subunit assembly into the cell membrane. Ultimately, expression and targeting of neurotransmitter receptor to the synaptic cleft will lead to the establishment of a functional synapse.

Cortical Development: Pharmacologic Changes

Over the course of late embryonic and early postnatal development progenitor cells migrate to form cortical layers and then extend axons and dendrites. Concurrent with these events, there is the appearance of multiple and distinct neurotransmitter receptor subunits and ion channels that mediate functional synaptic connectivity (Fig. 1). The major neurotransmitter systems include the glutamate and GABA systems, and the primary ion channels include calcium, sodium, and potassium channels. Of course, other molecules such as neuropeptides, neurohormones, and unique compounds such as adenosine and nitric oxide play important though not fully defined roles in the development of cortical excitability.

The Glutamate System

Glutamate is the primary excitatory neurotransmitter in the brain and its effects are mediated via two excitatory receptor subtypes: Inotropic and metabotropic receptors (see Chapter 22). The ionotropic glutamate receptor family can be further divided into the *N*-methyl-D-aspartate (NMDA) receptor (NMDAR) and the non-NMDA receptor (Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionate [AMPA] receptor [AMPAR] and kainate receptor) subfamilies. The NMDA, AMPA, and kainate subtypes are ligand-gated, cation-selective channels consisting of multiple protein subunits. The expression of these subunits, like GABA receptors, fluctuates during embryogenesis and early postnatal development. All of these subtypes exhibit enhanced expression from embryogenesis to early postnatal life. In the rodent, AMPA and NMDA receptors exhibit a peak in expression in early postnatal life but then diminish to a relatively constitutive level with further maturity. Glutamate receptors have been implicated in synaptogenesis, learning, and memory and likely are pivotal in the establishment of normal cortical excitability.

The NMDA receptor complex consists of two NR1 subunits (which have eight splice variants) and up to two of four NR2 subunits (NR2A to NR2D). Functional NMDARs are heteromeric complexes, permissive for calcium, and composed of at least one NR1 subunit and one or more NR2A to NR2D subunits, the presence of which modulates channel functional properties. The NR2 subunits confer distinct pharmacologic and kinetic properties on the receptor. The subunit composition of all ionotropic glutamate receptors changes during development and varies in different regions of the mature brain.[27] It is likely that particular NMDA receptor subunit combinations underlie different functions of the receptor and regulate synaptic plasticity during brain development.

In the rodent, ionotropic glutamate receptors undergo rapid maturational changes.[18,27] NMDAR density peaks late in the first postnatal week in many forebrain structures, including hippocampus and neocortex, whereas AMPAR density peaks in the second postnatal week at around postnatal day 10 (P10). Both NMDA receptor and AMPA receptor expression transiently peak above adult expression levels, resulting in heightened glutamate-mediated plasticity. The ratio of GluR2 expression to that of other AMPA receptor subunits is significantly lower in immature neocortex and hippocampus compared to the adult, and AMPA receptors that lack a GluR2 subunit exhibit higher Ca^{2+} permeability than those that contain GluR2. In the human, similar developmental changes in receptor subunit expression occur over a more protracted time course. Maturational regulation of glutamate receptor subunit composition enhances their ability to mediate activity-dependent synaptic plasticity in early postnatal life. The maturational regulation of AMPA receptor composition and function also enhances glutamate-mediated plasticity in early postnatal life.

Although many synapses express both AMPARs and NMDARs, some have only NMDARs. Synaptic responses mediated only by NMDARs are more prevalent earlier in development, and the subsequent developmental recruitment of AMPARs to synapses may involve an activity-dependent process. Shortly after birth, cortical neurons exhibit relatively large and long-duration NMDAR-mediated excitatory postsynaptic currents (EPSCs). However, during postnatal development, the decay kinetics of the NMDAR become faster, there is an increase in the expression of NR2A subunits, and there is a decline in the ability of the specific NR2B antagonist ifenprodil to inhibit NMDAR function, resulting in much shorter EPSCs.[1] These changes suggest a developmental progression in the composition of the NMDAR complex from predominantly NR1/NR2B to NR1/NR2A isoforms.

Of particular interest is that both AMPA and NMDA sites are expressed largely postsynaptically and are relatively more permeable to calcium during early development. In the developing brain, electrical activity guides the formation of synaptic connections, with long-term effects on adult brain function. Many connections are organized by selective stabilization of synapses when they are activated simultaneously on the same postsynaptic cell during a sensitive period in early life. This Hebbian process often involves calcium entry through the NMDARs. The magnitude of the calcium current passed by this receptor depends on its subunit composition, which varies with age and brain region. Receptor configurations that admit large calcium currents are permissive of synaptic plasticity, and in most regions of developing brain, activity that can drive NMDA receptors initially is low and increases with maturation. As developing inputs increase in number and strength, the increasing excitatory synaptic activity in young neurons should lead to increases in postsynaptic Ca^{2+} influx through NMDA receptors. This Ca^{2+} flux is postulated to trigger a feedback system that changes the subunit composition of the NMDA receptor complex so that less Ca^{2+} enters postsynaptic cells upon NMDA receptor activation. Changes in NMDA receptor effectiveness resulting from manipulations of activity are consistent with the idea that NMDA receptor function is under the control of activity. Thus, the transition from NMDA receptors that flux large calcium currents during early periods of synaptic organization to NMDA receptor subtypes that flux less calcium as synapses become more active, more effective, and less plastic allows maturing neurons to maintain optimal levels of intracellular calcium in the face of drastic developmental changes in their inputs. Experimental observations indicate that glutamate blockade in the rodent in the immediate perinatal

P.388

period can adversely affect synaptic and neuronal development. Disruption of NMDA receptor function during development interferes with synapse elimination and sensory map formation.

In the adult nervous system, glutamatergic neurotransmission is tightly controlled by neuronâ€“glia interactions through glial glutamate reuptake by the specific glutamate transporters GLT-1 and GLAST.[36] At birth, GLT is not detectable, but GLAST is present at significant concentrations both in the forebrain and in the cerebellum. GLT is first detected in the forebrain and cerebellum in the second and third week, respectively. Both transporters reach adult levels by postnatal week 5. In somatosensory cortex, GLT-1 and GLAST are early and selectively expressed from P5 to P10. Confocal and electron microscopy confirm that the expression is restricted to the astroglial membrane. The regional distributions of both GLAST and GLT in the tissue are similar in young and adult rats, although GLT is the predominant transporter in the adult brain.[36]

The GABA System

GABA is the main inhibitory neurotransmitter in the brain, and it modulates neuronal excitability, plasticity, and network synchronization (see Chapter 23). GABAergic neurons are found in all cortical layers and account for nearly 30% of all cortical neurons.[4] Most neocortical GABAergic cells are aspiny nonpyramidal neurons whose axon terminals form symmetric synapses. Several factors are involved in GABA's postsynaptic effects: Presynaptic factors (release), factors acting at the synaptic cleft (diffusion and selective transporters), and postsynaptic factors (receptor subtypes, location, number). The inhibitory action of GABA results from interactions with the GABA$_A$ and GABA$_B$ postsynaptic receptor subtypes. These heteromeric protein complexes gate chloride ions and are widely expressed in the developing and mature brain. The GABA$_A$ site is a pentomeric complex composed of five protein subunits (e.g., Î±, Î², Î³, in multiple combinations). The GABA$_B$ site is a G-proteinâ€“coupled metabotropic receptor also composed of multiple protein subunits that is expressed primarily in the hippocampus, thalamus, and cerebellum.

There are spatiotemporal expression patterns of GABA$_A$ receptors.[5,38] Proliferating precursor cells in the neocortical VZ express GABA$_A$ receptors, as do immature postmigratory neurons in the developing cortical plate. In situ hybridization studies have shown that the transcripts for GABA$_A$ receptor Î±3, Î±4, Î²1, Î²3, Î³1, and Î³2 subunits are expressed in the VZ and embryonic cortex. Cells in the VZ may express mRNAs for GABA$_A$ receptor Î±4, Î²1, and Î³1 subunits at the premigratory stage, just after completing cell division. GABA$_A$ receptors in the VZ have a higher apparent affinity for GABA and are relatively insensitive to receptor desensitization compared with neurons in the cortical plate. GABA$_A$ receptors on VZ cells are not activated synaptically, suggesting that these receptors are activated in a paracrine fashion.[28,29] In fact, GABA-induced current magnitude increases with maturation with the smallest responses found in recordings from precursor cells in the VZ. After neurons are born and migrate to the cortical plate, they begin to demonstrate spontaneous synaptic activity, the majority of which is GABA$_A$ mediated. Expression of Î±1 and Î³2 subunits increase from birth through adulthood in the cortex.

Temporal regulation of GABA$_A$ subunit composition may account for the differences in function of GABAergic transmission in the immature and mature brain.[5,28] In early postnatal development, GABA binding to GABA receptors leads to membrane depolarization and at times to cellular excitation.[35] In contrast, in maturity, GABA exerts an inhibitory effect via an influx of chloride. These important functional differences are related also to distinct mechanisms (e.g., low expression of the chloride transporter KCC2) for chloride buffering the developing brain.[22] Uptake of Cl^- by the Na^+-K^+-$2Cl^-$ cotransporter isoform 1 (NKCC1) has been shown to be pivotal for depolarizing GABA$_A$ receptorâ€“mediated responses in various types of immature neurons.[43] The ontogenetic shift to hyperpolarizing GABA action is caused by a concomitant developmental down-regulation of NKCC1 and an up-regulation of the K^+-Cl^- cotransporter isoform 2 (KCC2). Recent studies demonstrate that NKCC1 can facilitate seizures in the developing brain.[10] In the embryonic cortex, there are high intracellular concentrations of chloride and thus, when GABA receptors are activated, chloride flows out of neurons, leading to depolarization. The net effect of temporal alterations in GABA$_A$ receptor subunit composition in the cortex and hippocampus is the development of more rapid receptor:substrate interaction kinetics and enhanced sensitivity to Î±1 agonists like zolpidem.

Similar differences in expression of the GABA$_B$ site may have functional relevance.[11] In the rodent, presynaptic expression of GABA$_{B1a}$ sites is dominant at birth but then declines by 2 weeks of age. Expression of the postsynaptic GABA$_{B1b}$ site rises from immaturity to adulthood. In addition to its role in synaptic modulation and inhibition, it appears that the GABA$_B$ site may contribute to the structural assembly of the cortex and in particular to migration of inhibitory neurons form the ganglionic eminence. Virtually all neurons migrating through the lower intermediate zone from the medial ganglionic eminence to the cortical plate express GABA$_B$ receptors (GABA$_B$Rs). Blockade of GABA$_B$Rs results in an accumulation of tangentially migrating neurons within the ventricular/subventricular zones of the cortex. Thus, GABA$_B$Rs have an important modulatory role in the migration of cortical interneurons.

GABA-mediated inhibition exerts a powerful control over cortical neuronal activity, and GABA transport contributes to modulate GABA's action.

At the synaptic cleft, high-affinity plasma membrane GABA transporters (GATs) in association with variable

$GABA_A$ receptor subunit composition appear to modulate phasic (synaptic) and tonic (extrasynaptic) GABA-mediated inhibition.[16] Phasic inhibition reflects intermittent inhibitory postsynaptic potentials (IPSCs) and tonic inhibition plays a central role in controlling neuronal and network excitability. Four cDNAs encoding highly homologous GATs (GAT-1, GAT-2, GAT-3, and BGT-1) have been isolated in the rodent and human nervous system.[9] These sites exhibit different ionic dependencies and inhibitor sensitivities, and are differentially distributed within the cortex. GAT-1 and GAT-3 have the most relevance for cortical excitability. In the rodent, GAT-1 mRNA and protein first appear at late embryonic stages and their expression increases in the first 2 postnatal weeks. The mature pattern of expression is reached by P30.[9] Most GAT-1 expression is within axon terminals, some of which form symmetric synaptic contacts with dendrites or with somata in the early phases of development. In human temporal cortex, GAT-1 expression appears in the marginal zone by gestational week 33, and is then identified in all layers by weeks 38 to 39. GAT-3 expression appears in the marginal and intermediate zones of the cerebral cortex in late embryonic life. Colocalization studies have demonstrated GAT-3 expression in astrocytes and GABAergic neurons.

GAT-1 and GAT-3 expression follows the same pattern as inhibitory synaptogenesis, suggesting a role for GABA transport in the formation and maturation of cortical GABAergic synapses by P30. GAT-1 and GAT-3 may modulate GABA concentration in the vicinity of nascent synapses. GABA itself regulates the expression and functional properties of $GABA_A$ receptors and chloride transporter KCC2, whose appearance correlates with the onset of GABA's inhibitory action. Local

P.389

GABA transport may contribute to the maturation of GABAergic synapses and indeed, in both rodent and human cortical development, GAT-1 expression is coordinated with that of other GABAergic presynaptic proteins (i.e., the synthesizing enzyme GAD65 and the vesicular transporter VGAT) and parallels that of the Î±1 subunit of the $GABA_A$ receptor, which participates in mature GABAergic transmission (see, for example, reference 9).

Ion Channels

Cortical pyramidal neurons are considered to be less excitable in the immature cortex than in adults. One explanation for this finding is that in addition to immaturity of functional synapses, embryonic and early postnatal cortical neurons lack the full complement of ion channel subunits necessary to initiate or propagate a viable action potential.[31] The gradual appearance of sodium (Na), calcium (Ca), and potassium (K) channels in cortical neurons coincides with the expression of neurotransmitter receptor subunits and culminates in functional maturity of the cortex. Indeed, the excitability of neurons depends largely on the movement of ions through specific membrane channels. Ion channels have been extensively investigated by means of voltage clamp recording techniques, whereas the effect of ion currents on cell membrane potential have been studied by means of single-unit current clamp recordings.

In various studies of membrane properties of the embryonic rodent neocortex, proliferating populations have been found to primarily express voltage-gated K^+, Ca^{2+}-activated K^+, and small Na^+ conductances when input resistances are sufficient to permit detection of small currents. In acutely dissociated embryonic rat cortical cells, two cell subpopulations with distinct estimated resting membrane potentials have been identified during the period of cell proliferation (E11 to E13): One at approximately -70 mV and the other at approximately -40 mV. Analysis of these two subpopulations revealed that >80% of the latter cells were in proliferative phases of the cell cycle, whereas >90% of the former cells were in postmitotic phases. Na^+ currents then increase throughout development as cells begin to migrate and differentiate. In addition, changing levels of expression of L-type, low- and high-voltageâ€"activated (LVA and HVA) Ca^{2+} currents as well as voltage-gated inactivating (IA) and delayed rectifier K^+ currents occur during both embryonic and postnatal development.

Cells in the developing cerebral cortex generate activity as early as E18, and both Na^+ and outward K^+ currents can be modulated by increasing activity. In acute slices of mouse cerebral cortex, several changes in physiologic properties occur from embryonic day 14 to postnatal day 17.[7] For example, inward $Na(^+)$ current density is up-regulated, while outward $K(^+)$ current density remains almost unchanged, input resistance drops, and a hyperpolarization-activated current appears. As a result of these changes, the action potential becomes larger and shorter in duration, and the threshold shifts to more negative potentials.[7] There is a dynamic development of resting membrane potential, with concomitant expression of K^+ channels and voltage-dependent Na^+ channels in the developing cortex as it transforms from proliferative to postmitotic cell types.[18,19] In addition, new cells arriving in the cortical plate become capable of firing repetitively and generating spontaneous action potentials.

Voltage-dependent sodium channels are responsible for the initiation and propagation of the action potential in most excitable cells, and neuronal action potentials are predominantly sodium dependent during embryonic and early postnatal ages.[6,23] The heterocomplex structure of these ion channels consists of a highly glycosylated Î± subunit, which is noncovalently associated with disulfide-linked Î²1 and Î²2 subunits. Furthermore, multiple isoforms of the *a* subunit have been identified, giving rise to the notation of Na^+ channels I, II, and III, which individually contain single Î± subunits and the Î²1 and Î²2 subunits. The expression of each Na^+ channel has been well documented in the brain and is differentially regulated depending on age, region, and cell type.[2,6,14] For example, Na channel I expression was virtually absent at E18. The expression of sodium channel I mRNA rises after a lag phase to adult levels during the second and third postnatal weeks, with stronger increases in caudal regions of the brain and in spinal cord. In the adult brain, expression of Na channel I was nearly absent in the neocortex. Sodium channel II mRNA increases steadily until the first postnatal week, keeping high adult levels in rostral regions of the brain or reaching low adult levels after the second postnatal week in most caudal regions of the brain and in the spinal cord. In comparison with types I and III, sodium channel II mRNA was the most abundant subtype at all developmental stages. Sodium channel III was mainly expressed at the embryonic stage and showed a decrease to very low levels with little regional preferences in the adult. Sodium channel III mRNA attains maximum levels around birth and decreases during the first and second postnatal weeks to reach variable low adult levels.

At least four distinct sodium channels, named NaV1.1, NaV1.2, NaV1.3, and NaV1.6, have been found, which exhibit different patterns of expression during development. In rat brain, at E15 the mRNA of NaV1.2 and NaV1.3 channels are predominant and are coexpressed at approximately equal levels. At postnatal stages all four Na^+ channel mRNAs were detected, but to different extents in the various brain regions. In cortex, at early postnatal stages (P1 to P7) the predominant one was NaV1.2 mRNA, and at late postnatal stages the predominant one was NaV1.6 mRNA.[2,6,14]

Calcium channels also exhibit a spatiotemporal pattern of expression regulation.[39] For example, the developmental expression of the L-type voltage-gated Ca($^{2+}$) channel is dynamic.[25] Using the Î±1C subunit of this channel as a marker, there is progressive increase in expression in layer V to VI pyramidal neurons from P4 onward, and in layer II to III pyramids by P9 onward. Prior to this time there is sparse expression in the L-type Ca channel in embryonic cortex. The Î³ subunit of voltage-dependent Ca^{2+} channels (VDCCs) is characterized by molecular diversity and regulation of AMPA-type glutamate receptors as well as VDCCs. The expression of the VDCC Î³1 to 8 subunit mRNAs is distinct in developing in adult mouse brains. In embryonic brains there are well-preserved spatial patterns of select subunits (e.g., Î³2, Î³5, Î³7, and Î³8), while other subunits exhibit developmental up- (Î³3) or down-regulation (Î³4). The Î³1 and Î³6 subunit mRNAs were negative or very low throughout brain development, while in adult brains, the Î³3 and Î³8 subunit mRNAs were maximal in the telencephalon and hippocampus. The developmental changes in expression of intracellular calcium release channels are dynamic. mRNA encoding the intracellular calcium release channels (e.g., inositol triphosphate receptors [IP3R] and the ryanodine receptors [RyR]) was detected in developing cortex by embryonic day 11. Expression of these proteins increases progressively throughout brain development.[12] Therefore, the spatiotemporal diversity in gene expression for individual Ca channels subunits likely reflects the functional diversity of these proteins.

K^+ channels play a critical role in limiting neuronal excitability, and mutations in specific voltage-gated K^+ channels have been associated with hyperexcitable phenotypes in both humans and animals. Using an antibody recognizing the C-terminus of the KCNQ2 channel, a progressive increase in expression in the cortex was observed from postnatal day 8 onward and gradually increased between P11 and P21. In the mouse cortex, an increasing number of KCNQ3-labeled

P.390

neurons during development showed intense somatic staining beginning with P21 and leading to its maximum at P31. Colabeling with a parvalbumin antibody revealed KCNQ3N immunoreactivity in both parvalbumin-positive and -negative neurons. Expression of the KvÎ² subunit is not detected until the first postnatal week in hippocampal and cortical pyramidal cells.[12]

While the expression profiles of each ion channel subunit are variable across brain regions and through each developmental epoch, by contrast, cortical astrocytes do not show significant regional differences in their ion channel complement and essentially all astrocytes express a combination of delayed rectifying outward $K^{(+)}$ currents, transient A-type $K^{(+)}$ currents, and small $Na^{(+)}$ currents.[3] Developmentally, an increasing percentage of astrocytes express inwardly rectifying $K^{(+)}$ currents. In fact, all astrocytes contain voltage-gated ion channels that display a common pattern of expression during development.

The Development of Cortical Excitability and the Relationship to Epilepsy

As outlined above, the development of neuronal circuits in the neocortex during embryogenesis and postnatal periods is dependent on numerous coordinated processes including generation of appropriate neuronal connections, precise synapse formation, axon outgrowth, dendritic arborization, and experience and activity-dependent cues.[30] There are numerous genetic, molecular, or structural abnormalities occurring in these time epochs that can lead to dramatic dysregulation of these tightly integrated circuits. Abnormal or enhanced cortical excitability may be a consequence of these alterations and result in aberrant neuronal firing, establishment of abnormal connections, and seizures. The events leading to altered cortical excitability may have subtle effects on cortical cytoarchitecture or be dramatic abnormalities in brain structure. For example, at least ten monogenic epilepsy syndromes have been reported that result from mutations in select Na, Ca, or K channel genes. These gene mutations do not significantly alter cortical organization or structure but clearly have dramatic effects on cortical neuronal excitability. Indeed, targeted gene knockouts of select ion channels (Ca, Na, or K) leads to hyperexcitability and epilepsy but little structural disorganization. Even more interesting is that there is a temporal dimension to seizures in select channelopathies (e.g., K^+ channel mutations and benign familial neonatal seizures) that perhaps belie a critical period for altered excitability. In contrast, mutations in select genes that lead to malformations of cortical development (e.g., lissencephaly, hemimegalencephaly) are highly associated with intractable epilepsy. In each of these disorders, the *sine qua non* anatomic feature is a loss of normal cortical cytoarchitecture. How these structural changes lead to altered excitability is not fully understood, and it is unlikely that enhanced excitability reflects only the effects of the gene mutation. In these disorders, altered cytoarchitecture likely disrupts normal synaptic connectivity or, for example, mechanisms of inhibition in the cortex. For example, knockout of the dlx gene, a homeodomain transcription factor necessary for the production of forebrain GABAergic interneurons, leads to a reduction in inhibitory interneurons in cortex, a reduction of GABA-mediated inhibitory postsynaptic current in neocortex, and generalized electrographic seizures.[8] Thus, alterations in cortical excitability may reflect numerous mechanisms at the molecular, pharmacologic, and anatomic levels. The implications of these distinctions may have significance for the future development of targeted drug therapies that affect, for example, particular molecules in brain regions at particular time epochs.

Summary and Conclusions

The development of cortical excitability is a spatiotemporally regulated process that begins in the early phases of corticogenesis and extends well into the postnatal period. The establishment of appropriate cortical layers and, ultimately, synaptic connectivity are required for the maturation of cortical excitability. There are temporal expression gradients for gap junctions, neurotransmitter receptor subunits, uptake sites, and ion channels in the cortex that permit synaptic transmission and action potential generation. While the expression of these proteins is governed to a large extent by developmental and molecular genetic programs, experiential stimuli can obviously modulate expression as well. The expression of select glutamate and GABA receptor subtypes plays a pivotal role in the appearance of neuronal excitability, as do ion channels. Not surprisingly, alterations in the timing or integrity of how these proteins assemble or localize in neurons can have dramatic effects on cortical excitability that culminate clinically in seizures. Indeed, understanding the mechanisms through which aberrant excitatory activity can be propagated through the cortex has important therapeutic implications in epilepsy research.

The establishment of cortical excitability is a requisite process necessary for learning, sensory perception, movement, and virtually all forms of behavior. Enhancement of cortical excitability or loss of regulatory mechanisms to inhibit or dampen aberrant excitability may be pivotal mechanisms in the generation and propagation of seizures.

Chapter 34

Early Events in the Development of the Cerebral Cortex

Volney L. Sheen

Christopher A. Walsh

Introduction

There is an increasing awareness that many epileptic conditions, particularly in the pediatric age group, are associated with developmental abnormalities of the cerebral cortex. This chapter provides an overview of normal development of the cortex. The developmental description is intended to provide a context for understanding the function of genes which, when disrupted, have been shown to give rise to these malformations of cortical development (MCD). Although the genetic causes and potential mechanisms leading to the MCD are discussed, a more thorough discussion of the pathology of epilepsy is presented in several other chapters.

The cerebral cortex must undergo a series of fundamental developmental processes to create the underlying neuronal scaffolding that is responsible for the cortical organization underlying complex cognitive functions. The development of the enormous diversity of cells of the nervous system spans a series of crucial events, from (a) the division and expansion of neural precursor populations, to (b) the migration of these neurons out of the ventricular zone (VZ) into the cortical plate, and followed by (c) the differentiation of neurons into the various neuronal subpopulations that make up the six-layered cortex.[1,40] Disruption of each of these processes has been suggested to give rise to a distinct set of human disorders of cortical development. Disorders of proliferation lead to microcephaly (â€œsmall brainâ€), disorders of initial migration give rise to periventricular heterotopia (ectopic nodules of neurons located along the lateral ventricles), disorders of subsequent migration contribute to classical lissencephaly (â€œsmooth brainâ€) and subcortical band heterotopia (referring to an additional layer of neurons beneath the cortex), disorders in neuronal arrest giving rise to cobblestone lissencephaly (smooth brain with ectopic nodules of neurons on the surface of the brain), and disorders in neuronal differentiation giving rise to potential abnormal cell connectivity.[73] Many of the genes responsible for these disorders have been identified. Moreover, such genes provide an initial foundation with which to understand the normal cellular and molecular mechanisms involved in the development of the cerebral cortex and, ultimately, the mechanisms responsible for some pediatric epilepsies.

Formation of the Mammalian Central Nervous System

Neurogenesis

The oldest neurons in the human cortex appear very soon after the regional definition of the cerebral cortex, at about 33 to 42 days postovulation.[54,62] The earliest neurons derive from an epithelium that is originally pseudostratified, in which the neuroepithelial cells have attachments to both the inner, ventricular face and the outer, pial surface. The early neural progenitor cells show a characteristic nuclear movement as the cells progress through the cell cycle: Neurons in the mitotic (M) phase have their nuclei immediately lining the ependymal zone, but as the cells move into synthesis (S)-phase, when they replicate their DNA, their nuclei translocate away from the ventricular lining (growth [G] 1phase). Cells then transition from S to the growth (G) 2phase, at which time their nuclei translocate back toward the ventricular surface and into M-phase. Finally, the nuclei of precursors, which re-enter the cell cycle, move back toward the upper half of the epithelium and away from the ventricular lining during G1 phase (Fig. 1A,B). Although the majority of neurons appear to derive from the ventricular lining, a second proliferative region develops just adjacent to the epithelium, called the *subventricular zone*. Neurons are generated along the neuroepithelial lining of the ventricular zone and indirectly from intermediate progenitor cells that reside in this region.[61]

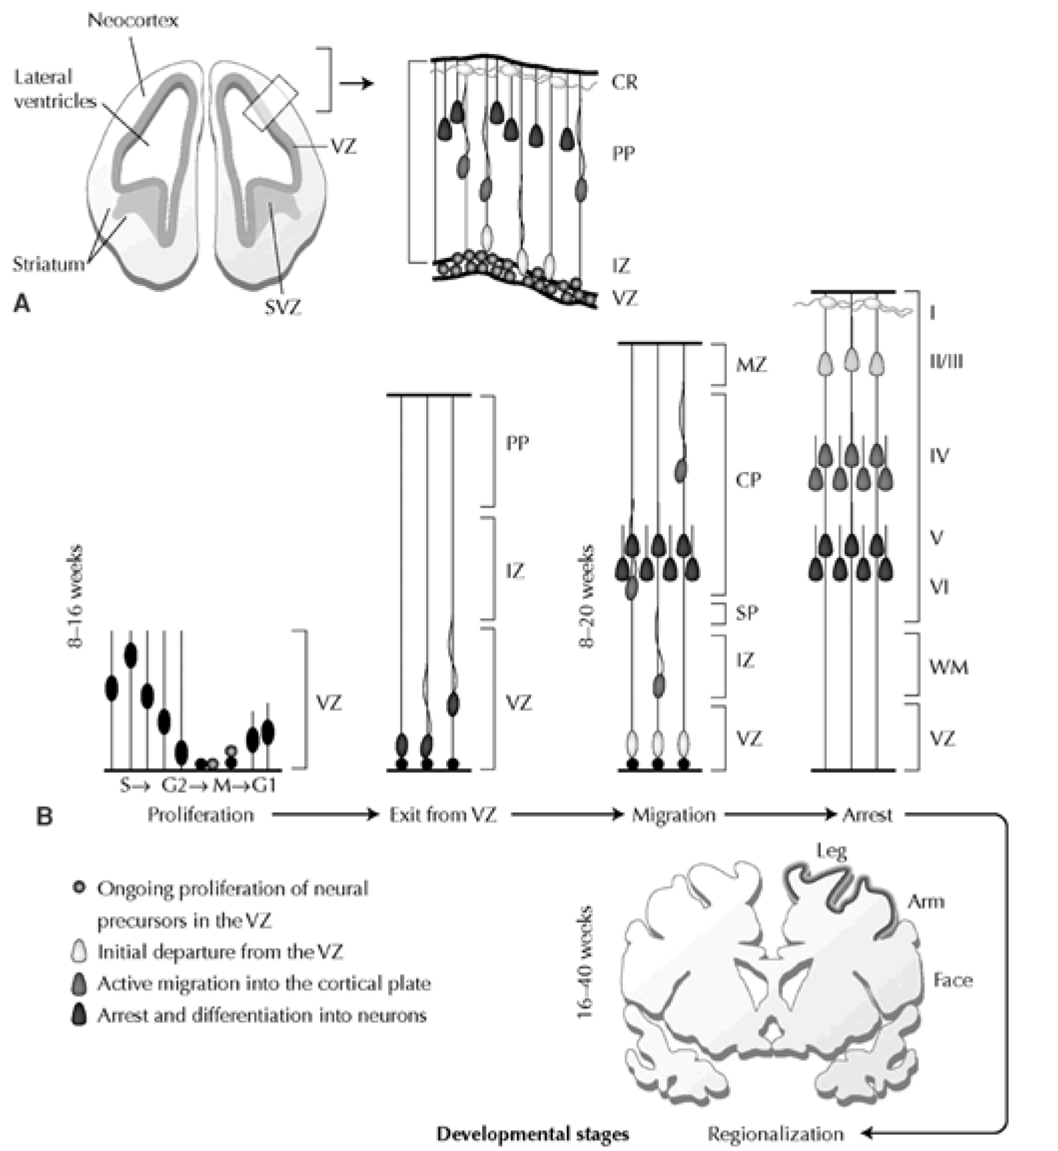

FIGURE 1. Diagram of the sequential developmental stages of the cerebral cortex. **A:** General anatomic overview of the developing cerebral cortex. Higher-magnification diagram (*right*) of inset (*left*) illustrates ongoing proliferation of neural precursors in the VZ (*circles*), initial departure from the VZ (*light gray*), active migration into the cortical plate (*dark gray*), and subsequent arrest and differentiation into neurons (*black*). **B:** Temporal progression of human cerebral cortical development. During the first 8 to 16 weeks of development, neural progenitors undergo proliferation, with the period of neuronal migration extending over 8 to 20 weeks. By 16 to 40 weeks, regional specification, with clear formation of sulci and gyri, is apparent. Earlier-formed neurons (*black*) become situated in deeper cortical layers (V to VI), with later-formed neurons (*light gray*) positioned more superficially in layers II to III. CP, cortical plate; CR, Cajal-Retzius cells; IZ, intermediate zone; MZ, marginal zone; PP, preplate; SP, subplate; SVZ, subventricular zone; VZ, ventricular zone. Revised with permission from Sheen VL, Walsh CA. Developmental genetic malformations of the cerebral cortex. *Curr Neurol Neurosci Rep.* 2003;(3):433â€“441.

During neural proliferation, precursors undergoing cell division in M-phase either remain as progenitors or adopt a neuronal cell fate. The neural progenitors split into two cells along a cleavage plane that is either vertical (perpendicular to the ependymal lining) or horizontal (parallel to the ependymal lining). Vertical cleavages produce identical daughter cells that resemble the original neural precursors. These symmetric divisions appear to expand or maintain the progenitor pool, because both daughter progenitors re-enter the cell cycle and their nuclei translate away from the lining during G1 phase. In contrast, horizontally dividing cells produce two types of daughter cellsâ€"one that behaves like a young migratory neuron and another that remains within the proliferative zone as a neural precursor and re-enters the cell cycle. These asymmetric divisions appear to give rise to the postmitotic neurons that will comprise the overlying cerebral cortex.[18]

Neuronal Migration

The six-layered adult cortex actually derives from three distinct populations of neurons with very different patterns of development. The oldest cortical neurons form a structure known as the *preplate* or the *primordial plexiform layer.*[52] When the earliest formed neurons of the preplate complete their final mitosis to become postmitotic, they do not actually migrate from where they are formed; instead, they translocate their nuclei through one cellular process, then retract their processes and begin differentiation into neurons (Fig. 1B).[52,54] Later-formed neurons divide the preplate into two layers, called the *marginal zone* (future layer I) and the *subplate* (future deep neurons of layer VI and the white matter) (Fig. 1B). These later formed neurons do not migrate directly to the cortex but rather display a retrograde movement toward the ventricle while in the VZ/SVZ, before migration back out into the cortical plate

(Fig. 1B).[61] These neurons form the vast majority of all cortical neurons, including cells in layers VI through II, and form a third transient layer called the *cortical plate*. The cortical plate is first seen at about embryonic day (E) 52 in the human, almost 3 weeks after appearance of the preplate.[54] Studies in many different mammals have repeatedly shown that neurons within the cortical plate follow a remarkable and precise sequence of events when inserting into the preexisting preplate.[9,67] The oldest neurons of the cortical plate (future layer VI cells) cease migration nearest the subplate cells, whereas the next cohort of cortical neurons (future layer V) migrates just beyond the older layer VI cells to settle nearer the pial surface. Successive waves of cortical plate neurons then all follow the same â€œinside-outâ€ gradient of neurogenesis (Fig. 1B), with cortical neurogenesis and migration completed by about 24 weeks of embryonic development.[54] The cortical-plate neurons are formed at a later time and in the context of a larger brain than are the preplate cells; consequently, they must migrate for distances of up to millimetersâ€"equivalent to hundreds of times their cell body size. This long-distance migration appears to involve mechanisms distinct from those that operate during the formation of the preplate.

Although the neocortical excitatory neurons originate from the proliferative ventricular zone of the cortex, many of the inhibitory cortical interneurons actually appear to be derived from the germinal zone of the basal ganglia. Most of these cells derive from the medial ganglionic eminence, but may also arise from the caudal and lateral ganglionic eminences, the septal region, and the cortex itself. These interneurons follow a tangential migratory pathway from the ganglionic eminences to the cortex.[4,5,84]

Table 1 Cortical Malformations and Associated Gene Abnormalities

Gene	Phenotype	Possible Biological Role
ASPM	Microcephaly	Found in spindle poles during mitosis in proliferating brain cells

CDK5RAP2	Microcephaly	Found in centrosomes of neuroepithelial cells lining the brain
CENPJ	Microcephaly	Same as *CDK5RAP2*
Microcephalin	Microcephaly	Involved in cell cycle control and possibly in DNA repair
Filamin A	PH	Involved in regulation of actin cytoskeleton
ARFGEF2	PH	Involved in vesicle transport
LIS1	Type 1 lissencephaly	Involved in cell motility through interactions with dynein and doublecortin
DCX	Type 1 lis/ SBH	Same as *LIS1*
ARX	XLAG	Homeobox gene that activates multiple molecular pathways
Reelin	LCH	Secreted by Cajal-Retzius cells; likely extrinsic signal to migratory neuroblasts
VLDLR	LCH	Receptor on neuroblasts that interacts with Reelin
Fukutin	FCMD/ Type II lis	Involved in glycosylation of extracellular matrix proteins along the pial surface
POMGnT1	MEB/ Type II lis	Same as *Fukutin*
POMT1	WWS/Type II lis	Same as *Fukutin*
POMT2	WWS/Type II lis	Same as *Fukutin*
GPR56	BFPP	G-coupledâ€"protein expressed with neural progenitors

MeCP2	Rett syndrome	Regulates biochemical switches that control gene expression
CDKL5	Rett-like syndrome	Mediates MeCP2 phosphorylation
TSC1	TS	Tumor suppressor function
TSC2	TS	Tumor suppressor function
SCN1A,SCN2A, SCN1B, GABARG2	Generalized epilepsies with febrile seizures	Channelopathies
GABARA1	Juvenile myoclonic epilepsy	Channelopathies
KCNQ2, KCNQ3	Benign familial neonatal convulsions	Channelopathies
CLCN2	Idiopathic generalized epilepsy	Channelopathies

PH, periventricular heterotopiaâ€"type I lissencephaly is synonymous with classical lissencephaly; SBH, subcortical band heterotopia in femalesâ€"type II lissencephaly is synonymous with cobblestone lissencephaly; XLAG, X-linked lissencephaly with ambiguous genitalia; LCH, lissencephaly with cerebellar hypoplasia; FCMD, Fukuyama congenital muscular dystrophy; MEB, muscle eye brain disorder; WWS, Walker Warburg syndromeâ€"type II lissencephaly is synonymous with cobblestone lissencephaly; BFPP, bilateral frontal and parietal polymicrogyria; TS, tuberous sclerosis.

Neuronal Differentiation

Although cortical plate neurons are generated and mature gradually, the earlier formed preplate and subplate neurons achieve a high level of morphologic maturity at early cortical stages (E30â€"E50 in humans).[45] In animal models, early subplate cells have been shown to receive the earliest connections from outside the cortex (especially from the thalamus) and to form the earliest efferent connections from the cortex to subcortical sites.[3] Remarkably, the high level of morphologic and synaptic maturity achieved by the subplate is transient because these neurons regress, and most appear to die off as a normal morphogenetic process during later cortical development. The transience of the subplate has given rise to the theory that subplate cells are â€œpioneerâ€ neurons that are present to guide and direct later-formed definitive cortical connections. Thus, the regression and death of subplate connections may be a necessary, perhaps even obligatory, step in normal cortical development.[3]

P.395

Within the cerebral cortex, the progressive differentiation of a given neuron can be divided into sequential phases. Some of the steps in neuronal development include the initial neuronal specification while in the ventricular zone and several subsequent phases of postmigratory neuronal differentiation, including formation of an axon and dendrites, synthesis of synaptic machinery, and expression of ion channels. Simple invertebrate organisms with small nervous systems show specific genetic mutations that affect each sequential step in neuronal development, suggesting that the steps occur in a defined sequence.[21] Although, for any given neuron, these developmental steps occur in series; for the cortex as a whole, the developmental steps do not represent entirely separate steps because cortical neurons are also formed in sequence. Thus, the elaboration of neurites in the oldest cortical neurons overlaps in time with the specification of newer cells, and so on.

Despite the overlap in the formation of cortical neurons of different layers, cell biologic study of vertebrate cortical neurons suggests that each neuron undergoes a fairly predefined sequence of developmental steps. For example, neuronal precursors appear to receive information about the specific type of neuron they will become during their final cell division and before they migrate out of the proliferative region of the cortex. Previous transplantation studies have suggested that, once a postmitotic neuron has obtained a neuronal fate and commitment to form one particular cell type, it will carry out its developmental program and migrate to an appropriate cortical location, even if it is challenged by having to migrate through a novel cellular environment.[53] A number of transcription factors that are activated in a cortical progenitor will determine its cortical neuron phenotype and promote the repression of certain genetic sequences that would specify a different cell fate.[27] Once the neurons have obtained their laminar position, cortical pyramidal cells and interneurons make and receive efferent and afferent projections. These processes depend on the interplay between intrinsic transcriptional factors and extrinsic signaling, thereby establishing the appropriate topographic intercortical and intracortical connections and proper connectivity with the thalamus.[66]

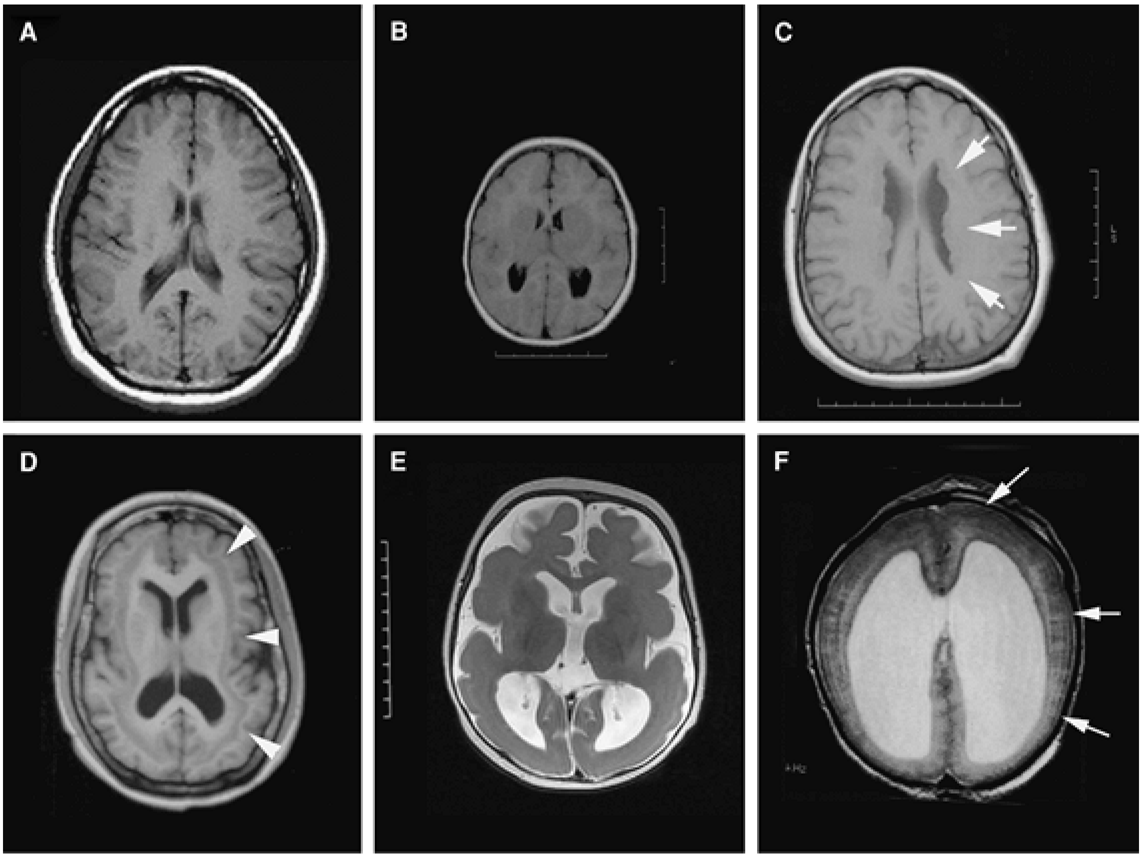

FIGURE 2. Genetically inherited malformations of cortical development. **A:** Axial T1-weighted MR image of a normal brain **B:** Microcephaly with simplified gyral pattern. The brain size is greater than two standard deviations below the norm. In microcephaly vera, the brain structures (cortical sulci and gyri, basal ganglia and fiber tracts) are normal in appearance but reduced in size. **C:** Periventricular

heterotopia due to *FLNA* mutation: The cortical layers are apparently normal, and intelligence is usually in the normal range. The heterotopia (*arrows*) consists of excessive numbers of neural cells, usually neurons, in the periventricular region. Because the periventricular region corresponds to the proliferative zones during development, the heterotopia presumably consists of neural cells that do not migrate out toward the cortex. **D:** Subcortical band heterotopia due to *DCX* mutation: The double-cortex syndrome is also known as *diffuse cortical dysplasia* and *subcortical laminar heterotopia*. In this disorder, the ependymal zone appears relatively normal, and heterotopic neurons (*arrowheads*) are found in great numbers in the subcortical white matter. The doublecortin gene that causes double cortex in females causes classical (type I) lissencephaly in males. **E:** Classical lissencephaly (*type I lissencephaly*) is characterized by the loss of the folds of the brain (sulci and gyri), an abnormally thick cortex, and loss in cortical lamination. In classical lissencephaly due to *LIS1* mutations, the spectrum of lissencephaly ranges from absent (agyria) or abnormally broad (pachygyria) convolutions. **F:** Cobblestone lissencephaly: Also termed type II lissencephaly, cobblestone lissencephaly consists of cobblestone cortex, abnormal white matter, and enlarged ventricles. A thin lining composed of ectopic neurons (*small arrows*), which have migrated beyond the superficial marginal zone, is seen on the surface of the brain. It is usually associated with eye malformations and congenital muscular dystrophy.

Malformations of Cortical Development

The complexity of proliferation, migration, and differentiation in the developing cortex make it hardly surprising that disruptions in these processes result in a number of neuropathologic disorders, including epilepsies (Table 1). Although malformations of the cortex are discussed in detail in Chapters 14 and 259, we present an overview of some genetically inherited

P.396

disorders to illustrate how our improved understanding of the basic biology of cortical development improves our insight into epileptic pathology.

Disruption of Neurogenesis

When the capacity to generate the numbers of cells needed by the developing cerebral cortex is impaired, not surprisingly, the human brain becomes microcephalic. Many genetic and nongenetic factors can result in a small brain. For example, congenital infection with toxoplasma, maternal alcohol overconsumption, as well as general disorders of cell metabolism or cholesterol synthesis can lead to a small brain. In general, however, disruption of such processes are readily apparent on examination and also affect various organ systems, leading to extra-central nervous system (CNS) manifestations.[58,63] For this reason, disorders that cause microcephaly vera (true microcephaly) have been used to more clearly delineate processes that directly affect cortical development. In such cases, the brain size is greater than two standard deviations below the norm (Fig. 2A vs. 2B). The disorder is associated with mental retardation, there is gross preservation of the brain structures (except on a smaller scale), and the disease occurs in the absence of findings outside the CNS.[57,58] Identification of the genes that cause macrocephaly vera indicates that some of them have direct relevance to neurogenesis.

Genes causal for microcephaly (*Microcephalin, ASPM*, *CDK5RAP2,* and *CENPJ*) have been suggested to play some role in neurogenesis along the ventricular neuroepithe- lium,[12,13,83] and appear to play direct roles in the mechanisms underlying cell division. *Microcephalin* is a gene that contains three BRCA1 domains that have been implicated in cell-cycle control and DNA repair.[39] Loss of DNA repair genes can lead

P.397

to increased programmed cell death, thereby suggesting that loss of *Microcephalin* function leads to increased cell loss along the ventricular neuroepithelium. More recent studies have suggested two potential roles for Microcephalin protein: One in the control of cell-cycle timing and the other in the control of DNA repair (following ionizing radiation damage).[78,85] *ASPM* (abnormal spindle-like, microcephaly-associated) is a gene that encodes a very large protein. In *Drosophila*, *ASPM* is essential for normal mitotic spindle function in embryonic neuro- blasts by stabilizing the tubulin ring complexes that organize the centrosomes.[22] CDK5RAP2 and CENPJ are also centrosomal proteins, localized to the centrosomes in interphase and to the spindle poles during mitosis.[13,38]

Although mental retardation has been a uniform feature seen in microcephaly vera,[83] seizures have not been included in the primary clinical phenotype, despite the high prevalence of epilepsy in microcephaly patients. More recent findings, however, have shown that mutations in *ASPM* can lead to epilepsy in some affected individuals. Seizures have onset at 2 to 3 years of age, and they appear focal in onset. EEGs demonstrate a generalized slowing interspersed with occasional Rolandic or central spike activity.[75] In other patients with macrocephaly, severe disruption of the gyral pattern and neuronal architecture occurs, and these conditions (known as macrocephaly with simplified gyri) are generally associated with early-onset seizures and early death; genes for these syndromes have not been identified yet.

Disruption of Migration

Malformations of cortical development that result from altered neuronal migration can best be appreciated by looking at the progressive stages of migration: The initial departure of neuroblasts from the ventricular zone, the motility required of neurons to migrate into the cortical plate, and the stop signals informing a neuron that it has reached its appropriate layer. Failure of neurons to exit from the VZ presumably gives rise to periventricular heterotopia (Fig. 2C), a malformation characterized by nodules of ectopic neurons lining the lateral ventricles.[28,42] Neurons that have delayed or impaired migration cause lissencephaly (Fig. 2E), a malformation characterized by the loss of sulci and gyri, as well as a thickened four (rather than the normal six) -layered cerebral cortex.[8,24] Disrupted migration in a subpopulation of neurons leads to subcortical band heterotopia (SBH) (Fig. 2D), a malformation characterized by heterotopic neurons positioned midway between the gyrencephalic cortex and underlying ventricular zone.[23,35] Failure of neurons to receive signals directing them to the appropriate layer can result in lissencephaly with cerebellar hypoplasia, a malformation characterized by an inverted cortex, whereby earlier-formed neurons form the superficial layers and later-formed neurons make up the deeper layers.[37] Failure of neurons to stop migration can lead to cobblestone lissencephaly (Fig. 2F), a malformation characterized by neurons that have migrated beyond the superficial marginal zone.[10,44,80,87] In each of these disorders, a failure in the mechanisms that guide migration at specific stages leads to distinct malformations of cortical development.

Neurons that fail to exit the ventricular zone during development cause periventricular heterotopia (PH). PH is characterized by continuous, bilaterally symmetric nodules of neurons, which are distributed throughout the ependymal layer and beneath an otherwise normal appearing cerebral cortex.[23] Dominant mutations in the X-linked gene *Filamin A* (*FLNA*) have been shown to result in periventricular heterotopia in females and lethality in hemizygous males.[28,70] Filamin A exists as a homodimer with a receptor and actin-binding region. Thus, the protein is believed to transduce signals from its receptor interactors onto interactions with the actin cytoskeleton, thereby regulating cell motility.[19,33] More recent studies have shown that a much rarer cause of PH with microcephaly is due to autosomal recessive mutations in the *ARFGEF2* gene.[71] *ARFGEF2* encodes an ADP-ribosylation factor (ARF) guanine exchange factor that converts guanosine diphosphate (GDP) to guanosine triphosphate (GTP), and thereby activates the ARFs. The ARFs have been implicated in vesicle transport. Although the shared mechanisms between these two genes (*FLNA* and *ARFGEF2*) are not clear, insights have been gained from studying features common to the function and expression of both genes. Namely, both BIG2 (the protein encoded by *ARFGEF2*) and filamin A are highly restricted to the ependymal lining along the ventricular zone; disruption of both genes leads to a loss in cell adhesion (with filamin A probably acting through the filaminâ€"integrin interactions, and with the guanine exchange factor (GEF) acting via impaired transport of cell adhesion molecules to the cell surface).[50,71] The overlying cortex in PH appears largely normal in both males and females,[42] suggesting that many neurons actually migrate normally into the cortex. Thus, PH may reflect a disorder of the ependymal lining in which a loss of cell adhesion may lead to a loss in neuroepithelial integrity. Alternatively, an interruption in the ependyma may disrupt the radial glial endfeet that are localized to the ventricular lining, and thereby alter the initial attachment of migratory neuroblasts onto the radial glial scaffolding.[49,74]

As neurons exit the VZ, impairments in cell motility may impede their migration into the cortical plate and cause classical lissencephaly. Classical lissencephaly (type I lissencephaly) is characterized by the loss of the folds of the brain (i.e., of sulci and gyri), an abnormally thick cortex, and loss in cortical lamination. Dominant mutations in the autosomal *Lissencephaly1*(*LIS1)* gene have been shown to cause classical lissencephaly.[48,56,68] Mutations in the X-linked *Doublecortin (DCX)* gene also cause this disorder in hemizygous males, but lead to subcortical band heterotopia in heterozygous females.[20,30] In affected females with subcortical band heterotopia, neurons are partially arrested in their migration, residing as a poorly organized layer of neurons within the white matter and beneath a relatively normal cortex. Several lines of evidence suggest that both genes (*LIS1* and *DCX*) are involved in neuronal motility. *LIS1* interactions with both dynein and doublecortin support some role in cell motility.[25,60] Moreover, neurons harboring a heterozygous *LIS1* mutation show altered dynein localization and reduced cell motility.[25] One role for DCX in neuronal migration may be through its ability to polymerize microtubules.[31] Inhibition of DCX also appears to delay or inhibit neuronal migration in rats.[6] Due to X-inactivation, neurons presumably harboring the normal DCX protein migrate into the cortex, whereas neurons harboring the abnormal DCX protein are inappropriately positioned under the normal layers of cortex.[2] Finally, a recent human case of subcortical band heterotopia was shown to involve a mosaic mutation in the *LIS1* gene, in which only some (but not all) of the cells harbored a mutation.[76] The observation that a mosaic *LIS1* mutation could result in SBH is consistent with a cell-autonomous process such as motility in giving rise to both types of cortical malformations.

Although a loss in the intrinsic capacity of neurons to migrate into the cortex can lead to lissencephaly, extrinsic molecular signals and cellular interactions are also necessary to direct neuronal migration into the cortex. Mutations in the *Reelin* gene can lead to a milder form of lissencephaly with cerebellar hypoplasia (LCH).[37] Interestingly, the causative mutation in this disorder was first described in mice that demonstrated an ataxic (reeling) gait likely secondary to the absent cerebellar folia.[16] Reelin is secreted by the Cajal Retzius cells located in the marginal zone near the surface of the brain. Presumably, Reelin provides some extrinsic signal to migratory neuroblasts. In

P.398

addition, Reelin interacts with the veryâ€"low-density lipoprotein receptor (VLDLR), apolipoprotein E receptor (ApoER)-2, integrins, and protocadherins, indicating that Reelin has some role in cell signaling and adhesion. Mice with mutations in *VLDLR* or *ApoER2* also share similar features with the reeler mice, including inversion of cortical layers and absence of cerebellar foliation.[37,79] Humans with *VLDLR* gene mutations have recently also been found to have LCH.[15] Although these interactors are known, the exact mechanisms leading to the disturbed migratory pattern remain unclear.

Disruption of the neuroepithelium along the lateral ventricles leading to PH mirrors the loss of structural integrity along the pial surface of the brain in giving rise to cobblestone lissencephaly (type II lissencephaly).[59,80,86] The autosomal recessive cobblestone lissencephalies have a gradient of severity ranging from the milder Fukuyama congenital muscular dystrophy (FCMD) that affects primarily the Japanese population, to the moderate Finnish muscle eye brain disorder (MEB), and to the most severe Walker Warburg syndrome (WWS) that leads generally to early postnatal lethality. In cobblestone lissencephaly, neurons have no inherent motility defect, but rather migrate beyond the marginal zone into the leptomeninges and through the external basement membrane during cortical development. The loss in integrity of the molecular layer leads to nodules of neurons, or heterotopia, on the surface of the brain (resembling cobblestones). Four genes have been associated with cobblestone lissencephaly (*fukutin* for FCMD, *POMGnT1* for MEB, and *POMT1* and *POMT2* for WWS)[10,44,80,87]; all are implicated in the glycosylation of the dystroglycans. Hypoglycosylation of dystroglycan abolishes binding activity for such ligands as laminin, neurexin and agrin, and thereby compromises the integrity of the dystrophin-associated extracellular matrix adhesion complex.[55] Loss of adhesion in the extracellular matrix results in a weakening of the structural integrity of the marginal zone (layer I) of the cortex, allowing migratory neurons to â€œovermigrateâ€ beyond this structural barrier onto the pial surface. Thus, the heterotopia seen along the lateral ventricles in PH reflects a similar process seen in the neuronal cobblestones seen on the outer brain surface in type II lissencephaly.

The severity of the neurologic deficits (including epilepsy) associated with these migration abnormalities appears to correspond with the severity of the neuronal migratory defect in these cortical malformations. In PH, ectopic neurons reside along the lateral ventricle with relative preservation of the overlying cortex. These heterotopic neurons do appear to extend projections, and they show some limited connectivity to other brain regions.[34] PH caused by mutations in the X-linked *FLNA* gene results in adolescent-onset seizures (up to 88% of affected individuals), which are generally not intractable and respond well to antiepileptic medications.[33,70] Consistent with the largely normal appearing cerebral cortex, affected individuals are of normal intelligence, although they may have some component of dyslexia.[17] When associated with *ARFGEF2* mutations, the onset of epilepsy in PH occurs in the early postnatal period, and infants show developmental delay and mental retardation. This increased severity of neurologic symptoms may, in part, arise from the added findings of microcephaly and delayed myelination observed in these individuals. Electroencephalographic (EEG) investigations demonstrate slowing or dysrhythmia with occasional spike and slow-wave discharges.[71,72] In SBH, the ectopic neurons reside in the white matter just beneath the cortex, suggesting a more severe malformation in cortical development. Affected individuals exhibit seizures of multiple types that usually begin in childhood and can be of varying severity and frequency.[7,23] The thickness of the ectopic band and the degree of pachygyria correlate with the likelihood of developing Lennox-Gastaut syndrome.[33] The thickness of the band also correlates inversely with the cognitive level of the patients, who demonstrate mild to moderate developmental delay, dysarthria, but minimal pyramidal signs. EEG studies usually show generalized spike-and-wave discharges or multifocal abnormalities.[7,23] Although the cortex appears relatively normal in PH and SBH, complete disruption of the normal cortical lamination seen in the type I lissencephaly usually results in more severe forms of epilepsy. Lissencephaly due to *LIS1* mutations causes seizures in over 90% of patients, with onset in the vast majority before 6 months of age. Approximately 80% of children will have infantile spasms within the first year of life, followed by mixed seizure disorders including atypical absence, drop attacks, myoclonic, partial complex, tonic and tonic-clonic seizures in later life. The lissencephaly also results in profound mental retardation, diffuse hypotonia, and later spastic quadriplegia.[32] The EEG typically shows a high Î±-Î² spike activity, which is not seen in type II lissencephaly.[46] Likewise, the severe disruption in cortical lamination seen in LCH results in seizures, severe developmental delay, and hypotonia.[37] Unlike type I lissencephaly, in which actual impairments in neuronal motility occur, the overmigration seen in cobblestone lissencephaly results in less severe epilepsy, presumably due to the fact that the cortex underlying the cobblestone heterotopia is somewhat preserved. Over 80% of patients with type II lissencephaly develop seizures; the average age of onset is in the third year of life, with seizures often occurring after a febrile event. Affected individuals have generalized tonic-clonic convulsions, followed by complex partial or secondarily generalized seizures. Less than 10% of patients go on to develop Lennox-Gastaut syndrome. The EEG studies show multifocal paroxysmal discharges superimposed on a Î¸- or Î´-wave background.[33,88] Discharges are less frequent and of lower amplitude when compared to the type I lissence-phaly.[11]

Disruption of Neuronal Differentiation

The sequential mechanisms that transform an immature neuron into the many subtypes of neurons in the cerebral cortex are not known. Furthermore, neuronal differentiation reflects a very complex process and is likely to involve a multitude of genes, including those that direct progenitors to become neurons and those that are preferentially expressed within subpopulations of mature neurons. Thus, in many ways, no simple view encompasses all the genetic mechanisms in neuronal differentiation. That said, genes involved in neuronal differentiation can be classified with respect to their function: Specifically, disrupted genes that reflect the make-up of the particular neurons and disrupted genes that direct the overall make-up of the brain.

With regard to the generalized idiopathic epilepsies, many of the monogenetic disorders have been attributed to ion channelopathies that are preferentially expressed by particular neuronal subtypes. The loss of function of certain ion channels can alter the firing properties of particular mature neurons (such as pyramidal cells, interneurons, or both) and, in this respect, the functional characteristics of such fully differentiated neurons are altered. Discussion of each of these genetic mutations can be found in Chapter 18. In summation, however, the generalized epilepsies with febrile seizures plus are attributed to mutations in sodium channels (*SCN1A*, *SCN2A*, *SCN1B*) and the Î³-aminobutyric acid (GABA) receptors (*GABARG2*). Another GABA receptor (*GABARA1*) has been associated with juvenile myoclonic epilepsy. Benign familial neonatal convulsions are caused by mutations in the potassium channels (*KCNQ2*, *KCNQ3*). Finally, mutations in the chloride channel (*CLCN2*) are thought to give rise to several idiopathic generalized epilepsies.[29] Each of these early-onset epilepsies is attributed to preferential loss of the expression and function of particular ion channels on subpopulations of neurons.

More regional and global impairments in neuronal differentiation leading to epilepsy can be seen in several neurodevelopmental disorders. Mutations in the G-proteinâ€“coupled receptor gene (*GPR56*) cause bilateral frontal and parietal polymicrogyria, with affected individuals having mental retardation, esotropia, and childhood-onset seizures.[64,65] GPR56 is preferentially expressed within cortical progenitors along the ventricular and subventricular zones. Moreover, the preferential disruption of the frontal and parietal regions would suggest that this gene plays some role in directing brain regionalization. As another example, mutations in the Methyl CpG binding protein-2 (*MeCP2*) gene and cyclin-dependent kinase-like-5 (*CDKL5*) gene cause Rett and Rett-like syndrome, characterized initially by mental retardation, ataxia, and nonpurposeful hand movement.[77,82,89] *CDKL5* encodes a nuclear protein and putative kinase whose expression in the nervous system overlaps with that of MeCP2 during neural maturation and synaptogenesis. CDKL5 also appears to phosphorylate itself and mediate MeCP2 phosphorylation.[51] Finally, MeCP2 appears to regulate many of the biochemical â€œswitchesâ€ needed to control the complex expression patterns of other genes. Failure in the activation of these gene pathways likely contributes to the progressive neuronal degeneration seen in affected individuals, leading to spastic paraparesis, vasomotor disturbances of the lower limb, and epilepsy. Thus, the capacity for some neurons to undergo appropriate neuronal differentiation is predetermined by cellular and molecular mechanisms earlier in development, thereby directing the differentiation of specific regional areas in the brain.

Disruption of Multiple Developmental Stages

Although the genetic mechanisms underlying the malformations of cortical development are conceptually easiest to understand when classified into the various developmental stages, several general observations can be made with regard to genotypeâ€“phenotype correlations. Genes involved early in development will likely influence later developmental stages. Moreover, no discrete boundary actually divides these respective developmental stages, so many of these developmentally active genes may have some overlapping functions across several developmental stages. Finally, extrinsic environmental influences can contribute to the extent and severity of these malformations.

Genes with early onset and broad function can, when disrupted, alter subsequent developmental processes. For example, another genetic cause of lissencephaly, the X-linked form of lissencephaly with abnormal genitalia (XLAG), is due to mutations in the Aristaless-related homeobox gene (*ARX*).[14,43] Homeobox genes act as transcription factors that direct the initial coordination of a cascade of genes in control of various aspects of development. In this respect, it is not surprising the mutations in *ARX* lead to a disruption of numerous brain structures: A moderately thickened cortex that has three layers, a loss in sulcal and gyral folds, and agenesis of corpus callosum. In mice, aberrant interneuron migration occurs, along with reduced brain size, loss of region-specific markers, and abnormal nerve fiber tracts.[43] Thus, a single gene responsible for early development can disrupt neuronal proliferation (microcephaly), migration (lissencephaly), and differentiation (agenesis of the callosum) in the cerebral cortex. These structural abnormalities likely contribute to the seizures and mental retardation in females, and early lethality in males. Similarly, but in a more limited sense, disruption of *LIS1* or *DCX*, while impairing neuronal motility and clearly affecting the cortical lamination, also lead to impaired differentiation. Neurons within the cortex appear dysmorphic, heterotopic in nature, and may actually be inverted.[81] The altered neuronal differentiation may in part result from the disruption in cortical lamination, causing neurons to reside in appropriate positions within the cortex, thereby interrupting the typical external signals required for appropriate connectivity.

Different developmental stages may share similar cellular and genetic mechanisms. For example, *LIS1* has a fundamental role in microtubule function, given its interactions with dynein. This interaction likely serves its role in cell motility. However, Lis1 protein also binds NUDE/NUDEL, which are regulators of cytoplasmic dynein, which is involved in organizing the centrosome in cell division.[26,60] In addition, humans with *LIS1* mutations do have microcephaly. Thus, the Lis1-dependent cytoskeletal regulation likely is required for both migration and proliferation. Another case in point is the microcephaly caused by mutation in *Microcephalin*, which has also been associated with PH.[78] Increased cell death along the ependymal lining could disrupt the integrity of the ependyma and lead to both PH and microcephaly. Similarly, individuals with PH due to

ARFGEF2 mutations also have microcephaly; presumably the GEF is involved in the vesicle transport of proteins involved in cell adhesion as well as cell proliferation along the neuroependyma lining.

The severity of some cortical malformations depends on extrinsic influences. For example, tuberous sclerosis (TS) is an autosomal dominant disorder leading to the formation of cortical tubers within the brain.[36,47] TS is caused by mutations in at least two genesâ€" *TSC1* and *TSC2â€"*which encode for hamartin and tuberin, respectively. Both hamartin and tuberin have tumor suppressor functions. Although all progenitors will have a mutation in either one of these genes, only some precursors will develop into cortical tubers. Thus, the disorder has been suggested to follow a classical Knudson â€œtwo-hitâ€ model for recessive oncogenes, in which some but not all progenitors receive a second external hit and result in a loss in cell cycle inhibition.[41]

In addition to extrinsic factors that alter gene expression and function, it is important to recognize that nongenetic insults during cortical development can give rise to cortical dysplasias and early-onset seizures. Maternal trauma, exposures to teratogens (drug and environmental poisons), infections, as well as strokes and hypoxia can all contribute to malformations of cortical development, depending on the timing and location of the insult. This topic has been reviewed.[69] Several animal models illustrate the nongenetic â€œtraumaâ€ and possible consequences on cortical development. Treatment of embryonic rodents during periods of neurogenesis using the DNA alkylating agent (methylazoxymethanol) or Î³-irradiation results in cortical thinning and cortical heterotopia, consistent with impairments in the proliferation and early migration of neural progenitors. Cortical freeze lesions on the surface of the skull of newborn rodents (at a time point after neurogenesis but during continued neuronal migration) results in a four-layered cortex reminiscent of the lissencephalic human brain, suggesting a disruption in cell migration.

Summary and Conclusions

This chapter provides a brief introduction to some of the issues that can be addressed in studying the development of the cortex. The abnormalities of cortical development frequently seen in epileptic brains represent important data that can inform the basic scientists. In turn, progress in understanding cellular and genetic regulation of cortical development may ultimately improve our understanding of the pathogenesis of epilepsy. Epilepsy is likely to be the end result of a large variety of genetic and nongenetic lesions that ultimately affect the development of the cortex. We hope that understanding these

P.400

genetic mechanisms may provide several contact points for the design of improved medical therapies.

Chapter 35

Synaptic Plasticity

Christophe Bernard

Introduction

Cognitive tasks are associated with specific firing patterns of neurons.[27,60] During learning and memory processes, a conditioning stimulus can trigger morphological and modifications at the neuronal network level to store novel information. This is known as *synaptic plasticity*. These modifications can result in changes in firing patterns in response to the same unconditioned stimulus. For example, in the cerebellum, the vestibulo-ocular reflex can be adaptively modified when vestibular-visual conditions are changed, with the triggering error signal being provided by the firing of climbing fibers.[52] The goal of this chapter is to describe the various mechanisms that have been proposed to explain how information processing can be modified via dynamic modifications at the synapse. These mechanisms are also important to consider in the context of epilepsy. First, many types of epilepsies are associated with cognitive deficits, raising the possibility that these mechanisms are compromised in patients. Second, ictal and interictal activities may activate these mechanisms to trigger further network modifications. Third, these mechanisms may themselves be involved in the construction of epileptogenic neuronal networks.

Many processes can be evoked to alter information process transiently or permanently. Because information is coded in spike trains, it is essential to understand the mechanisms responsible for changing the output firing patterns in response to given synaptic inputs. The firing pattern of a neuron usually results from the interaction between synaptic inputs and ion (voltage-gated, Ca^{2+}, ATP-gated, pH-gated, stretch-gated, etc.) channels. Any change at the synapse or ion channel level will result in a modified firing pattern. Changes in ion channels can modify firing patterns as efficiently as synaptic modifications do (in fact, both phenomena can occur simultaneously), be it during physiologic or pathologic conditions.[9,39,108,114,117,137]

Neurons use electrical and chemical processes to communicate at synapses. A chemical synapse is composed of four compartments (Fig. 1A): The presynaptic terminal, from which neurotransmitter is released; the postsynaptic terminal, which contains receptors for the neurotransmitter; the extracellular space between the pre- and postsynaptic elements; and glial cell processes, which contain various proteins, including transporters for the neurotransmitter. The arrival of an action potential in a presynaptic terminal usually results in the release of neurotransmitter that crosses the synaptic cleft to activate postsynaptic receptors. If these receptors are ionotropic, their activation leads to a flux of charged ions through the membrane. This flux of ions creates a current (I) that produces a change in membrane potential (V) (Fig. 1B). The term *synaptic plasticity* covers all of the mechanisms that ultimately result in a modification of V in response to an unconditioned stimulus (the activation of a presynaptic terminal by an action potential) following a conditioning stimulus. For example, at an excitatory glutamatergic synapse, postsynaptic depolarizing responses can be decreased on a short (short-term depression) or long (long-term depression, LTD) time scale, or increased (short-term facilitation or long-term potentiation, LTP).

Synaptic plasticity results from modifications that can take place at all four components of the synapse.

- The presynaptic terminal, through changes in neurotransmitter release probability or the vesicular content of neurotransmitter; in this case, synaptic plasticity is said to have a presynaptic origin

- The extracellular matrix (ECM), in which molecules can be involved in synaptic plasticity
- The glial cells, which clear neurotransmitters (hence controlling the postsynaptic response) and which can release chemical messengers that can modify neurotrans-mission
- The postsynaptic element, through morphologic alterations, changes in postsynaptic receptor density, or modifications of their intrinsic properties by intracellular processes (e.g., phosphorylation, interactions with partner proteins); in this case, synaptic plasticity is said to have a postsynaptic origin

This chapter focuses on the presynaptic terminal and the postsynaptic element.

Of note, multiple ways exist to induce synaptic plasticity and the underlying mechanisms are even more diverse.[77] The goal of the chapter is not to provide an extensive review of the different mechanisms, but to provide representative examples. Synaptic plasticity mechanisms always depend on the conditioning stimulus (e.g., high- versus low-frequency stimulation), time (milliseconds to months following the conditioning stimulus), the developmental stage (e.g., mature versus immature neuronal networks), the brain region (e.g., synaptic plasticity at mossy fibers versus Schaffer collateral connections in the CA3 and CA1 hippocampal regions, respectively), and the type of neuron within a given region (e.g., Î³-aminobutyric acid [GABA]ergic interneuron versus principal glutamatergic cells).

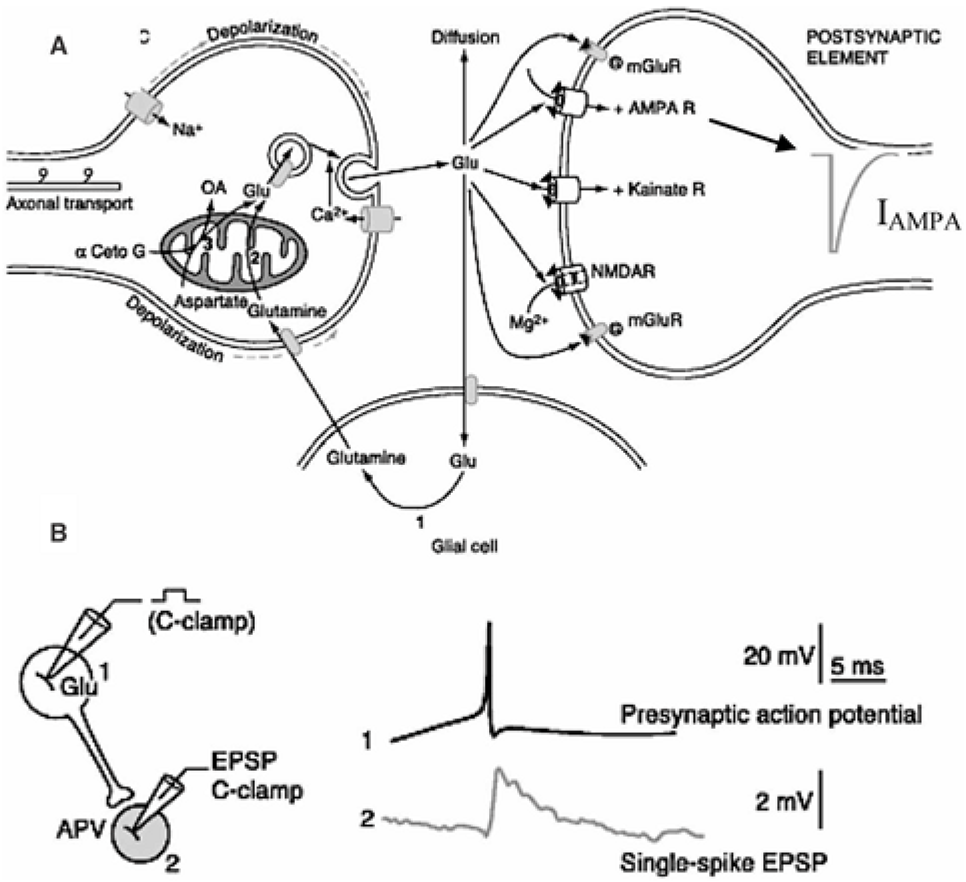

FIGURE 1. Synaptic transmission at a glutamatergic synapse. **A:** The four components of the synapse are the presynaptic and postsynaptic elements, the glial cell process, and the synaptic cleft. Depolarization of the presynaptic site (e.g., by an incoming action potential) results in Ca^{2+} influx that triggers fusion of a synaptic vesicle containing the neurotransmitter glutamate with the inner presynaptic membrane. Glutamate diffuses into the synaptic cleft to reach postsynaptic receptors (AMPA, NMDA, kainate, metabotropic). Activation of AMPA receptors triggers an influx of Na^+ in the postsynaptic terminal, resulting in an inward current, $I_{AMPA.}$ Glutamate is pumped up by glial cells and presynaptic terminals by

specific transporters. **B:** Example of a recording of a connected pair of neurons. The presynaptic glutamatergic neuron (1) is connected to neuron 2. When an action potential occurs in neuron 1, the membrane of neuron 2 is depolarized. This depolarization is due to an influx of Na^+ through glutamate-activated AMPA receptors; that is, the transformation of I_{AMPA} into a change in membrane potential, following Ohm's law. Adapted from Hamon.

Presynaptic Forms of Synaptic Plasticity

The first stage of information processing at the synapse takes place in the presynaptic terminal, from which neurotransmitter is released. Demonstrating that synaptic plasticity occurs at presynaptic terminals is technically challenging, because it requires direct recordings from the presynaptic terminal, an experimental technique that is still limited to very large presynaptic structures in the central nervous system (CNS).[42] As a consequence, most presynaptic mechanisms are assessed indirectly, using recordings of the postsynaptic site. Despite this experimental constraint, presynaptic plasticity mechanisms have been established. Two forms of synaptic plasticity can be distinguished, short- and long-term.

Short-Term Plasticity

Neurons recorded *in vivo* display very different firing patterns in a brain stateâ€“dependent manner.[105,115] In addition, firing patterns are also characterized by large intrinsic variability, even during stable brain state.[105,115] The intrinsic properties of the presynaptic terminal determine how information is transmitted to the postsynaptic site. Here, the critical parameter is the interval between two action potentialsâ€”the interspike interval (Fig. 2). In response to closely spaced stimulations of a presynaptic terminal, some synapses display short-term facilitation. That is, the amplitude of the second response is larger than the first. Other synapses display short-term depression. That is, the amplitude of the second response is smaller than the first. Some synapses also display remarkable stability across a large range of interspike intervals, ensuring faithful neurotransmission (for example, the climbing fiberâ€“Purkinje cell synapse in the cerebellum).[13]

Paired-Pulse Facilitation Mechanisms

Increased intracellular calcium (Ca^{2+}) underlies paired-pulse facilitation.[139] The favored mechanism proposes that the first action potential triggers a large and rapid rise in intracellular Ca^{2+}, resulting in release of a neurotransmitter. This Ca^{2+} diffuses and equilibrates with the resting concentration of Ca^{2+} that was present before the action potential, thus giving rise to a residual Ca^{2+} concentration that will be cleared eventually. This residual Ca^{2+} facilitates neurotransmission when the second spike arrives at the presynaptic terminal (see Fig. 2).

Other, nonexclusive mechanisms have been proposed. For example, in the mossy fiber boutons of the CA3 hippocampal region, Ca^{2+} influx in the presynaptic terminal can be dynamically regulated during repetitive stimulation by presynaptic sodium (Na^+) and potassium (K^+) channels.[11,36,42]

Paired-Pulse Depression Mechanisms

The simplest model assumes a use-dependent exhaustion of the store of neurotransmitter-containing vesicles that are ready to be released in front of the postsynaptic site, but the issue remains controversial.[139] Recovery from paired-pulse depression usually takes several seconds, but this can be facilitated by Ca^{2+} accumulation during high-frequency presynaptic activity.[124] This phenomenon explains why neurotransmission does not fail totally during trains of action potentials at synapses displaying paired-pulse depression.

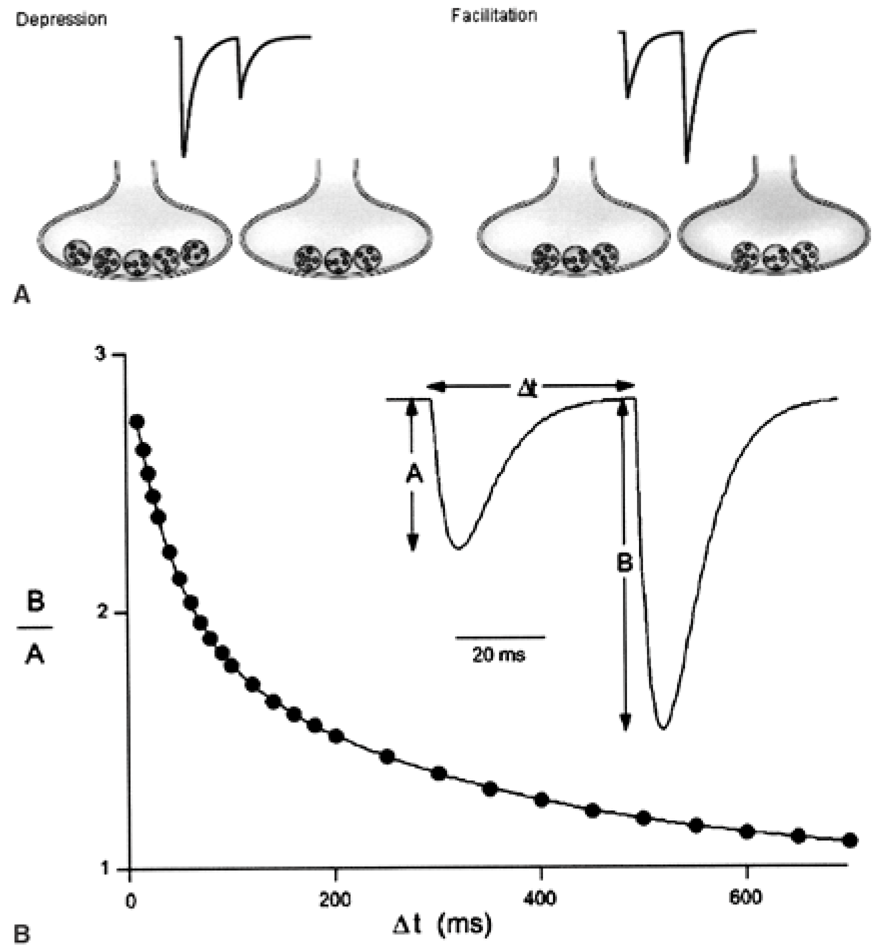

FIGURE 2. A: Paired-pulse depression and facilitation at glutamatergic synapses. A presynaptic terminal is stimulated to release glutamate, giving rise to an inward synaptic current of a given amplitude. Glutamate release is induced by a second, closely spaced, stimulation. If the amplitude of the second evoked current is smaller than the first one, the synapse is characterized by paired-pulse depression. A smaller number of vesicles ready to be released for the second stimulation may explain this phenomenon. If the second current is larger, the synapse is characterized by paired-pulse facilitation. An increased intracellular Ca^{2+} concentration (*grey shading*), thus increasing the probability of release in response to the second stimulation, may explain this phenomenon. Adapted with permission from Blitz DM, Foster KA, Regehr WG. Short-term synaptic plasticity: a comparison of two synapses. *Nat Rev Neurosci.* 2004;5:630â€"640. **B:** Simulation of paired-pulse facilitation showing that the amount of facilitation depends upon the interspike interval Î"t. When the second stimulus occurs >600 ms after the first one, the amplitude of the second response is similar to the first. Facilitation is maximum at the shortest time intervals. Adapted with permission from Zucker RS, Regehr WG. Short-term synaptic plasticity. *Annu Rev Physiol.* 2002;64:355â€"405.

Modulation of Neurotransmitter Release by Presynaptic Receptors

The two short-term forms of plasticity involve mechanisms directly linked to the machinery for neurotransmitter release. The release of neurotransmitter can also be dynamically modified by chemical messengers acting via receptors located on the presynaptic terminal. For example, consider the mossy fiber terminals, the axons of hippocampal dentate granule cells that form giant synaptic boutons with CA3 pyramidal cells. Upon repetitive activation of mossy fiber terminals, released glutamate reaches high enough concentration to activate ionotropic (kainate; KA) and metabotropic (mGlu) receptors. The result of KA receptor activation is to increase excitability,[111] thus facilitating transmitter release (i.e., directly participating in the strong paired-pulse facilitation seen at this synapse).[26,112] Activation of type 2 mGlu receptors results in a decreased probability of glutamate release, probably via inhibition of presynaptic Ca^{2+} channels, thus limiting the

amount of facilitation.[110] Other receptor types are also present on mossy fiber terminals, including adenosine A1 receptors. These receptors are tonically activated *in vitro* and result in a permanent low initial release probability of glutamate at this synapse.[82] Synaptic vesicles can contain adenosine triphosphate (ATP) that, when released, is broken down into adenosine to activate presynaptic receptors.[43] Whether A1 receptors act as autoreceptors (i.e., ATP is released by the terminal) or as heteroceptors (the source of ATP/adenosine is not the terminal[136]) is not known.

Use-dependent facilitation or inhibition of neurotransmission also involves other types of presynaptic autoreceptors, including *N*-methyl-D-aspartic acid (NMDA) receptors[51] and Î±-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) receptors[109] at glutamatergic terminals, and metabotropic $GABA_B$ receptors at GABAergic terminals.[29] Facilitation may be the result of an increase in internal Ca^{2+} concentration resulting either from direct Ca^{2+} entry through Ca^{2+}-permeable receptors (e.g., NMDA) or Ca^{2+} voltage-gated channels opened by the receptor activationâ€“induced membrane depolarization. Inhibition may result from downregulation of Ca^{2+} voltage-gated channels by G-proteins following activation of metabotropic receptors. To make things even more complex, presynaptic terminals can possess heteroreceptors that are activated by chemical messengers not released by the terminal itself. For example, repetitive activation of glutamatergic parallel fibers in the cerebellum activates GABAergic interneurons. GABA is released in large enough quantities to activate presynaptic $GABA_B$ receptors located on parallel fiber terminals contacting Purkinje cells, thus decreasing the probability of glutamate release by a Ca^{2+}-dependent mechanism.[31]

Conclusion on Short-Term Plasticity Phenomena

Presynaptic terminals are complex information-processing units. They play a crucial role in shaping postsynaptic responses by increasing or decreasing neurotransmitter release as a function of the timing of the spike train reaching the presynaptic terminal. They use multiple mechanisms to modify their output depending on the type of activity they receive, the molecular properties of their release machinery, the biophysics of their ionic channels, and the type of autoreceptors they express. Through activation of heteroreceptors, presynaptic terminals also sense the activity of neighboring terminals, which can be of a different type. The properties of a terminal depend on its origin, target, and developmental stage.[139] These properties play a very important role in information processing, for example, by allowing proper routing of information in the network by adequately shaping information transfer.[104] Any alteration in the mechanisms that control paired-pulse facilitation or depression at a given synapse will result in a dramatic change in function. Such possibilities should be considered when investigating neurotransmission and information processing in pathologic conditions.

Long-Term Plasticity

Among the many loci at which a presynaptic form of synaptic plasticity has been found, LTP at the mossy fiber has received considerable attention.[91] High-frequency stimulation (e.g., 100 pulses at 100 Hz) of mossy fibers leads to a permanent enhancement of the postsynaptic response. Three questions are in order: Where is LTP expressed: Pre- or postsynaptically? What

are the expression mechanisms (what makes the response larger after the conditioning stimulus)? and, How is this phenomenon induced by the conditioning stimulus?

Presynaptic Expression of Long-Term Potentiation

The expression of LTP at mossy fiber cell synapses is due to an increase in neurotransmitter release. As mentioned previously, presynaptic mechanisms can only be inferred indirectly, and various approaches have been used to support a presynaptic rather than postsynaptic locus. The arguments supporting the former are a decrease in paired-pulse facilitation,[132,135] a decreased failure rate,[73,132] and a change of the coefficient of variation (CV)[73,132] following LTP induction, all classical properties expected to occur if the probability of neurotransmitter release is increased. The failure rate is directly linked to release probability. Transmitter release is a probabilistic phenomenon, because an action potential does not always trigger vesicle fusion. Some synapses (such as the cerebellar climbing fiber) are reliable, having a close to 1.0 probability, whereas others have a low release probability (such as the mossy fiber, in part due to the tonic activation of A1 receptors, as described earlier). Repetitive activation of presynaptic terminals with <1.0 release probability gives rise to failuresâ€”no postsynaptic response is recorded despite the presence of an action potential in the presynaptic terminal. A decreased number of failures indicates an increased release probability. The CV is the mean postsynaptic response divided by the standard deviation of the response (using repetitive stimulation). This parameter also depends strongly on release probability. Other arguments in favor of a presynaptic mechanism have been proposed, including the measurement of postsynaptic NMDA responses,[126] and the monitoring of extracellular glutamate concentration directly[76] or indirectly using glial cells.[58]

Expression Mechanisms

The mechanisms that underlie increased neurotransmitter release at mossy fiber synapses are not fully understood and still the subject of debate.[20] A simple scheme has been proposed[91] in which the conditioning stimulus leads to increased intracellular Ca^{2+} in the presynaptic terminal,[119] activation of Î±$_{1E}$-subunitâ€“containing R-type Ca^{2+} channels.[17] The rise in Ca^{2+} would activate Ca^{2+}/calmodulin-activated adenylyl cyclase (AC)-1, which is highly expressed in mossy fiber terminals.[131] Activation of AC1 would result in a rise in cyclic adenosine monophosphate (cAMP), leading to the activation of protein kinase A (PKA). Interfering with any one of these steps alters mossy fiber LTP.[50,73,119,123,125] How this leads to enhanced neurotransmitter release, and how LTP is maintained over the long-term, remain to be established.

Induction Mechanisms

In contrast to postsynaptic expression of LTP at Schaffer collateral synapses (see the next section), the induction of mossy fiber LTP does not require activation of postsynaptic NMDA receptors.[45] The key player is Ca^{2+}, because its removal or strong buffering prevents LTP.[119] The next issue is to determine if the induction depends on a rise of Ca^{2+} in the presynaptic terminal, the postsynaptic unit, or both. Several studies have reported that a rise in postsynaptic Ca^{2+} is necessary,[128,133] whereas others have shown the opposite.[81,135] This issue is functionally important, because a postsynaptic induction mechanism implies that a retrograde messenger must be sent by the postsynaptic cell to alter synaptic release in the presynaptic terminal. A reasonable way to explain this discrepancy (and others) is that different induction mechanisms exist, and their activation depends on the experimental conditions present. The role of KA and mGlu receptors is also fiercely debated, with contradictory results regarding their direct involvement or modulatory role.[14,16,81,133]

Long-Term Depression at Mossy Fiber Synapses

Synaptic responses are enhanced at mossy fibers following tetanic stimulation, and they are decreased (i.e., LTD) following low-frequency stimulation (e.g., 15 minutes at 1 Hz).[61,122] The expression of LTD is also presynaptic, and seems to involve mirror mechanisms when compared to those described for LTP at the same synapseâ€”a decrease in adenylyl cyclase and PKA activity.[122] Using mechanisms similar to those involved in LTD, after LTP, it is possible to reverse the synaptic responses to those of preconditioning stimulus values, a phenomenon known as *depotentiation.*[48]

Target Specificity of Synaptic Plasticity

The forms of synaptic plasticity described so far concern the synapse between mossy fibers and CA3 pyramidal cells. However, mossy fibers produce small filopodial extensions that contact CA3 GABAergic interneurons.[2] Indeed, GABAergic interneurons are the main target of mossy fibers, because 10 times more filopodial extensions than mossy fiber boutons contact pyramidal cells.[2] High-frequency stimulation induces LTD at mossy fiberâ€"interneuron synapses, which express postsynaptic Ca^{2+}-permeable AMPA receptors.[67] As in mossy fiberâ€"pyramidal cell LTP, this form of LTD is NMDA receptorâ€"independent, depends on type 7 mGlu receptor and protein kinase C (PKC), and is expressed presynaptically.[68,98] However, it requires a rise in postsynaptic Ca^{2+}, which means the involvement of a retrograde messenger that has yet to be identified. This illustrates that the same experimental protocol can trigger opposite synaptic modifications onto two different targets.

To illustrate further the importance of target specificity, it is interesting to note that the same conditioning stimulus triggers a different form of LTD at those mossy fiberâ€"interneuron synapses that express postsynaptic Ca^{2+}-impermeable AMPA receptors.[67] This form of LTD requires a postsynaptic rise in intracellular Ca^{2+} via the activation of an NR2B-subunit lacking NMDA receptors.[67] The expression involves a downregulation of postsynaptic AMPA receptors.[68] (Postsynaptically expressed long-term plasticity is discussed later.)

Other Examples of Plasticity Expressed Presynaptically

LTP can be expressed presynaptically at other glutamatergic synapses (e.g., in the cerebellum at the parallel fiberâ€"Purkinje cell synapse[44] or at corticothalamic synapses[19]). Mechanisms are similar to those described previously; and require involvement of adenylyl cyclase, cAMP, and PKA.[19,44]

More complex mechanisms involve a postsynaptic induction mechanism and a presynaptic expression. The lateral nucleus of the amygdala, a structure involved in the acquisition of conditioned fear responses,[64] receives thalamic and cortical glutamatergic inputs that can be potentiated by pairing protocols. Although induction of LTP depends on activation of postsynaptic NMDA receptors and L-type voltage-gated channels, LTP is expressed presynaptically, with the involvement of adenylyl cyclase, cAMP, and PKA.[5,49] This type of LTP implies the presence of retrograde messengers, such as nitric oxide (NO), at the cerebellum mossy fiberâ€"granule cell synapse.[28] A more complex form of LTP has been described in the lateral nucleus of the amygdala.[51] In this case, repetitive activation of both cortical and thalamic inputs leads to LTP only at the cortical pathway. The mechanism involves activation of NMDA receptors located on presynaptic cortical terminals by glutamate released from thalamic presynaptic terminals.[51]

Synaptic Plasticity at GABAergic and Glycinergic Synapses

The plasticity processes described thus far involve glutamatergic synapses. GABAergic and glycinergic synapses are also involved in multiple forms of synaptic plasticity.[40] In *Xenopus* tectal neurons, LTD can be induced through visual stimulation at GABAergic synapses.[69] The induction does not depend on activation of postsynaptic NMDA receptors or on increases in postsynaptic Ca^{2+}. The expression is presynaptic, as indicated by an increase of the failure rate and an increase in the CV. The mechanism underlying LTD in this system involves activation of presynaptic NMDA receptors located on GABAergic terminals, which are activated by glutamate released during the visual stimulation.[69] This example further illustrates how different synaptic pathways cooperate to produce synaptic modification at a specific locus.

LTD can be induced at hippocampal GABAergic synapses during the early stages of development.[40] This form of LTD expression is presynaptic, but it requires a rise in postsynaptic Ca^{2+} via activation of NMDA receptors.[18] LTD can also be induced during the later stages of development, and a few mechanisms have been identified.[21] Repetitive stimulation of Schaffer collaterals (axons of the glutamatergic CA3 pyramidal cells that contact CA1 pyramidal cells) activates postsynaptic group 1 mGlu receptors, triggering the production of endocannabinoids. Endocannabinoids then diffuse to the presynaptic GABAergic terminals to activate type 1 cannabinoid receptors, resulting in a persistent decrease of GABA release.[21] This mechanism may play a very important functional role, because it may facilitate information storage.[22]

Concluding Comments on Synaptic Plasticity Expressed Presynaptically

This section has emphasized the diversity of mechanisms that can be used to change synaptic efficacy at the presynaptic terminal. These mechanisms can be very complex, sometimes involving different neurotransmitters and molecular messengers not released by the presynaptic terminal. Cooperative action is an important concept to keep in mind. Another critical feature is target-specificity, because different forms of plasticity can be triggered between a given source neuron and its various targets (e.g., principal cells versus interneurons). Finally, most studies have concentrated on synaptic plasticity at glutamatergic synapses. Comparatively, fewer studies have been devoted to GABAergic synapses. Plasticity at these synapses is undoubtedly important because of the critical role played by GABAergic neurotransmission in shaping neuronal network activity.[38,115]

Extracellular Matrix and Synaptic Plasticity

The previous section described how neurotransmitter release can be modified. The next step of neurotransmission is diffusion of the neurotransmitter through the extracellular space to its target receptors. The extracellular space, including the synaptic cleft, contains collagens, proteoglycans, and glycoproteins that compose the extracellular matrix (ECM). There is growing evidence that suggests that molecules of the ECM play a role in synaptic plasticity.[32] Many studies using transgenic animals with altered ECM molecules or their partners report alterations in long-term plasticity (mostly investigated in the CA1 region) and cognitive functions.[32] Of course, the role of ECM goes beyond the control of neurotransmitter diffusion.

A representative example is provided by heparin-binding growth-associated molecule (HB-GAM or pleiotrophin), which interacts with the cell surface receptor syndecans. Intracellular application of HB-GAM to CA1 pyramidal cells inhibited conventional NMDA receptorâ€"dependent LTP (described later), but did not inhibit either basal synaptic neurotransmission or other forms of LTP.[63] In mice overexpressing HB-GAM, LTP was reduced. At the behavioral level, animals performed better in the water maze and displayed reduced levels of anxiety in the elevated plus-maze.[97] Opposite results were found in HB-GAM-deficient mice.[97]

The ECM can be remodeled in an activity-dependent manner[89,130] and, considering the fact that ECM molecules interact with pre- and postsynaptic molecules such as neural cell adhesion molecule (NCAM),[24] it is likely that the ECM participates in morphologic remodelling, clustering of channels, and other processes.[32] For example, a change in the ECM at the synaptic cleft or perisynaptic region could alter the diffusion of neurotransmitters, thus affecting postsynaptic or extrasynaptic responses.

Glial Cells and Synaptic Plasticity

Glial cells play a critical role in information processing, both in physiologic and pathologic conditions.[90,118] For example, astrocytes can be activated by neurotransmitters released by neurons, including glutamate[103] and GABA,[56] which in turn can trigger release of glutamate via an increase of intracellular Ca^{2+}.[56,95,96]

Neurons and glial cells can be considered complex, integrative information-processing units. In the CA1 region of the hippocampus, GABA released by interneurons can activate $GABA_B$ receptors located on astrocytes, leading to a rise in intracellular Ca^{2+} that in turn result in glutamate release from the astrocytes.[56,72] Glutamate then activates kainate receptors located on GABAergic interneurons, resulting in increased GABA release onto principal cells.[72] Such modification of synaptic transmission may be involved in short-term forms of synaptic plasticity.

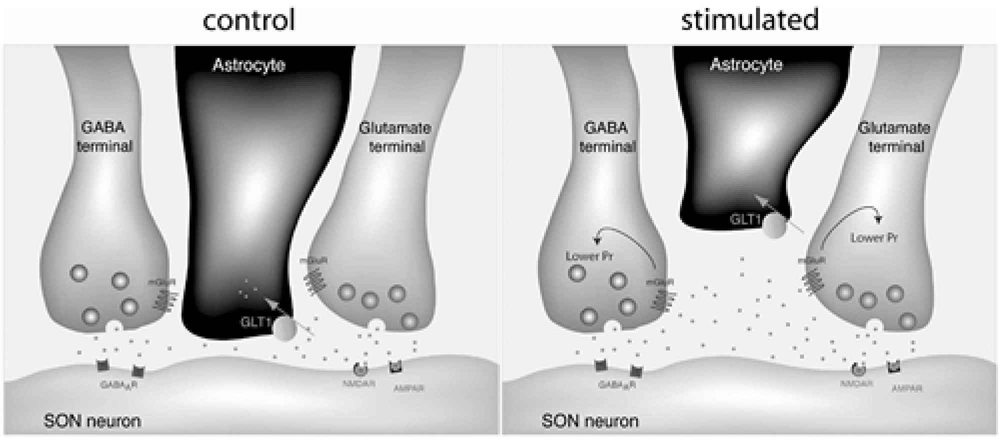

FIGURE 3. Synaptic plasticity due to astrocytic reorganization. In virgin animals (*left*), astrocytes coverage allows efficient recapture of glutamate by the glial transporter GLT1. In lactating animals (*right*), decrease of astrocytic coverage allows glutamate to diffuse and activate presynaptic mGlu receptors, resulting in lower probability of release of glutamate (homosynaptic depression) and GABA (heterosynaptic depression). S. Oliet, personal communication.

Glutamate is not the only molecular messenger released by astrocytes. High-frequency activation of Schaffer collaterals triggers a rise in intracellular Ca^{2+} in astrocytes, leading to the release of ATP, which results in decreased glutamate release from presynaptic terminals.[136] Such a short-term plasticity control system may be useful in limiting neurotransmitter release during intense periods of activity.

Glial cells are also involved in multiple forms of long-term synaptic plasticity. A good example is provided by the plastic modifications that take place in the supraoptic nucleus during lactation (Fig. 3). In virgin animals, glial processes provide a large coverage of synaptic terminals around magnocellular neurons.[94] The presence of specific transporters on glial processes ensures efficient clearance of glutamate.[8,107] In particular, glutamate cannot reach mGlu receptors located on presynaptic glutamatergic terminals. In lactating animals, the glial processes retract, decreasing synaptic coverage and allowing more glutamate to accumulate. This activates presynaptic mGlu receptors and decreases not only glutamate[94] but also GABA[99] release. This example demonstrates how a morphologic reorganization of glial cells contributes to synaptic plasticity. The freer diffusion of glutamate, results in depression of synaptic transmission at the glutamatergic terminals that released glutamate, as well as at neighboring GABAergic presynaptic terminals.

In addition to morphologic modifications, electrophysiologic responses can be modified in glial cells. For example, long-term plasticity at glutamatergic synapses can be triggered in glial cells.[41] Its induction and expression involves Ca^{2+}-permeable receptors (i.e., mechanisms different from those described at neuronâ€"neuron connections in the same region) (see

P.408

the section Long-Term Plasticity). The fact that synaptic plasticity also occurs at neuronâ€"glia connections is very important, because any modification of information transfer between neurons and glial cells will also result in a change in information transfer between glial cells and neurons (via the compounds glial cells release, such as glutamate, and ATP).

Finally, glial cells appear to play a key role in controlling synaptic function when long-term plasticity is triggered at neuronâ€"neuron connections. LTP at excitatory synapses can be accompanied by heterosynaptic depression at other excitatory synapses.[75,79] The underlying mechanism involves the activation of $GABA_B$ receptors on glial cells. This is dependent on release of ATP from glial cells, which degrades into adenosine and leads to activation of A1 receptors and, thus, heterosynaptic depression.[113] Glial cells are also the source of tumor-necrosis factor (TNF)-Î±, which enables synaptic scaling.[116]

Concluding Remarks

Synaptic transmission goes beyond the linear pathway that starts at the presynaptic terminal and ends at the postsynaptic site. A given synapse, as a functioning unit, comprises the synapse itself, the ECM, glial processes, and nearby synapses. Short- and long-term modifications can occur in any of the elements the surroundings a given synapse (in particular at the ECM and glial levels), and these modifications participate directly in the way the synapse transmits information. As more investigators turn to glial cell interactions with neurons, it will be particularly interesting to determine whether activity-dependent modifications can be triggered in astrocytes.

Postsynaptic Forms of Synaptic Plasticity

The postsynaptic site is the receiving end of neurotransmission. Synaptic plasticity can take place exclusively at this location, but its expression can take many forms. Perhaps the best approach to the vast repertoire of expression is to start with the binding of the neurotransmitter to a receptor, for example, glutamate to AMPA receptors. Binding depends on the affinity of the receptor for its ligand (a biophysical property). When the receptor is activated, an influx of Na^+ ions occurs for a time determined by the biophysical properties of the channel. Other properties include desensitization (despite the presence of the ligand, the receptor remains in a closed state) and recovery from desensitisation. Many of these biophysical properties are controlled by multiple intracellular processes (e.g., phosphorylation, anchoring mechanisms, partner proteins). A conditioning stimulus may alter any of these components and change the postsynaptic response. Other modifications include the number of receptors expressed at the postsynaptic site, their 3-D localization, and their subunit composition. Finally, the flux of ions through the channel creates a current, and this current creates a change in membrane potential. If the architecture of the postsynaptic site is modified, the same receptor-induced current results in a different change in membrane potential.[101] The change of architecture can be more dramatic with the creation and elimination of the synaptic contacts. Morphologic modifications have been extensively studied at glutamatergic synapses, which usually are made on spine heads.

Spine Plasticity

Spines are characterized by a high degree of plasticity.[46,127] For example, in the hippocampus, the spine number can vary by 30% to 40% during the estrus cycle,[129] following learning,[83] or when the environment is modified.[102] In barrel cortex, dendritic spines live less than 1 month, suggesting that experience induces a reorganization at the spine level.[120] In addition, the shape and size of spines are continuously changing in an age-dependent manner (spine motility declines with age).[34,37,62]

Spine shape can also change following conditioning stim-ulus-induced long-term modifications of synaptic responses (Fig. 4). LTP is associated with an increase in spine head and shape (even splitting into two functional synapses), whereas LTD is associated with spine shrinkage.[80,93,134,138] Such changes are consistent with the modifications of the postsynaptic density associated with LTP[30] and, in general, with the modification of the number of postsynaptic receptors (see discussion in next section). In addition to morphologic alterations, LTP, LTD, learning experience, and environment changes are associated with spine formation and pruning.[88] Spine motility depends on the activity of actin,[37] a contracting molecule, and Î±-N-catenin,[1] a cadherin-associated protein.

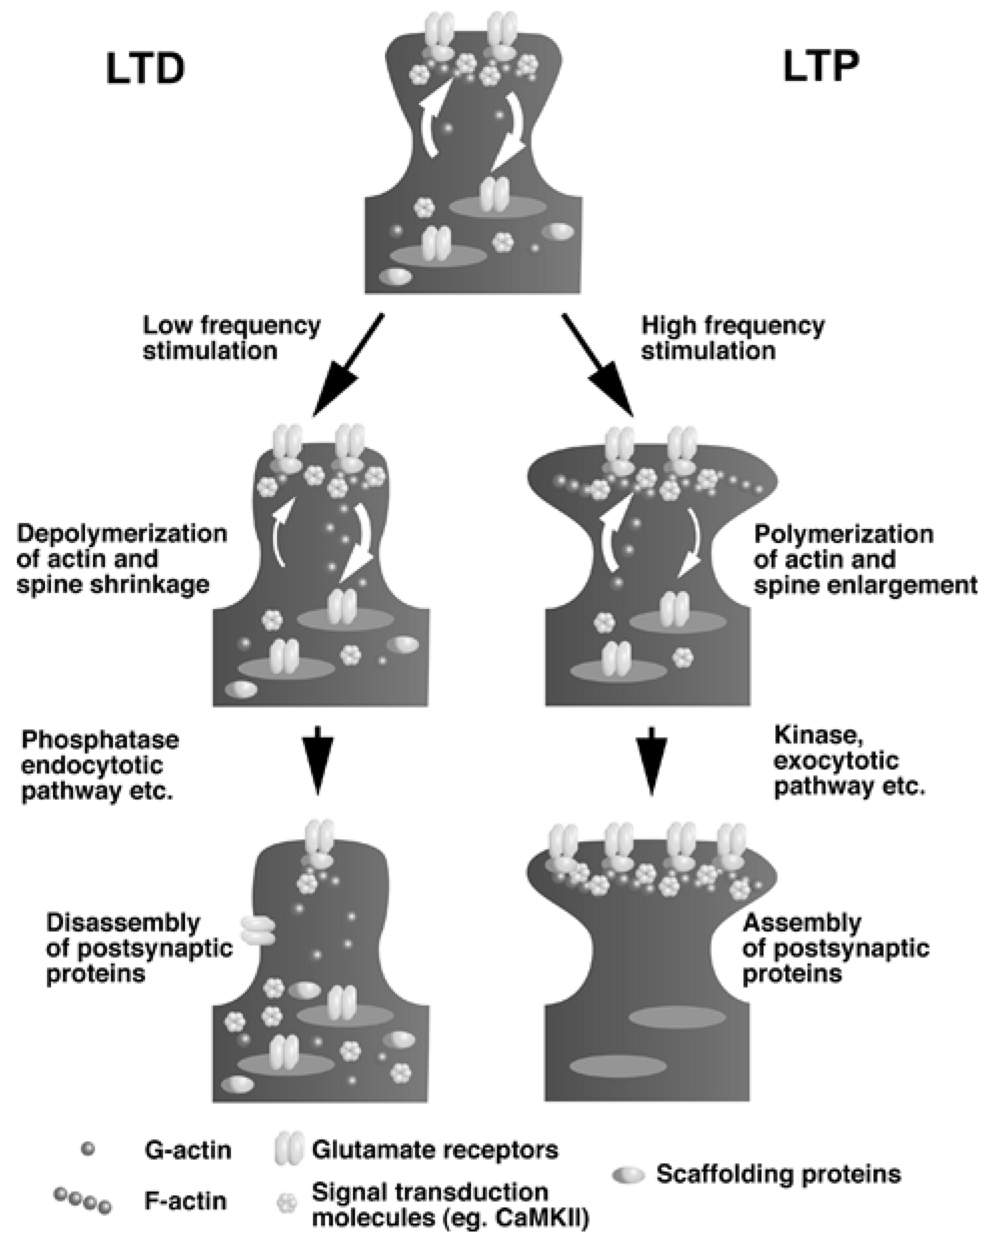

FIGURE 4. Structural plasticity during LTP and LTD. The conditioning stimulus inducing LTP triggers a morphologic modification of the spine resulting in an increase of the postsynaptic site. Various CaMKII-dependent mechanisms can be triggered, including a phosphorylation of AMPA receptors and the insertion of AMPA receptors. LTD involves reverse mechanisms. Adapted with permission from Hayashi Y, Majewska AK. Dendritic spine geometry: functional implication and regulation. *Neuron.* 2005;46:529â€"532.

What are the functional consequences of alterations in spine shape? Spine geometry affects membrane potential changes induced by synaptic currents in the spine (e.g., via a change in input resistance)[121] and postsynaptic Ca^{2+} concentration,[46] a parameter that plays a crucial role in controlling long-term synaptic modifications.

Concluding Remarks

Spine shape is important in the transfer of information between the pre- and postsynaptic terminal. Spines can be created, removed, or modified geometrically, and such changes may be spine-specific, i.e., dependent on the source, the target, and more generally on the brain region, as well as time-dependent (development, aging). Of course not all synapses are made on spines. Whether geometric modifications occur at nonspiny synapses is not known. A structural balance between excitatory and inhibitory synaptic contacts seems to be maintained

in the dendrites.[70] It is not yet known if balance is maintained structurally following a conditioning stimulus.

Long-Term Plasticity

There are multiple ways to induce long-term postsynaptic modifications in synaptic transmission. One of the best studied forms is NMDA-dependent LTP and LTD at Schaffer collateral synapses on CA1 pyramidal cells.[77] A conditioning stimulus can trigger long-term synaptic modifications, which can be separated into an early phase (~1 h) and a late, protein synthesis-dependent, phase.

Early Phase NMDA-Dependent Long-Term Potentiation

High-frequency stimulation (e.g., 100 pulses at 100 Hz) of Schaffer collaterals leads to a permanent enhancement of the postsynaptic response in a NMDA receptorâ€"dependent manner (it is blocked by NMDA antagonists).[12] As in the section on presynaptic plasticity, three questions are in order: Where is LTP expressed: pre- or postsynaptically? What are the expression mechanisms (i.e., what makes the response larger after the conditioning stimulus)? And, how is this phenomenon induced by the conditions stimulus?

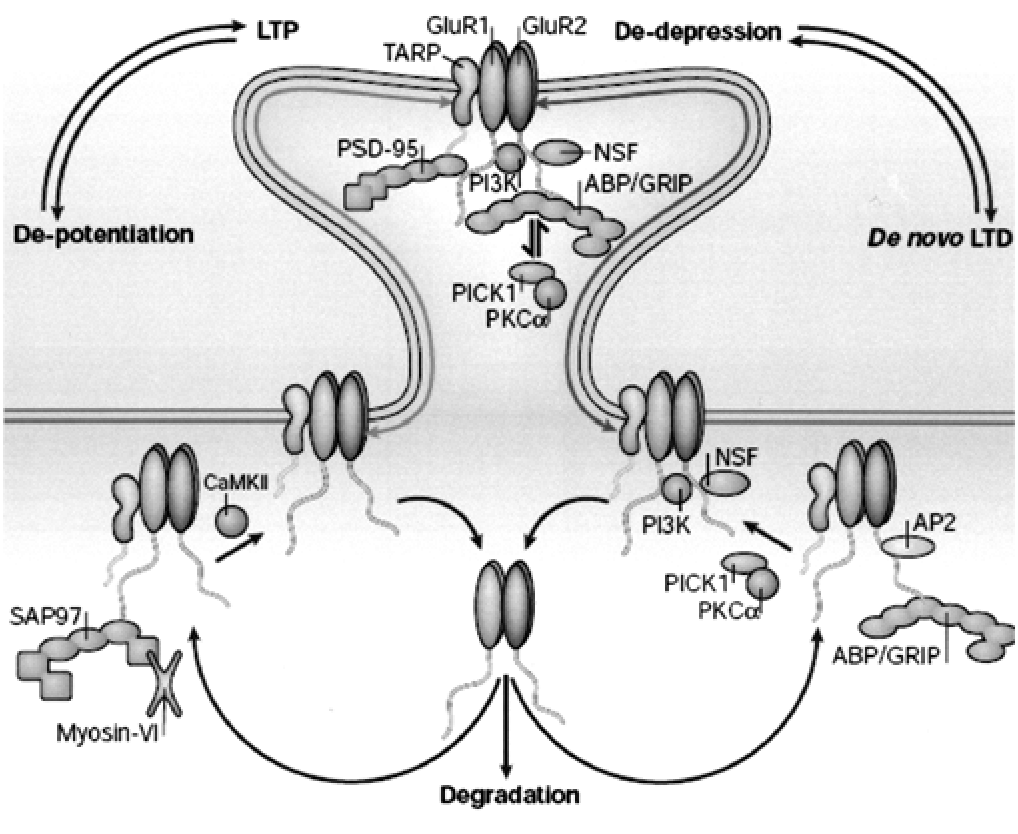

FIGURE 5. Bidirectional modifications of AMPA receptor distribution during LTP and LTD. The association between NSF and the GluR2 subunit of AMPA receptors allows their stabilization at the postsynaptic site. Its dissociation leads to receptor internaliza-tion. CaMKII may be involved in the insertion of AMPA receptors in the membrane via TARP. Depotentiation corresponds to LTD on previously potentiated synapses. Conversely, De-depression corresponds to LTP on previously depressed synapses. Adapted with

permission from Collingridge GL, Isaac JT, Wang YT. Receptor trafficking and synaptic plasticity. *Nat Rev Neurosci*. 2004;5:952â€“962.

Postsynaptic Expression of Long-Term Potentiation

Although the debate is not resolved,[23,35] many arguments support a postsynaptic locus, including modifications in receptor number and biophysical properties. However, most arguments are indirect because, as mentioned in the presynaptic section, it is very difficult to assess presynaptic modifications. Many electrophysiologic manipulations have been used to support a postsynaptic locus. First, no change in release probability occurred.[78] Second, paired-pulse facilitation was not modified after LTP.[87] Third, no modification of glial cell responses to extracellular glutamate occurred following LTP induction.[8,74] Finally, although glutamate does not have the same affinity for AMPA and NMDA receptors, if LTP is presynaptic, one would expect both responses to be increased following the conditioning stimulus (AMPA and NMDA receptors are often colocalized at the synapse). However, AMPA receptor-mediated responses were more increased than were NMDA responses.[57,86]

Expression Mechanisms

What can cause an increase in AMPA receptor-mediated responses following the conditioning stimulus? One contributing mechanism involves an increase in the conductance of AMPA receptors in a phosphorylation-dependent manner.[7] AMPA receptors at this synapse contain the GluR1 subunit, which can be phosphorylated by Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII)[4] and by PKC and PKA.[106] In that scheme, the biophysical properties are changed.

Another, nonexclusive mechanism involves the insertion of AMPA receptors (Fig. 4). A pool of AMPA receptor subunit-containing vesicles exists in the cytosol, and AMPA receptors can cycle on and off the synaptic membrane very rapidly.[15] After the conditioning stimulus inducing LTP, new AMPA receptors are inserted at the postsynaptic site in a CaMKII-dependent manner.[47] The mechanisms leading to an increase in the number of AMPA receptors are not fully elucidated. Numerous proteins that bind directly or indirectly to AMPA receptors have been identified (Fig. 5), including transmembrane AMPA receptor regulatory proteins (TARP), glutamate receptor-interacting protein/AMPA receptor-binding protein (GRIP/ABP), protein interacting with C kinase (PICK1), and N-ethylmaleimide-sensitive factor (NSF).[25,92] Whether these proteins are modulators or mediators of LTP remains to be established.

Induction Mechanisms

In the NMDA receptor-dependent form of LTP, a depolarization of the membrane during the conditioning stimulus is necessary to remove the voltage-dependent block of NMDA receptors by magnesium (Mg^{2+}).[12] This allows Ca^{2+} influx into the cell, a rise in intracellular Ca^{2+} being an absolute requirement for LTP induction.[12] However, the details of Ca^{2+} dynamics in the spine, the involvement of Ca^{2+} stores, and other issues remain to be investigated. Downstream of the Ca^{2+} increase, it is difficult to decide which intracellular cascades (CaMKII, PKA, PKC, etc.) are involved. The type of cascade may depend on the conditioning stimulus, development stage, type of neuron, and brain region.

Stabilization of Long-Term Potentiation

Early-phase NMDA-dependent LTP, which lasts 30 to 60 minutes, is translation- and transcription-independent. Late-phase LTP (>3 hours) is translation- and transcription-dependent. Dendrites and dendritic spines possess all the machinery necessary to translate mRNAs.[54] Post-translational modifications of existing proteins, which does not require de novo transcription, constitutes an efficient and rapid mechanism to control protein synthesis. Interestingly, multiple factors regulate translation at all levels (initiation, elongation, and release), pointing again at the multiplicity of pathways that can lead to LTP.[59] Activation of these translation mechanisms may allow tagging of the activated synapse for transcription and de novo protein synthesis.[100]

NMDA Receptor-Dependent Long-Term Depression

If synaptic responses can be increased, they can also be decreased. LTD can also be induced at Schaffer collateralâ€“CA1 pyramidal cell synapses. LTD can be induced by low-frequency stimulation; it requires the activation of NMDA receptors and a rise in intracellular Ca^{2+}.[33,85] How a rise in Ca^{2+} can trigger either LTP or LTD remains to be determined. The answer should depend on the spatio-temporal structure of the calcium signal and the type of NMDA receptor subunit activated during the conditioning stimulus.[71] LTD depends on the activation of protein phosphatase[84] and, in particular, on the dephosphorylation of PKA substrates.[55]

In many features, NMDA receptorâ€“dependent LTD appears to be the mirror image of NMDA receptorâ€“dependent LTP. It has a presynaptic origin, it is associated with a dephosphorylation of AMPA receptors[65] that affects the biophysical properties of AMPA receptors by decreasing its open probability,[3] and a loss of postsynaptic receptors occurs (Figs. 4 and 5). AMPA receptors can be internalized in a dynamin- and

clathrin-dependent manner.[6,66] The mechanisms responsible for the late-phase LTD remain to be determined.

Concluding Remarks on Long-Term Postsynaptic Forms of Plasticity

Long-term postsynaptic forms of plasticity are not limited to NMDA-dependent mechanisms or to AMPA receptors. For example, GABAergic responses also express postsynaptic types of plasticity.[40] It is not known if all synapses are endowed with mechanisms enabling them to change postsynaptic responses. The multiplicity of the players that can act at all levels to modify synaptic transmission (shape of the spine, biophysical properties of the receptors, cycling of the receptors) is impressive. Whether these distinct mechanisms are redundant (to ensure synaptic modification) or whether they are activated under specific conditions is not known, although both proposals are not mutually exclusive. In pathologic conditions such as epilepsy, such multiplicity may guarantee the expression of LTP and LTD.[10] Alternatively, some neuronal functions may be compromised, which may explain why some patients have cognitive deficits.

Summary and Conclusions

The transfer of information between neurons can be modified in multiple ways and at different sites, from the presynaptic terminal to the postsynaptic terminal. Synaptic plasticity involves most of these modifications. Synaptic plasticity can occur on different time scalesâ€"from short-term (hundreds of milliseconds) to long-term (months)â€"and these involve very different mechanisms. While short-term plasticity is known to play a physiologic role in information processing *in vivo*, the role of long-term forms also occur *in vivo* remains to be determined. However, it is clear that LTP and LTD can be triggered at the synapse, thus demonstrating the presence of plasticity mechanisms. Another important feature is the presence of different biochemical cascades that can be activated at a given synapse to produce synaptic plasticity. This may ensure redundancy of the plasticity mechanisms as well as specificity depending on the presynaptic pathway that are activated. Synaptic plasticity also depends on the target neuron. A conditioning stimulus generated by a given source neuron will trigger different mechanisms according to its target. Plasticity mechanisms may not be evenly distributed within the network, but targeted so as to adequately respond to environmental changes.

How does synaptic plasticity relate to epilepsy? Several nonexclusive hypotheses have been proposed. First, an episode of status epilepticus may trigger synaptic plasticity and result in tissue hyperexcitability, thus leading to the construction of epileptic regions during the latent, seizure-free, period. Second, recurrent seizures may trigger synaptic plasticity and result in a further facilitation of excitability and a predisposition of seizures, in generating seizures, thus creating. Third, because of the considerable remodelling that takes place in the epileptic brain, certain biochemical cascades may be compromised, resulting in a decreased ability to express short-term and/or long-term forms of synaptic plasticity. The impact on information processing and cognitive performance remains to be assessed but it may well be disadvantageous.

Chapter 36

Animal Models of Acquired Epilepsies and Status Epilepticus

Giuliano G. Avanzini

David M. Treiman

Jerome Engel Jr.

Introduction

In animals, epilepsies with focal seizures can be faithfully reproduced by various experimental procedures that can induce an initial status epilepticus (SE) followed after a latent period by a chronic seizure recurrence. Thus, the initial SE and the subsequent chronic epilepsy can be considered the biphasic expression of a common pathogenetic process, which is set in motion by the experimental manipulation.

This chapter reviews models for SE and for epilepsies with focal seizures obtained using experimental epileptogenic procedures in normal animals. Some procedures are relevant to both focal epilepsies and SE, whereas others are specific for either one; therefore, SE and focal epilepsy models are dealt with in two separate sections. Models of epileptogenic dysplasia are also discussed.

In principle, animals presenting with spontaneous seizures can be profitably studied to gain information on species-specific susceptibility and pathophysiologic mechanisms, but, in practice, their interest is limited by the difficulties of obtaining homogeneous populations and the obvious differences in the ability to study domesticated or laboratory species versus those in the wild.

In most domesticated species, spontaneously occurring SE has never been observed, whereas reports of spontaneous localization-related epilepsies are mostly anecdotal and do not provide a basis for defining any suitable model for systematic experimental studies. An exception is the dog, in which prevalence of epilepsy approaches that of humans.[64] Because there is evidence for genetically determined susceptibility to epilepsy and/or epileptogenic brain pathologies, canine epilepsies are not dealt with here. None of the other animal models of genetically determined epilepsies are included in this account because they also are models for generalized rather than focal epilepsies.

Reports of experimentally induced seizures in animals date back to the seventeenth century, when Robert Boyle[24] observed the occurrence of seizures in sparrows, larks, cats, and mice exposed to low air pressure in a decompression chamber. At the cusp of the nineteenth and twentieth centuries, pioneering studies by Fritsch and Hitzig,[81] Openchowski,[163] Baglioni and Magnini,[10] and later Kaufmann[109,110] revealed that other physical and chemical means were effective in inducing epileptic manifestations, including cortical electrical stimulation, freezing, and the topical application of strychnine. Other agents later shown to be effective as topical convulsants include metallic compounds, which were studied for many years by Lenore and Nicholas Kopeloff after their first report,[114] metabolic antagonists, and convulsant drugs (see Prince[172] for review). The application of intracellular recording to experimentally induced cortical foci provided an early insight into the cellular mechanisms underlying epileptogenesis,[134,135] and since then, a number of studies have considerably deepened our understanding of focal epileptogenesis in experimental animals and established a number of pathogenetic concepts that can now be reliably applied to human epilepsies.[8,173]

Experimental models provide a unique means of testing the efficacy of antiepileptic drugs and antiepileptogenic strategies, although the results may not always be generally applicable. Species-specific or mechanism-specific effects may, in fact, prevent their reproducibility in different species or in other types of experimentally induced or naturally occurring epilepsies.

Chemically Induced Focal Epilepsies

General Characteristics

Focal seizures are defined as those seizures whose symptomatology indicates the initial activation of a system of neurons limited to a part of one cerebral hemisphere.[69] Epilepsy is defined as a chronic condition of the brain characterized by an enduring propensity to generate epileptic seizures,[75] a definition that implies the tendency of recurrence of ictal manifestations over time. Thus, only animals with recurrent focal seizures can be considered as models for focal epilepsies.

In several instances, SE or closely spaced seizures are the initial event of a process leading to epileptic disorders presenting with recurrent seizures that occur spontaneously and do not require any further exogenously delivered precipitating stimulus. These characteristics correspond to those of human focal epilepsies, which are further classified as idiopathic (i.e., not preceded or caused by a neurologic disorder other than a possible hereditary predisposition), symptomatic (i.e., secondary to a known disorder of the central nervous system), or cryptogenic (i.e., secondary to a disorder whose course is hidden or occult). By definition, experimentally induced animal epilepsies fall into the category of symptomatic epilepsies because the causative factor (i.e., the experimental epileptogenic procedure) is always known.

The models reviewed in this section reproduce one important characteristic of human epilepsy, that is, its chronic course. They can be obtained by experimental manipulations that lead to a gradual development of persistent focal epileptogenic activities or by procedures capable of inducing acute epileptic manifestations that are able to set in motion a progressive epileptogenic process leading to a permanent epileptic condition. A typical example of the first possibility is topical application of alumina hydroxide gel, which induces progressive neuropathologic changes affecting cortical excitability, whereas the second possibility is best exemplified by the pilocarpine model,

---

in which the development of a chronic epilepsy is mediated by pilocarpine-induced SE. The role of the acutely induced limbic SE or closely spaced seizures is also important although not exclusive for kainic acid, whereas afterdischarges are relevant to epileptogenesis induced by focal electrical stimulation. Whether the epileptic manifestations occurring in the early phase contribute to the development of tetanus toxin**â€"**induced chronic epileptogenesis is not clear.

Animal models of acute seizures and in vitro models are dealt with in other chapters.

Interictal and Ictal Clinical Phenomenology

Ictal clinical phenomena depend on the complex of anatomic structures involved in the generation of ictal discharges, referred to as the *epileptogenic zone*. In principle, the main types of seizures observed in human epilepsies should be faithfully reproduced in experimental animals by creating epileptogenic zones in the appropriate cortical areas. However, the evaluation of ictal phenomenology in animals is necessarily limited to external observations of animal behavior and thus provide only an indirect assessment of the subjective experience, which is an important aspect of seizures originating in cortical areas involved in sensation, emotion, and higher cognitive function.

The evaluation of experimentally induced complex partial seizures presenting with variable sequences of typical symptoms (including loss of contact) is also difficult, as is the comparison of animal and human seizures because of species-related differences in central nervous system organization. Of course, the ictal involvement of some human-specific functions such as language can never be modeled in experimental animals.

Besides these intrinsic difficulties, further problems in assessing the reproducibility of human seizures in experimental animals derive from the scanty descriptions of ictal phenomenology in some experimental studies. For instance, it is insufficient to describe a seizure as focal with elementary motor symptomatology without a qualitative (clonic vs. tonic, tonic vs. postural, positive vs. suppressive, etc.) and topographic (massive vs. segmental, stationary vs. migrating, etc.) analysis of its motor manifestations.

Neurologic, psychic, and neuropsychological persisting signs during the interictal period have been reported in patients suffering from focal symptomatic epilepsies. Interictal neurologic and behavioral studies in animals made epileptic by different experimental procedures have been performed only occasionally (see later discussion).

Interictal and Ictal Electroencephalographic Features

In human localization-related epilepsies, interictal focal â€œepileptiformâ€ electroencephalographic (EEG) activities are often seen as spikes, sharp and slow waves, fast rhythms, and so on.[53] The transition from an interictal to an ictal discharge may be represented by repetitive interictal discharges, localized fast activity (often with a recruiting character), or other rhythmic discharges not necessarily colocalized with the interictal focus (if present).[53] Similar EEG changes can be detected in animal models of partial epilepsies, although the internal frequency of interictal and ictal discharges may not be the same as that seen in humans. This may depend on both species-related differences and technical factors (the type of electrodes, interelectrode distances, etc.). In particular, the current use of bone screws or intracranial wire as recording electrodes may exclude or reduce the filtering effect of bone on fast activities. To make recordings from animals comparable with those from humans, standardized EEG methodology and terminology should be developed.[74]

Natural History

Although human focal symptomatic epilepsies depend on various progressive, stationary, or remitting brain pathologies, their course is to some extent independent of the underlying disorder. In particular, the epilepsies secondary to acute brain insults (such as traumatic, vascular, and infectious epilepsies) display a typical biphasic course that includes an early phase with single or repeated â€œreactiveâ€[68] seizures or SE, which may then subside to give rise to chronic epilepsies after a more or less prolonged interval. Some of the experimental models reviewed here have contributed significantly to clarifying the mechanisms underlying such a biphasic course.

Questions that can be Addressed by Animal Studies

Experimental studies of epilepsies try to answer various questions concerning brain physiology, pharmacology, and pathophysiology that are all basically related to the aim of gaining a better understanding of the mechanisms underlying epileptogenesis.

The characterization of a cellular hallmark of epilepsy in the â€œpenicillinâ€ focus of cat neocortex, the paroxysmal depolarization shift (PDS),[134,135] was seen as a major breakthrough that could directly lead to the unraveling of the â€œbasic mechanism of epilepsy.â€ However, it was soon realized that the analysis of this characteristic burst-discharge seen in individual neurons only partially explains the biologic basis of epileptogenesis. Moreover, it became clear that similar shifts could result from a variety of experimental manipulations differentially affecting the excitable properties of cortical neurons, thus suggesting that a unitary explanation of epileptogenesis was unrealistic.[172]

Selection of a model for study depends on the specific question being asked. However, whether designed to replicate a specific component or an overall process, the ideal model is one that most closely approximates the phenomenon or process of interest. Thus, experimental models should closely approximate behavior, electroencephalographic characteristics, and pharmacologic responses of the type of human epileptic manifestation being studied.

In considering the questions to be addressed by a given experimental model, it must be borne in mind that the answers an investigator may obtain are valid only for that specific model unless otherwise demonstrated. Therefore, the relevance that an experimentally demonstrated epileptogenic mechanism may have in relation to human epilepsies depends on the strength of the evidence of its involvement in human epilepsies. Ultimately, therefore, parallel studies in patients are required.

The following is a discussion of some of the models that have been in use for many years. Others not discussed in detail that are being developed include models of traumatic brain injury, hypoxia-induced epileptogenic encephalopathy, stroke, febrile seizures, intraparenchymal bleeding, and cerebral infection.[168]

Alumina Model

The epileptogenic effect of the topical application of alumina hydroxide gel to monkey neocortex was discovered by Kopeloff et al.[114] in the context of a study aimed at investigating

P.417

immunologic factors in epilepsy. Among the many other metallic compounds that were later shown to induce epileptic foci, alumina cream is the most suitable for inducing chronic focal epilepsy.

Methods

Autoclaved aluminum hydroxide 4% gel is injected in a few adjacent sites of the exposed neocortex using a small syringe needle.[247] Epileptogenic foci are optimally induced in primates but less consistently in dogs, cats, and guinea pigs. There are no reports of spontaneous seizures induced by intracortical alumina in lower forms. Alternatively, the systemic[76] and intracisternal[111] administration of aluminum salt or aluminum metallic powder[29] has been used to induce encephalopathy with multifocal seizures in susceptible animals (rabbits, cats, and ferrets, but not rats).

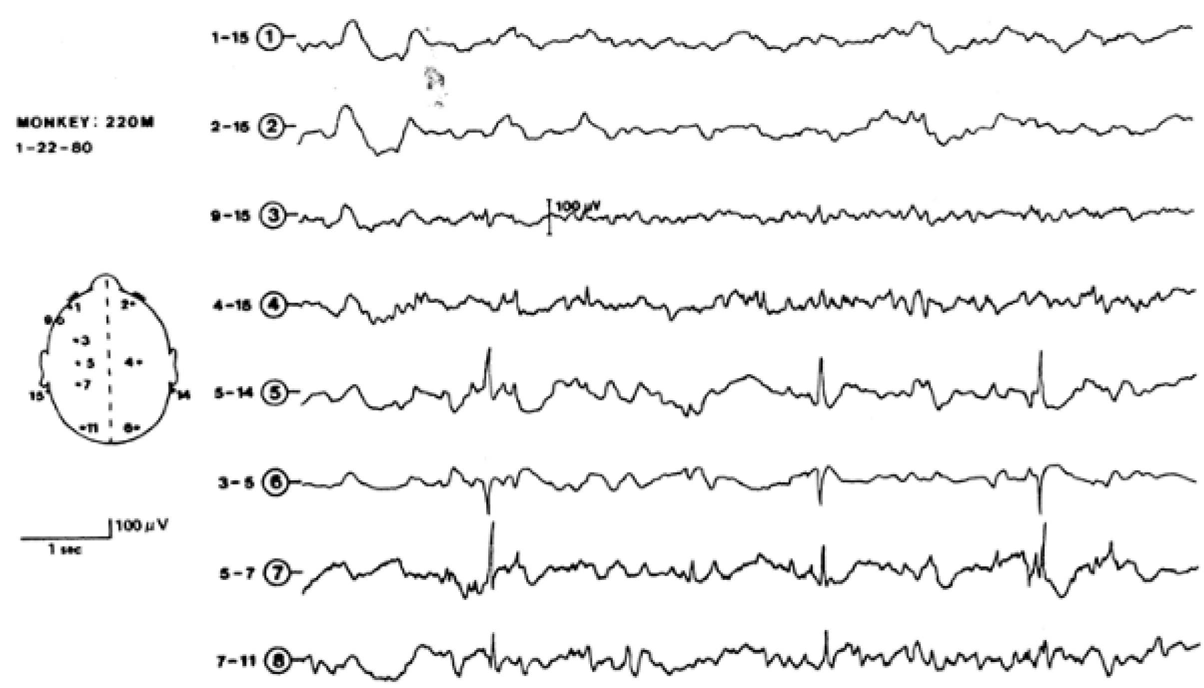

FIGURE 1. Sleep recording from a *Macaca mulatta* injected in left pre- and postcentral gyrus with aluminum hydroxide. The electrodes 1â€“8 and 10â€“13 are skull-screws. The electrode 9 is placed in temporalis muscle, and electrodes 14 and 15 are implanted in the mastoid process. Note the spike activity on the left hemisphere. (From Lockard JS. A primate model of clinical epilepsy: mechanism of action through quantification of therapeutic effects. Note in panel B the irregularities in dendritic size and the repetitive discharge superimposed on a prolonged depolarizing shift. (From Franceschetti S, Bugiani O, Panzica F, et al. Changes in excitability of CA1 pyramidal neurons in slices prepared from $AlCl_3$-treated rabbits. *Epilepsy Res.* 1990;6:39â€"48; with permission.)

Neuropathology

Dendritic distortion with decreased branching size irregularities and spine loss has been observed in pyramidal neurons within an alumina cortical focus.[250] These changes are due to a toxic effect leading to neurofibrillary degeneration, which has been studied in aluminum encephalopathy induced by both systemic and intracisternal administration.[29,111] The further stages of toxic degeneration lead to neuronal loss with marked gliosis, which is particularly prominent in â€œmatureâ€ alumina cortical foci.[102] A decrease in GABAergic nerve terminals at the sites of alumina foci has also been reported.[178] In most experiments, alumina has been topically applied to the sensorimotor cortex or the hippocampus; in both regions, pyramidal neurons have been found to be consistently affected after the intracisternal injection of aluminum powder.[29]

Natural History and Clinical Phenomenology

Spontaneous clinical seizures appear between 2 weeks and 6 to 8 months after intracerebral injection of alumina cream, depending on the number of injections and the width of the involved area.[247] Once established, the seizures spontaneously recur, probably throughout the life span of the animals; in monkeys, they have been observed for at least 7 years.[247] With large foci, seizure frequency may increase to status epilepticus and require antiepileptic treatment to maintain a viable preparation. The seizure patterns depend on the location of the focus. According to Ward,[247] in monkeys receiving alumina injections in the face and arm area of the somatomotor cortex, the seizures begin with contralateral facial or hand twitching, spread gradually to the entire contralateral side (mimicking a jacksonian march), and may eventually become generalized. During the seizures, muscular jerks occur at an increasing rate, which then fuse into a tonic contraction with superimposed strong generalized jerks, cyanosis, and sialorrhea. The tonic or tonicâ€"clonic phase ceases abruptly, giving place to a postictal depression with hypotonia and unresponsiveness to external stimulation of variable duration. When a particularly intense epileptogenic focus has been obtained, focal motor status epilepticus can be observed, with continuous 1/10-second jerks of the contralateral face and hand, mimicking Kojeknikoff epilepsia partialis continua. Behavioral seizures reminiscent of human complex partial seizures of temporal origin can be observed after alumina injection in the anterior part of the temporal lobe and/or in the amygdala of monkeys and cats.[83,251] Soper et al.[203] consistently obtained chronic temporal lobe epilepsy in monkeys only by means of bilateral alumina injections in the hippocampus; the clinical seizures consisted of head-turning, lip-smacking, mastication, and salivation.

Electroencephalogram

Serial recordings show the gradual development of interictal foci of slow and sharp waves, spikes, and delta activity in the region of the scalp corresponding to the underlying alumina focus (Fig. 1).[96] The transition to ictal discharge may be difficult to identify when interictal activity is sustained; otherwise, it is characterized by focal fast activity of increasing amplitude.[202] As the seizure progresses, spikes and sharp waves tend to recur rhythmically and spread to other regions. In animals with bilateral foci, ictal discharges invariably begin at the site of the older focus.[202]

Pharmacology

Antiepileptic drug efficacy on interictal EEG discharges or seizure frequency has been widely studied in correlation with pharmacokinetic parameters.[121] Phenytoin (Dilantin), phenobarbital (Arco-Lase, Bellergal-S, Donnatal, Quadrinal Mudrane, Rexatol, Solfoton), primidone (Mysoline), and carbamazepine (Atretol, Tegretol) showed a significant effect on both seizure frequency and interictal EEG discharge. The efficacy was correlated with drug plasma levels. A less clear level/effect correlation was found for sodium valproate (which improved when the correlation was evaluated on an hour-by-hour basis).

Pathophysiology

Neurons belonging to alumina foci have a high probability of burst-firing, closely associated with surface epileptiform waves.[173] These putative epilepsy-related changes are not maintained in in vitro slices prepared from monkey alumina foci, which have been found to have physiologic properties that are not significantly different from those of control tissue.[186] On the contrary, Franceschetti et al.[77] observed significant changes in the excitable properties of hippocampal pyramidal neurons in slices prepared from intracisternally $AlCl_2$-injected rabbit. These changes were accounted for by a decrease in the efficacy of Ca^{2+}-dependent K^+ conductances and GABAergic transmission and by electrotonic shortening due to dendritic debranching (Fig. 2). They were clearly detectable in the very early phases of the aluminum-induced encephalopathy, even before the manifestation of neurofibrillary degeneration, cell loss, and gliosis. On the other hand, the hypothesized epileptogenic role of the gliotic scar (which is believed to impair K^+ regulation and thus lead to K^+ accumulation in the interstitial space) is controversial[102] and could not be directly demonstrated by Heinemann and Dietzel,[100] who found that the spatial buffer capacity of gliotic tissue for K^+ was not severely impaired in cat alumina cream foci.

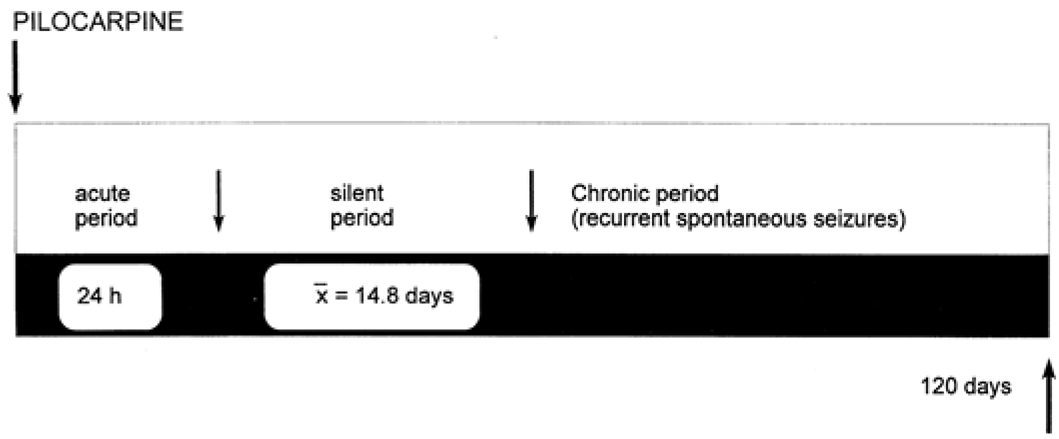

FIGURE 3. Schematic representation of temporal evolution of behavioral and electroencephalographic changes induced by an intraperitoneal injection of pilocarpine (380 mg/kg) in rats. (Redrawn from Cavalheiro EA, Leite JP, Bortolotto ZA, et al. Long-term effects of pilocarpine in rats: structural damage of the brain triggers kindling and spontaneous recurrent seizures. *Epilepsia*. 1991;32:778â€“782; with permission.)

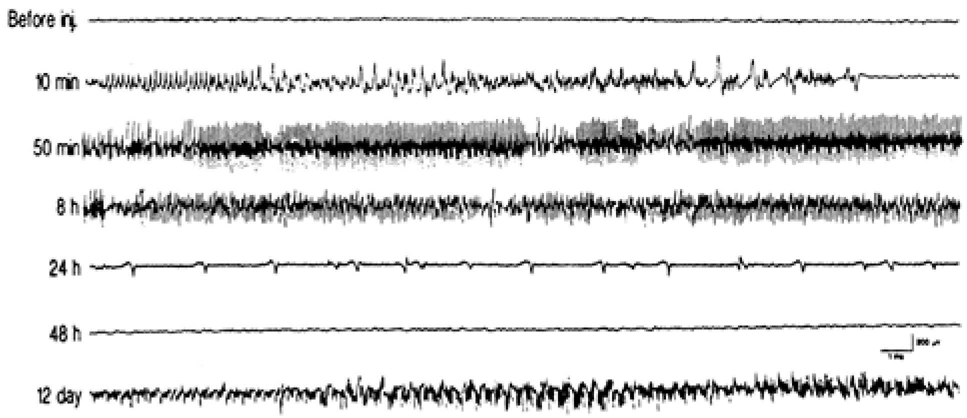

FIGURE 4. Skull-screw electrode electroencephalographic recording from frontoparietal region of a rat at different time intervals after intraperitoneal injection of pilocarpine (400 mg/kg). Continuous spike activity appeared 50 minutes after injection and lasted up to 8 hours. Isolated spikes persisted up to 24 hours, then disappeared during the latent period to show up again 12 days after injection. (From Liu Z, Nagao T, Desjardins GC, et al. Quantitative evaluation of neuronal loss in the dorsal hippocampus in rats with long-term pilocarpine seizures. *Epilepsy Res.* 1994;17:237â€“247; with permission.)

Pilocarpine Model

The first evidence that rats with brain damage induced by the cholinergic agent pilocarpine develop spontaneous recurrent seizures after a silent period of 14 to 15 days was provided by Turski et al.,[226] who were investigating the acute effects of pilocarpine treatment. As was stressed later by the same authors,[34] this natural history is reminiscent of that of human temporal lobe epilepsy, which often begins with prolonged status epilepticus in infancy and develops with recurrent seizures in later life.[89]

P.418

P.419

Methods

Thirty minutes after subcutaneous pretreatment with scopolamine, 1 mg/kg (to minimize peripheral cholinergic effects), a single high dose of pilocarpine (300â€“380 mg/kg) is injected intraperitoneally in rats and mice.[33] The acute pilocarpine-induced status epilepticus must be continuously monitored by behavioral observation and EEG recording because of the high mortality rate (30%),[33] which can be partially prevented by repeated intraperitoneal injections of diazepam 10 mg/kg plus phenobarbital 30 mg/kg[117] at 30 minutes 1, 2, and 6 hours after the beginning of the status epilepticus. Further behavioral-EEG monitoring is indicated during the silent period to detect the onset of chronic recurrent seizures.

Neuropathology

At the end of the acute phase, widespread bilateral morphologic changes appear that involve the hippocampus, amygdala, thalamus, pyriform and entorhinal cortices, neocortex, and substantia nigra.[226] These consist of massive swelling of dendrites and neuronal cell bodies with relative sparing of axons and astroglial cell swelling.[40,159] During chronic stages, there is invariably cell loss in all of the structures mentioned, including the hilus of the dentate gyrus. Clear-cut evidence of supragranular sprouting of the mossy fibers, beginning 4 days after the episode of status epilepticus and reaching a plateau after 100 days, can be found using Timm staining.[152] The severity of the chronic neuropathologic changes is proportional to the duration of the status episode[117] but not to the number of chronic seizures.[120]

Natural History and Clinical Phenomenology

The temporal evaluation of pilocarpine-induced behavioral and EEG changes is schematically illustrated in FIGURE 3. Immediately after the pilocarpine injection, the animal is hypoactive; subsequently, there is the appearance of facial automatisms, including chewing and eye blinking, followed by head bobbing and motor limbic seizures (forelimb clonus, salivation, and rearing on hind limbs). Generalized convulsions and limbic status usually occur 40 to 80 minutes after the injection, depending on the injected dose.[33,120,226] After a silent period of 4 to 44 days, the spontaneous seizures that characterize the chronic period appear and recur with a variable frequency of 2 to 15 per month, with no evidence of spontaneous remission for at least 6 months.[33]

Electroencephalogram

During the acute phase, the electroencephalographic changes evolve from early surface low-voltage fast activity correlated with a theta hippocampal rhythm to high-voltage fast activity associated with spiking in the hippocampus and, finally, surface spiking activity that correlates with head bobbing.[120] Limbic seizures are associated with high-frequency, high-voltage spike discharges that become continuous during limbic status. The EEG progressively normalizes at the end of the acute phase, although spontaneous spike discharges reappear after the silent period. The ictal electrographic discharges of the chronic period consistently originate in the hippocampus and subsequently spread to the cortical electrodes.[33] FIGURE 4 summarizes the evolution of EEG changes.

P.420

Pharmacology

Diazepam (Dizac, Valium) and scopolamine, 10 mg/kg, provide effective protection from acute seizures and limbic status.[33] Phenobarbitone 40 mg/kg/d, phenytoin 100 mg/kg/d, and carbamazepine 120 mg/kg/d have been found to be effective against the spontaneous seizures occurring during the chronic phase. Sodium valproate has been found to be effective only at very high doses (600 mg/kg/d); ethosuximide (Zarontin) 400 mg/kg/d is totally ineffective.[116]

Pathophysiology

In vitro experiments[15,16] have shown that the epileptogenic effect of cholinergic agents depends on the facilitation of burst discharges in hippocampal pyramidal neurons by means of a block of the K^+ transmembrane current I_M. This mechanism explains the massive activation of hippocampal neurons during pilocarpine-induced status epilepticus, which leads to cell death, axonal sprouting, and a synaptic reorganization of hippocampal circuitry that results in permanent epileptogenic changes.[33,35,120] The neuronal damage is not attributed to a direct toxic effect of pilocarpine, but to a seizure-related excitotoxic effect involving glutamate receptors and Ca^{2+} influx.

Tetanus Toxin

The epileptogenic properties of intracerebral tetanus toxin have been known since the end of the nineteenth century[180] but have been exploited in experimental studies of epileptogenesis only more recently after studies published by Brooks and Asanuma[28] and Carrea and Lanari[32] in cat and dog neocortex and by Mellanby et al.[152] in rat hippocampus and neocortex.[106]

Methods

Tetanus toxin is a protein with a molecular weight of 150 kDa released by *Clostridium tetani* and is now available in a purified form. It is quite stable and can be kept at 4Â°C for months. Tetanus toxin is extremely toxic and must be handled only by effectively immunized people wearing protective clothing (gloves and a mask). Tetanus toxin is active in all of the mammalian species tested[180] when very small amounts are injected in appropriate regions. The dose is usually expressed in toxicologic units that correspond to different quantities, depending on the degree of purification: 5 to 20 mouse half lethal dose (LD_{50}) has been used in rat hippocampus,[106] 2 to 30 minimum lethal dose in rat neocortex,[24] 10 to 10^3 mouse lethal dose in cat neocortex,[25] and 28 to 83 LD_{50} in dog neocortex.[32] It is important to bear in mind that tetanus toxin is very efficiently transported along axons.

Neuropathology

Early tetanus toxinâ€"induced histologic changes with minimum effective doses injected into the hippocampus are very mild and consist of a loss of neurons in the CA1 region. Much higher doses cause neuronal loss at the injection site. It is suspected that late changes in hippocampal circuitry occur, but these have not yet been systematically investigated.[106]

Natural History and Clinical Phenomenology

Animals that are injected with low doses in either the neocortex or hippocampus develop seizures 3 to 7 days after the injection.[27,106] Shorter intervals are reported with higher doses.[28] In rats receiving hippocampal injections of the toxin, there is a reduction in the number of seizures after some weeks of intense epileptic activity; the seizures eventually disappear but may relapse in the longer term.[106] In neocortex-injected rats[27] and cats,[125] tetanus toxinâ€"induced foci can be permanent. Hippocampal injections induce limbic seizures that start with a behavioral arrest, followed by vibrissal and facial twitching and forelimb myoclonus that may eventually develop into a clonicâ€"tonic seizure involving the hindlimbs. Injections in rat cortex are followed by early focal motor seizures in the jaws and/or contralateral limbs, tending to progress to generalized convulsive seizures after 16 hours.[27]

Electroencephalogram

Interictal biphasic sharp waves are recorded from the injected hemisphere 3 to 5 days after the injection and, a few days later, from the contralateral homotopic sites with synchronous or asynchronous expression (Fig. 5).[27] Ictal discharges of 3- to 20-Hz spikes and spikes-and-waves may be limited to one hemisphere or may spread rapidly to the contralateral side. The injected hemisphere leads in the early phases, but 5 to 13 days after the injection, the ictal discharge can be initiated in the contralateral hemi-sphere.[27]

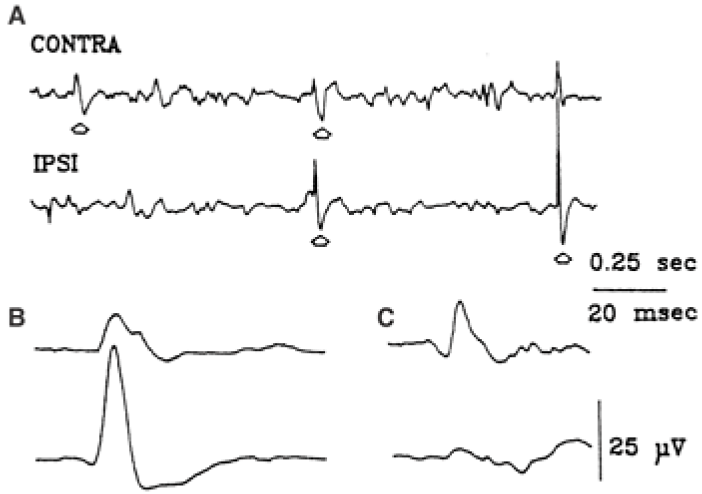

FIGURE 5. Skull-screw recording in a rat 22 days after injection of tetanus toxin. Interictal spikes occur in both injected (IPSI) and contralateral hemisphere (CONTRA) **(A)** either synchronously **(B)** or asynchronously **(C)**. (From Brener K, Amitai Y, Jefferys JGR, et al. Chronic epileptic foci in neocortex: in vivo and in vitro effects of tetanus toxin. *Eur J Neurosci.* 1991;3:47â€“54; with permission.)

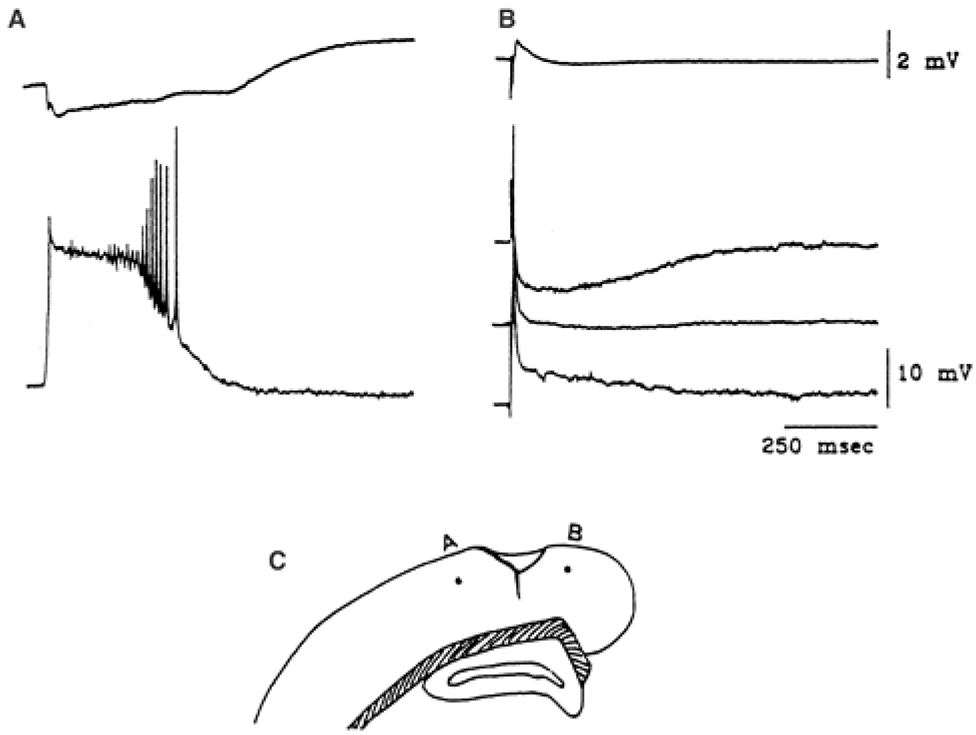

FIGURE 6. A, B: Simultaneous field (*upper trace*) and intracellular (*lower trace*) recordings made from A and B sites indicated in the schematic diagram **(C)** of a slice prepared from a rat injected with tetanus toxin in parietal neocortex 8 days before. Although the two recording points are equidistant from the injection track, site A generates epileptiform response, whereas site B appears relatively normal. (From Brener K, Amitai Y, Jefferys JGR, et al. Chronic epileptic foci in neocortex: in vivo and in vitro effects

of tetanus toxin. *Eur J Neurosci.* 1991;3:47â€“54; with permission.)

Pharmacology

Drugs effective in human focal epilepsies, such as carbamaze-pine, have also been found to be quite effective in the tetanus toxin model but not the *N*-methyl-D-aspartate (NMDA)â€“receptor antagonist 2-amino-5-phosphonopentanoic acid (APV).[106]

Pathophysiology

The tetanus toxinâ€“dependent epileptogenic process has various phases. At the very beginning, the toxin induces epileptiform discharges in the injection site as a result of a block of Î³-aminobutyric acid (GABA) release,[46] leading to the impairment of the local inhibitory circuits established by GABA interneurons in both the hippocampus and the cerebral cortex. The epileptiform neuronal aggregate is contained in hippocampal and neocortical slices prepared from the injected areas, and this has allowed a detailed electrophysiologic analysis.[67,105] In a second phase, the toxin is transported through the axons to even remote sites, where it can move transsynaptically inside local GABAergic neurons. A transport velocity of as much as 200 mm/d has been estimated in peripheral nerves,[185] and, therefore, transport-related patches of epileptiform activity can be generated in a few hours through corticocortical and callosal connections (Fig. 6). This mechanism might account for the rapid generation of mirror foci.[27] In a third chronic phase, GABA-mediated inhibition recovers, due probably to an increased RNA expression of glutamic acid dehydrogenase (GAD). The epileptic activity persisting in this chronic phase is attributed to seizure-induced plastic changes in the hippocampal or neocortical circuits, leading to the functional disconnection of GABAergic neurons or the sprouting of new excitatory axons.[106]

Kainic Acid

Kainic acid is a highly potent glutamate agonist that is obtained from the seaweed *Digenea simplex* and used as an ascaricide. Kainic acid was found to be excitatory when applied iontophoretically to rat cortex[195] and to induce seizures when injected intracranially[19,20] or systemically.[21,47,126] Olney et al.[160] highlighted its neurotoxic properties and reported its toxicity to be particularly prominent on the hippocampus, even when systemically injected. Kainic acidâ€“induced cell injury is attributed to an excitotoxic mechanism triggered by the activation of excitatory amino acid (EAA) receptors. The same mechanism is also responsible for the hippocampal seizures occurring in animals injected, either intravenously[126] or in the hippocampus,[34] with doses less than those required to produce direct cell damage.

Methods

Most of the studies with kainic acid have been done in rats. Systemic doses of 4 mg/kg[126] and local injections of 0.4 mg[8] are effective in inducing persistent seizures. Similar effects have been obtained by means of intracisternal ventricular injections in mice,[227] for which a 50% convulsive dose of 0.3 nmol has been calculated. A single intra-amygdaloid injection of 1 Âµg in cats has been found to be effective in inducing focal status epilepticus.[126,214]

Neuropathology

The systemic administration of kainic acid induces a variable pattern of cortical and subcortical damage involving the pyriform and entorhinal cortices, the hippocampus, the lateral septum, and several thalamic and amygdaloid nuclei.[159] In the hippocampus, degenerating neurons are found in the dentate hilus, CA1, and CA3.[74] A similar pattern of hippocampal degeneration has been found after local hippocampal injection during the acute phase,[133] with evidence of active cellular phagocytosis of the necrotic zone in the next active phase.

The Timm[217] sulfide silver method for heavy metals, subsequently modified,[54] shows an initial sprouting of zinc-containing mossy fibers into the inner molecular layer. This sprouting progressively increases during the latent phase, reaching its maximum at the beginning of the chronic phase, when a thick band of Timm-positive fibers is permanently found in the inner molecular layer (Fig. 7). With unilateral injection, the changes are largely unilateral, resembling human hippocampal sclerosis.

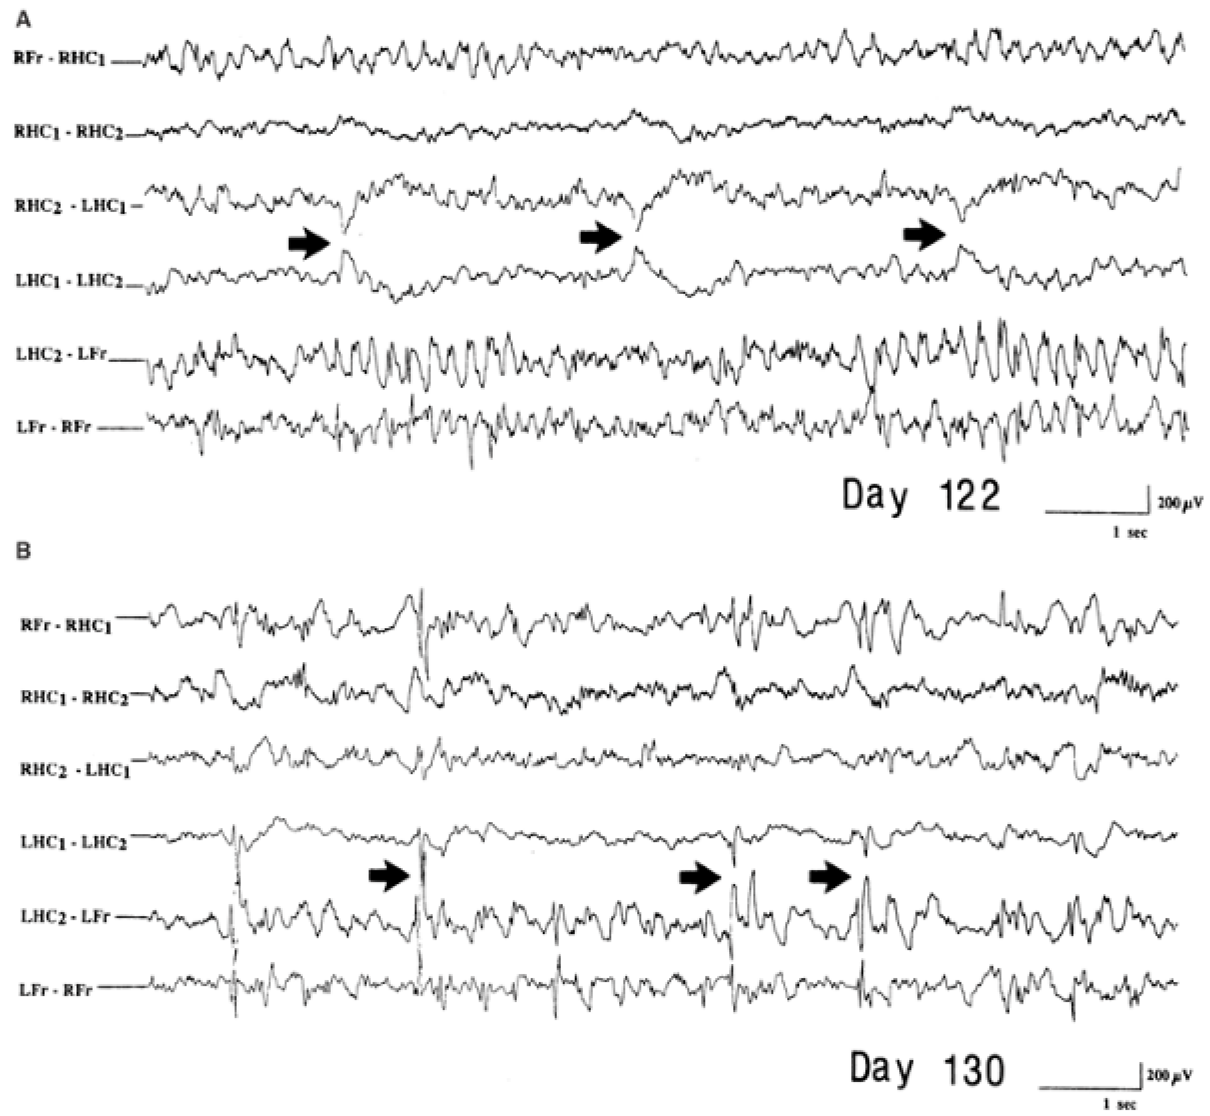

FIGURE 7. Interictal recording from a rat bilaterally injected with kainic acid in the hippocampus 122 **(A)** and 130 **(B)** days before. Fr, single wire electrodes placed into the frontal cortex; HC1, 2, double-twisted wire electrodes inserted in the hippocampus; L, left; R, right. The independent epileptiform transient (*arrows*) are seen mostly in the left hippocampus, which showed evidence of mossy fiber sprouting, as shown by Fig. 8. (From Mathern GW, Cifuentes F, Leite JP, et al. Hippocampal EEG excitability and chronic spontaneous seizures are associated with aberrant synaptic reorganization in the rat intrahippocampal kainate model. *Electroencephalogr Clin Neurophysiol.* 1993;87:326â€"339; with permission.)

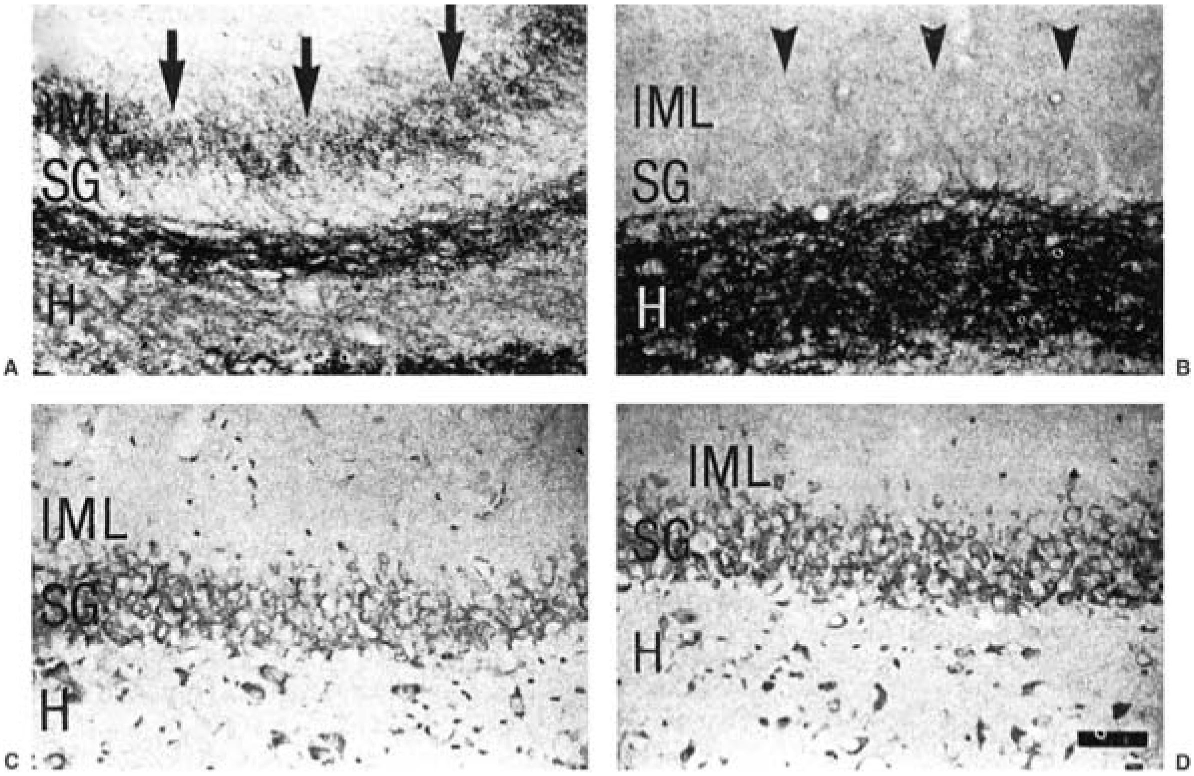

FIGURE 8. In the same animal whose electrographic recording is shown in Fig. 7, Timm-stained sections show a zinc-positive band (*arrows*) in the left **(A)** but not in the right (**B**) inner molecular layer (IML). Note that both hippocampi (**C, D**) show evidence of neuron loss in the stratum granulosum (SG) and hilus (H). (From Mathern GW, Cifuentes F, Leite JP, et al. Hippocampal EEG excitability and chronic spontaneous seizures are associated with aberrant synaptic reorganization in the rat intrahippocampal kainate model. *Electroencephalogr Clin Neurophysiol.* 1993;87:326â€"339; with permission.)

Natural History and Clinical Phenomenology

The evolution of the epileptic phenomenology and electrophysiologic correlates induced by low doses of kainic acid injected

P.422

bilaterally in rat hippocampus has been longitudinally studied by Mathern et al.[133] and correlated with concomitant histologic changes. Similar asymmetric changes occur with unilateral hippocampal injections, which more accurately reproduce the predominantly unilateral condition of human mesial temporal lobe epilepsy.[25] On the basis of the clinical and electrophysiologic course, four phases have been recognized as sequentially occurring after kainic acid injection at the following approximate time intervals in days: acute (0â€"10), active (10â€"30), latent (30â€"90), and chronic. The earliest seizures characterizing the acute phase occur within 1 hour after hippocampal injection and consist of behavioral arrest; the association of sniffing and facial myoclonus is ascribed to the frontal spread of the discharge. After several hours, the seizures increase in duration and may eventually evolve into a partial status characterized by simple staring. The active phase is characterized by short-duration seizures (<1 minute) with generalized motor clonus and very rapid behavioral recovery. The seizures disappear during the latent period but relapse during the chronic phase, with characteristics similar to those of the acute stage: A motionless stare that may occasionally progress to a more complex phenomenology, including facial automatisms, forelimb clonus, and generalized clonicâ€"tonic seizures. The chronic seizures do not tend to subside, but rather increase in frequency and duration and may generalize over time.[133]

Electroencephalogram

Mathern et al.[133] and Bragin et al.[25] monitored the hippocampal activity recorded by stereotaxically implanted deep electrodes and the frontal activity derived from intracortical wires.

In the acute phase, discharges of spikes and multispikes in the hippocampus are associated with behavioral arrest and spread of the discharges toward the frontal cortex with sniffing and facial myoclonus. Postictal diffuse slowing of background activity is regularly observed and is sometimes associated with periodic lateralized epileptiform discharges (PLEDs). The active phase is characterized by interictal fast activity and polyspikes limited to the hippocampus, the transition to the ictal discharge being marked by a pronounced spike activity that rapidly generalizes. During the latent phase, there is a reduction in the interictal spikes, and background activity is almost normalized; in the late part of the latent phase, however, spikes and sharp waves are increasingly recorded, and there is a marked tendency to asynchronous expression in both hippocampi. The asynchrony of interictal spikes and sharp waves becomes more and more evident during the chronic phase, when ictal discharges limited to one hippocampus reappear in association with motionless staring episodes. A bilateral spread of discharges is observed during generalized seizures (Fig. 8). In addition to the clinical seizures, more frequent electrographic seizures can also be recorded, usually during sleep.[25] Whereas the EEG patterns during clinical seizures resemble the low-voltage fast ictal onset of human mesial temporal lobe epilepsy, the electrographic events resemble the hypersynchronous onsets usually associated with auras in patients.

More recently, microelectrode recordings from unilateral intrahippocampal kainic acidâ€“treated rats have led to the discovery of 150- to 500-Hz â€œFast Rippleâ€ oscillations identical to those recorded from human epileptic hippocampus.[25] Fast Ripples can also be recorded shortly after kainate injection and predict which rats will develop spontaneous seizures.[26] The significance of this novel finding is discussed in Chapter 13.

Pharmacology

Drug responsiveness of the kainate model is essentially the same as that for the pilocarpine model.

Pathophysiology

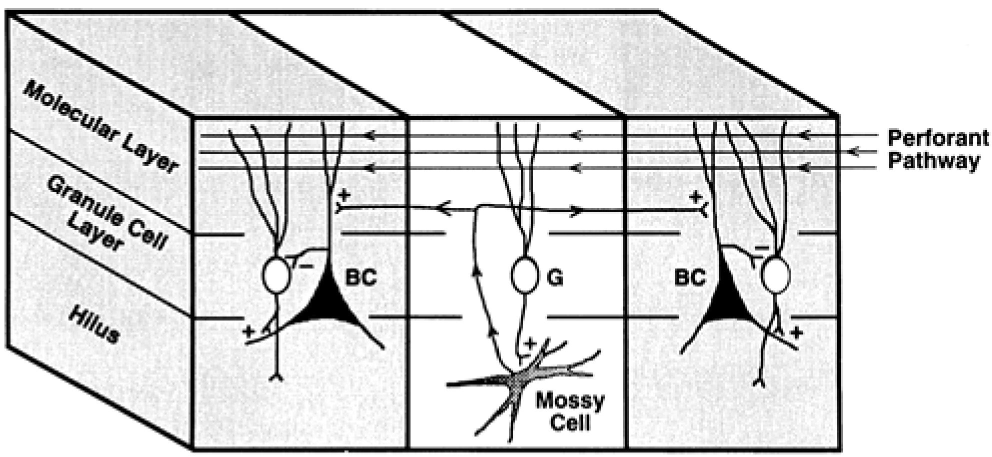

FIGURE 9. Diagrammatic representation of dentate network circuitry and the hypothesized translamellar mossy cell innervation of inhibitory basket cells. BC, basket cells; G, granule cells. A Manual for the Laboratory Worker*. New York: Raven Press; 1972:147â€"172; with permission.)

The early seizures occurring during the acute phase are attributed to the direct effect of the excitatory amino acid receptor agonist kainic acid, which is especially prominent in the hippocampus due to the particularly high concentration of kainic acid receptors in this region. The permanent changes in hippocampal excitability underlying chronic seizures is ascribed to neuronal damage of the vulnerable hilar mossy cells due to kainic acid excitotoxicity or the ensuing sprouting of mossy fibers. The first effect is thought to lead to a selective denervation of the neurons that mediate granule cell inhibition (Fig. 9), thus increasing their excitability.[199] On the other hand, the newly formed recurrent mossy fiber collaterals could re-excite the dentate granule cells through newly formed synapses.[215] The role of these two putative epileptogenic mechanisms will be further discussed later.

P.424

Electrical-Stimulationâ€"Induced Focal Epilepsies

Self-Sustained Status Epilepticus

The possibility of eliciting epileptic manifestations by means of the repeated electrical stimulation of discrete regions of the central nervous system has been known since the nineteenth century following the experimental studies of Fritsch and Hitzig,[81] Ferrier,[73] and Luciani.[128] The analysis of the electrographic correlates of stimulation-induced seizures showed that the associated discharge may outlast the end of the stimulation train.[3] Although self-sustained, this electrically evoked afterdischarge is still a stimulation-dependent acute epileptic phenomenon. Later, Alonso-De Florida and Delgado[5] discovered that appropriate paradigms of repeated stimulation may induce permanent changes in excitability and lead to the recurrence of spontaneous seizures. Electrogenic models of SE are discussed later in the SE section.

Methods

The optimal stimuli for the production of afterdischarges are 4- to 6-second trains of repeated (25â€"60 Hz) 2.5- to 8.0-mA, 2- to 5-msec diphasic square pulses.[4] After a first effective train, a second afterdischarge can be obtained only after a delay of at least 15 seconds. Using more prolonged and/or intense stimulating trains, Lothman et al.[126] and Handforth and Ackermann[93] overcame this refractory period and reduced the intertrain interval to 0.5 second by using a protocol currently defined as â€œcontinuousâ€ hippocampal stimulation. Focal electrical stimulation has been found to be effective in all studied species, including humans. The greatest susceptibility is in the hippocampus and amygdala. All of the neocortical areas can generate afterdischarges, the most and least prone regions being the precentral motor area and the temporal gyri (Fig. 10).[4]

Neuropathology

By definition, afterdischarges are evoked in normal tissue, which should not be directly damaged by the stimulation procedure, provided appropriate parameters are used. However, Sloviter and Damiano[201] and Sloviter[198] found that indirect damage to hilar mossy cells can be induced by the stimulation of a perforant path capable of inducing repetitive discharges in their target granule cells, which innervate the hilar mossy cells themselves. In addition, there is evidence that, during repeated stimulation, use-dependent structural rearrangements of the involved neuronal network occur (e.g., mossy fiber sprouting) that are similar to those observed in other chronic models of hippocampal epilepsy.[17]

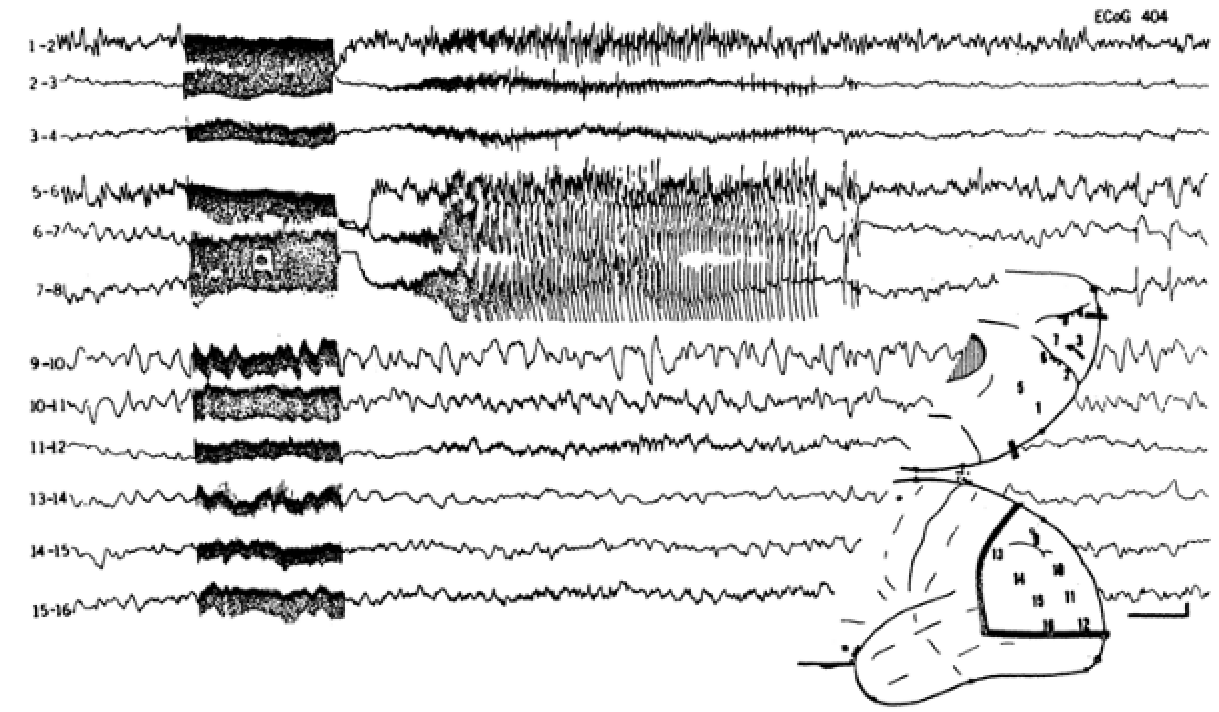

FIGURE 11. Electrocorticographic recording of a typical, relatively well-localized afterdischarge in an epileptic patient with surgical exposure of the occipital region, as indicated in brain outline with electrode position. The stimulation was delivered in the region indicated by the bent arrow. (From Ajmone Marsan C. Focal electrical stimulation. In: Purpura DP, Penry JK, Tower D, et al., eds. *Experimental Models of Epilepsy. A Manual for the Laboratory Worker*. New York: Raven Press; 1972:147â€"172; with permission.)

Natural History and Clinical Phenomenology

The stimulation-induced afterdischarge can be purely electrical or associated with clinical manifestations appropriate to the functional properties of the involved areas. Continuous hippocampal[124] or amygdala stimulation[93] leads to self-sustained epileptic states defined as â€œimmobile, exploratory, minor convulsive, and clonicâ€ according to a behavioral-electrographic hierarchy of severity.[94] After a latent period, as

P.425

with pilocarpine and kainic acid, animals exhibit spontaneous seizures.

Electroencephalogram

The electrographic activity characterizing typical afterdischarges becomes evident 1 to 2 seconds after the end of the stimulating train. It begins as 15- to 30-Hz low-voltage oscillations, which progressively increase in amplitude and decrease in frequency, leading to large voltage oscillations (Fig. 11). The episode lasts from 10 to 90 seconds and ends abruptly, giving way to a postictal depression lasting from 2 to 15 seconds.[4]

Pharmacology

The effect of antiepileptic drugs can be tested on the threshold or duration of the afterdischarge. Carbamazepine, phenobarbital, and diazepam, but not sodium valproate, ethosuximide, or phenytoin, have been found to be effective on the maximal dentate activation obtained by means of contralateral region stimulation.[209]

Pathophysiology

The self-sustained character of the afterdischarge has always been attributed to a failure in inhibitory mechanisms,[4] a view that was subsequently supported by the perforant path stimulation experiments of Sloviter and Damiano[201] and Sloviter.[198] The hyperexcitable state, leading to the facilitation of afterdischarges, electrogenic status epilepticus,[93,126] and, eventually, the epileptogenic process, is the result of complex changes involving cell excitability and circuitry rearrangements that are discussed for other models (see also next section on kindling).

Kindling

Although physiologic psychologists carrying out electrical stimulation studies in rats had noted for some time that a few eventually developed seizures, this was considered a nuisance because it disrupted their research paradigms. Goddard, however, recognized this to be an interesting phenomenon in itself and developed the concept of kindling.[90,91] Electrical kindling refers to the process of brief subthreshold brain stimulation that, when repeated, gradually results in ictal behaviors. Stimulation-induced seizures then persist indefinitely after the kindling process is discontinued. Electrical kindling, therefore, was an ideal mechanism for bringing the process of epileptogenesis under laboratory control, and it rapidly became the most commonly used animal model for studying basic mechanisms of epilepsy. Kindling as usually practiced, however, is not a model for chronic epilepsy because seizures do not occur spontaneously but need to be provoked by electrical stimulation. Although animals kindled for prolonged periods of time after maximal seizures occur eventually do develop spontaneous seizures,[165] this model of chronic epilepsy is rarely used because of the time required and the difficulty in maintaining viable animals. Consequently, although kindling remains a useful model for the study of epileptic phenomena, particularly with respect to the limbic system,[49,50,230,231,232,233,234] it has now been largely replaced by the excitotoxic and stimulation-induced self-sustained status epilepticus models that more faithfully

P.426

reproduce human mesial temporal lobe epilepsy with hippocampal sclerosis.

â€œChemical kindlingâ€ refers to the process of repeated treatments with chemoconvulsants such as metrazol or carbacol, which, like electrical kindling, eventually results in epileptic seizures in response to the chemical treatment.[87] Although chemical kindling presumably produces many of the same epileptogenic plastic changes induced by electrical kindling, the former models have been less well studied.

Methods

The classical kindling model involves electrical stimulation of the amygdala, although stimulation of hippocampus, piriform cortex, and other limbic structures results in the same epileptogenic phenomenology.[145] The time course of kindling differs depending on the site of stimulation, stimulus parameters, interstimulation intervals, and species. Kindling can also be achieved with stimulation of nonlimbic brain areas such as neocortex, thalamus, and caudate, but this is associated with a different behavioral evolution and less consistent progression than limbic kindling. Many other structures, such as brainstem and cerebellum, however, do not support kindling.

Typically, limbic kindling begins with a stimulus intensity that produces afterdischarge without behavioral effects. With repeated stimulation, the afterdischarge duration increases and ictal behaviors begin with arrest, ipsilateral eye blinking, and chewing (stage 1), followed over time by head bobbing (stage 2), then forelimb clonus (stage 3), rearing (stage 4), and falling with generalized tonicâ€“clonic movements (stage 5).[176] It is also possible to begin kindling with subthreshold stimulation intensity (below that necessary to induce afterdischarges), in which case repeated stimulation eventually produces afterdischarges, which then reiterate the electrographic and behavioral epileptogenic progression.[175] The usual stimulation parameters are 60 to 100 Hz delivered for 1 second, although slower frequencies and different durations are also effective. The time required for kindling to stage 5 depends on the area stimulated and the interval between stimulations. A typical paradigm involves stimulation for 1 second once a day, which requires approximately 2 weeks for amygdala kindling and 4 weeks for hippocampal kindling.

Neuropathology

Although limbic kindling is associated with mossy fiber sprouting, resembling this pathologic finding in human hippocampal sclerosis and chronic animal models of this disorder,[210] cell death, particularly in the dentate hilus, is minimal. Neurogenesis and astrocytic proliferations have also been reported, but there are no neuropathologic findings specific to kindling.[211]

Natural History and Clinical Phenomenology

Kindling is not a single phenomenon, but a series of phenomena that underlie a progressive epileptogenic process. With subthreshold kindling, for instance, there are changes that occur only at the tips of the stimulating electrodes that eventually result in the appearance of afterdischarge. As stimulation continues, or with classical kindling, the increase in duration of afterdischarge also involves epileptogenic plastic changes at the electrode tips, but most likely in surrounding tissue as well. The appearance of clinical signs reflects propagation of epileptiform afterdischarge to distant structures, requiring transsynaptic alterations. This process evolves to recruit primary motor cortex and other brain areas, eventually engaging brainstem systems responsible for tonicâ€“clonic seizures. The progressive transsynaptic recruitment is not merely a reflection of more intense afterdischarge at the electrode tips, but true synaptic plasticity, because stage 5 seizures, once achieved, almost always occur with any stimulation at the kindling site capable of inducing afterdischarge. Many widespread areas of the brain, therefore, develop an enduring epileptogenic potential with focal kindling. If kindling proceeds for months, spontaneous seizures eventually appear, and these typically do not originate at the site of kindling stimulation but from their efferent projection areas.[165]

Other enduring distant effects of kindling also occur. For instance, â€œtransferâ€ refers to the fact that whereas it may take 2 weeks of daily stimulation to reach a stage 5 seizure with unilateral amygdala kindling, stage 5 seizures can then be provoked with only a few stimulations of the contralateral amygdale.[144] On the other hand, contralateral kindling has an interhemispheric seizure-suppressing effect, in that it might take several additional days of stimulation to reestablish a stage 5 seizure with stimulation of the primary site.[144] Ipsilateral seizure facilitating and seizure-suppressing effects can also be demonstrated with electrical kindling. Other evidence of kindling-related seizure suppression also exists during the postictal period. There is a refractory period after kindled seizures during which time another stimulation will not generate a seizure. Animals that have been subjected to frequent seizures during a relatively short period of time develop postictal seizure refractoriness that can last weeks.[155] Investigations into this phenomenon could provide insights into natural homeostatic mechanisms that protect against recurrent seizures.

Neocortical, thalamic, and caudate kindling produces an entirely different epileptogenic progression. Rats do not go through the initial stages associated with limbic behaviors but eventually exhibit focal motor and generalized tonicâ€“clonic seizures. Whereas limbic kindling progresses consistently, once a stage is achieved, rarely does the animal backslide to a lower-stage seizure on the subsequent stimulation; backsliding is a common occurrence with neocortical, thalamic, and caudate kindling. Kindling-like phenomena can also be produced by stimulation of other subcortical structures such as nucleus accumbans, but these may not be epileptic behaviors.[207] Electrical kindling has been carried out in a variety of species, from frogs to primates.

In general, the higher the species is on the phylogenetic scale, the longer it takes to kindle. Genetic factors also appear to influence kindling rate; for instance, whereas it can take hundreds of stimulations to complete amygdala kindling in a rhesus monkey, it takes only about 70 in the *Papio papio* with genetic photosensitive epilepsy.[234]

The relationship of the various mechanisms of kindling to those of human epileptogenesis and seizure generation are unclear, but it is likely that kindling mechanisms (a) are involved in permitting subclinical electrical discharges eventually to manifest as behavioral seizures, (b) contribute to the progression of an epileptogenic abnormality, resulting in more frequent, more severe, and more pharmacoresistant seizures, (c) recruit distant structures in some forms of epilepsy, leading to secondary epileptogenesis (the development of new epileptogenic regions), and (d) induce enduring neuronal dysfunction, which could contribute to the appearance of interictal behavioral disturbances.

Electroencephalogram

As with human epilepsy, limbic kindling is associated with interictal EEG spikes that appear not only in the kindled limbic area, but also independently in other ipsilateral and contralateral limbic structures.[108] These interictal spikes appear early in the course of kindling and persist after stage 5 seizures occur. Interictal spikes are more common immediately following seizures, and there is some evidence that at least some types of postictal interictal spikes reflect mechanisms of seizure suppression.[70] Propagation of stimulation-induced ictal EEG discharges progressively recruits structures responsible for

behavioral manifestations, but there is no strict correlation between the duration of afterdischarge and the severity of the behavioral seizure. It is interesting that the very high frequency (200â€“600 Hz) oscillations associated with interictal spikes, termed Fast Ripples (FR), which in chronic animal models of mesial temporal lobe epilepsy and in the human disorder are believed to indicate tissue capable of generating spontaneous seizures, do not occur in kindled animals, perhaps because these models do not generate spontaneous seizures.[25]

Pharmacology

A number of studies over the years have been carried out to test the effectiveness of standard antiepileptic drugs as well as other compounds on kindling. It is of particular interest that drugs that are effective in preventing the development of kindling are not necessarily effective in preventing stimulation-induced seizures, whereas not all drugs effective in preventing stimulation-induced seizures disrupt the kindling process. This model, therefore, is capable of dissecting out antiepileptogenic versus anti-ictogenic properties of pharmacologic agents. Although kindling provides an effective model for screening potential antiepileptic compounds for antiepileptogenic and anti-ictogenic effects, it is much more labor intensive and expensive than the standard screening models of subcutaneous metrazol and maximal electroshock, and therefore it is rarely used. Recently, however, levetiracetam, which failed these two standard screening procedures, was tested and found to be effective against kindled seizures.[123] As a result, levetiracetam is now available as a highly effective agent against partial onset seizures.

An interesting phenomenon of contingent tolerance has been described whereby pretreatment with an effective anticonvulsant prior to, but not after, daily amygdala-kindled seizures results in a loss of efficacy.[169] Similarly, contingent inefficacy refers to the fact that pretreatment of an effective antiepileptic drug prior to daily stimulation during kindling results in the loss of effectiveness after kindling is achieved.[170] The mechanisms of contingent tolerance and inefficacy are unknown; however, they provide opportunities for studying neuronal processes underlying the development of pharmacoresistance and suggest that certain dosing schedules in patients may be counterproductive.

Chemical kindling can be achieved with a wide variety of chemical agents administered either intracerebrally or systemically.[87] Behavioral and electrographic features for most chemoconvulsants are similar to those of electrical limbic kindling, and once kindling is completed, the ability of subthreshold doses of chemoconvulsant to induce a stage 5 seizure is persistent. Reports of neuropathologic changes are variable. Crossovers among various chemoconvulsants as kindling agents, as well as between chemical and electrical kindling, suggest common mechanisms, although chemical kindling appears to involve much larger areas of the brain than localized electrical stimulation.

Pathophysiology

Although many investigations have been carried out to elucidate pathophysiologic mechanisms underlying kindling, no single underlying epileptogenic neuronal process has been revealed. This is undoubtedly due to the fact that kindling is not a unitary phenomenon but involves a great variety of alterations in cellular excitability, synaptic plasticity, neuronal loss, neurogenesis, glial proliferation, and synaptic reorganization, not only at the point of electrical stimulation for electrical kindling, but also transsynaptically in local and distant structures ultimately responsible for behavioral ictal manifestations, as well as related phenomena such as transference, the development of homeostatic seizure-protective mechanisms, and the generation of spontaneous seizures if kindling is continued. Specific fundamental neuronal mechanisms by which such changes occur are covered in more detail in other chapters in this section, and there is no indication that there are any unique to either electrical or chemical kindling.

Epileptogenic Dysplasia

The word â€œdysplasiaâ€ defines a tissue that has failed to develop perfectly during embryonic or fetal life as a result of genetic determinants[59,66] or pathogenic factors impairing the ordered sequence of maturational events, and it is known that dysplasias giving rise to macroscopic structural malformations that are clearly visible in neuroimaging studies are often associated with severe epilepsies.[13,60,163]

Genetically determined developmental brain abnormalities have been found in spontaneous mutant rodents such as dreher[189] and reeler mice,[36,71] and local[6] and bilateral subcortical neuronal heterotopias[115] have also been detected in some strains of genetically epilepsy-prone rodents. Animal models of cerebral dysplasia can also be obtained by means of embryonic exposure to physical (i.e., X-rays, freezing) or chemical teratogenic agents (e.g., ethanol, methylazoxymethanol) capable of killing neuroblasts and/or disarranging neuronâ€“glial relationships. Finally, targeted genetic manipulations can lead to a selective impairment of cortical development that may be associated with spontaneous seizures, as has been demonstrated by Acampora et al.[2] in a mouse model lacking the Otx1 gene.

However, it should be noted that most of the genetic and experimentally induced animal models of dysplasia do not present with obvious spontaneous epileptic seizures, which can only be induced by means of proconvulsant manipulations that are not effective (or significantly less effective) in control animals.

In this section, we concentrate on the models obtained by means of methylazoxymethanol (MAM), freezing, or the deletion of the orthodenticle gene (Otx1 $1^{-/-}$) and on TISH (telencephalic internal structural heterotopia) rats with laminar heterotopia.

Methylazoxymethanol Model

MAM is an alkylating agent extracted from the King Sago Palm *(Cycas revoluta)* that was found to induce cerebral dysplasia by Singh[197] and Johnston and Coyle.[107] It kills neuroblasts in mitotic phase, thus leading to a narrower and disarranged neocortical mantle. It also induces structural abnormalities of the radial glia that lead to the obstructed and misdirected migration of neocortical precursors that is responsible for subcortical heterotopias.

Methods

A single intraperitoneal injection of MAM 15 mg/kg administered to pregnant rats on embryonic day 15 (E15) regularly induces microcephaly, hippocampal heterotopias, and altered neocortical lamination in the offspring.[11,12,38,45,57,86,107,196] In addition, the double transplacental administration of MAM (15 mg/kg in the morning and, 12 hours later, the same dose injected intraperitoneally on E15) induces large heterotopic aggregates surrounding the ventricular floor (in continuity with hippocampal heterotopia) and large irregular neuronal clusters in the sensorimotor cortical area.[13,42]

Neuropathology

Morphologic analyses of MAM-treated rat neocortex show disrupted layering with evidence of a thick subpial band of heterotopic neurons in layer I. As observed in human

cortical dysplasia (see earlier discussion), the lateral somatosensory and auditory cortices contain clusters of enlarged cortical neurons positive for specific anti-SMI311 and anti-MAP2 antibody neuronal markers surrounded by a dense terminal network that is immunoreactive to antibodies against calbindin, a calcium-binding protein expressed by cortical interneurons.

The subcortical heterotopic nodules consist of normally differentiated cortical neurons randomly oriented within the nodule core with their major axis parallel to the edge of the nodule in the marginal zone. The nodule borders are characterized by a dense, GABA-positive network. In some animals, the periventricular nodules were in continuity with the overlying cortex, which was also characterized by a similar nodular structure or extended into the hippocampus and disrupted CA1 and CA2 layering.

Natural History and Clinical Phenomenology

The animals born of MAM-treated mothers show microcephaly, but postnatal developmental milestones (including eye opening, fur growth, sucking, ambulating, and grooming) are reached at the same age as controls. Spontaneous seizures and EEG changes indicating epileptic activities have never been reported, but there is evidence of increased susceptibility to epileptogenic agents or procedures such as fluorothyl,[11] hyperthermia,[86] kainic acid,[84] and kindling.[85]

Electroencephalogram

EEG monitoring reveals an increased delta frequency that positively correlates with the severity of the cortical disarrangement but no evidence of epileptiform activity.[85] Intracellular recordings from neurons located 350 to 550 Âµm below the surface of brain slices of dysplastic sensorimotor cortex show a slightly higher percentage of intrinsically bursting (IB) neurons than that found in layer V of untreated rat sensorimotor cortex.[182] Baraban and Schwartzkroin[11] reported a similar finding in the CA2 hippocampal region, with a definitely higher percentage of IB neurons in MAM-treated rats than in controls.

Aberrant firing patterns of repetitive bursts of action potentials, which gradually increase in duration and eventually merge in a long-lasting discharge, can be induced by both depolarizing current pulses[182] and an increase in extracellular K^+ concentrations.[11,12]

Pharmacology

There are no data concerning the effect of drugs on the seizures (because there are no spontaneous seizures) or susceptibility to epileptogenic agents.

Pathophysiology

The neurotoxic effect of MAM on dividing neuroblasts, which is due to the methylation of nucleic acids, affects the migrating neuronal progenitors and the radial glia along which they migrate. The results are cortical disarrangement and the formation of subcortical nodules consisting of heterotopic neurons that were originally committed to the neocortex but do not find a normally permissive environment for correct migration to their final destination.

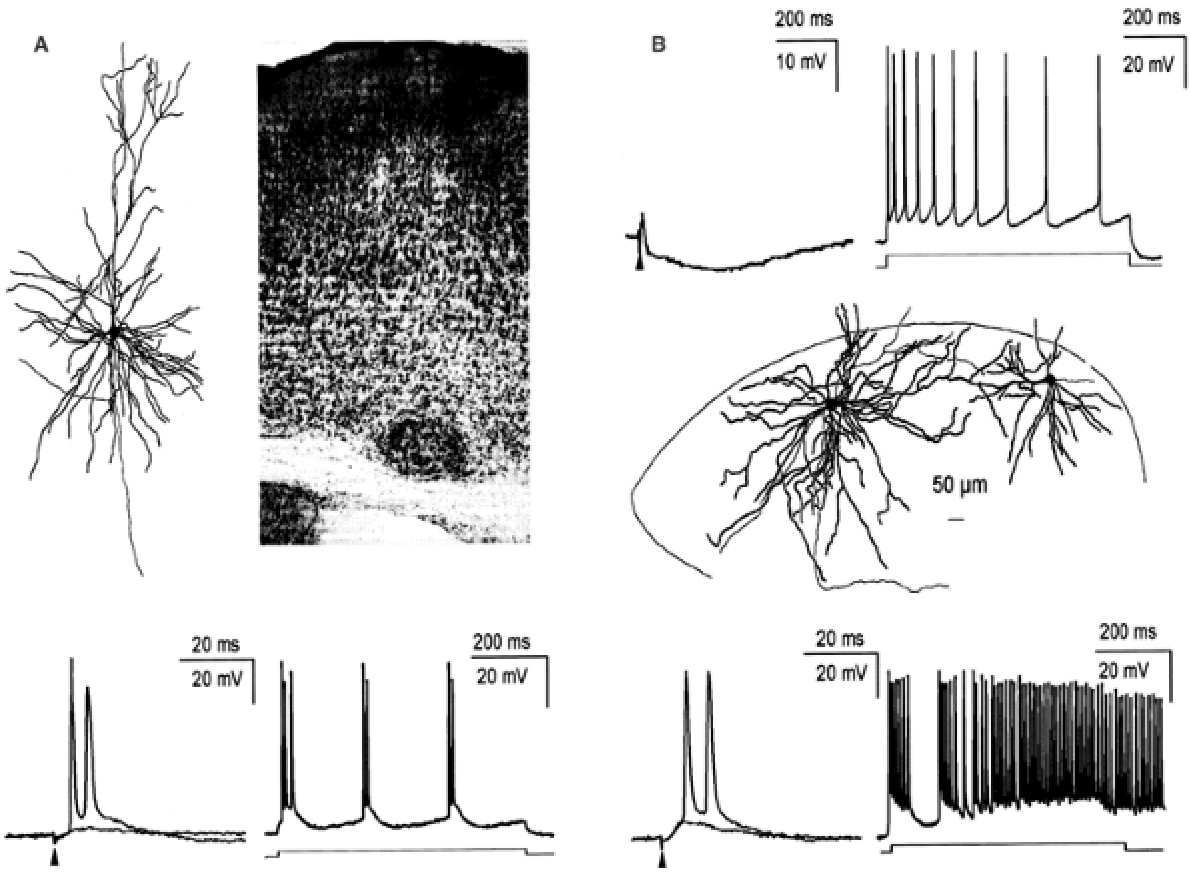

FIGURE 12. Pyramidal neurons recorded in dysplastic neocortex **(A)** and in periventricular heterotopia (PVH) **(B)** of MAM-treated rats. In panel A, the microphotograph of a thionin-counterstained slice shows abnormal neocortical layering and irregular neuronal clusters. The pyramidal neuron drawn on the left responded to both synaptic and direct activation with short burst firing. Panel B shows intracellular recordings from two PVH neurons. The left neuron shows normal responses to both synaptic and direct stimulations (*uppermost traces*), and the right neuron responds with a short burst to the synaptic activation and with an excessive bursting behavior to the direct stimulation with injection of a depolarizing pulse. (Modified from Sancini G, Franceschetti S, Battaglia G, et al. Dysplastic neocortex and subcortical heterotopias in methylazoxymethanol-treated rats: an intracelular study of identified pyramidal neurons. *Neurosci Lett*. 1998;246:181â€“185.)

Incoming inputs can affect the neurons in dysplastic neocortical areas, as well as those located in periventricular and parahippocampal heterotopias (Fig. 12). There is also evidence of reciprocal synaptic connections establishing aberrant cortico-subcortical circuitry[38,42,78,182] that is excessively susceptible to epileptogenic agents. The factors responsible for this greater susceptibility are the larger proportion of IB neurons and changes in intrinsic K^+ current-related properties,[11,182] and the possible influence of clustered GABAergic hyperinnervation should also be taken into account. The association of a smaller number of GABA-reactive neurons with a dense network of parvalbumin (PV)-immunoreactive terminals suggests that axonal sprouting of the PV-positive subpopulation of GABAergic neurons may take place during the development of MAM-treated rats. The expected functional consequence is a pacing effect due to the occurrence of highly synchronized inhibitory postsynaptic potentials in a large population of pyramidal neurons, which are then simultaneously released from inhibition and thus become prone to synchronous discharges.

Freezing-Induced Layered Microgyria in Rats

The word polymicrogyria indicates an excessive number of small and prominent convolutions separated by shallow and enlarged sulci, which give the cortical surface a lumpy appearance. Two types of polymicrogyria have been recognized: (a) unlayered polymicrogyria due to exogenous insults occurring between gestational weeks 13 and 18 or to genetic factors and (b) four-layered polymicrogyria due to a perfusion failure between gestational weeks 20 and 24. The perfusion failure causes laminar necrosis of the intermediate layers with a consequent late migration disorder and the postmigratory overturning of cortical organization. Human polymicrogyria is quite often associated with epileptic manifestations.

The application of a freeze probe to the skull of newborn rats generates a focal region of necrosis with a loss of deep layers whose basic structure is quite similar to that observed in four-layered human polymicrogyria.[62,63] The results of stimulation and lesion experiments suggest that aberrant development in the zone adjacent to the microgyrus underlies epileptogenesis.[174]

Methods

A freeze lesion is induced in rat pups 3 to 30 hours after birth by means of a freeze probe with a diameter of 1 mm to a few millimeters that is cooled to between -40Â°C and -70Â°C and applied to the skull for 3 to 8 seconds.[104,128] Neocortical slices for electrophysiologic recordings containing the lesion and the surrounding neocortex have been prepared from rats at postnatal ages ranging from 9 to 118 days.[104,128]

Neuropathology

A freeze lesion consists of an infolded cortex that creates a more or less deepening microsulcus and a surrounding mic-rogyrus that typically contains four distinguishable layers: The first and second correspond to the molecular and II/III layers of the adjacent neocortex, the third layer contains some glia and a few neurons, and the fourth layer partially corresponds to the VI layer of the adjacent neocortex (VIb).[104] The parvalbumin immunoreactive neurons normally concentrated in layers IV and Vb are completely absent in the microgyrus during the first 13 postnatal days but normalize after postnatal day 21.[179]

Natural History and Clinical Phenomenology

Scantlebury et al.[185] demonstrated increased susceptibility to hyperthermia-induced seizures in freeze-lesioned immature rats. Generalized, convulsive hyperthermic seizures were evoked by significantly lower temperatures in lesioned pups than in controls.

Electroencephalogram

No in vivo demonstration of spontaneous epileptic EEG abnormalities has been provided in rats with microgyrus, but the

P.429

ictal EEG correlates of hyperthermic seizures induced in freeze-lesioned rats show a topographic correlation between spike activity and the microgyrus.[185] In slice experiments, interictal-like epileptiform activity can be evoked from freeze-lesioned rats after postnatal day 12 and have been found until postnatal day 118, with a decreased incidence being observed after postnatal day 40 in rats lesioned on postnatal day 0 but not in those lesioned on postnatal day 1. Jacobs et al.[104] obtained evidence of decreased synaptic inhibition leading to local multiphasic epileptiform activity in neocortical areas closely surrounding the microgyri, and Luhmann and Raabe,[129] Luhmann et al.,[130] and Prince and Jacobs[175] reported similar results.

Pharmacology

The multiphasic discharges are reversibly blocked by NMDA-receptor antagonists in slices from both mature and immature freeze-lesioned rats, which suggest that they are attributable to disinhibited excitatory postsynaptic potentials mediated by the excitatory glutamate or aspartate amino acids.

Pathophysiology

Freezing interferes with cortical development through mechanisms similar to those responsible for human polymicrogyria because neuronal migration in rodents continues after birth until postnatal days 2 to 3.[187] It has been suggested that the basic mechanism supporting the increased seizure susceptibility is an imbalance between synaptically driven excitation and inhibition.[130] A number of observations suggest that aberrant synaptic connectivity develops in the rat cortex surrounding the microgyrus and causes a focal epileptogenic zone whose capacity to generate epileptiform activities does not depend on connections with the malformation itself because the evoked epileptiform activities in the paramicrogyral cortex remain unaltered if this zone is separated from the microgyrus by means of a transcortical cut in adjacent area. It has been hypothesized

that afferents originating from cortical and extracortical sites lose their targets in the region of the malformation but make appropriate laminar contacts in the cortex adjacent to the malformation and thus create an overabundance of excitatory inputs to this cortical zone. The resulting imbalance between the excitatory and inhibitory synaptic systems may be further aggravated by the loss of the parvalbumin-immunoreactive GABAergic neurons found in early developmental stages.

Otx1$^{-/-}$ Model

Mutations leading to the replication of body segments (a process called homeosis) were first observed in insects, and it has since been established that they affect a special category of genes that contain a DNA motif (or homeobox) coding for a 61â€"amino acid domain called the homeodomain. The proteins containing homeodomains act as activators or repressors of downstream target genes, thus controlling the development of body segments. The role of the Otx1 homeobox gene in mouse corticogenesis was investigated by Acampora et al.,[2] who confirmed that Otx1 is required for the development of the entire dorsal telencephalic cortex, has a more pronounced effect in the temporal and perirhinal areas, and may affect the mechanisms specifying neuronal identity. Moreover, Otx1-null mice exhibit epileptic seizures.

Methods

Otx1-knockout mice were generated by replacing the Otx1 gene with the *Escherichia coli* lacZ gene.[2] Heterozygous Otx1$^{+/-}$ mice are healthy and fertile, and their cross-breeding generated the homozygous mice Otx1$^{-/-}$, which are smaller and show epileptic manifestations; 30% die during the first postnatal month. Electrographic recordings from Otx1$^{-/-}$ mice have been made using screw electrodes over the occipital cortex and deep electrodes inserted in the hippocampus.[2] Intracellular recordings have been obtained from pyramidal neurons in neocortical slices prepared from Otx1$^{-/-}$ and control mice.[183]

Neuropathology

Gross examination of the brain reveals that the adult Otx1$^{-/-}$ mouse brain is about 25% lighter than that of heterozygous and wild-type mice. The overall thickness of the neocortex is reduced in the homozygous mutant, especially in the temporal and perirhinal areas, where the reduction may be as much as 40%. The sulcus rhinalis is displaced dorsally and the hippocampus is shrunken with a divarication of the dentate gyrus, whereas the volume of the colliculi is increased, and there is an additional protuberance between the superior and inferior colliculi. The cerebellar abnormalities include the presence of an additional lobule and a duplication of the rostral end of the declivus.[2] Morphologic analyses of Otx1$^{-/-}$ neocortex have shown that, despite their overall reduction in thickness, all of the cortical layers are recognizable; however, the cells appear to be more tightly packed in the mutant IV layer, whereas their density is clearly reduced in the V layer and particularly in the VA sublayer.[183] Outside of the central nervous system, Otx1$^{-/-}$ mice have no ciliary process in the eye, no lachrymal or Harderian glands, and no lateral semicircular duct in the inner ear.

Natural History and Clinical Phenomenology

Epileptic symptoms occur in all Otx1$^{-/-}$ mice but have never been observed in heterozygous Otx1$^{+/-}$ mice. The seizures are of two main types: (a) short, 30-second episodes of head bobbing and teeth chattering that may subside or evolve into (b) generalized seizures characterized by upper extremity clonus, rearing and falling, and convulsions that last for approximately 60 seconds with complete recovery or, occasionally, evolve into status epilepticus and exitus. The frequency of the seizures tends to be less in older Otx$^{-/-}$ mice, but they never disappear. In addition, Otx1$^{-/-}$ mice show nonepileptic turning behavior.

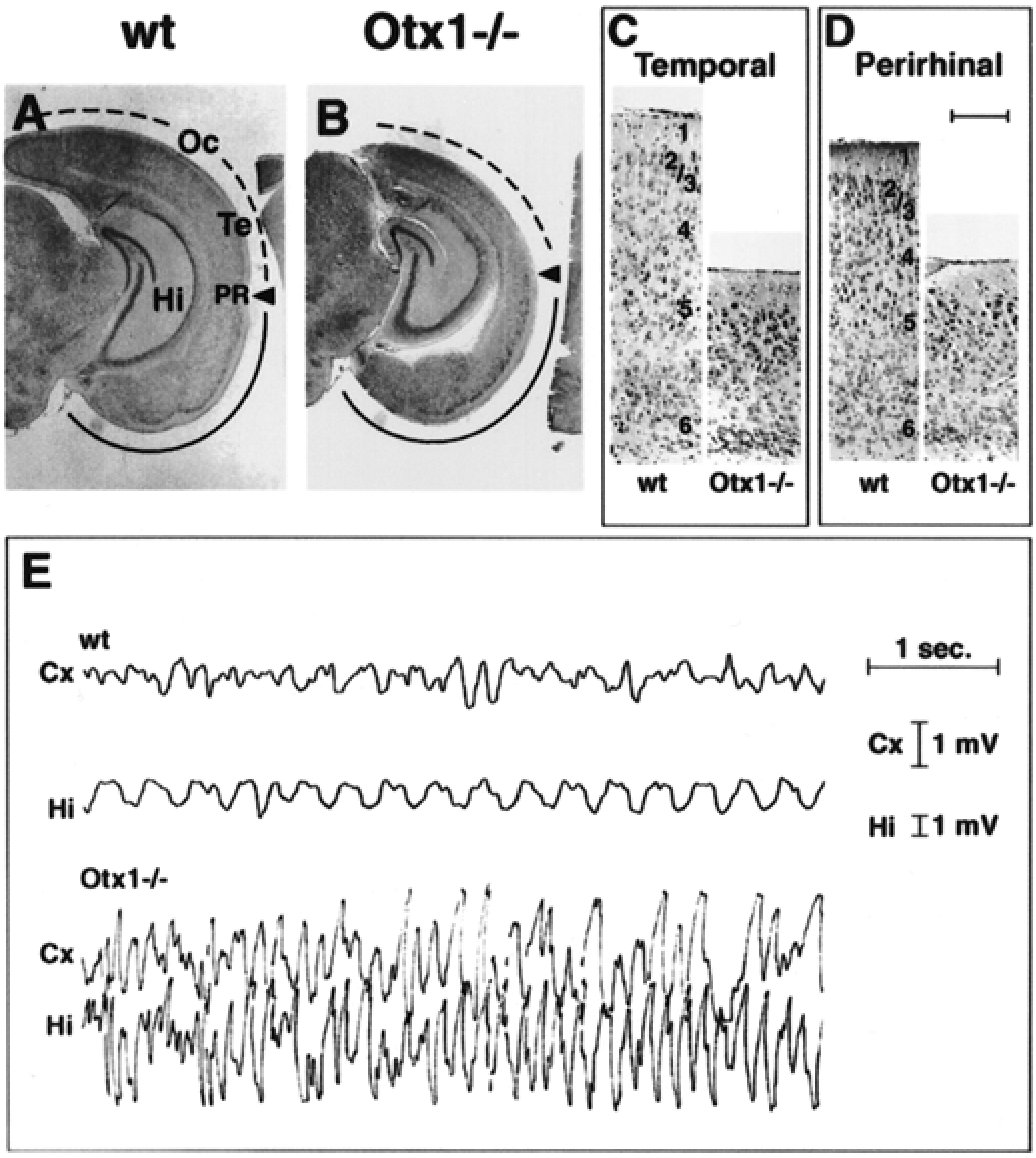

FIGURE 13. Morphologic **(A, B)**, histologic **(C, D)**, and electroencephalographic (EEG) **(E)** comparison of wild-type (wt) and Otx$^{-/-}$ mice. Note the reduction of temporal (Te) perirhinal (PR) cortices and hippocampus (Hi) in Otx$^{-/-}$ mice. Representative EEG recordings from neocortex (Cx) and Hi during a convulsive seizure of Otx$^{-/-}$ mice is shown in panel E, where the EEG recording from a wild-type (wt) animal is shown for comparison. (From Acampora D, Barone P, Simeone A. Otx genes in corticogenesis and brain development. *Cereb Cortex.* 1999;9:533â€"542; with permission.) (See color insert.)

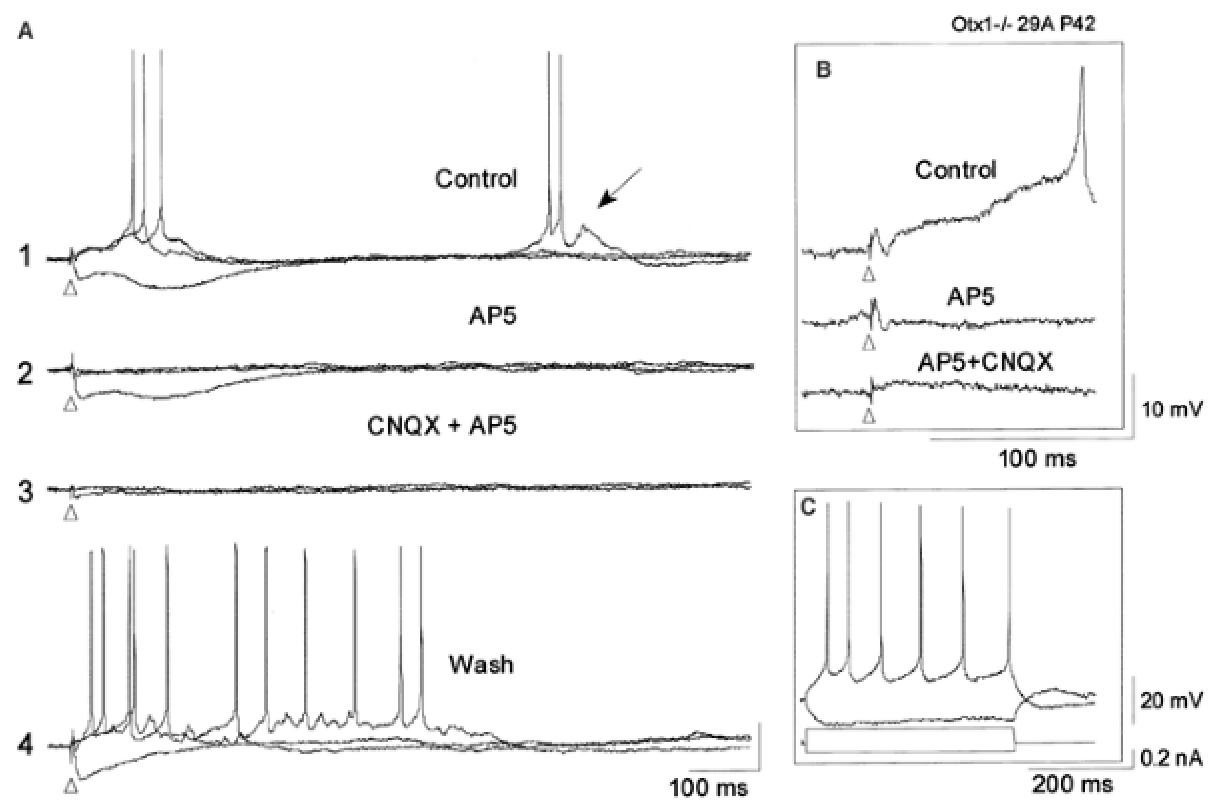

FIGURE 14. Recordings from an Otx1+/Â± pyramidal neuron. **A1:** Responses to two different stimulus intensities under control conditions. Note the postinhibitory depolarizing event reaching the threshold for action potential generation (*arrow*) that is abolished by the *N*-methyl-D-aspartate (NMDA) antagonist D-2-amino-5-phosphonovalerate (AP5) **(A2)**. **A3:** The addition of both AP5 and the Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) led to an almost complete block of excitatory synaptic activity that was reversed after 20 minutes of washout **(A4)**. **B:** Magnification of the foremost segment of the same traces as in panels A1 to A3, showing more clearly the effect of AP5 and CNQX (the stimulus is marked by open triangles). **C:** Characterization of the tested neuron by means of low-amplitude depolarizing and hyperpolarizing current pulse injections. (From Sancini G, Franceschetti S, Lavazza T, et al. Potentially epileptogenic dysfunction of cortical NMDA- and GABA-mediated neurotransmission in Otx1-/- mice. *Eur J Neurosci*. 2001;14:1065â€"1074; with permission.)

Electroencephalogram

The â€œminorâ€ episodes are associated with high-voltage spikes in the hippocampus and some fast activity in the neocortex, thus suggesting that the epileptogenic discharges have a localized origin; the convulsive seizures correlate with high-voltage synchronized activity involving both the hippocampus and neocortex (Figs. 13 and 14). Electrophysiologic experiments on neocortical slices have revealed some important differences in synaptic activities, which are characterized by pronounced multisynaptic excitatory postsynaptic potentials often leading to late action potential generation and strong $GABA_A$- and $GABA_B$-mediated inhibitory postsynaptic potentials that have a pacing effect on pyramidal firing.[9] Both late excitatory postsynaptic potentials and postinhibitory excitation are selectively suppressed by NMDA-receptor antagonists but not by Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) antagonists.[183]

Pharmacology

The effect of antiepileptic drugs on the seizures occurring in Otx1$^{-/-}$ animals has never been systematically tested.

Pathophysiology

The fact that the layer V neurons so far reconstructed from the mutants seem to be smaller than those of control animals suggests that neurons originally committed to the upper layers may not migrate properly but be stopped in the fifth layer, where they induce the reorganization of GABAergic circuitry.

On the basis of the foregoing data, it can be concluded that the abnormalities in Otx1$^{-/-}$ mice neocortex due to the selective loss of large projecting neurons lead to a complex rearrangement of local circuitry that is characterized by an excessive NMDA polysynaptic excitation that is counteracted by GABA-mediated inhibition in only a limited range of stimulus intensity. Prominent postsynaptic inhibitory potentials may also act as a further proepileptogenic event by synchronizing abnormal excitatory potentials.

Mutant Rats With Telencephalic Internal Structural Heterotopia

TISH rats are mutants presenting subcortical band heterotopia. They were identified by means of postmortem anatomic analyses during the course of unrelated experiments on Sprague Dawley rats by Lee et al.[116]: Spontaneous recurrent partial seizures with variable secondary generalization were present in some TISH rats.

Methods

A breeding colony was established by identifying the living relatives of deceased TISH individuals and screening them by means of magnetic resonance imaging.[116] Crosses between two affected animals produced 100% TISH progeny, whereas crosses between one affected and one unaffected animal produced no affected offspring, but their intercrossing produced 29% of affected offspring. The overall incidence of affected males and females was respectively 47% and 53%, which is

P.431

consistent with an autosomal-recessive pattern of inheritance of a single-gene defect.

Neuropathology

The brain of these mutants has a large region of heterotopic gray matter located bilaterally beneath the neocortex and extending from the frontal to the occipital lobe (Fig. 15). It is particularly prominent in the frontal and parietal cortices but is usually absent from the temporal cortex. The normotopic neocortex overlying the heterotopia is usually organized into six laminae (but thinner than in normal animals), whereas the heterotopia lacks precise lamination. Pyramidal neurons are present in both normo- and heterotopic cortices, but the apical dendrites in the latter are not consistently radially oriented and may even be inverted, and the dendrites near the edge of the heterotopic region often bend to follow the contour of the band. The heterotopia also contains nonpyramidal neurons (fusiform and stellate cells) lacking a regular tectonic organization. The normotopic cortex shows a normal laminar organization of the different cell types, but there are significantly fewer parvalbumin-positive interneurons (43% of those found in control neocortex), and the intensity of the parvalbumin plexus is likewise reduced in the neuropil of layer V.[24] Other laminar structures, such as the hippocampus and cerebellum, show a normal laminar pattern and do not contain heterotopic neurons.

Natural History and Clinical Phenomenology

Seizure activity was observed in several of the animals in the colony established in Charlottesville, Virginia, by Lee et al.[116] Chen et al.[37] made prolonged video-electrographic recordings lasting 4 to 6 months in a sample of animals and found that seizure frequency ranged from 1.5 to 15.1 events per week. The seizure phenomenology consists of twitching of the face and paws and turning to one side, occasionally followed by falling and convulsive activity; seizure duration is between 1 and 2 minutes. No seizures have been observed in animals younger than postnatal day 30.

Electroencephalogram

Electrographic recordings made using depth electrodes positioned bilaterally on both normotopic and heterotopic areas show that ictal spiking activity arises almost simultaneously in the normotopic and heteroptopic areas of one hemisphere and spreads rapidly to the homologous contralateral regions. Field potential recordings from in vitro slices bathed with epileptogenic agents show synchronous spiking activity in normo- and heterotopic areas. Making a cut between the two bands significantly decreases the threshold for epileptiform spiking in the

normotopic area but significantly increases the threshold in the heterotopia. Patch-clamp recordings from identified pyramidal neurons show a consistent reduction in inhibitory postsynaptic current (IPSC) amplitude and frequency in both normo- and heterotopic cortical areas.[224]

Pharmacology

No data are available concerning the drug sensitivity of the seizures observed in TISH rats.

Pathophysiology

Injecting 5-bromo-2â€²-deoxyuridine (BrdU) to label cells in the S-phase in pregnant dams has demonstrated that the heterotopic neurons are generated during the normal period of cortical neurogenesis and that the inside-out pattern of neurogenesis is intact in the normotopic neocortex of TISH mutants.[115] Alterations in cell proliferation and migration are considered to be responsible for the TISH malformation.[115]

In relation to the mechanisms underlying epileptogenesis, electrophysiologic studies have shown that both normo- and heterotopic areas are involved in seizure activities, which are initiated by the normotopic cortex (see earlier discussion). Moreover, there is evidence that normotopic neurons have an excitatory synaptic influence on heterotopic neurons, which, conversely, have a net inhibitory effect on normotopic cortical cells. The results of Trotter et al.[224] discussed earlier provide evidence of a reduced synaptic inhibition of pyramidal neurons that may account for an epileptogenic increase in excitability.

Status Epilepticus

General Characteristics

A variety of chemical convulsants have been administered systemically to induce various forms of experimental status epilepticus (SE). Chemical convulsants used to induce experimental SE do so by either increasing neuronal excitation or decreasing neuronal inhibition. Experimental models based on systemic administration of chemical convulsants have the advantage of simplicityâ€"SE can be induced simply by parenteral administration of the convulsant agent. The disadvantage of such agents is their continuing presence once SE has been induced. Results may be confounded by the continuing presence of the inducing agent or by potential drug interactions between the inducing agent and an experimental therapeutic agent. Electrogenic models have the advantage that the status-inducing stimulus is eliminated once the stimulation has stopped, so that

subsequent pathophysiologic changes or consequences of status epilepticus can be construed as being due to the seizure activity without the possible confounding effect of the initial stimulus. However, electrogenic models tend to be labor intensive, and thus do not lend themselves to large-scale studies.

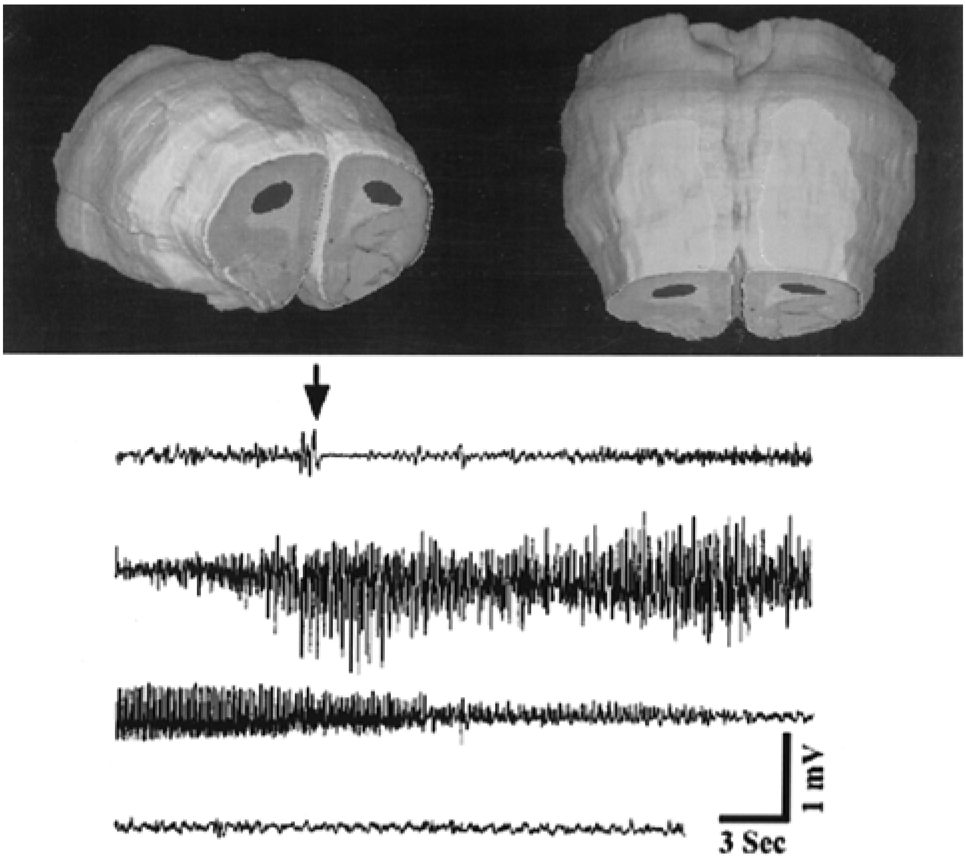

FIGURE 15. Top: Three-dimensional reconstruction of the telencephalic internal structural heterotopia (TISH) shown in red at the cut surface of the brain and in pink where it is viewed through the overlying cortex. **Bottom:** Electroencephalographic (EEG) recordings of a convulsive seizure in a TISH rat. The four lines show continuous EEG recording from a single electrode positioned in the normotopic neocortex (*arrow* indicates seizure onset). Seizure activity can be observed as changes in the frequency and amplitude of the EEG. (Modified from Lee KS, Schottler F, Collins JL, et al. A genetic animal model of human neocortical heterotopia associated with seizures. *J Neurosci*. 1997;17:6236â€"6242). (See color insert.)

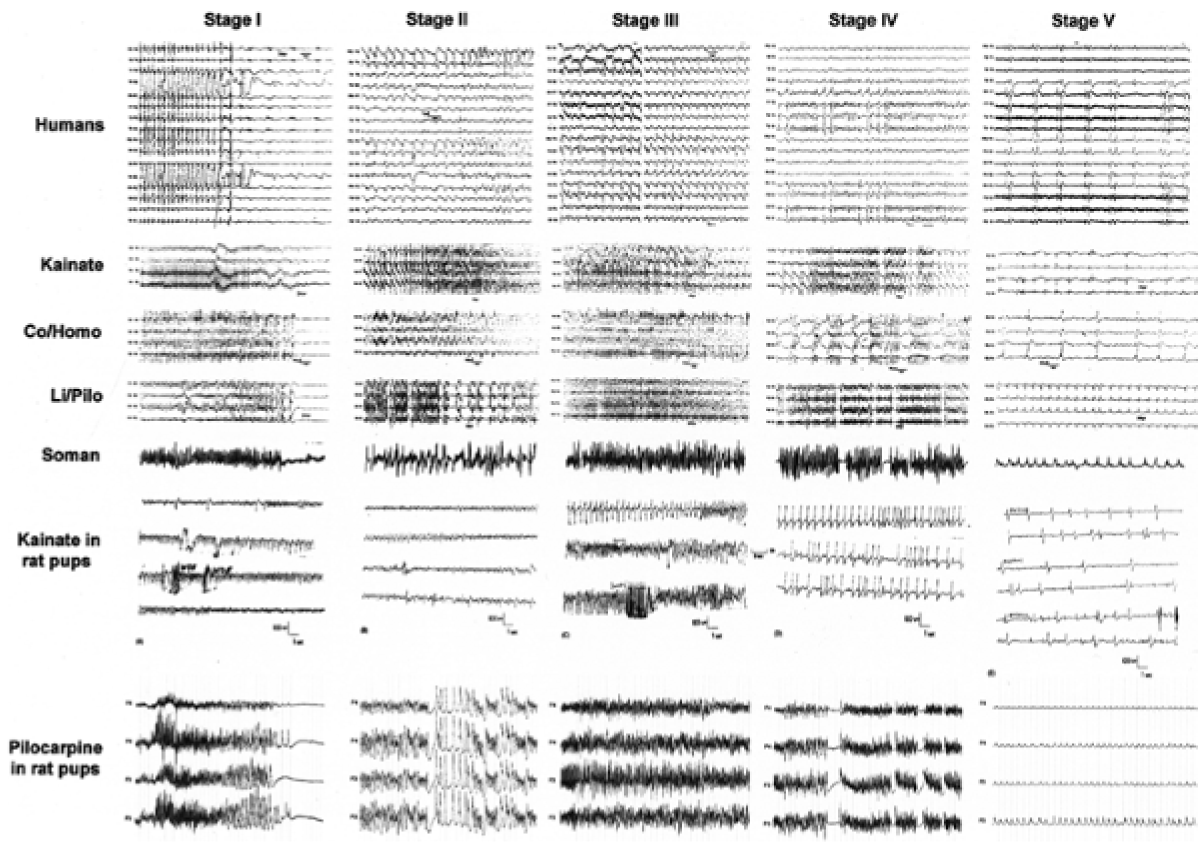

FIGURE 16. Examples of the five electroencephalographic (EEG) stages observed in human patients during generalized convulsive status epilepticus and in all animal models of experimental status epilepticus in which EEG changes over time have been systematically studied. The time required for initial appearance of epileptiform activity and for progression through the five stages varies with the model, as do details of the morphology of the ictal discharges. Nonetheless, the fundamental progression from discrete electrographic seizures (stage I), through the waxing and waning pattern (stage II), the continuous pattern (stage III), continuous ictal discharges punctuated by brief periods of relative flattening of the EEG (stage IV), to periodic epileptiform discharges on a relatively flat background (stage V) is seen in all models. See Table 1 for technical details. Co/Homo, cobalt/homocysteine; Li/Pilo, LiCl/pilocarpine.

Ictal Phenomenology

Most epileptic seizures last only from a few seconds to a few minutes. This is because seizure-terminating mechanisms operate during an isolated single seizure. A refractory period follows during which it is difficult to elicit a subsequent seizure. However, under some circumstances, the mechanisms responsible for seizure termination and the postictal refractory period fail, so that epileptic seizures recur before there has been complete recovery from the neurochemical and pathophysiologic consequences of the preceding seizure or persist beyond the usual, quite short, duration of individual seizures. This, in pathophysiologic terms, is the operational definition of SE,[218,219] whereas in clinical terms SE can be defined as â€œa condition in which epileptic seizures recur before there has been complete recovery from the consequences of the preceding seizure.â€[48,75]

Natural History

Status epilepticus is a surprisingly common[58,98] and potentially life-threatening medical emergency. There is increasing recognition that status epilepticus is a dynamic condition, with an evolution of clinical phenomenology, EEG changes, response to treatment, histopathologic changes, and behavioral consequences if it is untreated or inadequately treated.[218] Nonetheless, much remains to be learned about this disorder. The mechanisms of the transition from a single seizure to SE are not known. Our understanding of the pathophysiologic changes that cause SE to be progressively resistant to treatment is incomplete. We have only begun to understand the metabolic and pathologic consequences of sustained seizure activity; the time when permanent neuronal damage occurs during the course of SE is still not well worked out. Treatment of clinical SE is not always successful, and there remains a need for the development of more effective and less toxic drugs for this purpose. The potential role for neuroprotective agents in the clinical management of SE is unresolved, as is the cause of the differential susceptibility of young and adult brains to SE-induced neuronal damage.

Electroencephalogram

One of the major advances in the use of animal models of status epilepticus has been the recognition of a predictable sequence of electrographic changes that is common to patients experiencing generalized convulsive status epilepticus[221] and all experimental models of SE that have been carefully studied, including lithium/pilocarpine,[221,236] kainic acid in adult[221] and juvenile[153] rats, cobalt-homocysteine,[221,235] high-dose pilocarpine in adult[111] and juvenile[222] rats, three different electrogenic models,[93,95,126] soman in rats[115,140] and rhesus monkeys (McDonough, personal communication), and in an extended hippocampal slice model.[178] FIGURE 16 illustrates the sequence in a number of different models. Initially discrete electrographic seizures are seen, separated by interictal generalized slowing (stage I; Table 1). However, if the episode of SE is untreated or undertreated, the discrete seizures begin to merge together to produce a waxing and waning of amplitude, frequency, and distribution of the ictal discharges (stage II). Subsequently, the ictal discharges become continuous (stage III). This stage is usually prolonged, but eventually the continuous ictal discharges begin to be punctuated by periods of relative flattening (stage IV), which lengthen as the rhythmic ictal discharges shorten,

P.434

P.435

until finally the record exhibits only periodic epileptiform discharges on a relatively flat background (stage V). The fundamental sequence of patterns is always the same, although different models may exhibit differences in morphology within a specific stage (e.g., triphasic-like spike-wave patterns vs. rapid spiking in stage III, variable frequencies and morphologies of periodic epileptiform discharge [PEDs] in stage V), and different models may progress through the five patterns at different rates, just as has been observed in human generalized convulsive status epilepticus (GCSE) depending on the etiology of the episode of SE.

Table 1 Technical Details for the Five Electroencephalographic (EEG) Stages Illustrated in Figure 16

Model/EEG stage	Stage I	Stage II	Stage III	Stage IV	Stage V
Human[221]	39-yr-old male	64-yr-old male	68-yr-old male	68-yr-old male	64-yr-old male
Kainic acid (KA)[221]	26 m after KA	75 m after KA	103 m after KA	148 m after KA	5 hr 46 m after KA
Cobalt/homocysteine (HCT)[221]	30 m after HCT	37 m after HCT	48 m after HCT	75 m after HCT	2 hr 12 m after HCT

LiCl/Pilocarpine[221]	21 m after pilocarpine	24 m after pilocarpine	28 m after pilocarpine	109 m after pilocarpine	2 hr 19 m after pilocarpine
Soman[115]	Onset 3.1 Â± 0.5 m after soman	Onset 5.1 Â± 0.7 m after soman	Onset 19.3 Â± 3.3 m after soman	Onset 33.9 Â± 5.6 m after soman	Onset 231.4 Â± 9.5 m after soman
Kainate in rat pups[154]	P35 rat; mean onset 15 m (P15)/21 m (P35) after KA	P15 rat; mean onset 35 m (P15 and P35) after KA	P35 rat; mean onset 126 m (P15)/50 m (P35) after KA	P15 rat; mean onset 374 m (P15)/9 hr (P35) after kA	P35 rat; mean onset 10.25 hr (P15)/14.4 hr (P35) after KA
Pilocarpine in rat pups[222]	Onset 11.79 Â± 11.85 m after pilocarpine	Onset 22.78 Â± 22.11 m after pilocarpine	Onset 34.90 Â± 13.15 m after pilocarpine	Onset 61.64 Â± 21.76 m after pilocarpine	Onset 160.67 m after pilocarpine

Questions That Can Be Addressed by Animal Studies of Status Epilepticus

Experimental models have the potential of answering many of the questions posed earlier. Specifically, experimental models can be used to test drugs for the management of status epilepticus before they are tested in human clinical trials. Other questions that can be addressed using status epilepticus models include the reasons for other dynamic changes during status epilepticus, such as (a) the EEG changes discussed previously, (b) the progressive loss of motor activity as overt convulsive status epilepticus progresses to subtle and eventually nonconvulsive status, and (c) the progressively severe consequences of prolonged status epilepticus, including learning and memory deficits, neuronal damage at histology, and the development of chronic epilepsy. Models are now being used to understand the mechanisms that underlie the increasing refractoriness to treatment seen in human and experimental status epilepticus. Details of these studies are discussed in relation to the specific models described in what follows and in the chapter on generalized convulsive status epilepticus.

A number of experimental models of SE have been developed, including models in intact animals based on systemic and focal administration of chemical convulsants and focal and generalized electrical stimulation of the brain. More recently, some investigators have begun to study recurrent or sustained seizure activity in isolated neuronal circuits using slice preparations. The most useful and commonly used models of status epilepticus are discussed in what follows. Many of these models are also used for the induction of chronic epilepsy and are also discussed in the first section of this chapter. The discussion of the following models is focused on their use to further understand phenomenology and mechanisms of status epilepticus.

Bicuculline Model

Bicuculline is a highly potent alkaloid inhibitor of GABA-mediated neuronal inhibition[51,52] that has been used to induce experimental status epilepticus, initially by Meldrum and Horton in baboons.[150]

Methods

Bicuculline must be dissolved in a weak acid (0.1 N HCl) and then titrated with a weak base (0.1 N NaOH) to pH 5.6.[56] Bicuculline can be administered intraperitoneally (2â€“4 mg/kg for developing rats, 6â€“8 mg/kg for juveniles or adults)[228] or intravenously (2 mg/kg).[253]

Neuropathology

Meldrum and Brierley[149] described SE-induced ischemic-like neuronal damage in neocortex, cerebellum, and hippocampus in baboons. Similar but less severe changes were also seen in neocortex, thalamus, and hippocampus in paralyzed and mechanically ventilated baboons,[151] thus demonstrating that SE-induced neuronal damage is primarily due to ongoing seizure activity rather than to motor convulsions.

Natural History and Clinical Phenomenology

Meldrum and Horton[150] induced severe, generalized status epilepticus lasting up to 5 hours in adolescent baboons by injecting 0.4 to 1.4 mg/kg bicuculline intravenously. Seizures began with generalized myoclonic jerks that evolved within seconds to generalized flexor spasms. In rat pups, myoclonic seizures evolve to clonic and then clonicâ€“tonic seizures. After day 18, spike-wave discharges are seen, associated with motionless â€œfreezingâ€ of behavior.[253]

Electroencephalogram

A sequence of EEG changes, similar to those described by Treiman et al.[221] in generalized convulsive status epilepticus, can be observed in one figure in Meldrum and Horton's report, although the progressive nature of the EEG changes is not characterized in detail.

Pharmacology

Bicuculline-induced seizures respond readily to antiepileptic drugs, especially the benzodiazepines,[55] but the bicuculline model has not been used systematically to study potential anti-SE drugs. Peterson et al.[165] induced SE in rats pretreated with LiCl by focal injection of bicuculline methiodide into the deep prepiriform cortex. This procedure resulted in a model of SE that could be stopped with 5 mg/kg of diazepam, in contrast to the lithium-pilocarpine model.

Pathophysiology

Bicuculline induces seizures by competitive antagonism at the $GABA_A$ receptor. More recently, blockade of K^+ channels and prolongation of Ca^{2+} action potentials has also been suggested as a possible mechanism of seizure induction by bicuculline.[190]

Cobalt-Homocysteine Model

Walton and Treiman[235] developed a model of secondarily generalized convulsive SE that closely approximates human GCSE in the natural history and characteristics of the induced seizures, the EEG changes, and the response to antistatus drugs. The model was specifically designed to test new agents for the treatment of GCSE, and a number of antiepileptic drugs have been studied in the model (see later discussion).

Methods

An epileptic lesion is created over the left motor cortex in adult male Sprague Dawley rats by placing 25 mg of powdered cobalt onto the dura when epidural screw electrodes are implanted. It is important to disrupt the dura and to pack the powdered cobalt into the screw well to reliably induce status epilepticus with the administration of the chemical convulsant, homocysteine thiolactone. When the lesion becomes electrographically active with brief focal ictal discharges and the rat is exhibiting intermittent focal motor seizures, usually about 7 days after surgery, SE is induced by intraperitoneal administration of 5.5 mmol/kg

D,L-homocysteine thiolactone.

Neuropathology

The necrotic cobalt lesion can been seen on gross inspection of the intact brain, and a profound area of encephalomalacia is

observable on histologic sections. However, the pathologic consequences of cobalt-homocysteineâ€"induced SE have not been reported.

Table 2 A comparison of the serum concentration produced by the median effective dose (ED_{50}) for control of generalized tonicâ€"clonic seizures (GTCS) in the cobalt/homocysteine secondarily generalized convulsive status epilepticus model with serum concentrations of the same drugs that have been reported to be clinically effective

Drug	Serum concentration produced by ED_{50} vs. GTCS	Serum concentration reported to be clinically effective
Phenytoin	26.2 mg/mL	23.8 Âµg/mL
Diazepam	168 ng/mL	30â€"80 ng/mL 30â€"200 ng/mL
Phenobarbital	12.8 mg/mL	8.4 Âµg/mL 18.3 Âµg/mL
Lorazepam	196 ng/mL	30â€"160 ng/mL 70â€"330 ng/mL

Modified from Walton and Treiman.[244]

Natural History and Clinical Phenomenology

Status epilepticus in this model resembles human secondarily generalized tonicâ€"clonic SE behaviorally,[235] electrically,[221,235] and pharmacologically[235,244] (Table 2), and thus fulfills criteria proposed by Walton and Treiman[235] for an ideal model of SE: (a) induced seizures should be similar in appearance to those seen in human SE, (b) electrographic patterns seen should also be like those seen in human SE, and (c) the induced SE should be responsive to the same drugs used in treating human SE. In the initial description of this model, a mean of 18.3 convulsions occurred over a mean time of 103.8 minutes after injection of homocysteine. Initially, the seizures are true, focal-onset, secondarily generalized tonicâ€"clonic seizures. However, as SE continues over many convulsions, the seizures alter in appearance and may become prominent on only one side of the body or exhibit only subtle manifestations, as has been described in humans.[218]

Electroencephalogram

SE is induced when brief focal runs of spikes with phase reversal around the left frontal electrode (the cobalt site) are evident on the EEG. Ten to fifteen minutes after homocysteine injection, these epileptiform discharges increase in amplitude, frequency, and distribution until a generalized convulsion occurs about 20 to 30 minutes after injection. Over the next 90 minutes, the EEG progresses through the five EEG stages described by Treiman et al.[221] and illustrated in FIGURE 16, although not all animals exhibit the full progression and some die before reaching stage V.

Pharmacology

Walton and Treiman[244] validated this model's ability to predict clinical effectiveness of a putative anti-SE drug by demonstrating that serum concentrations of diazepam,[235] lorazepam,[239] phenytoin,[246] and phenobarbital[237] effective at stopping generalized convulsions in this model closely approximate serum concentrations of these drugs reported to be effective in human GCSE. Subsequently, they used this model to evaluate the potential usefulness for the treatment of GCSE of other marketed and experimental antiepileptic drugs, including valproic acid,[241] tiagabine,[245] fosphenytoin,[238] NPC-17742,[242] lamotrigine,[246] and remacemide.[243]

Pathophysiology

For at least three decades, cobalt has been known to induce focal onset seizures.[43] However, the mechanism of seizure induction by cobalt remains unknown. Homocysteine appears to be an NMDA agonist, and thus the mechanism whereby homocysteine induces seizures is most likely by activation of excitatory amino acid receptors.[79]

Flurothyl Model

Flurothyl (bis-2,2,2-triflurothyl ether) is a convulsant gas[225] that has been used by a number of investigators to induce experimental status epilepticus.

Methods

Nevander et al.[159] developed a model of SE to study the effect of SE on neuronal necrosis. They induced continuous seizure activity in anesthetized (60% nitrous oxide/40% oxygen), paralyzed, mechanically ventilated rats by injecting 80 ÂµL of flurothyl directly into the rebreathing system. Additional boluses of flurothyl were used to maintain a burst-suppression pattern on the EEG during the seizure period. When flurothyl was discontinued after 15 minutes, seizure activity resolved spontaneously; a single dose of intravenous thiopental, 15 mg/kg, also arrested seizure activity. Acute seizures and SE have also been produced in initially awake, freely moving rats by dripping liquid flurothyl (1.2â€“3 mL/hr) onto filter paper suspended in a closed plastic box[252] or infusing 20 ÂµL/min into an airtight chamber. Immature rats can survive 60 minutes of such repetitive seizures without mechanical ventilation; adult rats cannot.[103,202,215]

Neuropathology

Nevander et al.[159] observed that infarction of the pars reticulata of the substantia nigra occurred in five of the six animals with seizure duration of 30 minutes and in all animals with longer seizure durations when brains were examined for histologic damage 1 week after the episode of SE. The central part of the globus pallidus was also commonly affected. Neocortical, amygdaloid, thalamic nuclear, and hippocampal pyramidal cell damage was seen in SE of longer duration. However, Sperber and Moshe[205] found no evidence of flurothyl SE-induced histologic damage when SE was induced in 14-day-old rats, suggesting that in this model, as well as others, SE-induced neuronal damage is age dependent.

Natural History and Clinical Phenomenology

The behavioral characteristics of flurothyl-induced seizures are age specific.[206] Swimming movements and tonic posturing are seen during the first week, and clonic seizures developed after P10, initially preceded by a few myoclonic jerks and then evolving into a clonicâ€“tonic seizure. By the third postnatal week, episodes of motionless staring associated with spike-wave discharges are seen. These seizures have been suggested as a model of absence seizures and the clonic and tonicâ€"clonic seizures as models of primarily generalized convulsive seizures. In adult rats, early seizures during flurothyl exposure are similar to those seen in P14 rats: myoclonic, then clonic, then tonicâ€"clonic seizures. However, because freely moving, nonventilated adult

rats cannot be kept alive during flurothyl-induced status epilepticus, there are no descriptions of the evolution of behavioral changes during status epilepticus in adult rats.

Electroencephalogram

Sperber and Moshe[205] reported discrete electrographic seizures initially, followed by a waxing and waning of seizure discharges throughout the 60 minutes of EEG recording during flurothyl-induced status epilepticus in rat pups. These descriptions correspond to what Treiman et al.[221] labeled SE EEG stages I and II. However, EEG recordings were not continued long enough in Sperber's studies to determine whether the pups would have exhibited SE EEG stages III to V. EEG changes during flurothyl-induced SE have not been described in adult rats.

Pharmacology

No pharmacologic studies have been reported using flurothyl-induced experimental status epilepticus.

Pathophysiology

Woodbury suggested that flurothyl induces seizures by opening sodium channels in neuronal membranes.[250a] More recently, antagonism of GABA-mediated inhibition[7] and activation of cholinergic transmission[65] have been proposed as possible mechanisms.

Kainic Acid Model

Kainic acid is a potent agonist for the AMPA/kainate subtype of ionotropic glutamate receptor that has been used extensively to induce status epilepticus as a means of generating a model of chronic epilepsy. Thus this model is discussed in detail earlier in this chapter. The model has not been nearly as popular for the specific study of status epilepticus. Nonetheless, it has certain advantages for this purpose, which are discussed here.

Methods

Kainic acid (KA) usually is dissolved in phosphate-buffered saline and administered intraperitoneally. Doses in the rat are age and strain dependent.[207] For rat pups, 1 to 8 mg/kg may be sufficient to induce SE; for adults, 8 to 15 mg/kg is usually necessary. The model has a relatively low efficiency. Status induction is frequently inconsistent, and acute mortality may be high. For this reason, some have advocated multiple repeated small doses tailored to the individual rat.[101,148] Focal onset SE can also be induced by direct injection of 0.4 to 1.6 Âµg into the amygdala or hippocampus.[18] It is important to use fresh kainic acid because of a loss of potency over time, which may result in high mortality when the bottle is first opened and low efficacy subsequently. Furthermore, kainic acid has been difficult to obtain at times, and is currently very expensive.

Neuropathology

See the section under chronic models for a discussion of status-induced chronic pathology. There have been no studies of the time course of neuropathologic changes during kainate-induced experimental status epilepticus.

Natural History and Clinical Phenomenology

See the section under chronic models for a discussion of the natural history and behavioral changes during kainate-induced status.

Electroencephalogram

Experimental status epilepticus induced by kainic acid injection in adult rats results in the same sequence of EEG changes originally described by Treiman et al.[221] However, in the kainic acid model, 5 to 6 hours are necessary to progress to stage V. This is similar to the time course reported for soman-induced SE, and contrasts with the 2 to 2Â½ hours required to reach stage V in the cobalt-homocysteine and lithium/pilocarpine models of experimental status epilepticus.

Pharmacology

Several compounds have been studied for their efficacy at suppressing kainate-induced status epilepticus. Nefiracetam (100 mg/kg intravenously) suppressed focal seizures induced by focal infusion of kainate into the amygdala.[97] Zonisamide (100 mg/kg intravenously) only suppressed seizure spread but not the epileptic focus.[214] MK801 [(+)-5-methyl-10,11-dihydro-5H-dibenzo[a,d]-cyclohepten-5,10-imine] is anticonvulsant against KA-induced seizures in adult rats: It reduces their severity and protects against neuronal damage, although it may worsen electrographic seizures.[22,41,72,117] A similar effect of MK801 has been reported in lithium/pilocarpine-induced late SE.[240] In neonatal rats (P11â€"P12) pretreated with MK801, there is prevention of neither seizures nor KA-induced death.[208] Pretreatment with neuroactive steroids[113] or vigabatrin[92] prevents the development of status epilepticus, but these drugs have not been tested against ongoing SE.

Pathophysiology

Acute seizures in this model of status epilepticus are presumably due to the direct excitatory effects of kainate on AMPA/KA-type glutamate receptors, which are of greatest abundance in the hippocampus, amygdala, perirhinal cortex, and entorhinal cortex.[155]

Lithium/Pilocarpine and High-Dose Pilocarpine Models

Pilocarpine- and lithium/pilocarpine-induced SE has been used both to create models of chronic epilepsy and specifically to study various aspects of status epilepticus. Many features of the model are discussed earlier in this chapter; here we focus on elements specific to their role as SE models. Lithium/pilocarpine-induced SE is almost uniformly fatal within 24 hours and can be viewed as an experimental model of a severe form of generalized convulsive SE, perhaps approximating the clinical condition when GCSE develops as a complication of a severe systemic illness or generalized encephalopathy in patients without a prior history of epilepsy.

Methods

Status epilepticus can be induced by the intraperitoneal administration of 300 to 400 mg/kg pilocarpine (usually preceded by scopolamine 1 mg/kg given subcutaneously 30 minutes before pilocarpine to minimize peripheral cholinergic effects). Peripheral cholinergic effects can also be reduced by administering lithium chloride (3 mEq/kg) 24 hours before SE induction. With LiCl pretreatment, 20 to 30 mg/kg pilocarpine intraperitoneally is sufficient to induce SE. There is a high mortality rate, especially with lithium/pilocarpine administration, which can be largely eliminated by giving 10 mg/kg acepromazine 1 hour after the pilocarpine injection.

P.438

Neuropathology

Neuropathologic changes following pilocarpine-induced status epilepticus in the rat have been reviewed in detail by Turski et al.[226] and are summarized in the discussion of chronic models. Fujikawa[82] studied the relationship between duration of lithium/pilocarpine-induced SE and the extent and severity of pathologic changes and observed progressively severe and increasingly widespread neuropathologic changes during the initial 3 hours of the SE episode.

Natural History and Clinical Manifestations

The temporal evolution of pilocarpine-induced behavioral changes and of seizure activity is discussed earlier in this chapter. Age-related deficits in visual-spatial learning after prolonged lithium/pilocarpine-induced SE have been reported by Holmes and colleagues,[39] which, it is interesting to note, can be improved by enriched environments.[182] Marsh et al.[131] recently showed that the degree of impairment of visual-spatial learning and memory in adult rats is predicted by the EEG stage at which SE is stopped. SE that progresses to EEG stage IV or V results in profound deficits in both memory and learning when tested in the Morris water maze.

Electroencephalogram

The progressive sequence of five EEG stages originally reported by Treiman et al.,[221] which was described in detail earlier, has been observed in lithium/pilocarpine-induced SE in adult rats[221,236] and in pilocarpine-induced SE in adult[111] and juvenile[222] rats. The initial seizure activity on the EEG is seen about 20 minutes after pilocarpine injection, and stage V is reached in about 2 hours.

Pharmacology

Diazepam (5â€"10 mg/kg) is effective at stopping early lithium/pilocarpine-induced SE.[236] A cocktail of diazepam, 10 mg/kg, and phenobarbital, 25 mg/kg, can stop later SE at some stages, but is not always effective unless combined with isoflurane. Pilocarpine models of SE have not been used systematically to study pharmacotherapy of status epilepticus. The seizures are too severe and pharmacoresistant to be useful for predicting efficacy of antistatus drugs for the initial treatment of generalized convulsive status epilepticus, but they may be useful as a model for the development of drugs for the treatment of refractory status epilepticus in humans.

Pathophysiology

Pilocarpine is a muscarinic acetylcholine receptor agonist and, like acetylcholine esterase inhibitors, induces status epilepticus by its initial excitatory role. However, the inability of anticholinergic agents, such as atropine, to stop ongoing pilocarpine-induced SE suggests the recruitment of other excitatory mechanisms, so that the episode of SE becomes self-sustaining. The mechanism whereby pretreatment with lithium markedly reduces the dose of pilocarpine necessary to induce SE is not known.

Soman and Other Cholinesterase Inhibitor (Nerve Agent) Models

Soman (pinacolyl methylphosphonofluoridate) is an organo-phosphorus cholinesterase inhibitor nerve agent that causes peripheral signs of cholinergic poisoning, convulsions, central neuronal damage, respiratory arrest, and death.[44,88,147] Soman and other organophosphorus agents have been studied extensively by military research facilities because of the potential of these agents to be used in warfare or terrorist attacks.

Methods

Almost all studies of these agents have been done with rats, guinea pigs, or rhesus monkeys, and most have been conducted by military investigators. Agents studied include tabun, cyclosarin, sarin, soman, VR, and VX. Median lethal doses (LD_{50}) range from 8 to 300 Âµg/kg, depending on the agent and the species in which it is studied.[192,193,194] Administration is usually subcutaneous.[193] In pharmacologic studies, guinea pigs are usually pretreated with pyridostigmine Br (0.026 mg/kg, intramuscularly) and 30 minutes later challenged with two times the LD_{50} of the test agent, followed 1 minute later by treatment with atropine SO4 (2 mg/kg, intramuscularly) and pralidoxime chloride (2-PAM Cl; 25 mg/kg, intramuscularly).[143]

Neuropathology

After early seizures in organophosphorus-induced status epilepticus, when anticholinergics readily terminate seizures, no neuropathology is evident. However, if the seizures are not stopped early, anticholinergics become less effective, and mild neuropathology is occasionally observed. With prolonged epileptiform activity, neuropathologic changes are observed in multiple brain regions, probably due to excessive influx of calcium due to repeated seizure-induced depolarization and prolonged stimulation of NMDA receptors, as seen in other models of prolonged status epilepticus.[141]

Natural History and Clinical Phenomenology

The initial behavioral change after soman administration is purposeless chewing, followed by head tremor and then lordosis-like posturing. Seizure activity begins with rhythmic movement of the ears and facial musculature and sometimes forepaw clonus, and sometimes progresses to class IV limbic seizures.[140]

Electroencephalogram

Koplovitz and Skvorak[115] reported the same sequence of five progressive EEG changes during soman-induced experimental status epilepticus in the rat that Treiman et al.[221] initially described in humans and three experimental models of SE in the rat; they pointed out that McDonough and Shih[141] had previously described EEG changes corresponding to stages I, III, IV, and V in soman-intoxicated rats. McDonough has also observed a similar sequence of EEG changes following soman administration to rhesus monkeys (J. H. McDonough Jr., personal communication). In the Koplovitz and Skvorak study,[115] the mean time of onset of stage I after soman administration (180 Âµg/kg subcutaneously) was 3.1 minutes, and it was 231.4 minutes for stage V.

Pharmacology

Diazepam can block soman-induced convulsions, electrographic seizure activity, and neuronal damage.[99,120,132,142] Soman has been used to induce experimental SE in guinea pigs to test the ability of the anticholinergic agent scopolamine[31] and the noncompetitive NMDA-receptor blocker dizocilpine (MK-801)[204] to prevent or arrest seizure activity and thus to prevent neuronal necrosis. The dose of atropine can significantly affect the toxicity of the nerve agent and the efficacy of anticonvulsants.[195]

Pathophysiology

Organophosphorus agents are potent irreversible inhibitors of acetylcholine esterase, the enzyme responsible for degradation

of acetylcholine. Inhibition of acetylcholine esterase increases the availability of acetylcholine at all subtypes of acetylcholine receptors. Elevated acetylcholine levels in brain can be detected as early as 3 minutes after soman administration.[191] McDonough and Shih[141] proposed a three-phase â€œmodelâ€ of the neuropharmacologic processes responsible for the seizures and neuropathology produced by nerve agent intoxication. Initiation and early expression of the seizures are cholinergic phenomena. If not checked, a transition phase occurs during which the neuronal excitation of the seizure per se perturbs other neurotransmitter systems. With prolonged epileptiform activity, the seizure enters a predominantly noncholinergic phase and becomes progressively refractory to all pharmacologic treatment, as is seen in other models of status epilepticus.

Electrogenic Models

Electrogenic models of SE have the advantage that the inducing stimulus immediately ceases when the electrical stimulation is stopped. Thus, response to drug therapy and evaluation of effects of status are not compromised by an ongoing exogenous stimulus.

Although several investigators had used repeated electroconvulsive shocks to produce prolonged seizure activity to study metabolic and biochemical consequences of prolonged seizures and SE,[61,248,249] the first electrogenic models of self-sustaining SE were an outgrowth of kindling studies. Following Goddard's[90] initial description of the kindling phenomenon, Pinel and Van Oot[167] demonstrated that SE could be produced in rats when kindling stimuli were administered over several months. Subsequently, Taber et al.[213] found that by using an interstimulus interval of 1 minute applied to hippocampal electrodes they could produce long-term, self-sustained, limbic or generalized SE in mice and subsequent deficits in an inhibitory avoidance task. McIntyre et al.[146] used a kindling-based electrical stimulation model of SE in the rat to study the pathologic consequences of partial-onset SE induced by 60 minutes of continuous electrical stimulation of the amygdala. The extent of pathologic change was determined by the duration of the episode of SE. Untreated rats showed massive gliosis and neuronal degeneration of the ipsilateral hemisphere; barbiturate-treated rats demonstrated less pathology. Sloviter and colleagues[161,198,201] used electrical stimulation of the perforant pathway (the main excitatory pathway to the hippocampus) to replicate limbic SE and study seizure-induced neuronal damage independent of the metabolic effects associated with generalized convulsions. Sloviter[199] demonstrated a persistent loss of recurrent inhibition and irreversibly damaged adjacent interneurons following granule cell seizure activity. GABA-containing neurons survived, but there was a profound loss of adjacent somatostatin-containing interneurons and mossy cells, thus suggesting that seizure-induced loss of a basket cellâ€“activating system may cause disinhibition. Vicedomini and Nadler[229] also used stimulation of hippocampal afferent pathways to study the effects of prolonged seizure activity. They used a stimulus current administered through electrodes implanted in the angular bundle or fimbria to induce self-sustaining seizure activity that persisted after cessation of the electrical stimulation. In this model, the development of self-sustained seizure activity was essential for the production of neuronal damage: As little as 17 minutes of self-sustained seizure activity was sufficient to cause at least some neuronal loss, whereas as many as 759 stimulus trains (2.1 hours of evoked synaptic activity) produced no evidence of neuronal degeneration. EEG changes suggestive of a waxing and waning pattern (stage II) and of periodic epileptiform discharges (stage V) are illustrated in the description of this model, but whether continuous ictal discharges with or without flat periods (stages III and IV), as described in other models,[95,221] occurred with this model cannot be determined from the data provided. Lothman and colleagues,[125] on the other hand, described a model of self-sustained limbic SE that did exhibit the progressive EEG changes originally reported by Treiman et al.[220,221] In this model, as little as 30 minutes of continuous focal electrical stimulation of the hippocampus elicited self-sustaining SE that persisted for many hours after discontinuing the electrical stimulation. Subsequently, Bertram and colleagues,[23,171] using this model, noted that rats that progressed to stage V (periodic epileptiform discharges) were likely to develop chronic epilepsy, whereas animals in which SE stopped by early in stage III were not.

Cain et al.[30] also used a continuous stimulation paradigm as a simple and rapid procedure to induce limbic SE. These investigators administered 3-Hz biphasic square wave pulses via an electrode placed in the amygdala to reliably induce SE in almost all rats studied.

Almost all electrogenic models of self-sustained SE have resulted in limbic seizures, although occasional generalized convulsions are sometimes observed. However, Handforth and Treiman[95] described a nonpharmacologic model of limb clonic convulsions in the rat. Status epilepticus was induced by pulsed trains of suprathreshold electric current administered bilaterally to one of four forebrain sites: (a) orbital cortex, (b) medial prefrontal cortex, (c) deep prepiriform cortex, or (d) rostral caudate-putamen. Phenobarbital at very high serum concentrations stopped behavioral and electrical seizure activity; phenytoin, even at extremely high concentrations, did not. Handforth and Treiman[95] thus suggested this model for evaluation of the mechanisms and treatment of refractory SE. Mazarati, Wasterlain, and colleagues have used a perforant path stimulation model of self-sustaining status epilepticus (SSSE) in adult rats to study the response to a number of drugs. Diazepam and phenytoin are effective early, but much less so later in the episode.[137] NMDA-receptor blockers but not an AMPA-receptor blocker (NBQX) stop SSSE,[136] as does felbamate.[138] Levetiracetam in combination with diazepam appears to have some efficacy at high doses.[139] Pitkanen and colleagues developed an amygdala stimulation model of SSSE[157] and have used it to study consequences of pharmacologic treatment during status epilepticus. Treatment with diazepam within 2 hours reduces subsequent chronic epilepsy,[168] but lamotrigine does not.[158]

Summary and Conclusions

Models can be used to understand basic mechanisms of a disease process, its consequences, and its treatment. Focal or systemic administration of chemical convulsants and direct cerebral electrical stimulation have been used to create a large variety of experimental models of epilepsy and of SE. Recently, sustained seizure activity in hippocampal slices has also been used as a model of SE.[178]

The mechanisms of SE are now understood to be the result of failure of seizure-terminating mechanisms or of the mechanisms that make the brain refractory to subsequent seizures after a single discrete seizure, although many of the details of these mechanisms remain to be elucidated. Experimental models provide a method with which to study such phenomena. Furthermore, experimental models can be used effectively to test new drugs or new combinations of drugs for their utility in the treatment of chronic epilepsy and of SE before incurring the risk and expense of clinical trials.

Investigations on status epilepticusâ€"induced neuronal damage and chronic epilepsy that occur after prolonged seizure activity are contributing to a better understanding the epileptogenic mechanisms underlying focal human epilepsies. In particular, the experimental results obtained in animal models of

chronic epilepsies induced by pilocarpine, kainic acid, tetanus toxin, and focal electrical stimulation have cast some light on the mechanisms by which acute epileptic conditions can induce lesion- and seizure-dependent epileptogenic changes.

The animal models reviewed in this chapter have proven to be particularly suitable for testing the efficacy of antiepileptic drugs and may open new perspectives to the development of novel antiepileptogenic strategies.

Chapter 37

Genetic Models of Epilepsy

Jeffrey L. Noebels

Introduction

The success of molecular genetic strategies in finding genes underlying human monogenic epilepsies has set the stage for a new generation of defined experimental genetic models to unravel the mechanisms of inherited seizure disorders. While each discovery of a causative human epilepsy gene offers the promise of an accurate molecular diagnosis, identification of the mutant gene alone is unlikely to lead to advances in medical therapy until its cellular mechanism of action is at least partially understood. This is based on two simple reasons: First, mutations can alter gene function in various ways, most notably as a loss or a gain of biologic function, each requiring entirely different strategies for pharmacologic intervention. Second, the inherited gene defect is likely to trigger epilepsy through a complex sequence of downstream cellular changes in the developing brain, leading to the emergence of a specific seizure phenotype at a particular age. This developmental plasticity means that the destabilizing action of the gene on network excitability must be isolated from many other potentially misleading structural and functional alterations.

Genetic animal models offer the opportunity to experimentally dissect these manifold effects of the inherited disease gene in the developing brain, and to precisely define which alterations in brain circuit microanatomy and physiology directly contribute to the onset of seizures. Once this therapeutic target is obtained, a rational search for pharmacologic compounds to prevent or reverse the imbalance can begin. Since many different biologic pathways have now been implicated by known epilepsy gene mutations, it is hoped that similarities among the models may point to a smaller number of common synaptic pathways and membrane excitability defects that are shared among seizure syndromes.[66] This principle of *convergent epileptogenic defects* for specific seizure types predicts that information from individually rare inherited epilepsies will one day be translatable into broad-spectrum antiepileptic drugs. In this sense, along with continuing gene discovery, the current efforts at target discovery (i.e., to precisely define the pathogenesis of epilepsy in genetic models at the molecular and cellular levels, rather than simply at the gene and electroencephalographic levels) will provide the long sought framework for major advances in the development of effective pharmacologic therapy for many inherited seizure disorders.

General Description

Two general categories of genetic models have been historically important. Over the past 50 years, the discovery of a lowered threshold to convulsant stimulation or actual spontaneous seizures in *inbred strains* of various species provided the substrate to search for brain mechanisms underlying epilepsy and to screen for anticonvulsant efficacy. Some of these original strains, which reflect the deleterious effects of many unidentified genes, have been preserved in colonies; others have been created de novo using recombinant inbred strain methods,[29] a strategy that allows the genetic propagation of randomly combined sets of hyperexcitability alleles already present but asymptomatic in the â€œwild typeâ€ genetic background. These models all possess the virtue of displaying either spontaneous electrographic and behavioral seizures or a lowered threshold to seizures evoked by various modalities, and thus share polygenic susceptibility increases resembling those that contribute to many human seizure disorders. These inbred strains provide highly reproducible laboratory models for elucidation of anatomic seizure pathways and antiepileptic intervention.

A second, more powerful approach has been to survey animals for epileptic phenotypes linked to *single locus mutations*, either those which have occurred spontaneously, or increasingly, those engineered by recombinant DNA mutagenesis techniques.[12,64,67] The latter are typically created by the insertion of additional copies of a gene to *increase the expression levels* of a gene product, the deletion of a specific gene by homologous recombination to create a *loss of function* of the targeted gene, or the alteration of a gene sequence to produce an entirely novel *gain of function*. A refinement of this approach is to replace a wild-type allele with one engineered by site-directed mutagenesis to achieve a desired effect upon the function of the protein, typically one that has been designed to exactly replicate a human mutation. Recreating the precise molecular lesion of a form of human epilepsy in another species, an *orthologous gene model,* provides an exceptional opportunity to understand the natural history of the clinical disorder.

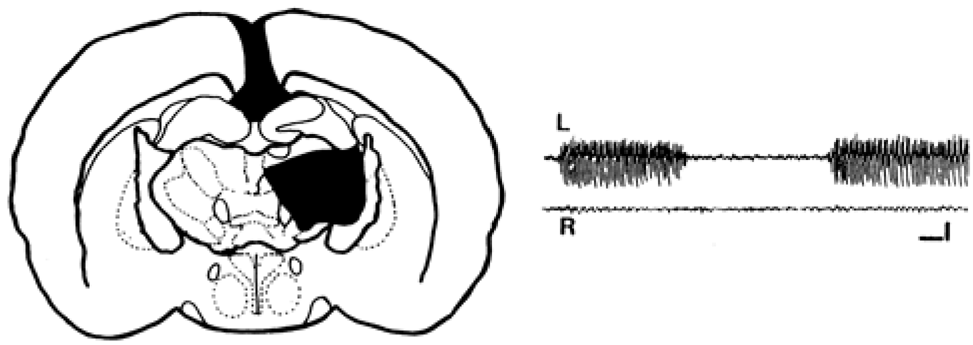

FIGURE 1. Ibotenic acid lesions of the thalamic reticular nucleus (nRT) abolish spike-wave discharges (SWDs) in the absence epilepsy model genetic absence epilepsy rat of Strasbourg. **Left:** Reconstruction of lesions induced by ibotenic acid, an excitotoxin that selectively kills neurons without affecting fibers of passage. **Right:** Electroencephalographic (EEG) recordings 4 days after unilateral nRT lesion show abolition of SWDs in the ipsilateral hemisphere, leaving only abortive low-frequency discharges. The animal was previously callosomized to prevent contralateral diffusion of the SWDs originating from the intact side. L, left EEG; R, right EEG. (From Avanzini G, Vergnes M, Spreafico R, et al. Calcium-dependent regulation of genetically determined spike and waves by the RTN of rats. *Epilepsia.* 1993;34:1â€“7.)

While many inherited human epilepsies may ultimately prove to be multigenic in origin, defects at a single gene locus suffice to produce a stereotyped seizure disorder and can be isolated and studied on many different experimental genetic backgrounds. Since the earliest electrophysiologic studies of behavioral mutants in fruitflies and mice,[36,39,68,103] spontaneous single gene mutations have contributed key examples of neuronal hyperexcitability mechanisms. *Drosophila melanogaster* hyperexcitability models of mutant ion channels, pumps, RNA binding proteins, and even KCC2-like cotransporters responsible for depolarizing GABA receptor responses continue to be described,[31,34,72] and this system shows great promise for rapidly identifying modifier gene loci,[33,88] an emerging frontier in epilepsy genetics. High-throughput mutagenesis protocols are now available to accelerate identification of relevant genes in other simple genomes, including zebrafish,[5] round worms,[101] and mice.[32] Of all of these genetic systems, defined mutations in the mouse offer the most comprehensive opportunity to identify genes linked to spontaneous, electroencephalographically proven epilepsy, and provide a powerful system to investigate the pathogenesis of single locus mutant phenotypes discovered in human mendelian pedigrees. Regardless of the species of origin, novel gene candidates for hyperexcitability discovered

P.446

through these experimental models narrow the search for genes in a linkage region mapped for human positional cloning studies, and thereby greatly facilitate human epilepsy gene discovery.

Questions That Can Be Addressed in Genetic Models of Epilepsy

Genetic animal models of epilepsy are useful to (a) define the nature, timing, and distribution of excitability changes leading to seizures in the developing brain; (b) implicate or exclude specific molecules, synapses, and networks in epileptogenesis as well as isolate gene modifiers that enhance or suppress seizures; (c) analyze the rate of progression and extent of seizure-induced neural damage during chronic epilepsy; and (d) evaluate the specificity of new antiepileptic therapies. While exact, mutation-specific (â€œknockinâ€) orthologous models of most known inherited human epilepsy syndromes are still under development, mouse models representing at least half of the known human epilepsy genes are currently available as targeted deletion (â€œknockoutâ€) or overexpression mutants. These â€œfirst generationâ€ models can mimic the overall effect of the mutation, namely, a loss or gain of function of the gene, but may not in fact reproduce the precise excitability phenotype seen in a given missense mutation of the same gene in a human proband. At the molecular level this is readily understandable, since a protein such as an ion channel that functions poorly yet continues to physically interact as a membrane protein with other channel subunits or intracellular signals often creates a different cellular defect than no protein at all. Nevertheless, these mutants provide general information on basic neural processes likely to be involved in the human clinical counterpart.

Brief Description of the Individual Models

A variety of inbred models that remain genetically uncharacterized have been of significant historical importance in the experimental analysis of epilepsy, including photosensitive baboons,[62,91] and chickens[92]; however, with a few important exceptions, including a novel unstable dodecamer expansion repeat mutation of Epm2b (Nhlrc1) identified in dogs with canine Lafora disease,[53] newer models are based on defined gene lesions in rodents. Due to the large number, this chapter will focus on recent work in a smaller number of exemplary models currently under study.

Table 1 Single Gene Models Displaying Absence Epilepsy in Mice

Mutant	Gene	Protein	Function
*Tottering**	Cacna1a	Î± subunit of calcium channel	Excitability, transmitter release
*Lethargic**	Cacnb4	*Î²*4 subunit of calcium channel	Excitability, transmitter release
*Ducky**	Cacna2d2	Î±2Î´2 subunit of calcium channel	Excitability, transmitter release
*Stargazer**	Cacng2	*Î³*2 subunit, TARP protein	AMPA receptor surface expression

mocha2j	AP3d	Adaptor protein Î´ subunit	Endosome protein trafficking
Gabrb1	Gabrb1	GABA B1 receptor subunit	GABAergic signaling
Gabrb2	Gabrb2	GABA B2 receptor subunit	GABAergic signaling
Coloboma	SNAP25	SNARE protein	Transmitter exocytosis
Swe	Nhe1	Sodium hydrogen exchanger	Intracellular pH
Hcn2[54]	Hcn2	Hyperpolarization-activated/cyclic nucleotide-gated cation channel	Membrane excitability

* Multiple alleles at these loci express spike-wave seizures.

Generalized Absence Seizure Models in Inbred Strains

Two inbred rat models of absence epilepsy, the genetic absence epilepsy rat of Strasbourg (GAERS) and the Wag-Rij rat strain, continue to serve a seminal role in defining the networks and cellular excitability mechanisms of absence seizures emerging from aberrant thalamocortical oscillations.[22,26] Inheritance of spike-wave (SW) epilepsy in these models is not due to a single gene locus, although potentially contributory gene variants can be identified that are absent in other unaffected rat strains, for example, a variant in the KCNK9 gene coding for the TASK3 (Twik-like acid-sensitive K^+) channel in the GAERS model.[35] Both inbred rat models exhibit spontaneously occurring bilaterally synchronous 5- to 11-Hz SW with behavioral arrest with a late onset at 3 to 4 months of age lasting into adulthood. The neocortex, thalamic relay neurons, and reticular thalamic nucleus are involved in the aberrant synchronous discharge, cognitive performance during the seizure is impaired, and the oscillations share major features of the circuitry and pharmacology, if not developmental onset, of slower 3/sec absence seizures in humans. Occasionally, the same discharge pattern is reported in other inbred rat strains.[84]

A number of important electrophysiologic and pharmacologic insights have been derived from these two strain models. Key among these are the involvement of the nucleus reticularis thalami in the expression of spike-wave epilepsy (Fig. 1) and the role of elevated low-voltage T-type calcium currents in this discharge.[97] Additional control over thalamic oscillations is regulated by enhanced HCN1 gene expression and decreased cAMP responsiveness of a second pacemaking current, Ih, favoring rebound excitation in these neurons.[11] Other recent findings point to regional blood flow increases,[63] cortical excitability changes in deep layer neurons,[23] a low threshold trigger zone in barrel cortex,[58] and Î³-aminobutyric acid (GABA)-ergic signaling impairments.[6] These models have served as a mainstay for the analysis of thalamocortical spike-wave seizure modulation by a variety of receptor families, as well as a wide range of antiepileptic pharmacology.[26]

P.447

Generalized Convulsive Seizure Models in Inbred Strains

The genetically epilepsy-prone rat (GEPR) is a model of experimental audiogenic seizures, a form of reflex epilepsy that has been useful in tracing the brainstem pathways mediating high decibel-induced convulsions with wild running.[41] While a rare clinical counterpart of this behavioral seizure type, *epilepsia cursiva*, has been recognized in humans,[37] the model set the stage for analysis of audiogenic mouse mutant models with defined single gene lesions, including the serotonin 5HT2C receptor,[8] the FMR1 Fragile X mouse,[105] and the JAMS1 mouse locus[59] that corresponds with a human locus for febrile seizures. Interestingly, a loss of function mutation in MASS1, another gene shown to underlie audiogenic seizure susceptibility,[86] was subsequently found within a human pedigree with febrile seizures.[61]

The *EL* mouse inbred strain is notable for the development of seizures following repeated episodes of vestibular stimulation. Susceptibility begins at 10 weeks of age, and the seizures are manifest as running fits followed by convulsions of possible cortical origin.[60,90] A variety of defects have been described in this model, and it continues to find a use in imaging GABAergic receptor signaling plasticity in chronic epilepsy.[30] Another model of convulsions evoked by stress and handling has been described in various strains of the domestic Mongolian gerbil. This model was once used extensively in neuropharmacologic testing, and more recently has been found to exhibit changes within the GABA interneuron population.[10]

The spontaneously epileptic rat (SER) was developed by crossing the *tremor* and *zitter* strains and exhibits spontaneous tonic convulsions, absencelike seizures, and spongiform encephalopathy ending in lethality by 20 weeks of age. Recent studies add abnormalities in glutamate transport to a diverse set of other neuropathologic changes resulting from coexpression of these two loci.[2] The *zitter* locus contains a splicing mutation in the gene encoding *attractin*, an enzyme with a critical role in myelination.[46] As a model displaying two distinct seizure types, it finds use in studies of antiepileptic drug profiles.[40]

An inbred rat strain with a cortical band heterotopia and convulsions resembling the human double cortex malformation syndrome, the telencephalic internal structural heterotopia (*Tish*) rat, has been described.[48] Spontaneous seizures in these animals arise nearly simultaneously in both normal and ectopic cortical circuits due to extensive interconnections between the two.[16] The genes underlying this malformation have not yet been identified; however, one epileptogenic mechanism described involves a reduction in the number of parvalbumin-containing GABAergic interneurons in *Tish* necortex.[96] This lesion is suggestive of the interneuron migratory defect seen in some targeted mouse mutants.

Absence Epilepsy in Defined Single Locus Mouse Models

Systematic electroencephalographic (EEG) screening of murine mutants for cortical excitability defects has so far revealed ten single gene loci for spike-wave epilepsy phenotypes (Table 1). All are recessive, save for the autosomal dominant *Coloboma* locus, a deletion containing the exocytosis-related SNAP25 gene, and many show additional neurologic phenotypes in the homozygous mutant. Except for the 3/sec spike-wave epilepsy mutant *Swe* lacking a functional NHE1 sodium hydrogen exchanger gene,[21] these mice express spontaneous, brief (1- to 10-second), generalized 6- to 7-Hz spike-wave discharges in the cortical EEG associated with arrest of movement. Seizures in these models typically begin in the third week of life, continue into adulthood, and respond dramatically to ethosuximide. *Swe* mice are the sole mouse model to reproduce a 3/sec spike-wave discharge in juvenile mice, disappearing in adulthood. Neurons in NHE1-deficient mice show prolonged recovery from an acid load and increased sodium ion channel expression.[104]

The *tottering* mutant develops in adolescence (postnatal day 17) a generalized 6 to 7/sec cortical spike-wave discharge with brief (1- to 10-second) bursts occurring at a mean rate of up to 60/hr. Many laboratories have now studied neuronal

excitability in these classical calcium channel mutant models and their multiple alleles, and they confirm a range of cellular abnormalities in each. Loss of function mutations in the P/Q type Î± subunit of voltage-gated calcium channels reduce calcium entry through the pore; however, at many synapses, release defects are partially compensated by N-type calcium channels[77] and similar compensatory rearrangements by other related subunit genes can follow the loss of channel regulatory subunits, as seen in the *lethargic Cacnb4* mutant.[13,14] In the *tottering* mouse, several key mechanisms underlie the genesis of spike-wave synchrony, including an elevation of T-type calcium currents in thalamic neurons that precedes the onset of epilepsy (also shared by *lethargic, stargazer*, and *Coloboma* models),[107,108] and a reduction of feed-forward inhibition onto layer IV neurons in the neocortex,[80] all correlating with the onset of epilepsy. The presence of thalamic T-type currents is essential for the expression of spike-wave discharges in these models, since deleting the *Cacna1G* gene encoding T-type currents in thalamic relay nuclei abolishes the seizure phenotype.[44,87] Other downstream plasticity mechanisms are likely to modulate spike-wave epileptogenesis and may serve as additional therapeutic targets.[70] Analysis of *tottering* mice also provided the first example of a model where a potential therapeutic target may be far removed from the mutant gene itself. The *tottering* brain shows a gene-linked proliferation of noradrenergic locus coeruleus axon terminals in neocortical and thalamic regions, and neonatal correction of this inherited hyperinnervation with a selective neurotoxin prevents the expression of epilepsy.[50,65] The neuromodulatory effects of noradrenaline on the compensatory N-type calcium channel may explain why removal of this downstream target rescues the *tottering* phenotype.[51] *Lethargic* and *ducky* mice express an absence seizure phenotype similar to *tottering*, including the accompaniment of paroxysmal dystonias, but since they bear mutations of regulatory subunits that interact with multiple calcium channel Î± subunit pore proteins (not simply *Cacna1a*), they share only some of the regional profile of excitability changes.

The *stargazer* mouse bears a mutation in the calcium channel/TARP gamma 2 subunit gene (*Cacng2*) and shows an identical EEG spike-wave seizure disorder as the calcium channel subunit mutants, but lacks episodic dystonia and has a severe vestibular defect.[49,69] Like other spike-wave mutants, seizures in *stargazer* mice are immediately blocked by ethosuximide, but unlike the *lethargic* and GAERS models, GABA$_B$ receptor blockade is ineffective in preventing SW, and unlike the *tottering* mouse, no noradrenergic abnormalities are evident in *stargazer* brain, indicating that the two mutant genes produce spike-wave seizures through different intervening defects. Recent work identifying the gamma 2 subunit as a founding member of a novel family of transmembrane Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor regulatory proteins (TARPs) suggests a role other than calcium channel regulation. The latter proposal, initially based on its sequence homology with a subunit of muscle voltage-gated calcium channels, has been replaced with a proven role mediating AMPA receptor plasticity at dendritic spines.[71] Î³ Subunits interact with PSD-95 and other synaptic scaffolding proteins[25] and are essential for the surface expression of AMPA-type glutamate receptors, as well as two direct modulatory effects on channel function: A reduction in glutamate-evoked desensitization and an increase in the relative size of responses to the partial agonist kainate.[98]

GABA$_A$ receptor mutations linked to various human absence epilepsy syndromes have been described. One such report is a *GABRA1* truncation, which displays no current following exposure to GABA,[57] and the other is a trafficking defect in the gamma 2 subunit of GABA$_A$ receptors that reduces membrane surface expression of the receptor.[42] These defects predict that a null mutation would provide a good model of these phenotypes.

To summarize, analyses of the single locus models of absence epilepsy have revealed several general principles regarding the heredity of this cortical synchronization trait. First, a defect at a single gene locus is sufficient to produce a generalized spike-wave seizure disorder.[68] Second, the EEG pattern itself is genetically heterogeneous, and can arise from mutations in multiple independent loci that may display distinct neurologic comorbidities. Third, the intervening cellular excitability mechanisms underlying the generation of spike-wave cortical discharges are not identical, but share some features in common. Fourth, each of the mutant genes gives rise to syndromes that can differ in their seizure frequency, sensitivity to antiepileptic drugs, and severity of the associated neurologic phenotype. Fifth, due to the reproducible developmental expression of the abnormal synchronization, primary defects can be distinguished from secondary cellular alterations, and the specific patterns of these pathologic changes are linked to the inherited mutant allele.

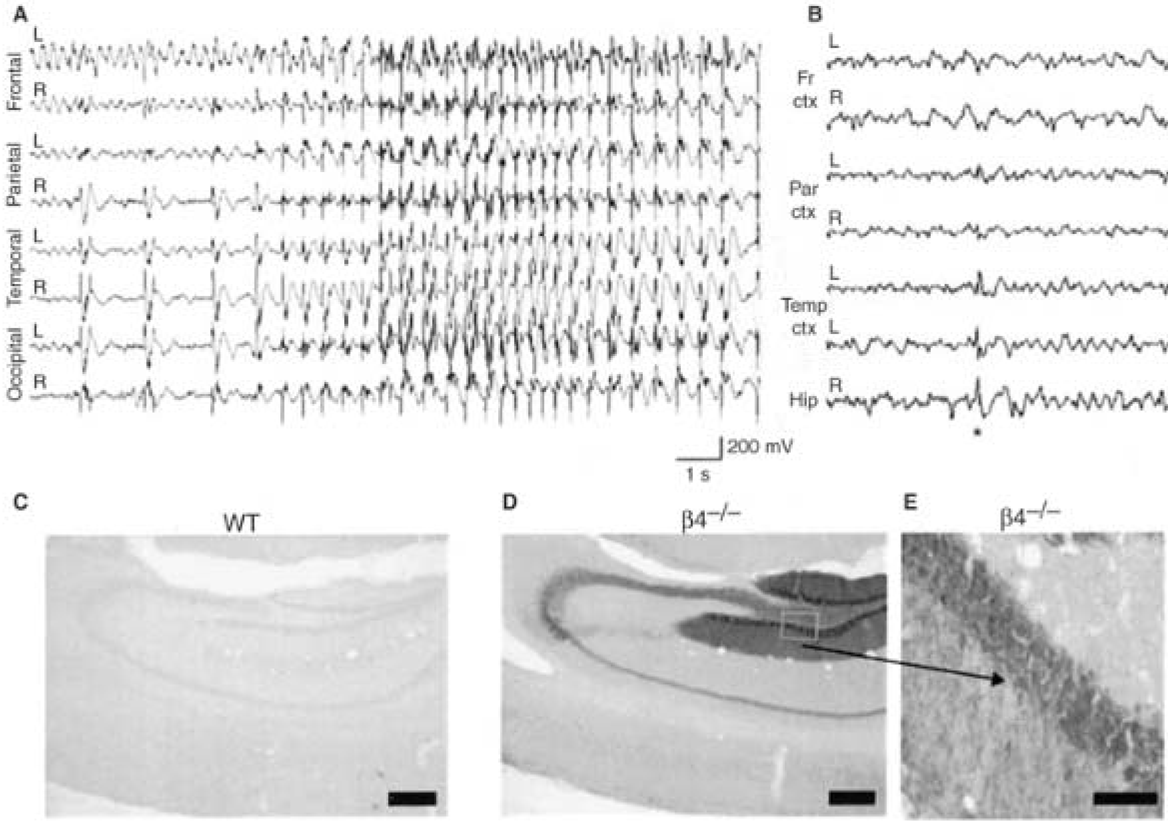

FIGURE 2. Deletion of the Î²4 subunit of BK calcium-activated potassium channels in brain causes nonconvulsive, partial-onset hippocampal seizures. **A.** Surface cortical electroencephalogram (EEG) recording shows initial interictal discharges in posterior and temporal regions with frontal spread to a generalized seizure activation pattern. **B.** Interictal spiking in depth recordings from the hippocampus (*bottom trace*). **Câ€"E.** Selective expression of Î²4 subunit in hippocampal formation and neocortex. Anti-GFP antibody shows no GFP (diffusible intracellular marker for cells deleted for Î²4 subunit expression) in wild-type mouse and strong dentate granule cell expression where the subunit gene has been deleted in mutant. (From Brenner R, Chen QH, Vilaythong A, et al. BK channel beta4 subunit reduces dentate gyrus excitability and protects against temporal lobe seizures. *Nat Neurosci.* 2005;8:1752â€"1759.)

Convulsive Seizures in Defined Single Locus Models

A variety of convulsive seizure models based on spontaneous single locus mutations have been described, and many more are certain to follow as the list of known human genes for this condition expands. At present there are over 140 mendelian syndromes that include generalized epilepsy reported in the Online Mendelian Inheritance of Man (OMIM) database.

Single Locus Models with Partial (Focal) Onset and Secondary Generalization

Using a ten-electrode recording array, Brenner et al. described a mouse model of generalized epilepsy with focal bilateral electrographic onset within temporal brain regions. This model is based on a null mutation of the BK Î²4 subunit gene (*Kcnmb4*), a negative regulatory subunit of the calcium-activated potassium channel that is expressed principally in the hippocampal formation and neurons within deeper neocortical layers (Fig. 2).[9] Loss of the braking function of the subunit that normally limits high-frequency firing patterns in dentate granule cells effectively enhances depolarizing afterpotentials and facilitates bursting in these cells in response to depolarization, thus degrading the intrinsic â€œgatingâ€ function of the dentate gyrus. The behavior of the mouse is remarkable in showing behavioral arrest in the early phase of the seizure, followed by grooming automatisms, while the EEG discharges generalize to involve the neocortex, a pattern expected of seizures in the limbic region. Interestingly, the interacting Î± subunit gene is strongly expressed in thalamus and all cortical layers, and a mutation causing a similar loss of Ca^{2+}-activated regulation of this channel has been linked in humans with childhood absence epilepsy.[28] This pair of genes is the first to differentially localize with brain circuits known to mediate these two distinct seizure types.

A second mouse model based on a mutant potassium channel is of interest due to the use of conditional genetic engineering techniques to suppress the expression of the channel gene in the brain at different developmental stages. The *Kcnq2* gene encodes a potassium channel subunit that dimerizes to form a channel mediating the M current, a strong hyperpolarizing afterpotential in hippocampal neurons, and is one of the genes linked to a human benign neonatal epilepsy (BNE) syndrome.[7,85] Mice were created with a transgene encoding a dominant-negative copy of the KCNQ2 protein that inactivates the M current. This transgene was placed under the control of

a promoter construct sensitive to the antibiotic doxycycline, and M currents were attenuated by doxycycline exposure.[74] Suppression of M currents at early developmental time points caused a mixed (partial, generalized tonicâ€"clonic, and generalized spike-wave) seizure disorder lasting into adulthood. Interestingly, genetic suppression of M currents after several postnatal weeks of age did not create a seizure phenotype, only pronounced hyperactivity and severe cognitive deficits. Neither of the models has so far provided an explanation for the disappearance of seizures in the benign human syndrome.

Primary Generalized Seizures

Disruptions in a wide variety of molecular pathways lead to the generalized convulsive seizure phenotype, including defects in neurotransmitter and receptor levels, vesicle proteins and exocytosis, transporters, and a lengthening list of transcription factors underlying programs of neuronal migration. It now appears that in a majority of cases, clear decrements in synaptic inhibition are found in regional brain networks. While GABAergic signaling may not be the sole defect, these models demonstrate that the gene mutations selectively disinhibit neural circuitry favoring epileptic synchronization. Representative examples from these categories are highlighted here.

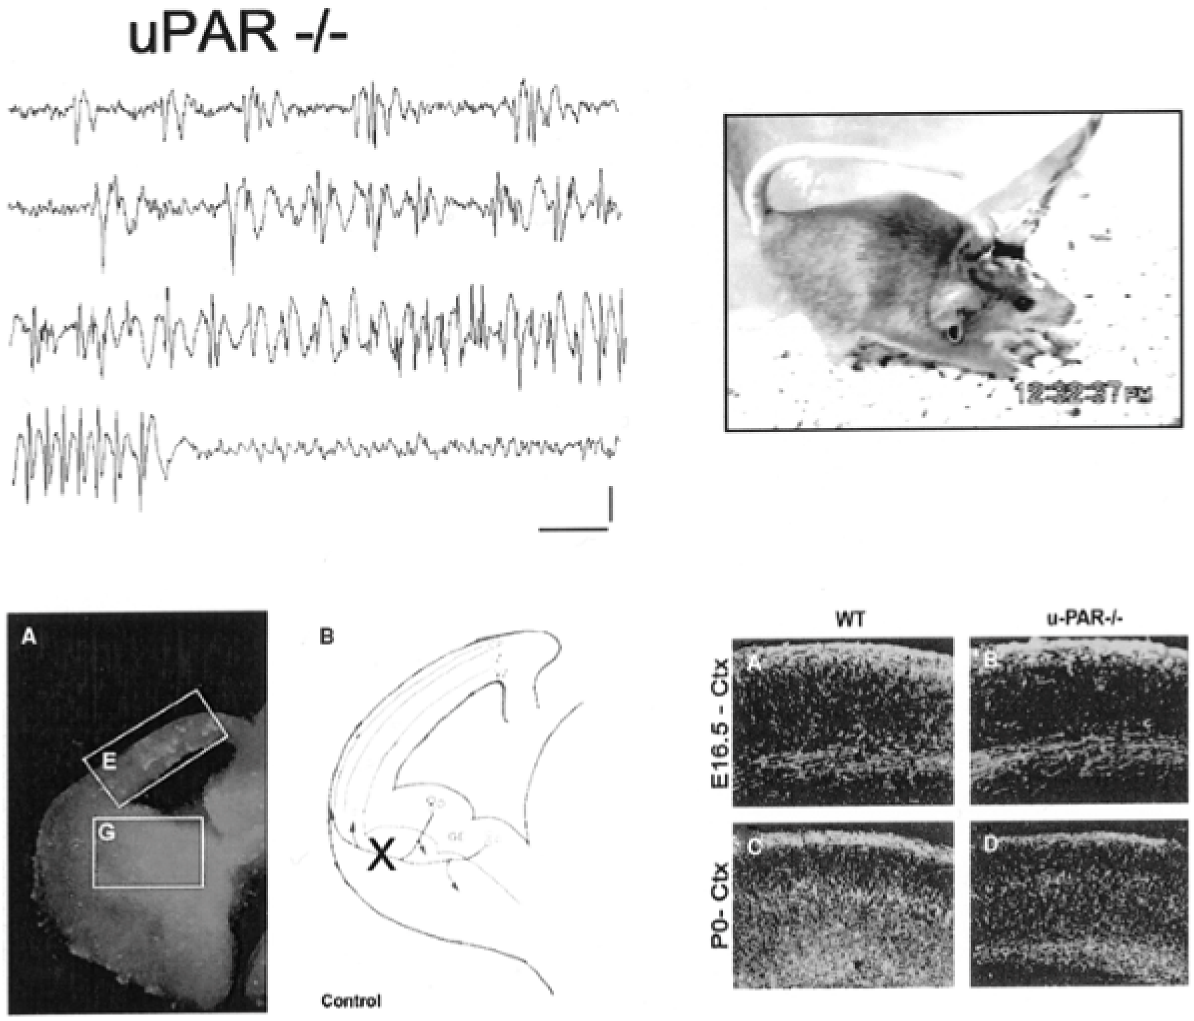

FIGURE 3. Impaired interneuron migration and myoclonic seizure activity in *upar*$^{-/-}$ mutant mice. **Above:** *At left*, Electrocorticographic monitoring of control (WT) and adult *upar*$^{-/-}$ mice reveals abnormal bilaterally synchronous interictal discharges and spontaneous seizures progressing from isolated to continuous spike and spike-wave rhythmic discharges, terminating abruptly. Representative stages of the seizure (76 seconds in duration) are shown. *At right*, posture of a *upar*$^{-/-}$ mutant mouse during the final stage of a seizure. Calibration: 500 ÂµV, 1 second. **Below:** *At left*, Absence of *upar* gene interrupts tangential migration of interneurons from birthplace in germinal eminence to neocortex, where, *at right*, relative loss of Î³-aminobutyric acid (GABA)-ergic neurons in middle cortical layers is evident at birth. (Adapted from Powell EM, Campbell DB, Stanwood GD, et al. Genetic disruption of cortical interneuron development causes region- and GABA cell type-specific deficits, epilepsy, and behavioral dysfunction. *J Neurosci.* 2003;23:622â€"631.)

Proliferation, Migration, and Maturation of GABAergic Interneurons

A primary defect in embryonic progenitor cell neurogenesis, and the first monogenic rat epilepsy model to be genetically identified, gives rise to severe seizures due to proliferation defects. The *flathead* rat is a spontaneous null mutant of the citron kinase gene, required for cytokinesis, early cell proliferation, survival, and postnatal hippocampal neurogenesis following seizures.[1] Generalized seizures in this model begin in the second postnatal week at a time when substantial apoptosis becomes apparent within cortical proliferative zones.[79] A mouse null mutant of the citron kinase gene with seizures has also been described.[27] Targeted deletion of the transcription factor NeuroD/Î²2 in the mouse creates a striking failure of proliferation of granule cell precursors in the dentate gyrus, leading to the complete absence of the granule cell layer. The adult

â€"/â€" mouse develops spontaneous generalized electrographic discharges with partial myoclonic seizures.[52]

The ability to target genes encoding molecules essential for the correct migration of specific populations of cortical interneurons has created two important and very instructive models of epilepsy. The first, created by deletion of the *upar* gene encoding the urokinase plasminogen activator receptor, results in the arrested migration of inhibitory parvalbumin-containing interneurons in their early lateral trajectory from the medial germinal eminence to the middle layers of frontal and parietal regions in the neocortex.[75] The mice display dramatic episodes of axial clonic seizures with severely disorganized, high-amplitude polyspike-and-wave discharges (Fig. 3). A second model depleting forebrain inhibitory interneurons was generated by targeted deletion of the DLX1 gene, one of a family of five homeodomain transcription factors. Loss of DLX1 selectively reduced calretinin+ and somatostatin+ staining interneurons in the neocortex and hippocampus, leaving parvalbumin neurons unaffected.[19] Nonconvulsive generalized seizures are present in this model and were unusual in displaying electrographic-behavioral dissociation with a pattern of striking generalized EEG discharge activity while the mouse remained motionless. The developmental mechanism of this interneuronopathy is distinct from that of *upar*-deficient mice, in that loss of DLX1 affected the terminal maturation, rather than the migration of interneurons, which then undergo apoptosis following the migratory phase. Different subsets of missing interneurons were also responsible for creating either a myoclonic or absence seizure phenotype.

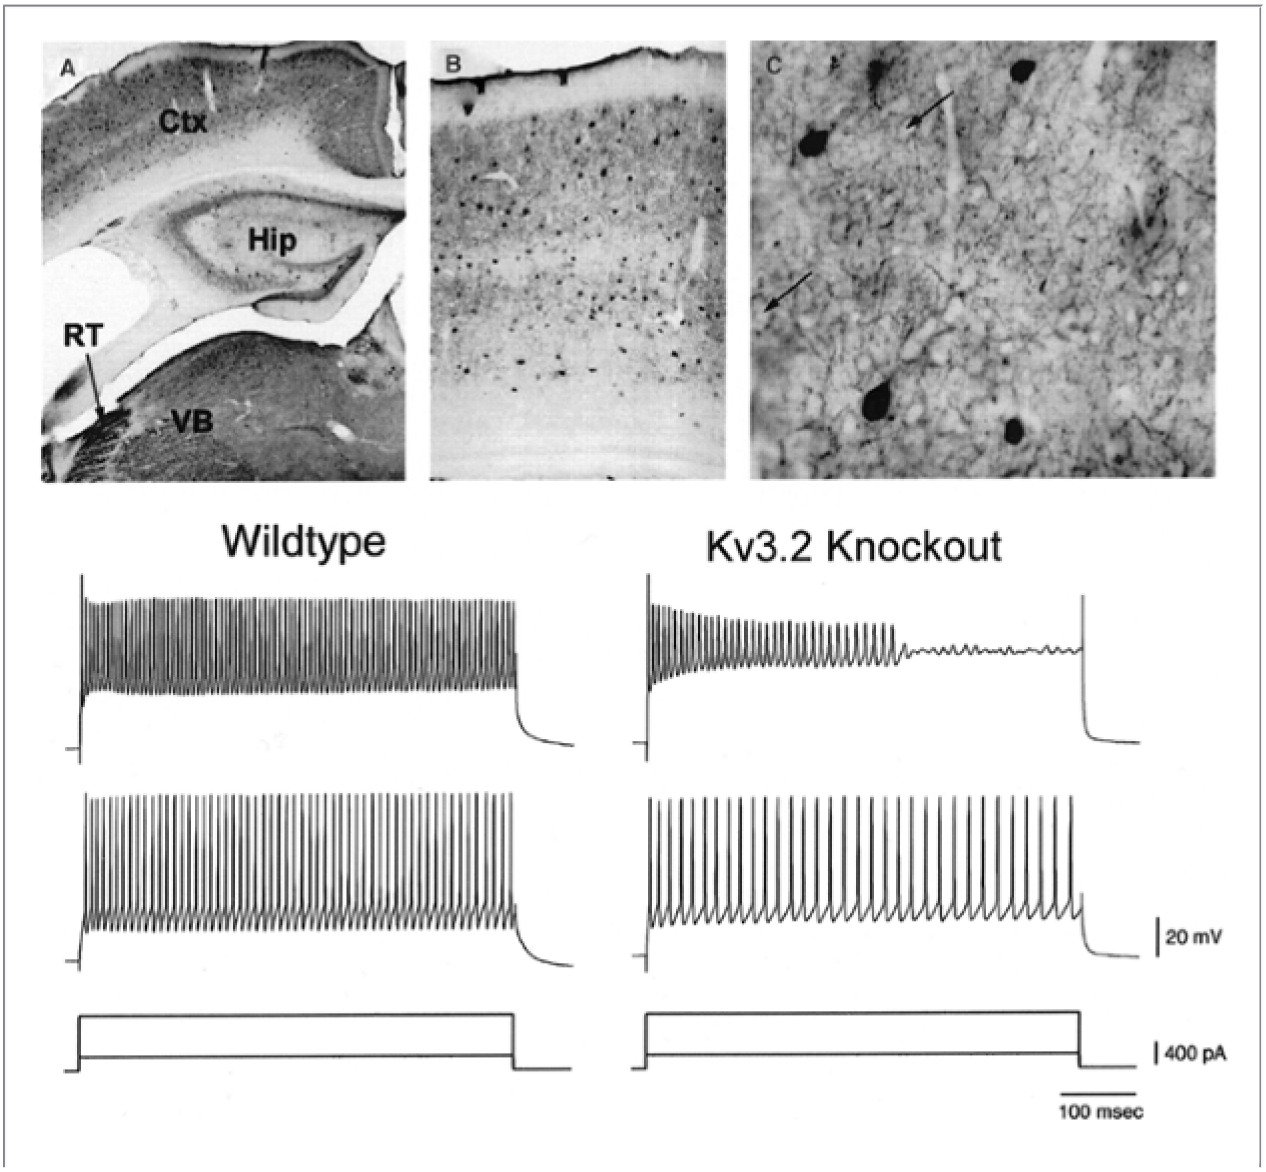

FIGURE 4. Selective impairment of high-frequency firing in inhibitory interneurons leads to generalized seizures in potassium channel Kv3.2 knockout mice. **Aâ€“C.** Kv3.2 delayed rectifier channels are expressed predominantly in parvalbumin+ staining interneurons in layers II and IV of neocortex as well as in hippocampal and thalamic networks, but not in principal excitatory neurons (**C**, *arrows*). **Below:** High-frequency firing behavior recorded from identified parvalbumin+ interneurons is limited by progressive spike adaptation during prolonged depolarization. Ctx, cortex; Hip, hippocampus; RT, reticular nucleus; VB, ventrobasal. (From Lau D, Vega-Saenz de Miera EC, Contreras D, et al. Impaired fast-spiking, suppressed cortical inhibition, and increased susceptibility to seizures in mice lacking Kv3.2 K+ channel proteins. *J Neurosci.* 2000;20:9071â€“9085.)

A variety of other developmental proliferation and migration models with epilepsy have been demonstrated, each targeting specific subsets of cells in unique patterns of the forebrain,

for example, the SOX1 mutation impairing ventral forebrain GABArgic projection neurons.[56] Analysis of mice lacking p35, a neuron-specific activator of the cyclin-dependent kinase Cdk5, that display cortical lamination defects and seizures reveals extensive network reorganization and dystopias of hippocampal interneurons.[15,73,100] Recent evidence suggests that this molecular signaling pathway may also be disturbed in human epileptic dysplasias.[82] An entirely different pattern of reorganization is seen in the OTX1-deficient mouse that shows epilepsy, a selective loss of large cortical projection neurons, and defects in the GABAergic inhibitory system.[17]

Interneuron Excitability and GABA Release

The *Kcnc2* mouse model provides a striking example of the importance of genetic models to understand intervening mechanisms of epileptogenesis, even when the product of the mutant gene is as well understood as the potassium channel. This gene encodes the channel mediating Kv3.2, a delayed rectifier-type potassium current. Mice targeted for deletion of the Kv3.2 current encoded by the *Kcnc2* gene show generalized tonicâ€“clonic epileptic seizures.[47] In the neocortex, this channel is selectively expressed in deep-layer fast-spiking parvalbumin+ interneurons (Fig. 4). Whole cell recordings revealed that mutant cells were unable to rapidly repolarize, and that accumulating depolarization suppressed high-frequency firing upon strong depolarizations, thus effectively disinhibiting the network. This limitation of high-frequency firing is a familiar mechanism underlying antiepileptic drug mechanisms in excitatory cells,[55] yet when it acts selectively in inhibitory interneurons, it has the opposite effect.

Disproportionate reduction of the excitability of inhibitory interneurons may also explain the epilepsy arising from

similar effects of a sodium channel mutation on firing properties in parvalbumin+ interneurons. Truncation and haploinsufficiency mutations in the *Scn1a* gene (one of five Î± subunits of voltage-gated sodium channels expressed in brain) lead to the severe myoclonic epilepsy of infancy (SMEI) syndrome,[18,89] yet the mechanisms linking network hyperexcitability with a loss of function in a subset of sodium channels remained unclear. Analysis of heterozygous *Scn1a* knockout mice whose haploinsufficiency mimics the human SMEI genetic condition revealed that loss of *Scn1a* channels in hippocampal neurons preferentially reduces membrane excitability in inhibitory interneurons compared with excitatory pyramidal cells, resulting in a net disinhibition within this network.[106] Thus, channelopathies causing *hypoexcitability in interneurons* represent a distinct category of gene mechanisms leading to inherited epileptogenesis.

The ability to rapidly release sufficient quantities of GABA in response to high-frequency stimulation is a second key feature of effective neuronal inhibition. Targeted deletion of the gene encoding the synthetic enzyme GAD65 produces viable mice with a generalized seizure phenotype.[43] GAD65 is one of two enzymes involved in GABA synthesis in the brain, and is believed to synthesize a secondary releasable pool of neurotransmitter that is drawn upon during sustained high-frequency firing.[95] Therefore, the depletion of this pool can account for the preserved whole brain GABA levels and normal GABAergic signaling in this mutant at low frequencies, as well as the early lethality of the GAD67 deletion mutant that shows severely reduced brain GABA levels.[3]

GABA Postsynaptic Response

Altered responses to GABA are the final step in the signaling pathway, and several gene models exemplify what is certain to become a well-represented category of epileptogenic mutation. Mutations in $GABA_A$ receptors underlie human epilepsy, and the gene for the $GABA_A$ *Î²*3 subunit lies within the critical chromosomal region of patients with Angelman syndrome (AS), where silencing of this gene has been proposed to contribute to the epileptic phenotype. Targeted knockout of the *Gabrab3* gene produces a mouse with severe generalized seizures,[24] and electrophysiologic analysis of these mice revealed the complete absence of inhibitory GABAergic responses in the reticular nucleus of the thalamus, where this gene is expressed, with no effects within adjacent thalamic relay nuclei, where it is not expressed.[38] This model demonstrates that suppression of intrareticular nucleus (RTN) inhibition may contribute to intrathalamic and generalized cortical synchrony in affected AS patients.

An unexpected and markedly abnormal potentiation of GABA responses have been reported in the first â€œknockinâ€ model of a human epilepsy syndrome involving the Î±4 subunit of the neuronal nicotinic acetylcholine receptor.[45] Two human mutations described in patients with the partial epilepsy syndrome of autosomal dominant frontal lobe nocturnal epilepsy (ADFLNE), CHRNA4(S252F) and CHRNA4(+L264), were genetically engineered to replace the wild-type allele of the receptor gene in two related mouse models. Both of these mutant mice showed abnormal EEG slowing and exhibited frequent generalized seizures. Electrophysiologic recordings from layer II/III cortical pyramidal cells in vitro revealed a >20-fold enhancement in inhibitory postsynaptic currents in the presence of the receptor agonist nicotine, but no effect on excitatory postsynaptic currents. The cortical excitability and seizures in the mutants were reduced by exposure to low doses of a $GABA_A$ receptor antagonist. These orthologous mouse models suggest that a novel mechanism contributing to the ADNFLE seizure phenotype may involve abnormally increased inhibitory synchronization of cortical networks via activation of mutant Î±4-containing nicotinic acetylcholine receptors, known to be located on the presynaptic terminals and somatodendritic compartments of cortical GABAergic interneurons.

Two other epilepsy models demonstrate epileptogenic gene mutations that may share a presynaptic site of action. Metabotropic glutamate and GABA receptors, unlike their ion channel counterparts, are G-coupled protein receptors whose activation modulates both neurotransmitter release and postsynaptic response. Deletion of the presynaptic metabotropic receptor for glutamate, mGluR7, results in an epileptic phenotype.[78] Activation of mGluR7 decreases transmitter release at excitatory glutamatergic presynaptic terminals or via heterosynaptic effects on interneuron terminals.[81] G-proteinâ€“coupled $GABA_B$ receptors are present at both pre- and postsynaptic sites where they prolong inhibition by reducing presynaptic calcium entry and activating postsynaptic potassium channels. Targeted deletion of *Gabarb1* and a truncation mutation of *Gabarb2* both generate mice that show handling-induced generalized seizures in the second postnatal week.[76,83,93,94] In these two models, pre- and postsynaptic $GABA_B$ receptor responses are abolished, resulting in loss of heterosynaptic depression, depolarizing $GABA_A$ receptorâ€“mediated events, and hyperexcitable network activity in vitro.

Another mechanism of postsynaptic disinhibition has been modeled by altering the chloride gradient in neurons responsible for hyperpolarizing responses to postsynaptic $GABA_A$ receptors. This gradient is established by the potassium chloride cotransporter KCC2, whose postnatal expression increases to convert depolarizing GABA responses in the neonatal nervous system into the hyperpolarizing inhibitory potentials seen in the adult. Depolarizing GABA responses consistent with KCC2 impairment have been reported in epileptic human cortex.[20] Deletion of the KCC2 gene *Slc12a5* in mice produces a mouse with a spontaneous generalized epilepsy phenotype.[102] The regions most affected by seizures in the mutant are in the temporal and entorhinal cortices and hippocampus, where parvalbumin+ interneurons are found to be reduced in number, suggesting the possibility that KCC2 plays a role in their development. Finally, anomalous metabolic reserves may dysregulate a large number of energy-dependent inhibitory processes in neuronal signaling, and a recent model of the human neonatal *GLUT1* deficiency syndrome reveals that knockout of the neuronal glucose transporter *Glut1* gene in mice produces a mixed seizure disorder,[109] allowing experimental exploration of the cellular mechanisms underlying the common clinical finding of hypoglycemia and neonatal seizures.

Summary and Conclusions

The last decade has witnessed a dramatic expansion of defined single gene models of epilepsy. These models play an essential role in defining the molecular anatomy and biology of epilepsy. We have learned three lessons fundamental from these models so far: First, there is a preponderance of genes that impair inhibitory processes in the brain. Second, nearly one third of all known inherited causes of epilepsy consist of mutations in ion channel subunit genes with clinically distinct epilepsy syndromes. Third, a large number of epilepsy genes alter early steps in the program for neuronal migration in the brain, producing striking changes in neocortical circuitry and highly complex compensatory excitability alterations. We have discovered that a single defective gene can give rise to multiple seizure types, that modifier genes can be mapped and isolated, and that in some instances, the brain expression pattern of a mutant gene can accurately predict the seizure phenotype, while in

P.453

others the epileptic circuit arises unpredictably from a diffuse pattern of mutant gene expression. Identifying why, where, and when the hyperexcitability phenotype will emerge during the development of inherited epilepsy remains a key challenge for each of the genes linked to epilepsy.

The next generation of genetic models will feature the application of further advances in tissue engineering, including the delivery of gene-silencing probes into specific brain networks. A major emphasis will be to faithfully replicate human mutations identified in clinical epilepsy pedigrees using knockin genetic technology (â€œhumanized mouse modelsâ€). A second strategy will be to employ conditional mutagenesis techniques permitting a selective alteration of gene function in precise regions and at various developmental ages in the brain. Combining these methods will allow us to realize the full potential of genetic models, namely, to take a single human epilepsy gene mutation and determine the correct molecular target for therapy. Completion of the rat genome sequencing project and perfecting mutagenesis strategies in the rat will also strengthen our ability to explore therapeutic strategies. In addition, a new generation of complex multigenic models of epilepsy must be developed to begin to understand the contribution of genetic modifiers in common nonfamilial patterns of idiopathic epilepsy that appear in the general clinical population. Analysis of these new kinds of mutant models will improve our understanding of the complex mechanisms that regulate the age of onset and severity of seizure disorders, and should accelerate the identification of novel treatments for inherited epilepsies in man.

Chapter 38

Epilepsy in Vitro: Electrophysiology and Computer Modeling

John G. R. Jefferys

Introduction

Epileptic seizures and other kinds of epileptic activity are emergent phenomena from the interactions between cells organized into networks. To understand the relationship between the dynamics of cellular and local networks activity and epileptic discharges requires simplified models: This chapter outlines the use of in vitro preparations and computer models in this task. The chapter starts by describing different types of in vitro preparations and models of epilepsy, before outlining general aspects of computer modelling, and finally describing pathophysiologic mechanisms involved in epileptic phenomena.

In Vitro Preparations

Invertebrate preparations in vitro played an important role in the development of cellular studies of epilepsy, but they have largely been superseded by mammalian preparations, which are more directly relevant to the problem of epilepsy. In vitro preparations share the advantages of (a) mechanical stability, which is very helpful for cellular electrophysiology in which microelectrodes must to be precisely positioned in, on, or near neurons; (b) direct visualization, using suitable microscopes, of either general anatomic features or individual cells, both of which may be used for optical recording of Ca^{2+}, membrane potential, and other physiologic variables; and (c) simpler control over extracellular ions and drugs due to the absence of a blood–brain barrier. The following paragraphs outline the main preparations of mammalian brain tissue in vitro, starting from the simplest and going on to consider the brain slice in more detail.

- *Dissociated cell.* Neurons can be used for studies of their intrinsic properties shortly after they have been dissociated from tissue by mechanical agitation and enzymatic digestion of the extracellular matrix. This is a powerful technique for studying channelopathies in chronically epileptic tissue. Dendrites are amputated, which improves space clamp, but, of course, loses the contribution of all but the most proximal dendrites to the neuron's properties.[42,145]
- *Dissociated culture.* Neurons dissociated from pieces of brain tissue can be plated into culture dishes and maintained for several weeks. They will rewire into synaptic networks that can sustain epileptic activity. The limiting case is the single neuron culture that makes extensive connections with itself and generates spontaneous epileptic discharges.[106] Dissociated cultures are useful for those methods that take some time to work and/or need good access to neurons, such as transfection with molecular constructs to modify neuronal behavior. Non-neuronal cultured cells play a crucial role in identifying phenotypes associated with mutations found in monogenic epilepsies (see the section on chronic epilepsies). Cultured cells may also be used in the high-throughput screening of drugs with well-defined targets such as sodium channels.[23]
- *Brain slice.* This probably is the most widely used in vitro preparation in basic epilepsy research, and is the main topic of this chapter.[38] It is a section of brain tissue, a few hundred microns thick, maintained in physiologic saline or artificial CSF solution that contains the salts, glucose, and oxygen needed to sustain life. The thickness is a compromise between the need to retain the neuronal circuitry and the need to keep

the centre of the slice alive, most importantly by maintaining a high enough partial pressure of oxygen. In practice, brain slices preserve enough neuronal circuitry to sustain at least some kinds of epileptic activity. The underlying principles of brain slice preparation date back to the pioneering biochemical work of Warburg, during the 1930s. Typically, brain slices will survive several hours, perhaps a day or two.

- *Organotypic slice culture.* Slices prepared under aseptic conditions can be maintained for several weeks in appropriate tissue culture media. These slice cultures tend to flatten onto the substrate on which they are grown, which can be advantageous for visualization and manipulation.[49] They lend themselves to gene transfection and similar mid- to long-term manipulations that are much more difficult to achieve in simple slices.[12,41] One disadvantage is that the local connectivity changes as amputated axons die and surviving axons sprout, although this can be comparable to changes observed in chronic experimental and human epilepsies. Slice cultures allow the study of processes underlying damage and subsequent reorganization over prolonged periods.[76] Slice cultures lend themselves to high-throughput screening of potential anticonvulsants with a more realistic end point than the single ion channel or receptor used for similar work on isolated cells.[121]
- *Isolated brain region.* Seizures normally involve larger areas of tissue than can be preserved in a typical slice. To overcome this limitation, it is possible to cut slices in directions that preserve some longer-range pathways, for example, between the entorhinal cortex and hippocampus,[6,148] between the two hippocampi,[71] or the thalamus and cortex.[32]
- *Isolated brain.* The guinea pig brain can be isolated and perfused, providing many of the benefits of an in vitro preparation combined with in vivo connectivity.[78] Its main advantage is the maintenance of long range-connec- tions.[51] Its main disadvantage is that it is difficult (but not impossible) to maintain the tissue in good condition.

P.458

Table 1 Cellular Actions of Acute Convulsant Treatments

Drug	Action
Penicillin, bicuculline, picrotoxin	↓$GABA_A$ IPSPs
0-Mg^{2+}	↑Glutamate (NMDA) EPSPs and much more
4-Aminopyridine, dendrotoxin, MCD	↓Potassium currents →↑EPSPs; ↑IPSPs
High-K^+	↑Excitability; ↓IPSPs; ….
0-Ca^{2+}	↑Excitability, ↑nonsynaptic interactions (Ephaptic interactions; extracellular ions; gap junctions)

The choice of the most appropriate preparation depends on the question being asked. Brain slices from experimental animals have proved particularly useful for most issues addressed in this chapter, both the acute actions of convulsants and the pathophysiology of chronic models of epilepsy. It is possible to apply in vitro techniques to human tissue removed during surgery for medically intractable seizures. This method has obvious limitations on the number and consistency of samples, and controls require some ingenuity—and usually comparison with chronic animal models.[31,48,74,154] Slices from human epileptic foci usually do not produce spontaneous epileptic activity, but can generate some kinds of synchronous activity,[74] and can reveal stronger than normal responses to convulsant treatments such as increased potassium (K^+)[48] and 4-aminopyridine[5] (Table 1).

Perhaps the most commonly used brain slices in epilepsy research are from the hippocampus, and this chapter draws extensively from that literature. Similar principles, however, apply to other epileptogenic parts of the brain.

In Vitro Models of Epilepsy

In vitro models can be divided in two main groups: (a) acute convulsant treatments of normal brain tissue and (b) in vitro (or "ex vivo") studies of chronically epileptic tissue.[64] *Acute models* really model symptomatic seizures rather than epilepsy, but they have yielded major insights that can be applied to the abnormal brain tissue responsible for chronic epilepsy in vivo. Hypersynchronous epileptiform activity can be induced by perfusing normal brain slices with a variety of convulsant compounds (see Table 1).[65,67,127,128,132,137] Many of these agents block synaptic inhibition mediated by γ-aminobutyric acid $(GABA)_A$ receptors, but others can work by increasing neuronal excitability, strengthening excitatory synaptic receptors, or altering synaptic release. The challenge was to find out how acute changes in synaptic or other neuronal properties can make the normal circuitry of the brain generate epileptic activity.

The prolonged exposure of hippocampal-entorhinal cortex slices to either low magnesium (Mg^{2+}) or 4-aminopyridine[22,39] results in a state characterized by recurrent epileptic discharges that are resistant to most current antiepileptic drugs. They therefore provide in vitro models of drug-resistant seizures, an area for which novel antiepileptic drugs are most urgently needed.

Chronic models are also amenable to study in vitro, simply by making the preparation from a chronically epileptic laboratory animal (or perhaps from human patients undergoing surgical resection to treat medically intractable epilepsy). The more common chronic models of epilepsy[112] can be divided into (a) those that start with status epilepticus and are associated with substantial cell loss[30] (including those using systemic or intracerebral kainic acid,[13,98] systemic pilocarpine,[140] and sustained electrical stimulation[50,84,86]); (b) those not associated with status or with early lesions (including kindling[87] and intracerebral tetanus toxin[62,66]); and (c) genetic models (most commonly of absence seizures[94,114]). Essentially all these models alter neuronal structure and function in ways that reduce seizure threshold, often to the extent that seizures occur spontaneously. A central challenge for work on these models in vitro is to determine, at the subcellular, cellular, and network levels, how the properties of neurons, synapses, and circuits have changed in chronically epileptic tissue.

Introduction to Computer Modelling of Neurons

Epileptic discharges represent an emergent property of neuronal networks. Understanding the functional relationships between the properties of individual neurons and of the networks they form is difficult on the basis of experimental observations alone. Computer modelling can play a crucial role in linking these different levels of analysis.

Computer Simulations of Single Neurons

Simulations of single neurons come in a variety of flavors. The level of abstraction depends on the questions asked. Neurons can be highly simplified to "integrate and fire" formulations. Inputs to these model neurons produce a shift in their potential, which will decay with some time constant, forming essentially a simple circuit of a capacitance and resistor; a threshold detector determines whether each cell will generate an output. Such neurons have a much more limited repertoire of firing patterns than do real cortical neurons, in which the majority are regular spiking cells, a large minority are intrinsically bursting neurons (and many of the regular firing cells can be changed to intrinsically bursting by changing the ionic environment[8]), fast spiking cells (all are interneurons), and chattering cells (in the neocortex but not the hippocampus[24]). The underlying physiology is described in more detail in Chapter 29. It is possible to create model neurons using relatively simple equations that capture these firing patterns (Fig. 1).[60] Such equations are based on neuronal physiology but do not attempt to simulate individual ion conductances. They are computationally efficient and are particularly useful for modelling large scale networks.[99a]

An alternative approach, which is the basis of most of the modelling work described here, uses equations to represent specific ion channels known to be present in particular kinds of neuron. Such realistic neuronal simulations build on the pioneering work of Hodgkin and Huxley,[57] who showed that action potentials can be described quantitatively as ion conductances that are functions of membrane potential and time, with the time-dependence usually including components for activation and inactivation. The representation of specific classes of ion channel by differential equations allows a rather direct comparison of computer model and biologic experiment by using drugs and toxins that have well-defined effects on specific ion channels. Most importantly, this allows predictions made by such realistic models to be tested, and falsified, experimentally.

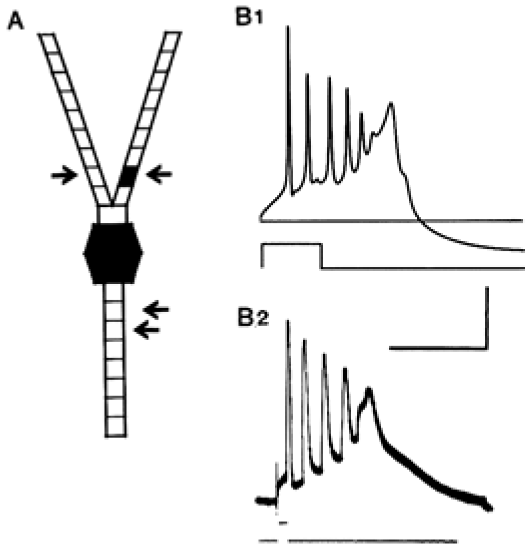

FIGURE 2. Intrinsic properties of CA3 pyramidal cells in the hippocampus. This early example of a compartmental model (*A*) with voltage-gated Na^+, K^+, and Ca^{2+}, and Ca^{2+}-activated K^+ currents in the soma (*filled hexagon*) and a single apical dendritic compartment (*filled quadrilateral segment*) reproduces (B_1) the intrinsic bursts seen in intracellular recordings from these cells recorded in the

guinea pig hippocampus (B_2). From Traub RD, Wong RKS. Cellular mechanism of neuronal synchronization in epilepsy. *Science* 1982;216:745–747, with permission.

Mammalian neurons are anatomically and physiologically much more complex than is the squid giant axon. Rall et al.[97] developed the approach of collapsing the complex anatomy of the dendrites and somata of neurons to electrically equivalent cylinders that are more amenable to computation than is the real anatomy. Traub et al.[133] developed compartmental models of hippocampal pyramidal neurons (Fig. 2), which have been refined extensively[131,134,137,138] and extended to many other types of neuron. Models of this kind include several key features:

- *Passive electrical properties* (membrane resistance and capacitance and intracellular resistance), usually of a series of linked "compartments." These are notional isopotential cylindrical segments that represent parts of the neuron, and together produce time and length constants similar to those in real neurons. The appropriate number of compartments depends on the purpose. Even those that use dozens generate new insights into dendritic function.[131] More detailed models of branched dendrites have revealed the complex processing of synaptic inputs.[73,115] Epileptic activity usually affects branches uniformly so that simpler nonbranched models often suffice.
- *Ion channels.* These are represented by equations of their dependence on voltage and time and, where appropriate, intracellular calcium (Ca^{2+}) or extracellular neurotransmitters. Individual currents, and the ion channels that generate them, are relatively well characterized. (Individual channels switch between two, or in some cases several, states; at the level of the whole neuron, however, their collective effects are more easily represented by Hodgkin-Huxley–type equations.) One complication that often arises occurs when the experimental evidence on specific currents is collected at subphysiologic temperatures; this data must be adjusted to the near-physiologic temperatures usually needed to sustain epileptic activity.
- *Distribution of ion channels* throughout the neuron, particularly on its dendrites and soma. These data are difficult to collect, but a reasonable body of work, largely from patch clamp, has been developed.[68,88] The distinct distributions of ion channels in different classes of neuron is an argument for using multiple rather than single compartments in models. A complication here is that dendritic ion channels are plastic and change in response to physiologic and pathophysiologic factors, including epilepsy.[46]

The quantitative details of ion channels usually will vary between individual real neurons,[83] and often will not be known precisely, so models should be robust to reasonable variation in their parameters; models that need very precise tuning to reproduce biologic reality need particularly critical evaluation. Once a model has been developed, it must be tested against real experimental data to ensure that its response to various kinds of stimulation and pharmacologic experiment match reality—or, perhaps more importantly, to identify where it fails so that the model can be refined or revised. Toxins and drugs exist that block or modulate most channels, and they can and should be used to test falsifiable predictions made by the model.[131] In the case of the hippocampal CA3 pyramidal cell, the intrinsic bursting depends on voltage-gated calcium channels in the dendrites, initially located in one dendritic compartment of the Traub mode 1 (see Fig. 2), but now distributed throughout the dendrites, in line with more recent electrophysiologic evidence.[88]

Just because a model reproduces the properties of a neuron does not mean it simulates how the real neuron works. In a revealing study, Prinz et al.[95] sought an alternative to "hand-tuning" model neurons. They tested a large (~1.7×10^6) database of a single-compartment model of the lobster stomatogastric neuron, in which the maxima for eight membrane conductances were varied systematically. They showed that multiple distinct combinations of ion channels could generate specific physiologic responses, and that the effects of varying a particular ion conductance could depend on the values of the other conductances in the cell. Interestingly, some neurons can adapt to changes in the expression of one ion channel, such

P.460

as I_A(an outward potassium current), by changing the expression of another, such as I_h(hyperpolarization-activated inward current).[80] Similar simulation database approaches are feasible, if more difficult, in multicompartment models. These simulation studies suggest that much more physiologic evidence is needed on the diversity of intrinsic and synaptic properties (and on their combinations within individual neurons) in both normal and epileptic tissue.

Simulation packages such as Neuron and Genesis make the building of compartmental models considerably easier than once was the case. Databases of typical models of many types of neurons are available, for example NeuronDB.[91]

Computer Simulations of Neuronal Networks

Building all but the simplest of synaptic networks remains less straightforward than making compartmental models of single neurons. Several projects exist that attempt to make relatively user-friendly packages for simulating networks, but they are not readily accessible to the nonspecialist. Several generic issues must be considered whatever the technical approach. Some form of randomization of neuronal properties across the population of model neurons is essential to avoid spurious synchronization. Real neurons will vary in their properties, both functional and structural, but experimental evidence on the extent of this variation is limited and often dismissed as experimental noise. That such variation exists is increasingly clear.[25,35,46,99,101]

Synaptic connectivity can be difficult to quantify experimentally in a statistically realistic way. Pairs of neurons will have some probability of a direct connection, but that probability will depend on distance and direction, among other variables. If these data are available, it should be fairly straightforward to generate a similar pattern of connections. A simple exponential decay of the density of excitatory synapses with distance from the parent soma reproduced many features of the propagation of epileptic activity through the hippocampus.[130] More precise information on the geometric organization of synaptic connectivity will help constrain network models.[110] The number of connections that must be modelled grows rapidly with population size, analogous with the Internet where, for example, Metcalfe's law argues that total connectivity scales as the square of the number of members of the network.

Simulations of small networks show that disparate combinations of synaptic and intrinsic properties can result in similar network dynamics,[96] and indeed, that the real networks in different animals may adopt different strategies to achieve the required output.[25] Despite such difficulties, network simulations have provided real insights into epileptic activity, as shown by the work outlined here. However, the potential for different sets of network mechanisms to result in similar emergent properties[96] emphasizes the importance of these network models to make experimentally testable, falsifiable predictions. The experimental tools are drugs and toxins, possibly applied focally, and molecular modifications (with the caveat that endogenous functional compensation can occur[80,122]).

Real neuronal networks have more complicated properties than do the models outlined so far. For example, synapses may facilitate or depress with repetitive use, with the direction of the change depending on the synapse and (critically) on the temperature.[72] Synapses may exhibit long-lasting potentiation (LTP)[17,36](see Chapter 35), and they may experience pre- and postsynaptic modulation.[33,82,113] Extrasynaptic receptors exist that, on the whole, have not been incorporated into compartmental models, but have significant impact on excitability.[77,107]

Lumped Computer Models

Compartmental models link directly with experimental neurophysiology and pharmacology in vitro, and they play a critical role in the work outlined within this chapter. Other approaches, however, can provide valuable insights. The use of simpler models of spiking neurons was mentioned earlier.[60,99] Other models use a "lumped" approach; in these models, the properties of individual neurons within a population are lumped together into equations that relate the population's net inputs to its net outputs. The lumped equations include elements for specific classes of synapse on the main types of neuron involved, and normally include a transfer function to relate the mean membrane potential of a population of neurons to their overall firing rate. This style of model has a long history (approaching five decades), back to the seminal work of WJ Freeman and others. Lumped models can, and should, make experimentally testable predictions. They have proved useful, particularly in the context of the thalamocortical system, where they have addressed issues such as the bistability of the electroencephalogram (EEG) between interictal and ictal states, and the potential therapeutic use of counterstimulation to reduce the frequency and/or duration of seizures.[120,151] Although these particular studies addressed absence seizures, mainly in vivo, such methods have also been used in vitro, for example in the hippocampal low-Mg^{2+} model, to study the dynamics of seizure-like events[120] or to model stereoencephalographic signal recorded from depth electrodes.[150]

Computer models have contributed greatly to the understanding of the underlying mechanisms of epileptic activity, particularly of the acute actions of convulsants on normal brain tissue.

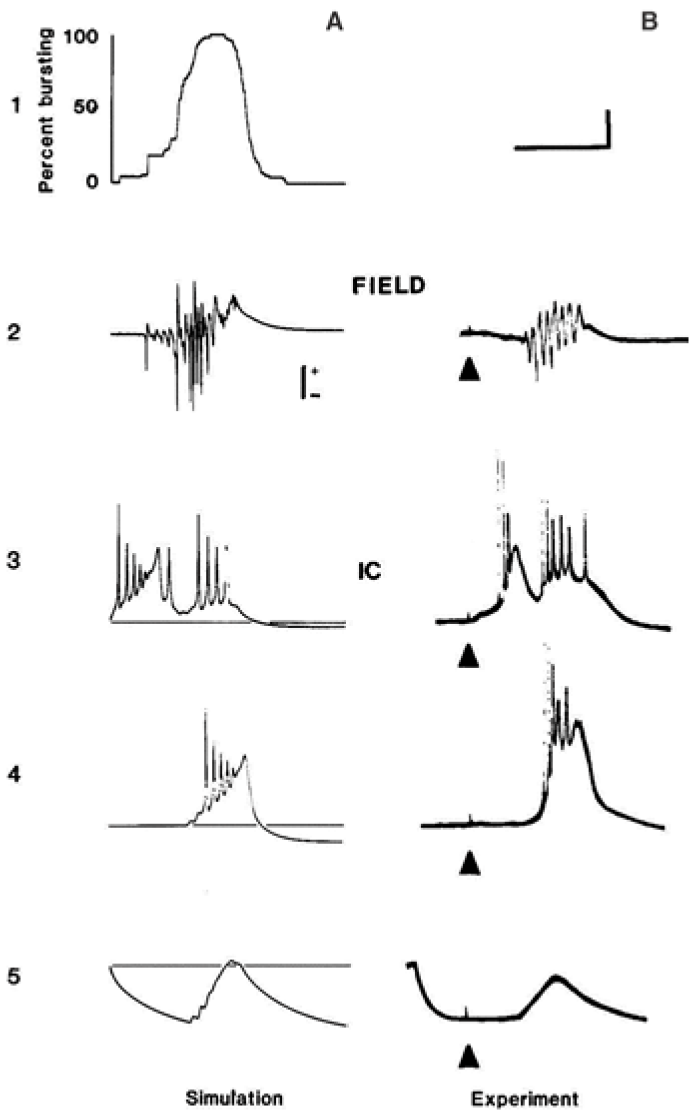

FIGURE 3. Simulation and experimental recordings of single synchronized bursts evoked by a localized stimulus in the disinhibited guinea pig hippocampal slice. The epileptic field potential (*line 2*) occurs after long latency in both simulation (*A*) and experiment (*B*). The simulation is of a network of the model neurons of FIGURE 2, sparsely connected by realistic excitatory synapses. Most cells generate PDSs synchronously with this field potential (*line 4*), and injecting hyperpolarizing current into the recorded cell reveals the underlying giant EPSP (*line 5*). A rare cell (*line 3*) fires a burst soon after the stimulus, along with another burst during the field event. The long latency corresponds to generations of exponential growth of the event; this takes time, because burst propagation can last tens of milliseconds. From Traub RD, Wong RKS. Cellular mechanism of neuronal synchronization in epilepsy. *Science*. 1982;216:745–747, with permission.

Epileptic Neurons and Mechanism of Interictal Spikes

Many acute convulsants result in brief synchronous discharges that look like interictal spikes[b] on the EEG or electrocorticogram (ECoG) from epileptic foci in humans. Some of the earliest intracellular studies in vivo (on penicillin foci) showed that these discharges were associated with substantial depolarizations and rapid action potential firing in most of the neurons in the epileptic focus. These abnormally large depolarizations were called paroxysmal depolarization shifts (PDSs) (Fig. 3B).[84]

Epileptic Neurons Versus Epileptic Aggregates (Networks)

This characteristic PDS behavior of epileptic neurons raised an intense debate several decades ago about whether it represents altered intrinsic properties of the neuronal membrane or derangement of network activity.[37]

One piece of evidence in favor of the "epileptic neuron" hypothesis is the observation that activity reminiscent of the PDS can occur in normal intrinsically bursting cortical and hippocampal neurons (see Figs. 1 and 2).[8] Intrinsic bursts in single neurons are the result of the combined operation of

P.461

voltage-gated ion channels. Essentially, they depend on slow inward (depolarizing) currents, either Ca^{2+} (typical in hippocampal area CA3[102,131]; Fig. 2) or persistent sodium (Na^{+}) (more common in CA1[8]). These slow channels provide a depolarizing envelope that drives a burst of action potentials. Ca^{2+} entry during the burst activates the slow afterhyperpolarization mediated by K^{+} currents which, with other hyperpolarizing currents, terminates the discharge.

Early in vitro studies played a key role in distinguishing the intrinsic burst from the PDS, showing that it depended on synaptic as well as intrinsic mechanisms. Johnston and Brown[67] showed explicitly that the PDS had the physiologic properties of a giant excitatory postsynaptic potential (EPSP): Both reversed at the same membrane potential and increased in amplitude with the injection of hyperpolarizing currents. The frequency of the PDSs was independent of membrane potential, implicating a synaptic network. The advent of good glutamate receptor antagonists allowed the direct demonstration of their dependence on excitatory synapses.

The question then was: Which synapses generated the PDS? In the case of the hippocampal CA3 region, the answer came from dual intracellular recordings that revealed direct (monosynaptic) excitatory connections between pyramidal cells.[7,81] The conceptual problem was that they appeared rather sparse. Extensive studies by Miles and Wong revealed monosynaptic EPSPs of ~1 mV between about 1% to 2% of pyramidal cell pairs.[90] Computer modelling of epileptic activity in these slices played a key role in determining whether this degree of synaptic connectivity was necessary and sufficient for synchronizing the epileptic discharges, and in confirming the relative contributions of the intrinsic and synaptic properties that had been found exp- erimentally.

Computer Simulations of Interictal Bursts in CA3

In a pivotal paper, Traub and Wong[137] tested whether a network of reasonably realistic CA3 pyramidal neurons could replicate key features of experimental epileptic bursts induced by penicillin (which blocks IPSPs) in hippocampal slices. The model neurons comprised 28 compartments. Of these, the soma and one of the proximal apical dendritic compartments contained voltage-gated Na^{+}, K^{+}, and Ca^{2+} currents, and a Ca^{2+}-activated K^{+} current (see Fig. 2). The individual model neurons replicated the ability of CA3 pyramidal neurons to generate intrinsic bursts. Traub and Wong replicated 100 of these neurons, connected them with synapses producing ~1 mV EPSPs so that randomly chosen pairs of neurons had a 5% probability of a direct connection, and then determined how these networks could become synchronized. No inhibitory neurons were included, because the experimental model depended on blocking inhibitory synapses, so that their activity was not relevant to the population. Exciting a small subset of these neurons (four of the 100 in the original paper) triggered a chain reaction, so that each of these neurons excited five postsynaptic neurons, which in turn each excited five more, and so on. The model explained the rather long delay between a weak stimulus and the hypersynchronous epileptic response, and predicted the existence of a minority of neurons, directly excited by the stimulus, that triggered the chain reaction (see Fig. 3).

The one notable difference between the simulation and experiment is in the detailed shape of the extracellular field (Fig. 3, row 2). The brain slice generated a more rhythmic waveform. This is due to a phenomenon not included in this model: field effect or ephaptic coupling.[61,63,129] This arises when the electrical field generated by active neurons excites neighboring neurons that are inactive, but close to threshold. The end result is that neurons that would fire in a disorganized fashion (as in the model in Fig. 3A2) become synchronized on a millisecond time scale. Their extracellular currents combine to produce the large, smooth, and relatively rhythmic population spikes seen in the experimental record (Fig. 3B2). (This kind of nonsynaptic synchronization is further explored in the section on seizure-like events.)

Further experimental evidence allowed this model of the disinhibited hippocampal slice to be refined. Experimental dissection of brain slices into progressively smaller segments showed that a minimum "epileptic aggregate" or population of neurons was necessary to sustain synchronized epileptic discharges; in the case of the guinea-pig CA3 region, this was ~1,000 to 2,000 neurons. The original estimates of synaptic connectivity (~5%[81]) were reduced to ~1% to 2% as many more dual

recordings were made.[90] Finally, it turns out that exciting a single neuron can trigger epileptic activity in both hippocampal slices and simulations.[89] Refining the model in the light of this evidence and of more detailed studies of the electrophysiology of the relevant neurons provided more realistic simulations, but the underlying principle remained a chain reaction that could take place as long as:

- Each active neuron synapses onto more than one postsynaptic neuron (divergence).
- These synapses are effective in exciting their postsynaptic targets. This not only is a product of the strength of individual synapses, but also of the physiology of the presynaptic neurons: Their ability to generate intrinsic bursts substantially increases the probability of triggering a postsynaptic burst by the process of temporal summation of EPSPs in the postsynaptic neuron.
- The size of the population of neurons exceeded a minimum aggregate, analogous to the critical mass of the nuclear chain reaction.

Similar studies of a range of acute convulsants show that the same basic ideas apply, although some details are specific to particular models, such as the relative roles of *N*-methyl-D-aspartic acid (NMDA) and non-NMDA glutamate receptors in the recurrent connectivity.[127,128,132,152] Similar approaches work in the neocortex, albeit with more complex neuronal architecture, and with the added importance of the strong connections with the thalamus.[53,120,125]

Termination of Interictal Bursts

Interictal bursts appear to be self-limiting. Several factors have been implicated in their termination, including afterhyperpolarization due to Ca^{2+}-activated K^+ currents,[27,44] GABA-mediated hyperpolarization,[132] depletion of available excitatory synaptic vesicles due to repeated release from the terminal during the epileptic burst,[118] receptor desensitization due to prolonged exposure to glutamate,[132] and presynaptic inhibition due to a variety of transmitters including glutamate, GABA, adenosine, and various neuropeptides.[82] In practice, several of these mechanisms may combine in each specific kind of epileptic activity. These self-limiting properties may contribute to the ability of interictal activity to inhibit seizures, which has been reported under at least some circumstances. Extending epileptic activity beyond the few hundred milliseconds of the interictal burst requires an excitatory mechanism that can outlast these termination mechanisms.[126]

The interictal epileptic bursts in hippocampal slices can be prolonged for up to a few seconds (resembling polyspikes on the human epileptic EEG) through the generation of repeated or "secondary" bursts (Fig. 4) following the initial "primary" burst discussed earlier (see Fig. 3). In an early simulation and experimental study of disinhibited hippocampal slices, it was found that the initiation of the primary (interictal) burst depended on non-NMDA glutamatergic receptors, but that the secondary bursts depended on NMDA receptors that could be blocked selectively.[135] The NMDA receptors did not contribute to the initiation of the primary burst because of their block with Mg^{2+} at resting membrane potentials, but the relief of that block by the PDS and the relatively slow kinetics of the NMDA receptor sustained an inward current beyond the termination of the afterhyperpolarization that normally terminated the burst. The secondary bursts then were shaped by the intrinsic properties (voltage-gated Ca^{2+} channels and Ca^{2+}-dependent K^+ channels) of the neurons, and synchronized by the glutamate released by each secondary burst acting on non-NMDA receptors (Fig. 4).[135]

Secondary bursts appear in other slice models, with slightly different mechanisms. In the case of 4-aminopyridine, the synchronization of the bursts is by non-NMDA receptors, and the sustained excitation needed for the secondary bursts may be due to depolarizing GABAergic potentials.[127]

Prolonged (Ictal) Epileptic Discharges in Vitro

Seizures in vivo are much longer-lasting than the interictal events described so far, and involve much larger areas than can easily be preserved, with their interconnections, in a slice. This is one reason why research on epilepsy in vitro should routinely be related to work in vivo. However, slices do exhibit prolonged "seizure-like" or "ictaform" events that can last tens of seconds. Such seizure-like events can be demanding—for example, submerged slices generally need rather high perfusion rates of ~4 mL/min to sustain them. One slice that does sustain seizure-like events is the combined hippocampal-entorhinal cortex slice, which is cut horizontally to include the ventral hippocampus and some relatively intact connections between these and other limbic regions (Fig. 5).[3,4,148] The entorhinal cortex and subiculum sustain such seizure-like events more easily than does the hippocampus proper,[6,34,40,154] but they can be induced in the hippocampus too, particularly in slices from young animals (Fig. 6).[19]

Enhanced Synaptic Excitation and Failure of Inhibition

The modulation of glutamatergic synaptic transmission can cause changes in excitation and promote seizure-like events in brain slices. Epileptic discharges can elicit long-term potentiation (LTP) of the synapses that sustain them,[36] increasing their efficacy and promoting epileptic synchronization (see also Chapter 35). Activating metabotropic glutamate receptors (mGluR) can promote seizure-like events in hippocampal slices: The induction of prolonged seizure-like activity depends on mGluR5, but its expression depends more strongly on mGluR1.[153] The "spill over" of neurotransmitters from the synaptic cleft may be especially important during the intense synaptic activity during epilepsy discharges, when it activates extrasynaptic receptors.[103] Furthermore, presynaptic receptors modulate transmitter release, whether in response to a presynaptic action potential[82] or not,[69] and can play a substantial role in epileptic discharges.

Equally important can be changes in inhibitory synaptic transmission. Inhibitory synapses can run down with repeated use.[123] They can become depolarizing instead of hyperpol- arizing,[117] perhaps because of impaired Cl^- homeostasis[28] or because of intracellular Cl^- accumulation due to excessive neuronal activity.[75] Depolarizing GABAergic potentials play a key role in prolonging epileptic activity in the low-Mg^{2+} model, in the CA1 region following excitation from the initial primary burst in CA3.[75] The depolarizing GABAergic activity drives a γ-band (30–100 Hz) oscillation that in turn leads to what can be termed tertiary bursts, making up a seizure-like event.

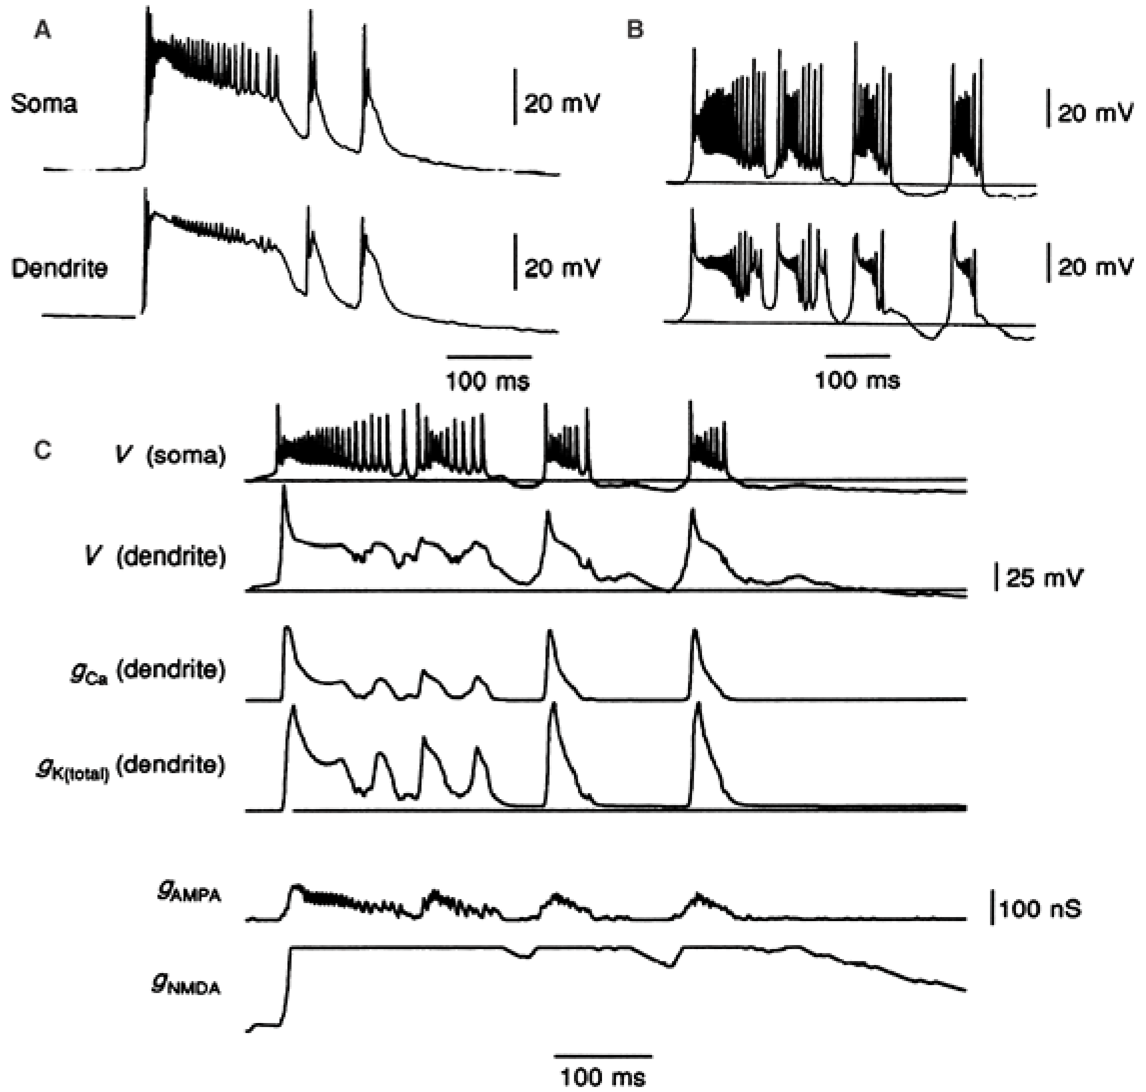

FIGURE 4. Polyspikes, or sequences of primary and secondary bursts, recorded with intracellular microelectrodes in the soma and apical dendrites of CA3 pyramidal cells in a guinea pig hippocampal slice bathed in picrotoxin (to block inhibition; (**A**) and in a simulation of a 100-cell network similar to that in FIGURE 3(**A**)). The model cells include both NMDA and non-NMDA (AMPA) glutamate receptors at the connections between the pyramidal cells, and these are shown in the summary of the model (**C**), where the dendritic data are for 0.6 space constants from the soma, the g_K term includes both medium and late AHPs. From Traub RD, Miles R, Jefferys JGR. Synaptic and intrinsic conductances shape picrotoxin-induced synchronized afterdischarges in the guinea-pig hippocampal slice. *J Physiol (Lond)*. 1993;461:525–547, with permission.

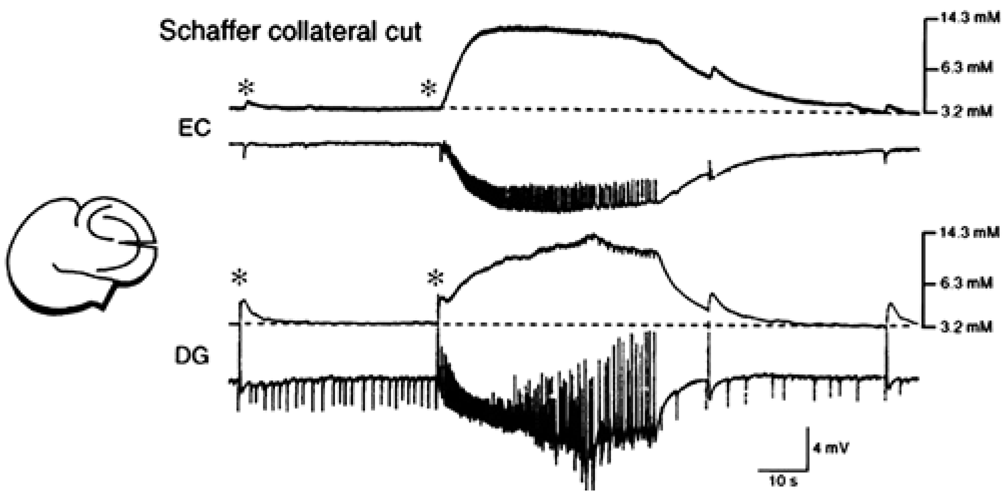

FIGURE 5. Fluctuations in extracellular K^+ measured in the rat combined hippocampal-entorhinal cortex slice exposed to 4-aminopyridine. The connection between CA3 and CA1 has been cut to remove the seizure-blocking effect of the interictal discharges generated by CA3. This allows seizure-like events to persist in entorhinal cortex (*EC*) and dentate gyrus (*DG*). Note the large, GABAergic interictal events marked by asterisks and associated with significant increases in K^+. One of these appears to trigger the seizure-like event. From Barbarosie M, Louvel J, D'Antuono M, et al. Masking synchronous GABA-mediated potentials controls limbic seizures. *Epilepsia*. 2002;43:1469–1479, with permission.

Increase in Extracellular Potassium

Epileptic discharges usually are associated with increases in extracellular K^+ from ~3 mM to a ceiling of 10 to 12 mM.[10,19,55] These increases in extracellular K^+ will feed back on the neuronal excitability in two ways: (a) by direct depolarization that results from the smaller gradient of K^+ across the membrane (and decreased repolarization after action potentials), and (b) by reducing the Cl^- gradient, as a result of the weakening of the drive to K^+/Cl^- cotransporters, thus weakening $GABA_A$ receptor–mediated inhibition.[124] These mechanisms also help explain the ability of elevated K^+ to elicit epileptic activity in brain slices in vitro[48,128](see Table 1).

P.463

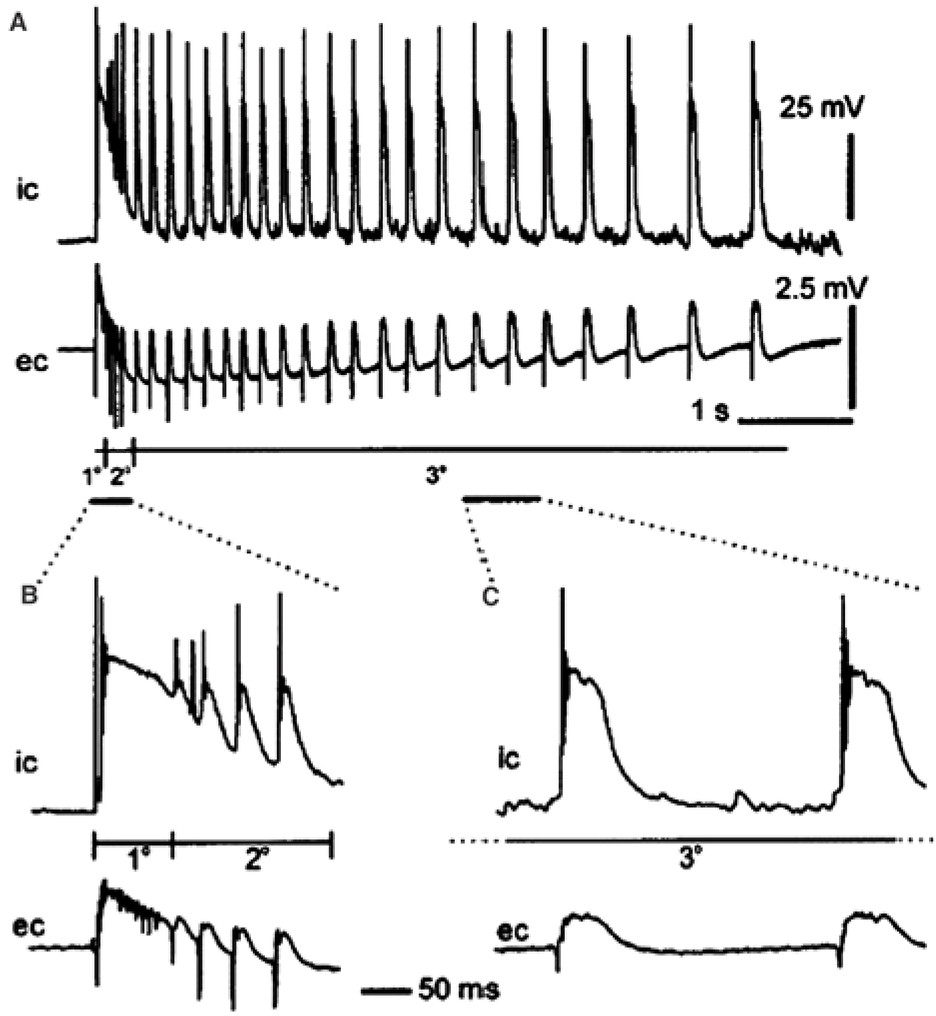

FIGURE 6. Prolongation of epileptic bursts in hippocampal slices showing primary, secondary, and tertiary bursts. The tertiary bursts occurred when extracellular K^+ reached 8 mM during an interictal event, and required both CA3 and the adjacent hilus. From Traub RD, Borck C, Colling SB, Jefferys JGR. On the structure of ictal events in vitro. *Epilepsia*. 1996;37:879–891, with permission.

At first sight, the increased neuronal firing during epileptic bursts is an obvious basis for the increases in extracellular K^+ during epileptic discharges, but the mechanisms can be more specific. For example, the combined hippocampal-entorhinal slice generates two kinds of interictal burst when exposed to 4-aminopyridine[10]: a glutamatergic chain reaction leading to minimal elevation of K^+, as described, and another mediated by GABA. The GABAergic version is associated with much bigger transients in K^+, which can trigger seizure-like events (see Fig. 5). The transporters that remove GABA from the extracellular space and Cl^- from the intracellular space both use the passive efflux of K^+ and therefore contribute to larger increases in extracellular K^+. A similar relationship between $GABA_A$ receptors and extracellular K^+ occurs in the seizure-like events seen in the low-Mg^{2+} (see earlier discussion) and tetanic stimulation models, in which depolarizing inhibitory postsynaptic potentials (IPSPs) sustain a prolonged depolarization and lead to increased extracellular K^+.[20,47,59,75]

When seizure-like events could be produced in disinhibited hippocampal slices (Fig. 6), they were associated with interictal bursts that produced increases in extracellular K^+ greater than 8 mM, suggesting that elevated K^+ provided the sustained excitation to drive the tertiary bursts in this case. In other cases, notably 4-aminopyridine, spontaneous ectopic action potentials may provide the sustained excitation needed to drive tertiary bursts.[126]

The dynamics of extracellular K^+ can be modelled using NEURON.[70] The movement of ions (particularly of K^+ ions) into a limited extracellular volume can be calculated from the currents through the various classes of ion channel. The model also needs to include elements to represent the glial compartment and the operation of ion pumps. It then can reproduce phenomena such as some kinds of epileptic seizure activity and spreading depression.[70]

Potassium is not the only ion released during epileptic activity that can modulate neuronal activity. For instance both zinc (Zn^{2+}) and hydrogen (H^+) can modulate postsynaptic receptors and other neuronal properties.[33,113]

Nonsynaptic Mechanism and Fast Activities in Seizure Transition

A very different kind of seizure-like event appears when Ca^{2+} is reduced to ≤0.2 mM and K^+ is increased to ≥5 mM. Despite the block of synaptic transmission under these conditions, hypersynchronous discharges lasting tens of seconds appear spontaneously. These are called “field bursts” (Fig. 7A).[65] These bursts exhibit at least two kinds of nonsynaptic synchronising mechanism[63]: fast synchronization, through the electric fields produced by active neurons (sometimes called ephaptic coupling); and slow synchronization, through fluctuations in extracellular K^+. Gap junctions also play a role.[26,136] These nonsynaptic mechanisms can operate in the presence of chemical synapses: The increase in extracellular K^+ associated with seizures has been known for decades, as has the sensitivity of neurons to electric fields smaller than those produced during seizures. The low-Ca^{2+} field bursts start with low-amplitude, high-frequency, irregular activity that continues for several seconds before the seizure-like event synchronizes fully (Fig. 7B).[15] Individual pyramidal neurons do not fire at these high rates (>100 Hz), but discharge on every second or third cycle (Fig. 7C), suggesting that the collective high-frequency activity is the combined consequence of multiple

P.465

small sets of synchronized neurons, and that the full seizure-like event emerges as these small sets fuse into a single large synchronous population that discharges rhythmically at ~30 Hz. The initial high-frequency activity has parallels to both the ripples and fast ripples that can be found in chronic experimental and human epileptic foci.[1,21,116]

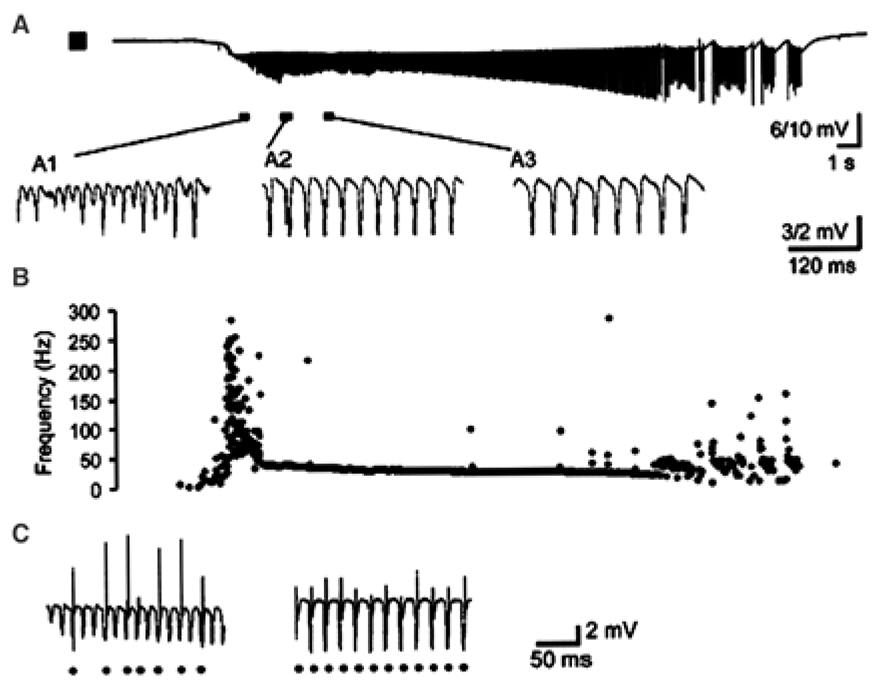

FIGURE 7. Seizure-like events, or field bursts, in rat hippocampal slices incubated in 0.2 mM Ca^{2+}. Field bursts (**A**) occurred rhythmically in these slices. They consist of a negative shift with superimposed negative population spikes (*inserts below A*). For most of the field burst, the population spikes occur at a

few tens of Hz (instantaneous frequency, or reciprocal of interspike interval is plotted in **B** at the same time scale as **A**). The very-high-frequency activity (>250 Hz) at the start of the field burst depends on the collective activity of neurons that do not fire on every cycle (**C**, *left*: Single unit produces a sharp upstroke on the negative population spikes), whereas the slower rhythmic activity later in the burst is generated by most neurons firing on every cycle (**C**, *right*: The apparently smaller size of the single unit is due to its firing close to the peak of the population spike). From Bikson M, Fox JE, Jefferys JGR. Neuronal aggregate formation underlies spatiotemporal dynamics of nonsynaptic seizure initiation. *J Neurophysiol*. 2003;89:2330–2333, with permission.

Glia

Glia are the most common class of brain cell. *Gliosis* is a consistent pathologic feature of focal epilepsies, which is most dramatic where neurons have died in substantial numbers, as in hippocampal sclerosis. Activation of microglia can occur in epileptic tissue, potentially producing inflammatory factors and contributing to epileptogenesis.[18,109] Astrocytes have long been known to play a role in K^+ homeostasis, in the "spatial buffering" hypothesis discussed earlier,[2,70,79,92,147] which is essentially an antiepileptic mechanism. Changes in K^+ currents found in sclerotic tissue in hippocampal slices from at least some patients with temporal lobe epilepsy (TLE) impair buffering and may contribute to epileptic activity.[56] More recently, the complexity of glial molecular biology and physiologic function have become much clearer. The reader is referred to several excellent reviews of the topic.[9,54,92] Astrocytes can release glutamate when their intracellular Ca^{2+} rises through mechanisms that are still under debate. Increases in intracellular Ca^{2+} can propagate through an inositol 1,4,5-trisphosphate (IP_3)-dependent mechanism throughout that astrocyte, and across the gap junctions that connect the glial syncytium. These phenomena provide plenty of scope for astrocytes to play an active role in epileptic discharges. Furthermore, astrocytes appear to play roles in synaptogenesis[111] and neurogenesis,[58] both of which are features of chronic epileptic foci.

Chronic Models Studied in Vitro

So far, this chapter has focussed on the effects of convulsant treatments on slices of normal brain. Epilepsy is by definition a chronic condition in which the brain contains abnormalities that lead to spontaneous seizures. Chronic experimental models go some way toward the clinical condition by altering brain structure and function, as discussed in Chapters 36, 39, and 40. In some chronic models, brain slices preserve epileptic activity in vitro; these can be investigated in ways similar to those used in acute models.[43,62] In other models, brain slices allow the investigation of the relationship between structural malformations and epileptic activity.[139] Perhaps the more important role of in vitro preparations made from chronic models, whether or not they preserve epileptic activity, is to find out what has changed in neuronal and network structure and function in the epileptic tissue.

Every chronic model has multiple changes in structure and function. In vitro preparations can reveal, and often quantify, many of these changes, including commonly recurring observations in chronic epileptic foci such as the sprouting of new axons and synapses, changes in neuronal excitability, and modifications in synaptic transmission.[108,144]

The sprouting of new synaptic connections is a common phenomenon in both clinical and chronic epilepsies. Mossy fibre (dentate granule cell axon) sprouting has been extensively characterised in many epilepsies, because they conveniently contain high levels of zinc and they rather specifically project to CA3 and not to the layers containing granule cell dendrites. Intracellular labelling methods in slices have shown sprouting by less easily visualised axons, such as those of CA1.[45] Physiologic methods show similar increases in connectivity. Antidromic responses evoked by focal electrical stimulation can identify the growth of axons into regions they do not normally innervate.[144] Focal application of glutamate allows an assessment of synaptic connectivity within the local circuits, without exciting afferent axons.[108] The methods used for focal glutamate application exploit the slice preparation very effectively: Pressure application through a micropipette is helped by being able to visualize the recording and application sites, whereas flash photolysis of a caged glutamate compound relies both on visualization and the ability to apply the flash to the correct zone in the tissue.

Slices allow the detailed pharmacologic and physiologic dissection of synaptic transmission that reveals many changes in chronic models, including alterations in the composition of

postsynaptic receptors,[93,141] release probability,[104] presynaptic modulation,[158] and extrasynaptic receptors.[104,105]

Changes in the properties or numbers of ion channels are common in chronic epilepsy. Several examples are known of increases in the proportion of intrinsically bursting neurons in chronic experimental models.[119,149] Given the role of intrinsic bursts in the acute models, as outlined earlier, it seems reasonable to conclude that this change contributes to epileptogenesis in the chronic models. The increase in intrinsically bursting neurons may be due to several molecular changes, including the upregulation of the low-threshold T-type Ca^{2+} channels[119] and/or changes in the properties of Na^+ channels, particularly slowing of their kinetics.[42,143] In the case of the animal models, we can be certain that the persistent Na^+ currents are related to the process of epileptogenesis, and the finding of similar changes in neurons isolated from surgically resected human epileptic tissue suggests that this applies to human cases as well.[145]

Several of the rare monogenic epilepsies are recognized as inherited channelopathies (see Chapter 18). When such a mutation is identified, the immediate question will be its functional consequences. This can be addressed by expressing the mutated gene in suitable cultured cells for subsequent electrophysiologic investigation.[11,146] Persistent Na^+ currents can drive burst firing, much as Ca^{2+} currents can,[149] but they also allow more rapid repetition of action potentials,[29] both of which are proepileptic.

In other cases, slices are essential for the analysis of ion channels, because their density varies along the dendrites: The truncation inherent in isolating individual cells can lose key epileptic changes. An interesting example comes from work on the pilocarpine model of TLE.[14] Dual whole-cell recordings from hippocampal slices showed that action potentials could invade further up the apical dendrites of pyramidal cells than normal. The pharmacology of this increased dendritic invasion (or back-propagation) showed that it could be attributed to a decrease in the density of the I_A channel.

Most of the changes outlined so far in this section are proepileptic, but work using slices in vitro and other approaches can reveal apparently antiepileptic phenomena in epileptic tissue, including changes in GABAergic transmission, neuronal excitability, glutamatergic transmission, neuropeptides, and so on.[16,52,100,142,144] Distinguishing pro- from antiepileptic changes in chronic epileptic foci remains a substantial challenge, and could suggest novel therapeutic approaches.

Summary and Conclusions

Electrophysiologic methods applied to brain tissue in vitro have provided major new insights into the cellular and synaptic mechanisms involved in epileptic activity. The strength of these methods is at the levels of ion channels, single cells, and local networks. These kinds of study benefit from quantitative computer models, especially those that can bridge the different levels of analysis, thus revealing the relationship between the properties and locations of ion channels to the firing characteristics of single neurons, or between single neurons and the emergent properties of the synaptic networks they form. Much of the benefit of in vitro preparations comes from their simplification of the problem of epilepsy, but this too is a limitation: Seizures involve interactions between multiple parts of the brain, which are not preserved with their interconnections in most preparations. In vitro preparations are important for epilepsy research, but they must be interpreted in the context of epilepsy in the intact animal or patient.

Acknowledgments

The author thanks Drs. Premek Jiruska and Martin Vreugdenhil for their helpful comments on the manuscript.

Chapter 39

Seizure Mechanisms and Vulnerability in the Developing Brain

John W. Swann

Tallie Z. Baram

Frances E. Jensen

Solomon L. MoshÃ©

Introduction

Throughout life, continuing maturational and functional changes within the brain impact seizure susceptibility and epileptogenesis. Early life is characterized by periods of excessive excitability to metabolic, electrical, and chemical stimuli as well as an inability to limit or suppress the effects of such stimuli. In humans, the incidence of seizures is highest in the first months of life, and several types of seizure disorders occur exclusively in infancy or childhood. Age-specific differences are noted in terms of motor behaviors and electroencephalographic (EEG) patterns, sensitivity to anticonvulsant treatment, and outcome. For example, in young childrenâ€"and particularly in infants and preterm neonatesâ€"behavioral and EEG phenotypes can be very subtle. Often, these seizures are missed, because of lack of motor phenomena, or considered generalized tonicâ€"clonic seizures because the features indicating focality are not overtly present. Another feature typical of early partial seizures is variability in clinical manifestations between individual seizures; the seizure phenotype is very much a function of brain developmental state. Unlike in the adult brain, focal dysfunction in the young brain can produce multifocal seizures or result in seizures with bilateral manifestations that can be loosely described as â€œgeneralizedâ€ (e.g., infantile spasms).[1]

Several factors, including altered permeability of the bloodâ€"brain barrier, continuing development of neurons and glia, and changes in neuronal connectivity contribute in many ways to developmental windows of increased seizure susceptibility. Such windows have been observed in all species in which studies of spontaneous or experimentally induced seizures have been performed, and these studies reveal differences that depend on developmental stage. To understand the mechanisms responsible for these age-related differences, it is necessary to examine developmental differences in experimental animal models of seizures. Comparisons to information from human studies can be invaluable and serve to validate the clinical significance of findings from animal studies. Animal models can also be useful in understanding the effects seizures have on brain development.

This chapter reviews experimental evidence from both in vivo and in vitro studies that demonstrate a critical period of heightened seizure susceptibility in early life. We also describe (a) age-dependent changes in the propensity for focal seizures with secondary generalization and in the expression of primary generalized seizures; (b) the age-dependent functionality of neuronal networks involved in the control of seizures, as demonstrated in animal models and human studies; and (c) the impact of seizures on brain development, including the circumstances under which early-life seizures may produce epilepsy and/or learning deficits in later life.

Critical Developmental Periods of Enhanced Seizure Susceptibility In Vivo and In Vitro

Experimental evidence shows that developmentally discrete periods of increased seizure susceptibility and expression exist. Several reviews of this topic are available.[154,183] The first period in the rat is during the first postnatal week, analogous to the preterm human infant; at this age, the immature rat brain exhibits an EEG pattern that can resemble the pattern of the preterm human.[91] Michelson and colleagues[116,117] have found that urethane-anesthetized or freely moving 7-day-old rats have the highest threshold for hippocampal afterdischarges. Mares also found elevated thresholds for hippocampal ADs in 7-day-old rats.[111] Seven-day-old rats have long refractory periods following electrical hippocampal stimulations, compared with rats in the second or third postnatal week.[11] In vitro intracellular recordings from hippocampal and neocortical slices taken during the first postnatal week have shown that action potentials routinely have slower rising and falling phases.[98,166,167] When seizures are elicited, they are far less synchronized than those recorded from tissue taken from rats 2 to 3 weeks of age.[98,167,186] Similar data have been obtained in kittens, in which electrical stimulations elicited broad action potentials and repetitive discharging was infrequent.[142,143]

During the second and third postnatal week of the ratâ€"ages roughly corresponding to human infants and young childrenâ€"peak susceptibility to focal seizures occurs. Indeed, the baseline EEG at these ages transitions from the patterns similar to the human neonate, to the infant and early childhood periods.[91] This increased excitability has been demonstrated in whole-animal experiments including neocortical focal epileptogenesis,[111] amygdala kindling,[128] hippocampal kindling,[73,118] hippocampal electrical stimulations,[193] hypoxia, hyperthermia, and systemic administration of chemoconvulsants.[127] In addition, at these same ages, numerous laboratories have demonstrated increased susceptibility to the induction of seizure-like activity using in vitro slice preparations. In most models, robust ictal events occur only during this critical period of seizures susceptibility. These ictal discharges can be readily induced by Î³-aminobutyric acid $(GABA)_A$ receptor antagonists, 4-aminopyridine, elevated extracellular potassium, hypoxia, and electrical stimulation.[43,77,78,91,186] Thus, the increased susceptibility to seizures during the second and third weeks of life is not restricted to a single structure or to a specific model, and it probably represents a widespread phenomenon intrinsic to a variety (but likely not all) of neuronal networks in the immature brain.

P.470

Mechanisms of Enhanced Seizure Susceptibility

Alterations in Synaptic Transmission

Glutamate.

The period of enhanced seizure susceptibility corresponds in time with a period of rapid axonal and dendritic outgrowth. The first 2 weeks of life in the rat and the first year of life in the human and primates are periods of dramatic increases in synaptic and spine density.[79,88,145] As the brain matures, an increase occurs in the number of excitatory synapses that use glutamate as their neurotransmitter.

Glutamate receptor subunit expression is developmentally regulated in a number of ways. There is prominent expression of the NR2B, NR2D, and NR3A subunits in rodents during the neonatal period, which gradually decreases over time, while simultaneously NR2A expression increases to as much as tenfold over levels of expression at birth.[120,158,213] The functional consequences of this â€œsubunit switchingâ€ is that, prior to the increases in NR2A expression, a net increase in excitability may be possible: NR2B results in longer current decay times,[61] whereas NR2D and NR3A expression are associated with minimal Mg sensitivity, thus resulting in an increase in both *N*-methyl-D-aspartate receptor (NMDAR) channel opening frequency and time.

Î±-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) expression is increasing simultaneously in the rat forebrain.[154,155] Furthermore, in early life, AMPAR expression is characterized by a relative lack of the GluR2 subunit in hippocampal and neocortical pyramidal neurons.[101,154,155,187,188] The lack of GluR2 allows for AMPARs to be calcium permeable, thus increasing intracellular signaling associated with glutamate receptor activation. Thus, differences in subunit composition could contribute to excitability during the critical period of neuronal hyperexcitability.

A limited number of human tissue studies confirm similar patterns of glutamate subunit expression across development. The mRNA for the NMDA receptor NR2B is expressed at high levels on principal neurons in cortex and hippocampus in the first year of life, whereas NR2A expression first appears around 1 to 2 years of age.[130] AMPAR expression is also highly developmentally regulated in the human. Immunocytochemical and Western blot analyses show that the GluR2 subunit does not appear on principal neurons in cortical gray matter until late in the first year of life,[171] suggesting that, like the rodent, immature human principal neurons express calcium-permeable AMPARs.

The changes in expression of molecular markers for glutamatergic synapses observed in early life in neocortex and hippocampus, as well as the number of synapses, most likely reflect an increase in both the number of excitatory fibers projecting from distant sites and the proliferation of local circuit connections. An example of the latter is excitatory axons that arise for CA_3 hippocampal pyramidal cells that make synaptic contacts with neighboring CA_3 neurons (both pyramidal cells and interneurons) and also project as Schaffer collaterals to CA_1 pyramidal cells. Studies on the maturation patterns of recurrent excitatory collaterals in CA_3 pyramidal cells[71] show that axon arbors are very short during the first postnatal week and, on average, branch infrequently. However, by the second postnatal week an exuberant outgrowth of these axons occurs, and branch number increases dramatically. Following this outgrowth, axon arbors appear to remodel. By adulthood, half the branches are lost, but the remaining axons increase in length concomitant with the overall growth of the hippocampus. The number of presumed presynaptic terminals increases dramatically from week 1 to week 2 and then remains unchanged into adulthood.

Alterations in Synaptic Transmission

GABA

Age-dependent differences in GABA-mediated synaptic transmission could also contribute to enhanced seizure susceptibility. In the rodent, $GABA_A$ receptors and glutamic acid decarboxylase (GAD) levels steadily increase until the third or fourth postnatal weeks, suggesting a relative lack of inhibitory tone in the immature brain compared with the adult.[27,185] Furthermore, a number of studies have shown that GABA is an excitatory neurotransmitter during early postnatal life.[42] This time period, postnatal (P)0 to P5, as originally reported, precedes the period of enhanced seizure susceptibility. Paradoxical depolarizing actions of GABA have been shown to be due to differential chloride (Cl^-) homeostasis in immature neurons compared with adult.[17,149] The immature neurons have high Cl^- concentrations since they lack the Cl^- extruding cotransporter KCC2, but have high expression of the Cl^- importer NKCC1.[57,149] Hence, GABA channel opening results in Cl^- outflow down the concentration gradient in the immature neuron, and hence to depolarization and neuronal excitation rather than the hyperpolarization and inhibition associated with Cl^- influx in mature cells. Rodent studies reveal that NKCC1 actually peaks during the first week of life, whereas KCC2 protein expression peaks between P5 and P10 (depending on rat strain) and does not reach adult levels until the end of the second week of life or even later.[17,149] The dramatic onset of expression of the Cl^- transporter, KCC2, is thought to herald a shift in the Cl^- reversal potential to a more hyperpolarized state, below the resting membrane potential.[150] Thus, during a developmental window, when recurrent excitation has become quite robust, excitatory GABA-mediated synaptic transmission in some pyramidal cells may further enhance excitability.[17,62,149] The relevance of Cl^- transporter maturation to the excitability of the immature brain is also supported by the fact that the NKCC1 inhibitor, bumetanide, can markedly attenuate seizures when administered to P7 rats.[57]

Limited parallel human data is available regarding the development of GABA systems. In human neocortex, $GABA_A$ receptors and GAD levels continue to increase into mid-childhood.[130] NKCC1 expression peaks around term.[57] In fact, KCC2 protein expression is not present in human neocortex until after 1 year of age, and rises to adult levels in early childhood.[57] Taken together, these observations suggest that, as in neonatal rodents, GABA inhibition is likely to be significantly reduced in human infancy and early childhood.

Alterations in Ion Channel Expression and Function

Developmental changes in the intrinsic properties of neurons and/or their responses to network input have been discovered and are governed to a large extent by the age-dependent expression patterns of ion channels. Indeed, work in both animal models and humans has highlighted the contribution of genetic and acquired changes in ion channel structure and function to states of hyperexcitability, seizure susceptibility, and frank epilepsy.[134,159,182,210]

Sodium channels.

Of the 13 expressed mammalian sodium (Na^+) channel genes, mutations in three subunits (Nav1.1, Nav1.2, Î²1) have been associated with epileptic phenotypes. The functional consequences of the nearly 200 different mutations identified in these genes are diverse,[115] but remarkably, the temporal evolution of the associated seizures indicates that the developing central nervous system (CNS) is particularly intolerant to these variations of Na^+ channel function. Seizures resulting from Na^+channel dysfunction commence during infancy or early childhood, and often disappear later.[163] The reasons for the developmental susceptibility to Na^+channel dysfunction are not clear. Although age-dependent expression patterns of Na^+channel subunits have been described,[14,31,72] they do not define vulnerability windows, when only a single isoform

is expressed in the CNS, nor do they suggest maturation-related compensatory upregulation of nonaffected isoforms. Alternatively, the apparent age-specificity of these Na^+-channel defects may be a result of age-specific insults that interact with these channels. For example, increased temperature (fever) may unmask specific deficits of mutated Na^+ channels.[174] Consistent with this notion, sodium channel defects are particularly common in individuals with febrile seizures plus (FSP).[163]

Potassium channel superfamily.

Developmental susceptibility to seizures that is governed by the function of potassium (K^+) channels is evident from studies of dysfunction of two members, KCNQ2 and KCNQ3, that carry the M-current, a slowly activating outward current that regulates subthreshold excitability and prevents repetitive action potential firing.[218] Mutations in these lead to benign familial neonatal convulsions, seizures that occur during the first days and weeks of life and disappear later.[45] Whereas age-dependent expression of splice variants of these channels have been described,[171,190] they seem to play little role in the temporal onset and resolution of the seizures. Intriguingly, the M-current, carried by these channels, may serve as a major inhibitory mechanism during the age when GABA is depolarizing,[136] so that even a 25% reduction of the current is sufficient to induce seizures,[93] explaining the occurrence of seizures neonatally. Once the role of GABA is reversed from depolarizing to inhibitory (e.g., the second postnatal week in the rat), a new powerful inhibitory system comes into play, so that persistent dysfunction of the KCNQ channels no longer renders the neuron hyperexci-table.

HCN (or h) channels, members of the K^+ channel superfamily, contribute to the maintenance of resting membrane potential, integration of dendritic excitability, and neuronal depolarization in response to network input.[138,151] The properties of the h channels are governed by the types of HCN channel isoforms that the neuron expresses, and the expression of HCN channel isoforms (1, 2, and 4) varies drastically as a function of age.[18,26] Importantly, hippocampal maturation is associated with marked increase in the expression of the HCN1 isoform[26] that tends to dampen dendritic excitability and minimize rebound depolarization in response to hyperpolarizing input[140] and could contribute to reduced seizure susceptibility in the juvenile and adult brain.[159]

Calcium channels.

Calcium (Ca^{2+}) channels are involved in age-specific seizure vulnerability at a somewhat later age than the neonatal-infant period discussed here. In the human, dysfunction of members of the (Ca^{2+}) channel superfamily (Cav2.1, Cav3.2, Î²4) may be involved in absence seizures.[41,58,95] An elegant explanation for the age-specific contribution of the Cav2.1 subunit to seizure susceptibility has been provided in experimental models by Noebels.[134] In neonatal mouse thalamic neurons, neurotransmitter release is dependent on both N- and P/Q-type channels.[89] With maturation, this function is taken over exclusively by the P/Q-type channels, formed by Cav2.1 subunits, so that dysfunction of these channels provoked seizure vulnerability.

The understanding of the contribution of intrinsic ion channels to age-dependent seizure vulnerability is rapidly evolving. New ion channels are being discovered that are expressed in an age-dependent manner and may enhance excitability in developing neurons (e.g., NKCC1),[57] thus further highlighting the importance of function and dysfunction of intrinsic ion channels to seizure susceptibility early in life.

Alterations in Peptide Neurotransmitters

Neuropeptides are released from neurons and can influence the excitability of a neuronal network through metabotropic receptors at post- or presynaptic sites (or both). Neuropeptide Y (NPY) is expressed in developing and adult rodent hippocampus in modest amounts.[5,80,168] Interestingly, it is also found in human hippocampus, starting prenatally and persisting to adulthood.[108,217] NPY, acting via the Y2 (and possibly Y5) receptors, reduces network excitability and seizure susceptibility.[44,205] Whether the relatively low levels of NPY during early development[5] contribute to the enhanced vulnerability of the hippocampus is unknown.

Corticotropin releasing factor (CRF) or hormone (CRH) is an excitatory neuropeptide that reduces spike afterhyper-polarizations,[4] and interacts with glutamatergic neurotransmission to promote excitability in vitro.[10,83] In vivo, the administration of CRH causes age-specific seizures, especially when infused in immature hippocampus. Hippocampal CRH receptors peak during the first 2 postnatal weeks in hippocampus and amygdala.[10] Interestingly, *endogenous* CRF is much more abundant in developing compared with mature hippocampus.[39] Thus, the actions of the endogenous peptide (which is released during stress)[40] favor increased excitability and seizure vulnerability during development.

Age-Dependent Alterations in Patterns of Seizure Propagation

Kindling is one of the best models of epilepsy to study the patterns of seizure propagation.[70] Kindling, once induced, permanently changes the susceptibility of the brain to seizures.[70] Amygdala or hippocampal kindling can be produced in 8- to 15-day-old pups using frequent stimulations (e.g., every 15 minutes).[105,123] In adults, stimulations delivered every 15 minutes either significantly retard or fail to induce kindling.[70,123,139,144] Progression through the various seizures stages in young animals is different from kindled seizure stages in prepubescent and adult rats. Stages 0 to 2 represent local events, stage 3 the involvement of the hemisphere ipsilateral to the stimulation site, stages 4 to 5 bilateral (generalized) seizures, while stages 6 and 7[74] may reflect spread to the brainstem.[29,32,64] Compared to older rats, pups spend proportionally less time in the early stages of kindling (stages 0â€"2) that are associated with focal seizures.[128] Instead, there is an early appearance of bilateral, although often asynchronous, seizures, indicating a tendency for seizure generalization. Pups experience many stage 3 to 4 seizures intermixed with isolated stage 5 seizures, followed by the explosive onset of stage 6 and stage 7 seizures.[74] Spontaneous seizures occur more readily in pups compared with adults.[11,75]

Another difference between adults rats and 15-day-old rat pups involves the phenomenon of *kindling antagonism.*[7] In adult rats, concurrent kindling of two limbic foci results in the suppression of generalized seizures from one or both sites. Pups do not show kindling antagonism to the development of generalized seizures between amygdala and hippocampus, or between the amygdala.[74] These data may indicate that, early in life, different brain areas can mutually enhance their epileptogenic potential and lead to the development of multifocal epilepsy, a common clinical phenomenon in young children, especially in those with infantile spasms. The data also suggest that, during the critical period, the immature CNS is more prone to the development of secondary generalized seizures. Thus, increases in seizure susceptibility extend beyond the local generation of epileptic discharges and involve mechanisms of seizure propagation to additional structures.

Kainic acid (KA) is commonly employed to induce focal seizures with secondary generalization throughout postnatal life. Administration of this excitatory amino acid leads to the development of seizures in all ages; however, the seizure manifestations are age-dependent, with specific manifestations such as scratching and swimming-like movements occurring in rats less than 15 days of age, while â€œwet dog shakesâ€ are rare in

these ages.[3] Tonicâ€"clonic seizures are regularly elicited in 7- to 25-day-old rats; however, their frequency decreases with age, especially after the third postnatal week. Rat pups are also more prone to develop status epilepticus (SE) than adult rats. In all age groups, EEG seizures start in the hippocampus; however, in young rats rapid involvement of the cortex occurs.

Age-Dependent Differences in Animal Models of Generalized Seizures

Most developmental models of generalized, predominantly motor seizures rely on the systemic administration of a chemoconvulsant, usually a GABA-related substance. The most commonly used agents are pentylenetetrazol

(PTZ), bicuculline, or picrotoxin, and glutamate agonists such as kainite.[126,192,195] After day 7, the seizures consist of motionless state (freezing), myoclonic twitches, face and forelimb clonus, and generalized tonicâ€"clonic movements. These seizure types, their latency to seizure onset, and their EEG correlates are dose dependent. The EEG correlate of motionless stare are rhythmic spike-and-wave discharges in a spindle-shaped envelope. Myoclonic body twitches are usually associated with isolated spike-and-wave discharges. Clonic and tonicâ€"clonic seizures may have similar EEG correlates consisting of fast multiple spike-and-wave discharges. The chemoconvulsant-induced phenomena are thought to be the models of different human seizures. The motionless state and its associated rhythmic EEG activity is considered to be the model of human absences. Clonic seizures are considered a model of human myoclonic seizures, whereas tonicâ€"clonic seizures may represent a model of primary generalized tonic-clonic seizures.

The expression of drug-induced motor seizures is age-dependent.[192] Thus, with PTZ, clonic motor seizures are not often observed in rat pups prior the second postnatal week, rather swimming-like movements occur, reflecting an immaturity of the motor pathways; the CD_{50} for clonic seizures remains constant after the third postnatal week. Myoclonic twitches and tonicâ€"clonic seizures occur throughout development, but the CD_{50} increases progressively with age. In rats less than 7 days old, the only seizure manifestations may be swimming movements of all four limbs, not accompanied by any EEG correlates. EEG discharges can be dissociated from behavioral seizures, and the duration of the epileptiform discharges decreases with age. Sharp waves become spikes after the second postnatal week, whereas the onset of electrographic seizures is synchronized in all areas after the third postnatal week.[165] With flurothyl, the seizure threshold increases with age. The clonic seizures become more apparent as the animal reaches the second week of life. During the first two postnatal weeks, clonic seizures in the majority of the models rapidly progress into tonicâ€"clonic seizures. Thus, clonic seizures may be masked by tonicâ€"clonic seizures.[200,203] One reason for the dissociation between behavioral and electrographic seizures may be the lack of cortical involvement in the expression of seizures in developing animals. Metabolic studies using the deoxyglucose technique have revealed that, in adults during clonic seizures, metabolic activity increases in the cortex, hippocampus, globus pallidus, and substantia nigra (SN). During tonicâ€"clonic seizures, metabolic activity increases also in the midbrain structures.[16] In contrast, in developing animals, decreases in neocortical activity occur with increases of activity in brainstem structures.[126,175,192] One notable exception is the lack of activation of the SN, a structure thought to play an important role in the control of generalized seizure.[125]

Generalized seizures can also be induced by electrical stimulation (electroshock seizures). Depending on the intensity the stimulating current, two types of seizures may occur:[110] minimal clonic seizures involving clonic movements of the head and forelimbs and maximal, generalized, tonicâ€"clonic seizures with a loss of righting reflexes. Minimal seizures probably represent a model of myoclonic seizures, and are generated in the forebrain.[107] Maximal electroshock seizures (MES) are a model of generalized tonicâ€"clonic seizures, and involve brainstem structures.[28] The mature pattern of MES emerges during the third postnatal week in the rat; younger animals show only forelimb flexion (PN 10â€"12 or earlier), or forelimb flexion followed by forelimb extension and hindlimb flexion (PN 13â€"15).[204]

Drug-induced models of absence seizures also are available.[46] The acute pharmacologic models of typical absence seizures are induced from systemic administration of a single pharmacologic compound [4,5,6,7 tetrahydroxyisoxazolo (4,5,c) pyridine 3-ol (THIP), Î³-butyrolactone, PTZ, or penicillin]. With appropriate doses, their administration leads to bilaterally synchronous spike-and-wave discharges associated with behavioral arrest, facial myoclonus, and twitching of the vibrissae. An acquired chronic model of atypical absence seizures has been derived from a timely prenatal administration of methylazoxymethanol (MAM) in combination with postnatal systemic administration of an inhibitor of cholesterol, AY-9944. For this seizure type, genetic models of absence epilepsy also are available, such as the GAERS and WAG/Rij rats, as well as various mouse mutants.[133]

Age-Dependent Activity of Brain Networks Mediating Seizure Control

Circuits involving several subcortical nuclei can regulate seizures. One such system includes a GABA-sensitive SN-based circuit. The SN and especially the pars reticulata (SNR) may be critically involved in the expression and control of bilateral, generalized seizures in rats.[125] The nigral effects are operative in both seizures of local origin (kindling) and seizures that appear to be generalized from their onset (flurothyl-induced seizures). These nigral effects on seizures are age- and sex-specific[196] and appear to involve two distinct regions within the SNR,

$SNR_{anterior}$ and $SNR_{posterior}$. The segregation occurs with maturation; before the third week of life, only one functional SNR region is present. Both GABAergic and glutamatergic systems are involved, with ample information on $GABA_A$-mediated neurotransmission available.[22,23,51,63,65,66,67,113,114,124,125,196,198,202] In male adult rats, bilateral microinfusions of muscimol into the $SNR_{anterior}$ produce anticonvulsant effects, whereas microinfusions into the $SNR_{posterior}$ are proconvulsant.[122] In male immature (less than 25 days old) rats, there is no regional compartmentalization for the SNR effects on seizures, and muscimol infusions produce only proconvulsant effects. Studies in female rats show that the effects of the SNR on seizures are sex-specific with differences in the maturation patterns and a universal lack of SNR-mediated proconvulsant effects following muscimol microinfusions.[199] Maturational changes in electrophysiologic neuronal properties, in subunit composition of $GABA_A$ receptors, expression of KCC2,[62] and in the output targets may each contribute to the emergence of pro- and anticonvulsant regions within the SNR.[194,197,198,202] The sex-specific differences appear to be under the control of postnatal testosterone and its metabolites.[69a,199,200]

Impact of Early-Life Seizures: Chronic Hyperexcitability and Epilepsy

Early-Life Status Epilepticus

Animal models have contributed significant data toward the understanding of SEâ€"related sequelae, and they offer the

P.473

opportunity to explore cellular, molecular, and functional changes following status as function of age and sex. In models, the pre-existing substrate is known, and thus changes occurring following status can be considered causally related to the status per se, although the means by which status was induced may have an impact. Combining different data sets can identify common model-independent findings. The consequence can vary depending on whether status is induced in animals with normal or abnormal brains.

Studies in animals with normal brains have shown that the immature brain is relatively resistant to SE-induced morphologic damage.[9,34,183,201] Long-lasting status, regardless of seizure origin (nonlimbic or limbic), induced by flurothyl,[176,208] pentylenetetrazol,[131] NMDA,[178] or KA,[3,15,76,179] and pilocarpine[34] is associated with little or no neuronal damage in the hippocampus or extrahippocampal regions in rats younger than 3 weeks. Synaptic reorganization in the supragranular layer of the dentate gyrus of the hippocampus does not occur following status before the third postnatal week.[19,76,157,177]. Many factors may contribute to the relative resistance of immature hippocampus to status-induced damage.[81] With maturation, the extent of hippocampal damage increases.[3,85,157]

It should be noted that several groups suggest that a degree of hippocampal or extrahippocampal injury may occur after SE during early development.[12,47,48,76,99,148,156,157,179,189,209] However, the extent of damage is far less prominent compared to status-induced changes in adulthood. Status early in life may also prime the brain to the effects of subsequent insults.[69,97] These consequences may be either detrimental to the brain or, in some cases beneficial, as is the case with the effects of 1-hour-long flurothyl status on subsequent focal ischemic insult later in life.[69]

The relationship of status to the subsequent development of epilepsy in normal immature brain is also age-dependent. In rats younger than P21 days, spontaneous seizures do not occur following KA, and are rarely observed following lithium/pilocarpine-induced SE.[157] In 21-day-old rats, spontaneous seizures occur irregularly in 10% to 73% of animals, depending on the seizure model used.[141,152,179,207] In adult rats exposed to status, the incidence of seizures reaches almost 100%.[179,207] Furthermore, 15-day-old rats exposed to KA-induced status are not more prone to develop amygdala-kindled seizures as adults than are controls; this is not the case in adults.[137] MRI changes identified within 48 hours after status can predict which 21-day-old rats will develop seizures.[152] Only rats with visible structural MRI abnormalities or without visible abnormalities, but with changes in T2 relation time, developed spontaneous seizures. Not all rats with epilepsy showed hippocampal damage. Three episodes of pilocarpine SE in 7- to 9-day-old rats produced long-term changes in epileptogenesis.[160]

Very few studies assess whether SE-induced neuronal damage may be enhanced in the setting of a compromised brain in developing rats. These studies seem to suggest that, in this scenario of a two-hit hypothesis, an augmentation of hippocampal injury occurs following status.[104,122,215]

With regard to two-hit models, a recent study by Scantlebury et al.[162] reported that hyperthermic seizures induced in P10 rats with a single freeze-lesion resulted in 86% of rats with spontaneous limbic seizures. Controls with freeze lesions were not epileptic, and a minority of those with hyperthermic seizures had abnormal EEGs.

Febrile Seizures

Febrile seizures (FS) are the most common type of seizures in infants and young children,[181] and it is important to understand their impact on the developing brain and potential contribution to epileptogenesis. To probe directly the mechanisms by which these seizures might contribute to temporal lobe epilepsy (TLE), several models are available, including one employing hyperthermia-induced seizures of 20-minute-duration evoked on postnatal day 10,[52,53,54,55,56] and those using heated water[68,121] or heated copper sheets.[86]

Early-life experimental FS produce a chronic state of hyperexcitability in an otherwise neurologically normal brain. This is manifest in vivo as an increased seizure susceptibility in animals experiencing experimental FS to convulsants given later in life, as compared with naive or hyperthermic controls,[52] the presence of interictal discharges in hippocampal EEGs in 88% of adult rats that had experienced prolonged FS early in life,[53] and the emergence of spontaneous seizures in a proportion (~35%) of FS-experiencing rats.[53] In vitro studies further localized this long-lasting hyperexcitability to the hippocampal circuit, despite increased inhibitory drive onto CA1 pyramidal cells.[37,52]

These findings raised the question of the mechanisms by which prolonged FS febrile seizures may convert a â€œnormalâ€ developing brain into a hyperexcitable or proepileptic state. The underlying mechanisms are not yet fully understood, but available evidence indicates that subtle changes of network properties rather than gross morphologic alterations play a role. Experimental prolonged FS do not kill neurons.[20,53,55,191] However, these seizures led to a significant and long-lasting change in the expression pattern of a specific ion channel, the hyperpolarization-activated cyclic adenosine monophosphate (cAMP)-regulated (HCN) channel (see the earlier discussion on ion channels). This â€œacquired channelopathyâ€ consists of coordinated, enduring changes in the expression of several subunits of this channel family, altering the current they conduct, I_h, in hippocampal pyramidal cells.[24,151,159] The mechanisms by which these changes promote hyperexcitability are discussed elsewhere.[36,159] It should be noted that, whereas transient changes in the pattern of HCN expression are found also af-ter kainate-evoked SE in the P10 rat, enduring transcriptional as well as posttranslational dysregulation of the HCN channels are unique to experimental FS,[25] and may derive from the involvement of cytokines in these, but not other seizures, during this stage of development.[54] Striking changes of the HCN channels are also found in human hippocampus from individuals with severe TLE and hippocampal sclerosis.[19]

Early-Life Hypoxia-Induced Seizures

Hypoxic encephalopathy is the major cause of neonatal seizures in the human infant.[2] Hypoxia-induced seizures can be associated with later-life neurocognitive effects and epilepsy.[21,60,132] Rats show a similar susceptibility to the epileptogenic effects of seizures in the immature period.[154]

The exposure of rats to a brief period (15 min) of global hypoxia (5%â€“6% O_2) around P7 to P12, depending on strain, results in both behavioral and electrographic seizures.[91,92] In addition, these rats exhibit increased susceptibility to chemoconvulsant seizures later in life.[92,96] Hypoxic seizures are not associated with either immediate or subacute neuronal death in forebrain structures.[92,96] However, a number of alterations in neurotransmitter receptors and signaling pathways are observed in the surviving hippocampal and cortical principal neurons. Both the mRNA and protein for the GluR2 subunit appear to downregulate within 1 to 2 days following hypoxic seizures at P10, suggesting an increase in the number and activity of calcium-permeable AMPARs.[155] In addition, activation of existing calcium-permeable receptors by hypoxia in turn activates a number of signaling cascades that result in posttranslational receptor modification.[153] Within minutes following a seizure in a P10 rat, AMPAR activation of the phosphatase calcineurin by calcium causes dephosphorylation of $GABA_A$ receptors and a decrease in inhibition.[153] Decreased inhibition due to GABA dephosphorylation and an increase in calcium

P.474

permeability due to downregulation of GluR2 may contribute to the enhanced network excitability seen in the hours to days following hypoxic seizures. It is likely that these changes are not specific to hypoxia, but that alterations of neuronal function and molecular structure occur in surviving neurons in the immature brain, given the lack of neuronal death.

Brief but Recurring Seizures

In addition to SE and seizures induced by hypoxia/ischemic episodes at birth, a clinical condition often encountered in young children is brief but recurring seizures. This is particularly true in children who are unresponsive to anticonvulsant medication. Thus studies have been undertaken to determine the effects recurrent seizures have on brain development. Particularly important is the question whether recurrent seizures in early life contribute to the epileptogenic process.[13] Do periods of repetitive seizures in early life increase neuronal excitability and/or produce epilepsy? To address this question, several animal models have been used. The tetanus toxin model, which was introduced a number of years ago in adult rats,[90] has been employed in immature animals.[103] Seizures are induced by a single unilateral stereotaxic injection of a very small quantity of tetanus toxin into the dorsal hippocampus on postnatal day 10. Tetanus toxin is known to block transmitter release by the proteolytic degradation of the synaptic vesicle docking protein, synaptobrevin.[49] However, tetanus toxin acts preferentially on inhibitory nerve terminals.[214] It is thought that by the selective blockade of GABA release, tetanus toxin is able to induce seizures. Tetanus toxinâ€“induced seizures in infant rats begin 24 to 48 hours after hippocampal injections. Long-term video-EEG (V-EEG) recording has shown that rat pups experience brief (30â€“120 sec) but recurring seizures. Seizure frequency peaks 5 to 6 days after injections, then rapidly declines. Rats are likely to experience as many as 50 to 100 seizures in the week following tetanus toxin injection.[147]

A number of studies of the tetanus toxin model have been carried out to characterize the effects of recurring early-life seizures. In this model, brief but recurring early-life seizures produce a chronic state of hyperexcitability that is most often characterized by interictal spiking on the EEG and in hippocampal slice recordings.[102,103,172] Spontaneous, electrographic seizures are far less frequent, commonly do not have a behavioral component, and likely occur in rats that have experienced very frequent seizures in early life.[6] Nonetheless, all animals appear to have an increased propensity for seizures when exposed to a convulsant.

The flurothyl model is a second model that has often been used to induce recurrent seizures in early life. Rats or mice are exposed to this volatile convulsant in an enclosed chamber. Flurothyl is thought to produce seizures by opening Na^+ channels diffusely and possibly by blocking $GABA_A$ receptors.[206] In most studies, between 25 and 50 seizures have been induced in infant rats. Spontaneous behavioral seizures have not been reported later in life in flurothyl-treated animals. Epileptiform activity has not been observed on EEG recordings.[50] However, significant decreases in seizure susceptibility have been reported later in life when the threshold to flurothyl[87,173] or pentylenetetrazol[84] have been examined. Thus, as in the tetanus toxin model, flurothyl-induced seizures appear to increase neuronal excitability long-term. However, the degree of hyperexcitabilty does not appear to be sufficient to result in overt epilepsy or interictal spikes on the EEG.

Impact of Early-Life Seizures: Learning and Memory Deficits

The catastrophic epilepsies of infancy and early childhood are often associated with learning deficits, including mental retardation.[33,82,135,170] Infantile spasms and Lennox-Gastaut syndrome (LGS) are among numerous severe childhood seizure disorders characterized by frequent seizures. It is not uncommon for a child to be developmentally normal before the onset of such seizures, only to have his cognitive abilities fail to progress or even regress in the face of unremitting seizures. This has led many to wonder if seizures contribute to cognitive decline.[112] However, it remains controversial if early-life seizures hinder learning and the formation of memories, since other factors, such as an accompanying neuropathology or anticonvulsant therapy, could be responsible for cognitive problems. However, recent results from numerous animal studies support the notion that early-life seizures may impair learning, although it was much different from that of seizures in adults.

Status Epilepticus

Since the mid 1980s, a large number of studies have examined the long-term cognitive effects of SE in the developing rats.[180] These studies varied greatly in the way in which seizures were evoked, the age at which they were induced, the age at which behavioral testing was undertaken, and the behavioral tests employed to evaluate outcome. Thus, comparison of results can be difficult. Nonetheless, in general, results reported suggest that SE in early life does not have as severe impact on cognitionâ€"particularly spatial learning and memoryâ€"as similar seizures in older animals, starting from 21 days of age.[100,109,161] One explanation for this age-dependency could be that SE incrementally induces neuronal cell deathâ€"particularly in hippocampusâ€"after 21 days of age in the rat.[109] Neuronal cell loss, especially in the hippocampus, would be expected to lead to spatial learning and memory deficits. Since neuronal loss has been more rarely reported during the first 2 to 3 weeks (see previous discussion) of life, the acquisition of spatial memories might not be expected to be as severely impaired. Nevertheless, although a prolonged seizure in early life may not kill neurons in the CNS, they appear to produce other cellular and molecular changes that result in life-long deficits in learning and memory.[109,161]

Brief Recurring Seizures

Unlike studies of SE, the effects of brief but recurring early-life seizures have consistently shown that they produce spatial learning and memory deficits later in life.[13] The majority of reports of memory and learning deficits following recurrent early-life seizures come from studies of the flurothyl model.[50,84,87,106,173] In most studies, seizures were induced beginning on the day of birth and extended through the first week of life; in some studies, seizure induction extended to postnatal 9 or 11, in order to increase the number of seizures evoked. In some studies, as few as 15 seizures were elicited; in others as many as 55. Rats could be tested for behavioral deficits as early as P24 or as late as P82. The Morris water maze and a subsequent probe test were used to assess spatial learning and memory. In all studies, the authors conclude that learning and memory were impaired. By comparing outcomes from several publications it would appear that the more seizures a rat experiences as a neonate, the more robust are the behavioral effects.

The behavioral effects of tetanus toxinâ€"induced seizures in early life have been reported to be quite robust also and comparable to the most dramatic reports from the flurothyl model.[102] This might be expected, because after a single injection of tetanus toxin, rats can experience as many as 50 to 100 seizures.[146] When these rats were 2 months of age, learning was compared across the three groups in the Morris water maze. The rats that had experienced recurrent seizures in early life were found to be markedly deficient in their ability to learn when compared with control groups. One possible confounding factor in studies of the tetanus toxin model is that,

as adults, a significant fraction of the rats display epileptiform activity on the EEG (see earlier discussion). Subclinical seizures or even interictal spiking may interfere with the ability of neuronal networks to acquire new memories. To address this issue, EEG recordings were undertaken after rats were trained in a water maze.[102] Results showed that rats without interictal spikes were just as impaired in their spatial learning abilities as those that had interictal spikes. Thus, the presence of interictal discharging could not explain the poor performance in this spatial learning task. The results are also in full accord with results from the flurothyl model, in which rats have been shown not to display epileptiform activity but are learning impaired.

A febrile seizure model in which rat pups were repeatedly made hyperthermic on P10 to P12 is a third model that has been employed recently to study the effects of brief but recurrent seizures.[35] Nine seizures were induced (three each day) that were 4 to 5 minutes in duration. The Morris water maze and probe test were used to access impaired cognition beginning on P60 and, as in all the other studies reviewed earlier, rats that had experienced recurrent seizures were cognitively impaired. Additional experiments showed that the learning deficits were not produced by hyperthermia but depended on the presence of recurring seizures. Thus, results from three different animal models are fully in accord with each other and suggest that brief but recurring seizures in early life can impair an animal's ability to acquire new memories.

Underlying Mechanisms

Because neuronal death does not appear to contribute to the learning deficits in rats that have experienced seizures in infancy, identification of other potential mechanisms is important. One possible clue comes from a neuroanatomic study of hippocampal pyramidal cells in the tetanus toxin model of early-onset epilepsy.[94] Marked alterations were observed in the dendrites of CA3 neurons, which included a reduction in branching complexity of basilar dendrites as well as a decrease in spine density on both the apical and basilar dendrites. Similar observations have been made in human tissue obtained during epilepsy surgery.[184] In studies of hippocampal and neocortical foci, a decrease in length and branching complexity of dendritic arbors was observed, as well as a reduction in spine density on the remaining dendrites.[129,164] Similar observations have been made in the chronic alumina cream model of epilepsy in primates.[212] Because dendrites and dendritic spines are sites of excitatory synaptic input onto neurons, the results suggest that glutamatergic synaptic transmission may be reduced. Moreover, because these synapses are recognized sites of activity-dependent alterations in synaptic transmission (e.g., long-term potentiation [LTP]), that are thought to underlie learning and memory,

[169] studies that examine how seizures reduce dendritic arbor complexity in the brain could be an important step in understanding the mechanisms responsible for learning and memory deficits associated with early-onset epilepsy.

Two recent lines of investigations are beginning to demonstrate how seizures may impair dendritic structure and function. The first is based on the fact that seizures in early life are stressful and activate stress-mechanisms, including the secretion of the excitatory neuropeptide CRH from hippocampal neurons.[40] As mentioned earlier, both the peptide and its receptor are abundant in developing hippocampus.[8,39] Recently, Chen et al. found that even in picomolar amounts, CRH interferes with dendritic growth and differentiation.[38] Mice lacking the CRH receptor had exuberant dendritic trees, whereas hippocampal pyramidal cells exposed to CRH during the first week of life had â€œatrophiedâ€ dendrites. The relevance of the stress-evoked, CRH-mediated damage to dendritic structure for cognitive deficits was highlighted in a recent report.[30] Early-life stress led to strikingly impoverished dendritic trees of hippocampal neurons later in life, and this was accompanied by learning and memory impairment, as well as reduced synaptic plasticity (LTP). The possibility that CRH may contribute to seizure-related dendritic atrophy is exciting, because antagonists for this peptide exist, and may prove useful to prevent or even reverse these deficits.[59]

A second line of investigation emerges from the study of the effects of recurrent febrile seizures. In this study, investigators not only showed that seizures resulted in impaired learning and memory but also disrupted signaling that normally results in activation of the transcription factor, CREB.[35] When rats are tested in an inhibitory avoidance learning paradigm, normally an activation of CREB occurs by phosphorylation at Ser133. However, the investigators found that this activation is impaired after recurrent febrile seizures. This suggests a seizure-induced modification of a signally cascade upstream of CREB. To explore this possibility, the investigators treated adult rats that had experienced febrile seizures in infancy with rolipram, a specific phosphodiesterase type IV inhibitor, which results in the activation of protein kinase A (PKA) and is known to activate CREB via the mitogen-activated protien kinase (MAPK) pathway. Rolipram treatment was able to reverse the learning deficits observed in rats that had experienced recurrent febrile seizures. Because the MAPK pathway and CREB signaling are both thought to play key roles in dendritic development,[119,216] it will be important to know from future studies where in the PKA-MAPK-CREB cascade that signaling is disrupted and if these changes are initiated very early in life by seizures and possibly contribute to the dendritic abnormalities observed.

Summary and Conclusions

Critical periods of enhanced seizure susceptibility have been identified in both man and animals, and mounting evidence suggests they share underlying mechanisms. It is unlikely that only one developmental process is responsible for the marked seizure susceptibility in early life. Instead, highly dynamic alterations in synapses and ion channels temporarily converge to produce neuronal network hyperexcitability. For example, during the second postnatal week in rodents, seizure susceptibility likely arises from a transient overlap between newly formed glutamatergic networks and the remaining excitatory GABAergic systems of the neonate that have yet to disappear. The interplay between these synaptic changes and coincident developmental alterations in ion channel function will be the subject for future studies.

In addition to similarities in seizure susceptibility, animal models of experimentally induced seizures share much in common with observations made clinically. While electrical and chemoconvulsive seizures may not be considered models of chronic epilepsy, they reproduce many of the age-specific electrographic and behavioral features of seizures observed in neonates, infants, and young children, and much has been learned from these models, especially in terms of understanding circuits underlying seizure propagation and control.

In recent years, numerous chronic models have been developed. They share features in commonâ€"like precipitation by an experimental induced seizure(s) in neonatal life or infancy in normal animals or, more recently, in animals with a brain malformationâ€"the so called â€œtwo-hit models.â€ Commonly, early-life seizures do not result in the loss of neurons, although some studies have reported modest changes (compared with those produced in adults). Later in life, most models show increased susceptibility to seizure. In some models, a minority of animals become epileptic, developing spontaneous behavioral and/or electrographic seizures. Suggested underlying mechanisms vary from altered expression and/or function of several ion channels to changes in expression of the AMPAR subunit, GluR2 which may in turn diminish $GABA_A$ receptor function. Another outcome from studies of early-life SE and brief/recurrent seizures are deficits in learning and memory. Dendritic abnormalities including spine loss may contribute to these behavioral deficits.

The field of experimental childhood *Epilepsy Research* has entered an era of great promise. Although many challenges remain, opportunities abound with respect to new animal models that are availableâ€"including emerging genetic mouse modelsâ€"that should lead to a greater understanding of the molecular basis of these disorders and avenues for the development of new therapies.

Chapter 40

The Effect of Seizures on the Brain

Jack M. Parent

Douglas A. Coulter

Edward H. Bertram

Introduction

For many decades there has been an ongoing discussion about the effect that seizures have on the brain, and, although there is a rapidly expanding body of knowledge on this topic, the answers may be only partially clearer. In this chapter we review some of these data and try to draw some conclusions from as-yet-incomplete information on the overall effect of seizures on the brain. As we will show, this issue is quite complex. The clinical answer we are looking for is how repeated seizures affect the patient with epilepsy. Most of the laboratory reports over the years examining that issue have studied the effects that induced seizures have on normal brains, and a number of interesting observations have been made, many of which are outlined in this chapter. Many of the observations from these models have been equated with epilepsy or the process of becoming epileptic. However, with the availability of an increasing number of animal models of epilepsy that have spontaneous seizures and structural changes that have significant similarities to human epilepsy, we are finding that the changes associated with epilepsy are not necessarily the same as the changes that have resulted from repeated seizures in normal brains.

These observations complicate the basic question of what is the effect of seizures on the brain, and now emphasize the need to differentiate the cause from the consequence of epilepsy. To make the interpretation of the new findings more difficult, some suggest that some of the changes found in these models could represent an attempt of the system to return everything to normal, a sort of counterbalance to the changes that are interpreted as epileptogenic or pro-seizure. For this reason it is important to understand the circuitry of the seizures and place the many changes that are found throughout the circuit in the context of the overall effect these changes have on circuit function. Our understanding of the changes and the circuitry of seizure initiation and spread is not yet to the point at which we can determine the effect of the observed changes in promoting or potentially inhibiting the generation and spread of seizure activity, but we will try to place the findings into context wherever possible.

In the course of this chapter we look at three different types of seizures that either have distinctly different consequences or clinical relevance. Although we try to make the distinctions clear wherever we discuss the different models, we highlight the distinctions among the different groups here. The first group includes intermittent seizures that are induced in normal brains. Perhaps the most common model for the study of this issue is kindling, which usually involves the focal induction of a seizure through an electrical stimulation via an implanted electrode. The number of seizures can be controlled, so that the cumulative effect of the seizures can be quantified in light of an exact number of seizures. The second group comprises the models that have epilepsy. Because we do not cover absence or other generalized epilepsies, most of the models that we discuss have some form of pathologic change that contribute to the epileptic condition. For this reason it will be difficult to differentiate which changes contribute to the epilepsy from those that may be the consequence. The third group is status epilepticus. There is no question that these prolonged seizures cause brain damage and chronic changes, including, in many cases, epilepsy. Status epilepticus is not really the focus of this chapter; rather, it is used as a tool for creating animals with epilepsy, so in this chapter it is discussed primarily in that light. In the course of this chapter we review the data that are available, including the effect of repeated seizures to increase the likelihood of having another seizure, the potential result of seizures on brain structure and on behavioral function, the potential of seizures to alter neurogenesis, and the consequences of seizures on receptors and channels and, as a secondary consequence, on the pharmacology. We also review the current state of knowledge on synaptic reorganization associated with seizures and epilepsy. As will become clear, not all seizures are created equal, nor do they affect the brain equally.

Seizures Beget Seizures?

There has been a long-standing concept that the occurrence of a seizure prepares the way for the next, so that each subsequent seizure induces changes that further enhance the odds of having another.[55] To some this hypothesized process represents epileptogenesis. But what is the evidence for seizures truly begetting seizures as opposed to each subsequent recurrence of a seizure representing a symptom of an independent underlying process that is causing the seizure? In this scenario the recurrences are simply a symptom of the abnormalities that are the true source for the seizures. Although the varying natural histories of different epilepsy syndromes support the concept that seizures do not necessarily beget seizures, there are experimental data on both sides of the discussion. How do the findings apply to human epilepsy?

Before we enter into a discussion of the many observations related to the topic we should make clear what is meant by epileptogenesis because it has taken on several connotations in the epilepsy literature. A commonly used definition is that epileptogenesis is the process by which seizures gradually lengthen and behaviorally intensify with each recurrence. A common example is the kindling model, in which each repeated stimulated seizure results in a lengthening of the seizure duration and the behavioral intensity until a plateau is reached.[50,109] The other definition for epileptogenesis is the process that leads to the first spontaneous seizure after the appearance of a potentially seizure-causing abnormality, such as a traumatic lesion, a malformation, or a tumor. Whether it's through the interruption of critical neuronal pathways, the loss of particular neuronal populations, or the secretion of a proexcitatory substance (sometimes casually referred to as epileptogenic goo),

a series of structural, pharmacologic, and physiologic changes evolve during a clinically silent time known as the latent period to the point of having a seizure.[49] Although both definitions have clinical relevance, understanding the mechanisms behind the changes that take place in a brain that ultimately lead to the first spontaneous seizure will likely provide us a greater understanding of the basis for the different epilepsy syndromes.

One can find human syndromes that either support or refute the idea that seizures beget seizures because there are a number of syndromes that remit spontaneously, regardless of the number of seizures experienced, and there are others that clearly have a worsening with regard to frequency and clinical severity. Benign epilepsy of centrotemporal spikes or rolandic epilepsy is well known to remit by the teenage years independent of the number of seizures experienced.[88b] On the other hand, seizures associated with the mesial temporal lobe or limbic epilepsy syndrome sometimes start with barely perceptible subjective events and gradually progress to longer seizures with loss of consciousness that become refractory to therapy.[49] There is enough variation from individual to individual even within one of these syndromes to support the interpretation that the natural history of each epilepsy syndrome is the natural history of the underlying cause because each syndrome has a common course unique to it. Although one cannot completely exclude the possibility that in some patients with particular syndromes the seizures do cause seizure-enhancing changes in the critical circuits, it does not appear to be a universal phenomenon.

The kindling model is most frequently cited as evidence for seizures begetting seizures. Clearly with each repeated stimulated seizure there is a more intense seizure, and the seizure increases in duration.[50,109] This observation has been made in many forms of human epilepsy as well as in some of the animal models of chronic limbic epilepsy.[17,31] There are a number of additional reports that with enough stimulated seizures the kindled animals will have spontaneous seizures. This observation has been made in rats, cats, and baboons (*Papio* sp.).[130,146,164] Some investigators have indicated that this susceptibility to developing spontaneous seizures also varies with the age of the animal at the time of kindling.[58,147] However, this observation is not universal across all investigators. There are some primate species that do not fully kindle in the sense that they never show convulsions and they have never been seen to have spontaneous seizures in the course of kindling stimulation.

Genetics clearly plays a role because the baboons that have spontaneous seizures observed following kindling come from lines that are known to develop epilepsy, whereas the macaques in which spontaneous seizures are not associated with kindling have not been associated with a predisposition to epilepsy.[165] In rats, the issue is complicated by strain susceptibility, variations in the site of kindling stimulation, and many variable stimulation protocols. The number of stimulations required before spontaneous seizures are observed varies from about 150 to 300 or more.[130,136] Others (by personal report, including one of the authors) have rarely seen spontaneous seizures, even after 1,000 or more stimulations. Although it is clear that in some labs and with some stimulation protocols, spontaneous seizures can be observed following a period of extensive kindling, it is not a universal phenomenon. The real question is whether kindling to spontaneous seizures has significant implications for human epilepsy, and here the answer is unknown. It is clear that in some patients with certain types of epilepsy the seizures can progress, but this progression happens after the onset of spontaneous seizures with an underlying associated pathology. The situation of recurrent stimulated seizures in people with an otherwise normal brain is seen only with patients that undergo electroconvulsive therapy for psychiatric disorders. Among these patients epilepsy as a consequence of the convulsive therapy is extremely rare, if it occurs at all. There is a report of a patient with 1,200 induced convulsions with no evidence for progressive brain injury or the development of epilepsy.[90] There are reports of patients who do have seizures following the therapy, but the observation is clouded by the concomitant use of medications that can lower seizure threshold.[91]

So, can seizures beget seizures? The data suggest that in certain strains or species of animals the repeated induction of seizures using a particular stimulus protocol at particular ages can result in spontaneous seizures. Is this phenomenon universal? No. More important, is this phenomenon relevant for human epilepsy? It is not possible to provide a blanket statement for all epilepsies in all individuals, but certainly there is little to no evidence suggesting that repeated exogenously induced seizures lead to chronic epilepsy. Can seizures in an individual worsen over time? There is certainly good evidence that they can, but that is more of a kindling phenomenon in which the seizure duration increases and the recruitment of brain regions expands once the spontaneous seizures have started. Alternatively, it could be a symptom of a worsening of the underlying condition that is causing the epilepsy. In some of the animal models of limbic epilepsy there is good evidence for a worsening over time until a plateau is achieved, after which a relatively stable pattern is maintained.[17,51] However, in some animals, as in some people, the seizures remain fairly stable for prolonged periods of time. In most cases the seizures are â€œbegottenâ€ by an underlying pathology, and although some can clearly progress over time with repeated seizures, other syndromes can spontaneously go into remission, an observation that suggests that the evolution of the disorder depends on the underlying etiology and less on the recurrence of seizures.

As a final observation regarding seizures and epileptogenesis, there has long been a desire to prevent the development of epilepsy or to cut the disease's natural history short by means of some early intervention, and the search for an effective prophylaxis has been going on for years. The most common approaches have been to treat patients with antiepileptic drugs following an event, such as head trauma, that has a significant risk for subsequent epilepsy. To date, none of these approaches has been effective in reducing the subsequent risk of epilepsy, although immediate postinjury treatment does block the acute seizures in the first week.[157] In animal work these attempts have been divided along two lines: (a) attempts to slow or prevent the kindling process by pretreatment before stimulation and (b) attempts to prevent the development of epilepsy following status epilepticus. The former approach, the inhibition of kindling, has been most frequently studied, and there are a number of compounds with varying, and in some cases unknown, mechanisms of action that have slowed the process (which means increased the number of stimulations necessary to achieve fully kindled seizures).[108,140,149] It may be, however, that the treatments were successful at suppressing seizures but not really altering the kindling process, because as soon as the pretreatment was stopped, the animals were often at the same stage as the untreated controls. Although there are some reports that drugs such as levetiracetam, when used prophylactically during the kindling process, result in a permanent reduction in seizure duration, this phenomenon has not been regularly seen.[92] Ultimately one is left with the conclusion that treatment in kindling may slow the process slightly but is unable to prevent it.

With the more recent appearance of the postâ€“status epilepticus limbic epilepsy models (kainic acid, pilocarpine, limbic electrical stimulation), there has been an opportunity to examine possible treatments for preventing the development of chronic epilepsy. A major problem for these studies in rats has been the maintenance of potentially effective levels throughout the treatment phase, which could last several weeks or more. In

P.483

the studies examining the prevention of kindling, the animals can be given the drug at a standard time before the stimulation, which for these studies is usually once daily. Maintaining therapeutic levels over a 24-hour period is not an issue in the kindling studies. Following status epilepticus, however, the latent period before the first seizure is usually several weeks to a month, and for most drugs, maintaining levels during that time is extremely difficult. There have been a few studies using antimetabolites that have reported some success in preventing anatomic features of chronic epilepsy without preventing the epilepsy.[89,168] The only studies that have been successful in preventing the development of epilepsy have been those that used treatments during the early stages of status epilepticus, usually during the first several hours, and the likely reason for success is that the intervention came early enough to stop the seizures and prevent the damage that the status epilepticus causes if left untreated.[131] Inasmuch as it is the damage that is thought to lead to the epilepsy, these interventions are likely successful because they prevent the cause rather than preventing the epilepsy once the cause has happened. Prophylaxis against the development of epilepsy following a potentially epileptogenic injury remains to be discovered.

Seizures and Brain Structure

Perhaps one of the greatest concerns in epilepsy is the question of whether repeated seizures damage the brain. The answers are confused by the mixing of different models, methods of documentation, and types of seizures. Brain damage, as evidenced by neuronal loss, gliosis, and focal atrophy, has been associated with epilepsy for as long as people have been studying the issue. As noted, the issue that is of greatest concern is which of these changes preceded the onset of the seizures and which appeared afterward, that is, what is the cause of epilepsy and what is the consequence. But there are other questions as well. Do seizures alter the structure of neurons in a way that alters their physiology? What effect do seizures have on glial cells? Do the type of seizure and the temporal patterning of the repeated seizures have different effects on the anatomy? What is the potential consequence of seizure-induced changes? Are the changes harmful or are they a protective reaction to the seizures? In this and several subsequent sections dealing with genes, channels, and neurogenesis we address these issues as best we can, given the nature of the data.

There is no question that some seizures affect the structure of the brain. There is almost universal agreement on this point. The issues are which seizures and what do they do to the brain. Absence seizures, which are brief, have a slow discharge pattern and use intrinsic brain rhythms, and they are generally considered not to have a significant effect on brain structure. At the other extreme, status epilepticus, and usually the status epilepticus associated with a progression of electroencephalographic (EEG) frequencies from continuous high-frequency activity to periodic epileptiform discharges, is unquestionably associated with significant neuronal loss and gliosis. The controversy lies in whether occasional seizures that have a tonicâ€“clonic pattern on EEG lasting for up to several minutes at a time induce neuronal loss. Furthermore, if damage does occur, does it ever plateau after a subset of vulnerable neurons is lost or does it continue to progress with each successive seizure? Clinical information is difficult to interpret in large part because it is rare to know what the structure of the brain was like before the onset of the seizures because much of the available tissue only becomes available after it has been removed surgically because of intractable epilepsy. There are a number of reports showing that patients who have more frequent or more intense seizures have more severe pathology/cell loss. Although this observation has often been interpreted to mean that more seizures or more intense seizures cause the greatest damage, this interpretation is based on the assumption that all individuals start from the same point and progress differently depending on the nature of the seizure disorder. An equally valid and more conservative interpretation is that the more severe pathology results in a worse seizure disorder. However, it is an issue that really cannot be resolved by clinical studies unless we begin collecting data well before the onset of epilepsy and watch for progression before and after the seizures begin. To study the issue under a controlled setting we have to use animal models of epilepsy.

There are several questions to answer in examining the issue of repeated seizures and neuronal loss. First, does it happen at all? Second, following the induction of an epileptogenic lesion, do the repeated spontaneous seizures cause additional loss? Two models have been used to study these questions. First, the kindling model allows us to start with a naive brain and induce seizures with an implanted electrode. We can control the number and frequency of seizures as well as the age of the animal before examining brain structure for change. The status epilepticus models result in a relatively stereotyped, but still somewhat variable, pattern of neuronal loss and gliosis. These rats then develop chronic epilepsy over a period of some weeks. The pattern of neuronal loss approximates mesial temporal sclerosis, and this model allows us to determine whether recurrent seizures on a background of preexisting pathology cause additional neuronal loss. These models of postâ€"status epilepticus limbic epilepsy are frequently compared to their human paradigm, and there are many points of similarity. One issue is not, and that is the origin of the pathology in the limbic structures. Although patients with limbic epilepsy frequently have an episode of a prolonged seizure (usually febrile) well before the onset of the seizures that are recognized as part of the symptoms of the chronic syndrome that first appear, the majority do not have a well-identified initial (and often considered precipitating) event.[12,33] Although the prolonged seizures can clearly induce neuronal loss, for those patients without a well-defined first event, the origin of the abnormality is less clear. It is possible that the precipitating event was unrecognized but still caused damage. There is some evidence to suggest that the abnormalities were present at birth because there has been frequent association with cortical dysplasias, and there is increasing evidence that genetic factors may also play a role as well.[25,87] It is also possible that the changes are the result of repeated seizures. Although the final answers are not in yet and the issue has supporters on both sides of the argument, there are a number of experimental results that are pointing in the direction of minimal loss as a result of repeated seizures.

The presence of neuronal loss is not controversial in limbic epilepsy. The questions are how it got there, and, more important, if is it progressive. It has been noted that there is considerable variability in the distribution of the pathology across patients.[102] As noted earlier, there have been a number of reports, especially quantitative magnetic resonance imaging (MRI) studies comparing volume loss and seizure severity, and the investigators have reported a relation. Some studies, however, have concluded that repeated seizures are not the cause of hippocampal atrophy seen on MRI scans.[23,24] A recent histologic study examined the relationship between the duration of the epilepsy (up to 30 years) and the severity of neuronal loss.[106] The authors found that there was a slight decrease in neuronal density over the years and that this loss was significant (see later discussion regarding the interpretation of density changes), but that there was considerable loss even among patients with a relatively short disease duration. The difference between control hippocampal densities and the neuronal

P.484

density in epileptic patients was much greater than that between epileptic patients with relatively short duration and those with the longest duration. This observation suggests that most of the neuronal loss occurs either before the onset of the epilepsy or very shortly thereafter.

There has been another interesting observation with regard to seizures and brain damage. There are reports that animals with prior seizures, whether kindled or electroconvulsive, have less neuronal loss when subsequently subjected to insults that usually result in significant brain damage. This has been reported for animals that had been subjected to status epilepticus, ischemia, or adrenalectomy.[74,79,104] The duration of the protective effect is likely transient, first coming into effect about 24 hours after the â€œprotectiveâ€ seizure and lasting at least 1 or 2 weeks. The mechanism is unclear but almost certainly involves the upregulation of factors that interfere with the apoptotic cascade.

Kindling has the distinct advantage in examining the question of seizure-induced neuronal loss because intervals between seizures and the number of seizures will be controlled as desired by the experimenter. It delivers a focal electrical stimulation to the desired part of the brain, and the stimulations can follow any pattern. There have been a number of kindling-based studies, and they are generally in agreement that repeated seizures result in lower neuronal densities. There are, however, quite different opinions regarding the significance of the reduced neuronal densities and the greater reduced densities with increasing numbers of seizures. On one side of the discussion the conclusion is that the reduced density is evidence for progressive seizure-induced neuronal loss.[32] The other side of the discussion holds that the reduced density is the result of seizure-induced changes in the neuropil (e.g., increased glial activation), and that once one corrects for the expanded neuropil, there is little or no change in the absolute numbers of neurons.[3,18,19]

One of the anatomic hallmarks of the limbic epilepsy syndrome is mossy fiber sprouting, in which the axons of the dentate gyrus granule cells that normally fill the dentate hilus and project to CA3 in the hippocampus are found in the supragranular layer of the dentate gyrus.[154,156] It is seen in human limbic epilepsy as well as in the animal models of the disorder. It is also seen in kindling, with a number of reports of progression of the sprouting with successive seizures. However, the degree of sprouting seen following kindling is usually a fraction of what is seen in epileptic animals and people.[105] The primary questions surrounding this phenomenon are why it occurs and what function it serves. The mechanisms underlying the process of sprouting are clearly unknown, and it is quite likely that the mechanisms associated with sprouting in kindling are quite different than those following status epilepticus. There is some evidence that in epilepsy the degree of sprouting is linked to the severity of neuronal loss in the hilus. A potential mechanism for the initiation of the sprouting is the loss of synapses and the creation of openings for new synapses. There is some evidence that neurotrophins may also be involved in bringing the aberrant axons into the molecular layer.[64] In kindling, with a less severe level of sprouting, the presence or absence of hilar neuronal loss is under-debated, so the mechanisms for the process are less clear. However, in relative terms, the degree of sprouting is much less in kindled animals.

More important than knowing the mechanism underlying the process of sprouting is the physiologic or functional consequence of the new synapses, and there are a number of hypotheses and some data that address the issue. The issue centers on the question of whether the sprouting is part of an overall process in the granule cell that is net excitatory, net inhibitory, or part of a zero-sum process in which the final effect is that all the changes balance out to no change in overall function. What many of the studies show is that the overall response to perforant path stimulation is not profoundly different from the naive nonepileptic state.[133] The data are somewhat conflicting in that there are varying shifts in the evoked responses in the granule cells, with some showing a slight increase in inhibition in paired stimulation and some a decrease. Overall, however, the highly epileptiform evoked responses that are seen in other brain regions are not seen in the dentate gyrus either following kindling or in the epileptic animals. However, there is evidence that these fibers form recurrent excitatory autosynapses. In addition, the granule cells appear to be more sensitive to the local application of glutamate and its analogs, with a heightened excitatory response.[170] As discussed later, changes have been reported in the Î³-aminobutyric acid (GABA)â€“mediated pharmacology, and, with regard to seizure-associated neurogenesis, there are multiple new dentate granule cells generated following status epilepticus. These new cells may contribute to the sprouting, although there are data that show that sprouting occurs even when the generation of new granule cells is prevented.[126]

Seizures and Behavior

On the clinical side of epilepsy, one of the major questions remains whether seizures have an effect on overall cognitive function or behavior. Epilepsy has long been associated with a number of problems in these areas. Although the overwhelming majority of patients with epilepsy have normal cognitive and behavioral profiles on formal testing, as a group they do not function quite as high as their nonepileptic counterparts. In seeking the reason behind this apparent overall lower performance, researchers have offered a number of plausible explanations, including medications, underlying preexisting abnormalities in the brain, depression that affects a high percentage of patients with uncontrolled seizures, and the consequences of the seizures themselves. In the clinical setting it is not really possible to separate all of the factors, but there is clear evidence that medications can play a role in some (but not necessarily all or even a majority of the patients), and the identified pathology often corresponds to particular neuropsychological deficits that a patient may have. However, these correlations are difficult to separate and also limit our ability to answer the question of whether the seizures themselves are playing a harmful role.

To determine whether seizures can have a neurobiologic effect on performance long term, we have to turn to animal models because we can use them to focus on the question of seizures alone, independent of the issues of precipitating pathology, affect, or medications. The two most frequently used animal models in behavioral studies have been the postâ€“status epilepticus model with chronic limbic epilepsy and the kindling model. The postâ€“status epilepticus model is associated with significant neuronal loss, and behavioral testing, performed when the animals are in the chronic phase with spontaneous limbic seizures, have consistently revealed that there are overt abnormalities in a number of behavioral areas. However, just as with patients with epilepsy, one is dealing with the confounding issues of underlying brain pathology, seizures, and, frequently, the potential confounding effect of a postictal state.

Table 1 Factors that modulate adult hippocampal neurogenesis

Factor	Effect	Stage affected	Reference

Aging	Decreased	Proliferation/neuronal differentiation	Kuhn et al. (1996),[81] Rao et al. (2005)[132]
Stress/adrenal steroids	Decreased	Proliferation	Cameron and Gould (1994),[28] Gould and Tanapat (1999)[52]
Exercise	Increased	Proliferation/?survival /?neuronal differentiation	van Praag et al. (1999),[160] Trejo et al. (2001)[159]
Environmental enrichment	Increased	Survival	Kempermann et al. (1997, 1998),[75,76] Nilsson et al. (1999)[117]
Estrogen	Increased	Proliferation	Tanapat et al. (1999)[155]
Basic fibroblast growth factor	Increased (postnatal)	Proliferation	Wagner et al. (1999)[167]
Brain-derived neurotrophic factor	Increased	Neuronal differentiation/survival	Lee et al. (2002),[84] Scharfman et al. (2005)[138]
Vascular endothelial growth factor	Increased	Proliferation/survival	Jin et al. (2002),[71] SchÃ¤nzer et al. (2004)[137]
Insulin-like growth factor-1	Increased	Proliferation/survival /?neuronal differentiation	Aberg et al. (2002)[1]
Glutamate	Decreased	Proliferation	Cameron et al. (1995)[30]
Î³-Aminobutyric acid	Increased	Neuronal differentiation	Mayo et al. (2005),[107] Tozuka et al. (2005)[158]
Serotonin	Increased	Proliferation	Brezun and Daszuta (1999),[24] Malberg

			et al. (2000)[100]
Nitrous oxide	Decreased	Proliferation (promotes neuronal differentiation)	Packer et al. (2003)[121]
Wnt	Increased	Proliferation/?neuronal differentiation	Lie et al. (2005)[88]
Sonic hedgehog	Increased	Proliferation	Lai et al. (2003),[83] Ahn and Joyner (2005)[4]
Sox2	Increased	?Proliferation/?neuronal differentiation	Ferri et al. (2004)[46]
Stem cell niche			Song et al. (2002),[151]
Astrocytes	Increased	Proliferation/differentiation	Palmer et al. (2000),[122]
Endothelium	Increased	?Proliferation	Jin et al. (2002),[71]
Microglia	Decreased	Survival	Monje et al. (2003),[113] Ekdahl et al. (2003)[44]

It is not possible to isolate the potential effects of seizures from the neuropathology in this situation, and for this reason the kindling model may be more appropriate because the seizures can be induced in any desired pattern, at almost any age, and, although this is a controversial issue, without the overt pathology that is found in the limbic epilepsy model. Although not absolutely perfect, it may be considered a purer model for studying the effects of seizures on behavior and memory because there is much less, if any, associated neuropathology. As can be expected, the results from the kindling model are

complex. Although there is no question that kindling can have a negative impact on spatial memory,[86] other studies suggest that the interactions may be more complex, with the overall effect depending on stimulation site, emotional state, and stimulation paradigm.[2,11] It is also likely that intermittent brief seizures that occur during development have an impact, although investigators point out that there may be beneficial effects as well as negative ones.[162] Overall the data suggest that seizures can have a negative effect, but that the effects may be relatively mild and are likely influenced by a number of factors in addition to the seizures themselves.

Altered Neurogenesis in Experimental Temporal Lobe Epilepsy

The dogma that neuronal production ceases after birth no longer is accepted. Evidence accumulated over the last five decades indicates that neurogenesis persists in the adult mammalian hippocampal dentate gyrus and subventricular zone (SVZ)-olfactory bulb pathway.[5,6,29,39,73,81,88a] Neuronal birth continues throughout life in every mammalian species examined, including human and nonhuman primates.[45,53,54,80a,128] In the dentate gyrus, neural stemâ€"like cells reside in the subgranular zone (SGZ) at the border of the hilus and dentate granule cell (DGC) layer. These cells express glial fibrillary acidic protein (GFAP) and nestin[42] and proliferate to generate clusters of neuroblasts that disperse and migrate a short distance into the DGC layer, where they differentiate into granule neurons.[6,29,73,81] Adult-born DGCs send axonal projections to appropriate targets in hippocampal area CA3[59,103,152,161] and acquire electrophysiologic characteristics of mature DGCs.[47,161,166]

Experimental evidence supports a role for DGC neurogenesis in learning and memory function (reviewed by Doetsch and Hen[43] and Ming and Song[110]). Stimulation of adult DGC neurogenesis with behavioral interventions such as exercise or environmental enrichment is associated with better performance on certain hippocampal learning tasks,[75,160] and the depletion of adult-generated hippocampal neurons disrupts hippocampal-dependent learning.[144,145,150] Recent work also suggests that DGC neurogenesis in the adult may be necessary for the positive effects of antidepressant medication.[135] Many physiologic states and molecular factors regulate adult hippocampal neurogenesis (see Table 1 and references therein). Aging and stress decrease DGC production, whereas exercise and environmental enrichment increase neurogenesis throughout adulthood. Most factors examined, such as growth factors, neuromodulators, estrogen, transcription factors, and the neurotransmitter GABA, increase the generation or survival of DGCs in the adult; glutamate and nitric oxide exert opposite

effects. Cellular elements in the neural stem cell niche, including astrocytes and endothelial cells, also positively regulate neurogenesis in the intact brain.

Seizure-Induced Neurogenesis

Studies of adult rodent models of limbic epileptogenesis or acute convulsions indicate that prolonged seizures potently stimulate DGC neurogenesis.[13,56,123,125,141] In the adult rodent kainate and pilocarpine models of mesial temporal lobe epilepsy (mTLE), chemoconvulsant-induced status epilepticus (SE) increases dentate gyrus cell proliferation approximately 5- to 10-fold after a latent period of at least several days.[56,123] About 80% to 90% of the newly generated cells differentiate into DGCs. Electrical kindling of the amygdala,[125,141] hippocampus,[13] or perforant path[116] also stimulates DGC neurogenesis. Similar neurogenic effects occur after acute seizures induced by intermittent perforant path stimulation in adult rats,[123] and even single, discrete seizure-like afterdischarges induced by hippocampal stimulation lead weeks later to increased numbers of newly differentiated DGCs.[13] Although more severe seizures enhance neuronal production to a greater extent, the survival of the newborn DGCs may decrease with increased seizure severity.[111] This effect probably relates to the degree of inflammation because it is reversed in part by minocycline treatment to decrease microglial activation.[44] The increased neurogenesis after SE is a short-term phenomenon, moreover, because adult rats with chronic epilepsy show decreased DGC production 5 months after chemoconvulsant-induced SE.[60]

Functional Significance of Seizure-Induced Hippocampal Neurogenesis

A prominent abnormality involving DGCs in human mTLE is mossy fiber sprouting (reviewed by Parent and Lowenstein[123]). In the pilocarpine mTLE model, developing axons from adult-generated DGCs contribute to aberrant mossy fiber reorganization in both hippocampal area CA3 and the dentate inner molecular layer.[123] When X-irradiation is used to kill DGC progenitors after pilocarpine-induced SE, however, mossy fiber sprouting persists.[126] Thus, SE appears to induce axonal remodeling in both mature and newborn DGCs in the epileptogenic hippocampal formation.

In addition to mossy fiber sprouting, the dentate gyrus in human mTLE often shows abnormal dispersion of DGCs and the presence of ectopic granuleâ€"like neurons in the hilus and molecular layer.[57,66,127] Hilar-ectopic DGCs appear in several different experimental mTLE models and persist for at least 1 year after the initial epileptogenic insult (Fig. 1).[40,123,127,139] The cells resemble the granule-like neurons identified in surgical specimens from humans with temporal lobe epilepsy in terms of both their morphology and expression of the DGC-specific marker Prox-1.[40,127,139] Studies of neurogenesis in experimental mTLE reveal a progressive increase in hilar 5-bromo-2â€²-deoxyuridine (BrDU)â€"labeled cells, as well as chains of migrating neuro-blasts extending from the inner DGC layer to the hilus, indicating that the hilar-ectopic DGCs migrate aberrantly from the dentate SGZ to the hilus.[127]

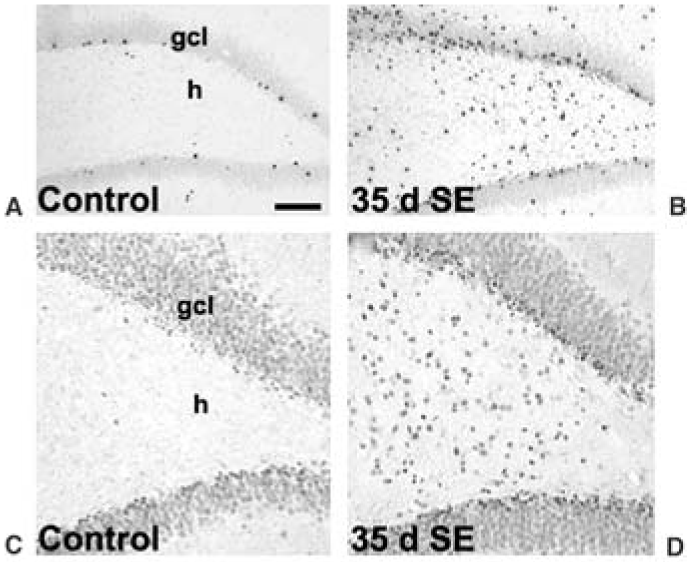

FIGURE 1. Pilocarpine-induced status epilepticus (SE) produces hilar-ectopic dentate granule cells (DGCs). Compared to a control **(A)**, bromodeoxyuridine (BrdU) labeling of proliferating cells shows increased cell proliferation in the DGC layer (gcl) and hilus (h) in an adult rat 35 days after SE (35 d SE) **(B).** BrdU was given 4 weeks earlier. **C, D:** Similar changes in hilar immunoreactivity for Prox-1, a DGC-specific marker.

Recent evidence suggests that hilar-ectopic DGCs arising after kainic acidâ€" or pilocarpine-induced SE integrate abnormally into the mature hippocampal formation.[40,139] Using intracellular recordings in hippocampal slices from epileptic adult rats, Scharfman et al.[139] showed that the hilar ectopic granuleâ€"like cells are hyperexcitable and fire in abnormal bursts synchronously with CA3 pyramidal cells. In addition, many putatively newborn DGCs located in the hilus or hilar aspect of the DGC layer after seizures exhibit a much higher percentage of persistent basal dendrites than is normally found.[40,139] Work by Ribak and colleagues suggests that the basal dendrites of hilar ectopic DGCs receive increased excitatory input,[40] suggesting a mechanism for seizure generation or propagation. In addition, Jung et al.[72] used the antimitotic agent araC to inhibit DGC neurogenesis after pilocarpine treatment and found that treated rats developed fewer and shorter spontaneous recurrent seizures than controls. Taken together, these data suggest that hilar-ectopic DGCs integrate abnormally, are hyperexcitable, and thus may contribute to seizure generation or propagation (Fig. 2). Given the likely function of adult hippocampal neurogenesis in learning and memory, moreover, defects in neurogenesis also may contribute to the substantial and progressive memory dysfunction seen in mTLE.[62]

P.487

Mechanisms Underlying Seizure-Induced Neurogenesis

The mechanisms by which seizure activity stimulates neurogenesis or gliogenesis are unknown. Experiments in which proliferating cells were labeled with BrdU prior to seizure induction have shown that epileptic activity stimulates dentate gyrus precursors that were proliferating prior to injury.[126] Huttmann et al.[69] used a reporter mouse in which green fluorescent protein selectively labeled nestin-expressing stemlike cells to show that kainate-induced SE specifically increases the proliferation of radial gliaâ€“like progenitors in the dentate gyrus. Seizures may act to increase neurogenesis indirectly through stimulation of astrocytosis because astrocytes stimulate hippocampal neurogenesis via wnt signaling and perhaps other mechanisms[88,151] or by inducing the death of mature DGCs, thereby leading to cell turnover in the dentate gyrus. SE also increases the expression of molecules with the potential to increase neurogenesis or gliogenesis such as growth factors[68] and neurotrophins.[70] Specific neurotransmitters or neuromodulatory systems that normally influence DGC neurogenesis (Table 1) also may be altered by seizure activity.

In terms of signals leading to hilar- or molecular-layer ectopic DGC formation, molecular factors that influence neuronal migration during development are prime candidates. The expression of one of these developmental factors, reelin, persists in the hippocampal dentate gyrus of adult humans and rodents and has been implicated in DGC layer dispersion in human TLE.[57] The expression of reelin decreases markedly after pilocarpine-induced SE (J.M.P., unpublished data), suggesting that loss of this migration guidance factor may be responsible for the aberrant migration of DGC progenitors during epileptogenesis. Another potential mechanism is loss of GABA, because this neurotransmitter influences DGC differentiation (Table 1) and decreases neuroblast migration in the other adult neurogenic region, the SVZ-olfactory bulb pathway.[22] Brain-derived neurotrophic factor (BDNF) is another good candidate. Scharfman et al.[138] showed that hippocampal BDNF infusion in adult rat increased DGC neurogenesis and led to the appearance of ectopic DGCs. Therefore, BDNF also might be involved in seizure-induced, aberrant DGC neurogenesis. The different stages of DGC neurogenesisâ€”including proliferation, migration, integration, and survivalâ€”likely are regulated by a delicate balance of multiple factors affecting DGC progenitors in the intact and epileptic hippocampal formation.

Epilepsy-induced Plasticity in Expression and Function of Neurotransmitter Receptors and Voltage-gated Ion Channels

In addition to pathologic changes in circuits due to loss or birth of neurons, epileptogenic injuries induce a multifaceted set of alterations in surviving neurons in the hippocampus, which may contribute significantly to the underlying excitability defect rendering the brain epileptic. Notable players in this plastic response to injury are alterations in neurotransmitter receptors and voltage-gated ion channels. Modification in the properties of these ion channels can contribute directly to generation of hyperexcitability within hippocampal circuits. For the purposes of the present discussion, here we summarize studies describing changes in specific responses mediated by pharmacologically or molecularly characterized receptors and ion channels. Although of interest, studies limited to examination of synaptic responses or intrinsic excitability will not be addressed in detail because the direct contribution of various subsets of receptors and ion channels is difficult to extrapolate from these types of data.

Methods for Characterizing Receptor and Ion Channel Plasticity at Cellular and Subcellular Resolution

To determine more definitively the nature of receptor and ion channel changes occurring in surviving neurons in epileptic (or epileptogenic) brain, specific sets of techniques are informative to establish the nature of changes at cellular and subcellular levels. These include immunohistochemistry (including immunogold labeling together with electron microscopy), in situ hybridization, single-cell mRNA profiling (reverse transcriptase-polymerase chain reaction [RT-PCR], antisense RNA techniques), directed pharmacology, and patch-clamp recording techniques. General immunohistochemistry, in situ hybridization, and single-cell mRNA profiling techniques provide cellular resolution when competently conducted, and immunogold/electron microscopy, directed pharmacology, and patch-clamp recording techniques can extend this cellular resolution to a subcellular level, examining changes in specific synapses and cellular compart-ments.

Alterations in Voltage-Gated Ion Channels: Focus on Dendrites

Most excitatory synaptic input impinges onto principal cells via dendritic synapses. How pyramidal cells process this dendritic synaptic input, integrate it, and generate output is an emerging area of potentially great importance in understanding mechanisms involved in seizure generation in the epileptic brain. Dendrites are endowed with a relatively unique ensemble of voltage-gated ion channels, which determine their function by regulating synaptic integration (reviewed by Magee[97]). Three ion channels in particular have a particularly prominent role in regulating dendritic processing of inputs. These are A-type (inactivating) potassium channels, hyperpolarization-activated (h-type or HCN) cationic channels, and T-type (low threshold) calcium channels. A-type potassium channels become increasingly more densely expressed in dendritic membranes as they are sampled at sites progressively more distal from the cell somata. Similarly, h-type cationic channels are densely expressed in the dendrites of pyramidal cells, resulting in a more depolarized membrane potential and decreased resistivity in dendritic plasmolemma, reducing propagation of excitatory synaptic input.[96,99] T-type calcium channels are also present in dendritic compartments, where they may serve to boost propagation of synaptic inputs.[97,98] In normal animals, propagation of distal synaptic inputs to the soma is strongly regulated by function of these ionic conductances, as well as by proximally targeted feedforward inhibition[7,97] (reviewed by Magee et al.[99]).

Several recent studies have been published demonstrating alterations in expression of all three of these dendritically prominent ionic conductances in animals rendered epileptic by a prior episode of pilocarpine- or kainate-induced status epilepticus. Of the three ion channel species that critically determine dendritic function, reductions in two (A- and h-type ion channels) and an increase in the third (T-type calcium channels) were recorded.[14,143,153] Because A- and h-type channels normally function to depress, whereas T-type calcium channels boost, propagation of excitatory synaptic input[97] (reviewed by

Magee et al.[99]), all three of these changes in intrinsic voltage-gated ion channel expression are consistent with enhancement in propagation of distal synaptic inputs to the soma. This type of enhanced propagation has been described, with very distal inputs onto CA1 pyramidal neurons, assuming a markedly (>10-fold) enhanced efficacy in epileptic animals compared to controls.[8,36,41,169]

The h-type current reductions in entorhinal cortical neurons described in the foregoing were accompanied by reduction in expression of both HCN1 and HCN2 subunits, assessed using Western blots.[143] A-type potassium channel reductions were accompanied by reductions in Kv4.2 mRNA levels in CA1 pyramidal neurons,[14] and T-type calcium channel increases were accompanied by increases in Î±1H subunit mRNA.[153] These latter data provide information on the molecular identity of the proteins mediating the epilepsy-associated shift in ion channel properties, and, at least in the case of the A-type potassium and T-type calcium channel alterations (and, to a lesser extent, the h-current changes), further suggest that these alterations may be transcriptional in nature.

The impact of the ion channel alterations just described on pyramidal cell dendritic integratory responses in epileptic animals may be enhanced by the coincident loss of feedforward inhibition evident in these same animals. Feedforward inhibition is critical to constrain excessive activation of excitatory pathways and has been demonstrated to be a primary regulator of the direct cortical input to CA1 neurons, the temporoammonic pathway, which innervates these cells on their extreme distal dendrites in stratum lacunosum moleculare.[7] This feedforward inhibition is compromised in animal models of epilepsy,[8,36,41] which, combined with dendritic ion channel alterations, could lead to an explosive amplification of temporoammonic input.[8,169] Once CA1 activates due to this aberrantly regulated cortical input, it will directly innervate and reactivate both subiculum and entorhinal cortex, which constitutes a â€œshort-loopâ€ reciprocally excitatory circuit, which may facilitate seizure initiation and/or propagation.

This interaction of ion channel alterations and loss of feedforward inhibition may be further compounded by loss of the selective feedback pathway regulating temporoammonic input, the oriens alveus interneurons that project to stratum lacunosum moleculare. These interneurons normally gate temporoammonic inputs in a feedback manner[7,82,170a] and are selectively lost in epilepsy.[42,65a,114] This would remove a further check on this pathway, allowing reentrant activity to proceed unchecked and loop activity between CA1, subiculum, and entorhinal cortex to escalate.

Is there any evidence that these dendritic ion channel changes evident in spontaneously epileptic animals are mirrored in the kindling model of temporal lobe epilepsy, in which there is little or no cell death? Many of the ion channels have not been studied to the same degree in kindled animals as they have in the postâ€“status epilepticus spontaneous epilepsy models. However, where they have been studied, very little overlap is seen in terms of changes in ion channel expression. A-type potassium channels and T-type calcium channels do not appear to be altered in expression or function in CA1 neurons from kindled animals.[63,163] Other calcium currents do exhibit short- and long-term alterations,[21,45a,163] including the expression of N-type calcium channels in dendritic fields of area CA1.[15,16] However, the latter studies did not discriminate between pre- and postsynaptic loci of these changes, and so they cannot be viewed as directly supporting the concept that dendritic integration is altered following kindling. To emphasize the effects of ion concentrations on the cellular physiology, the sensitivity of the neurons to shifts in potassium concentrations are clearly different between epileptic and naive animals. When placed in increasing concentrations of potassium, the CA1 neurons from rats with limbic epilepsy begin to have spontaneous bursts of action potentials at lower concentrations than neurons from control rats.[93]

Changes in Neurotransmitter-Receptor Expression in Kindled and Epileptic Animals: Spotlight on GABA$_A$-Receptor Alterations in Granule Cells

In addition to the dendritic voltage-gated ion channel alterations described previously, which have been described primarily in pyramidal neurons, neurotransmitter receptor expression and function are also altered significantly in animal models of temporal lobe epilepsy. Much of this evidence is acquired from studies of hippocampal dentate granule cells. This preponderance of findings in granule cells may stem from two primary sources. First, granule cells are very distinct from pyramidal neuron in terms of their properties and embryonic origin, and so they respond in unique ways to stress. Second, granule cells are relatively resistant to excitotoxic death, whereas pyramidal cells are susceptible. Therefore, granule cell findings may be compared more readily between control and epileptic tissue, whereas studies in pyramidal neurons are more difficult to interpret. Any measure needs to be filtered through a background of significant cell death and accompanying gliosis contributing to apparent receptor alterations, particularly when considering in situ hybridization and immunohistochemical studies conducted at the tissue level. In addition, findings in the hippocampal dentate gyrus may assume additional importance because of the pivotal, â€œgatekeeperâ€ role that this structure may play in regulating excitability of the entire entorhinal-hippocampal loop.[61,94]

Although changes in many neurotransmitter receptor systems have been described in models of temporal lobe epilepsy, including GABA$_A$, GABA$_B$, Î±-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), *N*-methyl-D-aspartate (NMDA), and metabotropic glutamate receptors, for the most part there are divergent data when comparing kindling and postâ€“status epilepticus models. The receptor system that seems to exhibit the most uniformity in terms of changes across models is the GABA$_A$-receptor system, particularly in the dentate gyrus. For this reason, this discussion focuses on changes identified in dentate granule cells of kindled and postâ€"status epilepticus models of temporal lobe epilepsy.

GABA$_A$ receptors are hetero-oligomeric protein pentamers, with a preferred stoichiometry of two Î± subunits, two Î² subunits, and a fifth subunit, usually a Î² subunit.[95a] However, in dentate granule cells, a Î´ subunit frequently replaces the Î³ 2 subunit in subsets of receptors, which may change the subcellular location of these receptors as well as their properties. Six Î±, three Î², three Î³, one Î´, and additional families of receptor subunits have been cloned. Receptors comprising differing combinations of subunits have differing kinetic and pharmacologic properties, as well as frequently differing subcellular localization. For example, receptors containing Î± 4 subunits are insensitive to modulation by benzodiazepines, frequently also associate with a Î´ subunit, and are much more sensitive to zinc-mediated inhibition than are receptors containing an Î± 1 subunit. These Î± 4/Î´ receptors tend to be localized extra- or perisynaptically, in contrast to Î± 1/Î³ 2 receptors, which are synaptic. Additional diversity in possible receptor configurations is conferred by alternate splicing of subunits, which has been identified in members of the Î² and Î³ families.[95a] Even given the limitations associated with a preferred pentameric stoichiometry described earlier, clearly there is a potential staggering diversity in possible GABA$_A$-receptor compositions. The

fact that GABA$_A$ receptors assemble into 10 to 20 preferred configurations in brain simplifies the situation somewhat.[107a]

Several studies have been published comparing properties and expression patterns of GABA$_A$ receptors in dentate granule cells of both postâ€"status epilepticus and kindled animal models of temporal lobe epilepsy. For the most part, these studies exhibit a remarkable consensus. The numbers of subsynaptic GABA$_A$ receptors as well as the efficacy of quantal GABAergic synaptic activation both exhibit a marked increase in both kindled animals[119,120] and epileptic animals months after status epilepticus, when rats are spontaneously seizing.[26,35,48,85] In the pilocarpine model, additional evidence has been published demonstrating that the frequency of miniature inhibitory postsynaptic currents (mIPSCs) and the amplitude of local stimulation-evoked IPSCs are reduced, reflecting a reduction in the number of GABAergic synapses associated with a loss of GABAergic neurons rather than any change in synaptic expression of GABA$_A$ receptors.[78]

Accompanying this enhancement in the number of GABA$_A$ receptors (and reduced numbers of GABAergic synapses in postâ€"status epilepticus models) are alterations in the pharmacology of GABA$_A$ receptors. These in turn correlate with and are accompanied by modification in the expression patterns of individual GABA$_A$-receptor subunits. GABA$_A$ receptors in dentate granule cells from either kindled or postâ€"status epilepticus rats exhibit enhanced sensitivity to blockade by zinc, as well as a decreased sensitivity to modulation by benzodiazepines and benzodiazepine site agonists[26,27,35,48,85,115] (reviewed by Coulter[37,38]).

These pharmacologic changes in dentate granule cell GABA$_A$-receptor responses in kindled and postâ€"status epilepticus models of temporal lobe epilepsy, in addition to being informative about possible shifts in subunit expression patterns (discussed later), may also have functional importance. Zinc is a biologically important divalent cation present in high concentrations in the central nervous system, particularly in the dentate gyrus. Zinc densely colocalizes with glutamate in synaptic vesicles of granule cells and is coreleased together with glutamate on activation of excitatory transmission. Extracellular zinc concentrations achieve concentrations of 10 to 100 ÂµM during repetitive mossy fiber activation.[10,67] Furthermore, mossy fibers sprout in epileptic hippocampus in both postâ€"status epilepticus and kindling models and reinnervate granule cells along their dendrites in the inner molecular layer.[95,156] This also occurs in the dentate gyrus of humans with epilepsy,[65,154] as does the appearance of zinc-sensitive GABA$_A$ receptors in dentate granule cells.[148] The apposition of a zinc delivery system and sprouted mossy fibers, together with the de novo appearance of zinc-sensitive GABA$_A$ receptors in granule cells of the epileptic hippocampus, has led to the formulation of the hypothesis that the combination of these two events could lead to a dynamic, zinc-mediated collapse of augmented inhibition in the dentate gyrus during seizure initiation and/or propagation. This in turn would compromise the filter or gatekeeper function of the dentate and facilitate seizures.[27,38] For these events to occur, extracellular zinc, which is released at excitatory synapses, must be sufficiently mobile to diffuse to and block neighboring GABAergic synapses. This has yet to be demonstrated either in vivo or in vitro, and at least one study has questioned whether this may occur.[112]

The pharmacologic data described here are consistent with an Î± subunit switch, which has been found to occur in dentate granule cells in both postâ€"status epilepticus and kindling temporal lobe epilepsy models. In single-cell aRNA amplification studies, Brooks-Kayal et al.[26] described a net downregulation in Î± 1 and an upregulation in Î± 4 subunit expression in individual granule cells that also showed altered $GABA_A$-receptor sensitivity to zinc and the benzodiazepine site agonist zolpidem. This switch occurred within 24 hours of status epilepticus and was permanent, manifest in animals as long as 1 year. Upregulation of Î± 4 subunit mRNA together with a downregulation in delta subunit mRNA has been found in in situ hybridization studies in dentate granule cells in both postâ€"status epilepticus and kindling models of temporal lobe epilepsy,[118] and immunohistochemical studies have corroborated this upregulation in Î± 4 and downregulation of Î´ subunits in the pilocarpine mouse model of temporal lobe epilepsy,[129] with the latter studies further demonstrating that these subunit changes are associated with a reduction of tonic GABA currents in dentate granule cells.

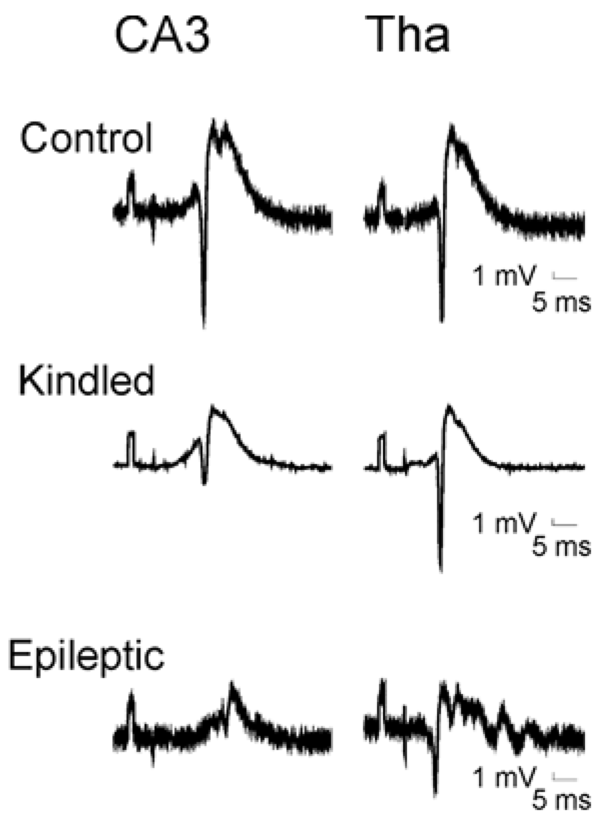

FIGURE 3. Comparison of evoked extracellular responses in CA1 following stimulation of either contralateral CA3 or the midline thalamic (Tha) region in rats. The recording site is the same for both stimulation sites. Although it is clear that there are differences based on the site of stimulation, more important are the differences across the type of animal from which the responses were obtained. Although the responses from the kindled animals are different than those from controls, these two groups are much more alike than the epileptic animals, which have much lower amplitude responses and multiple population spikes.

The consequences of the consensus finding of overall upregulation of subsynaptic $GABA_A$ receptors, reduction in tonic (extrasynaptic) GABA current, and kinetic and pharmacologic changes associated with Î± subunit switches on circuit excitability and seizure susceptibility are complex and difficult to extrapolate in either kindled or postâ€"status epilepticus temporal lobe epilepsy models. As discussed, one possible outcome is that inhibition may collapse on zinc release. A second possibility is that tonic inhibition may play a critical role in gatekeeper function of the dentate gyrus, so that reduction in this current could facilitate propagation of synchronous, epileptiform entorhinal cortical activity into the hippocampus. A third possibility is that these changes may be compensatory, a homeostatic response to hyperexcitability on the part of granule cells. In this case, alternate mechanisms, either within the dentate gyrus or in other structures, would be critical in generation of seizures, and the responses recorded in dentate would attempt to counteract these changes.

Although much of the research has been focused on the myriad of changes in the GABAergic system with an emphasis on the dentate gyrus, there is evidence for changes in the GABAergic system at other limbic sites. Furthermore, other neurotransmitter systems show evidence for alterations in the nature of drug effects as well as pharmacosensitivity. Although the work on these other regions, receptors, and channels has not come close to the depth or breadth of the studies on GABA function in the dentate, the evidence is clear. In CA1 the alterations in IPSP, including the $GABA_A$ and $GABA_B$ components, is profound, and there is evidence for changes in the presynaptic $GABA_B$ receptors as well.[101] There is evidence that the effect of drugs that work through the glutamatergic system is also profoundly different in epileptic animals. In some cases, drugs that have little effect in naive animals have a significant effect in epileptic animals, and in other cases, the opposite is true.[9,77,171,172] What is very interesting in these and other studies is that the pharmacology and physiology of kindled animals is very different from those in epileptic animals (Fig. 3).[20] This point is extremely important because it emphasizes that epilepsy is a very different condition than having experienced seizures.

Summary and Conclusions

This chapter is a complex mixture of the clinical and the scientific, crossing from the intact system to the synapse. There are several recurring themes in this data soup. First, it is essential to separate the underlying condition of epilepsy from the potential effects of seizures on the system. In this regard the message is fairly clear: The effect of the seizures on the system is not nearly as great as the changes associated with epilepsy itself. Another clear message is that there is no single change associated with epilepsy: There are changes in neuronal populations, channels, and receptors. Furthermore, there is strong and growing evidence that these changes precede the onset of epilepsy, suggesting that the contributions of seizures to the findings are limited (although there are clear contributions from the seizures). Finally, epilepsy likely has a unique pharmacology. This observation is extremely important as we continue the search for more effective therapies: We need to consider those epilepsy-specific changes so that we can develop epilepsy-specific drugs.

Chapter 41

Basic Mechanisms of Human Epilepsy

Jerome Engel Jr.

Marc A. Dichter

Philip A. Schwartzkroin

Introduction

Most of our views concerning the fundamental neuronal mechanisms of epileptic phenomena derive from investigations carried out on experimental animal models. An anonymous bioscientist, however, once stated, â€œThe best model of a cat is a cat, and preferably the same cat,â€ implying that the ideal approach to studying basic mechanisms of human epilepsy is actually to study patients with epilepsy. Although direct examination of the epileptic human brain has become much more feasible in recent years, experimental paradigms are severely limited by cost and ethical considerations. As a result, animal models remain an essential part of basic research into the pathophysiology of human epilepsy. Animal models are invaluable for expanding upon concepts, derived from observations of patients, that cannot be pursued with further human experimentation. Conversely, research on patients with epilepsy is essential to validate the relevance of data obtained from animal models. Both these goals are best met by designing parallel investigations involving patients with epilepsy and experimental animal preparations. Such parallel studies are greatly facilitated today by new clinical tools, such as advanced noninvasive structural and functional neuroimaging, and the unique opportunities for invasive investigations in vivo and the utilization of human tissue in vitro that exist in association with the surgical treatment of epilepsy.[38,48,102] Progress in molecular genetics promises yet another powerful means, not only for establishing similarities between specific animal models and human epileptic disorders, but also for defining epileptogenic defects in the human brain that can be precisely replicated in the animal laboratory.

There are many forms of human epilepsy, which undoubtedly reflect a variety of pathophysiologic mechanisms. In fact, a single, well-defined human epileptic condition, and even an individual epileptic seizure, involves several specific disturbances in neuronal function that occur simultaneously or in sequence before clinical manifestations appear. To carry out parallel studies in patients and animals, it is important to realize that few, if any, human epileptic conditions can be faithfully modeled in toto in the experimental animal laboratory. Consequently, it is necessary to identify and define component parts of human epilepsy that can be more easily investigated individually and replicated in animals.[33,35] This chapter, therefore, first considers one strategy for dissecting out components of epilepsy, and then examines what has been learned about the basic mechanisms of these component parts from parallel studies of the human condition and appropriate animal models.

Components of Human Epilepsy

An *epileptic seizure* is an acute event that can be a natural, albeit pathologic, reaction of a normal brain to a noxious insult. Although an epileptic seizure that has been acutely induced in an animal model may replicate certain aspects of epileptic seizures occurring in patients with epilepsy, the underlying intrinsic and enduring epileptogenic abnormality responsible for *recurrent* epileptic seizures in patients with epilepsy is missing in this situation. Consequently, investigations of acute seizures induced in otherwise normal experimental animal models provide limited information about the pathophysiologic substrates responsible for repeated *spontaneous* seizure generation in patients. Nevertheless, much information can be gained about mechanisms of ictal precipitation, ictal propagation, ictal termination, and postictal phenomena.

Epileptogenesis, or the mechanism by which an epileptic condition is acquired, undoubtedly takes many forms, but it is most evident in secondary (symptomatic) human epileptic conditions, in which habitual recurrent seizures begin many months or even years after lesions occur in the brain. Epileptogenesis has been studied in animals by introducing into the brain certain metals, such as alumina cream, and more recently by inducing status epilepticus (SE) with excitotoxins, such as kainic acid (KA) and pilocarpine, or electrical stimulation; this results in structural lesions and the development of recurrent spontaneous seizures.[95] The process of epileptogenesis has also been brought under more precise laboratory control with the various kindling models of epilepsy.[80]

Just as basic research on epilepsy made a paradigm shift with the realization that animals with chronic epilepsy more faithfully model the human condition than do epileptic seizures induced in a normal brain, investigations with animal models now requires a second paradigm shift. Given that a genetic predisposition often exists to symptomatic human epilepsies, identification of susceptibility genes and other predisposing factors should make it possible to create more realistic animal models of epileptogenesis by inducing a chronic epileptogenic lesion in a brain with these predisposing factors.[40]

The *interictal state* represents a period of relative quiescence, during which the enduring pathophysiologic disturbances that predispose to the spontaneous recurrence of epileptic seizures are minimally active, or held in abeyance by some active seizure-suppressing mechanism. These diverse phenomena can be studied in the laboratory, using animal models of chronic epilepsy in which seizures are generated spontaneously.

Ictal onset represents a functional transition from the interictal state; it can reflect a variety of processes, depending on the underlying pathophysiology and the type of ictal manifestation.[34] Increases in excitation or synchrony, decreases in seizure-suppressing mechanisms, and nonspecific precipitating factors can be studied during transition to ictus in animal models of chronic epilepsy.

Many types of seizures occur, and the *ictal state* undoubtedly reflects a variety of aberrant neuronal mechanisms involving different patterns of excitatory and inhibitory events, different synchronization processes, and different brain regions and pathways. Individual ictal events often also show evolution,

P.496

involving a variety of forms of propagation of ictal discharge and resulting in variable ictal mechanisms specific to the region to which propagation has occurred. With focal seizures, this includes local spread, propagation to structures that impair consciousness when simple partial seizures evolve to complex partial seizures, and propagation to structures that generate generalized convulsive manifestations when seizures secondarily generalize. Such propagation patterns, and peculiarities of ictal discharges in particular brain regions, can be studied in the animal laboratory with acute as well as chronic models. However, pathways, and therefore ictal spread, vary across species and may not accurately replicate the human condition; for example, interhippocampal connections are strong in rats and weak in humans, a difference that can affect the manifestations of temporal lobe seizures.[121]

Ictal termination also takes many forms. It undoubtedly involves both active and passive neuronal mechanisms, which vary according to seizure type and underlying pathophysiology. Even though ictal termination can be easily investigated using animal models of acute seizures, relatively little research has been carried out on this phenomenon, compared with the attention given to ictal onset.[25]

The *postictal period* can be associated with brief or prolonged neuronal dysfunction, ranging from isolated focal neurologic deficits to coma. These clinical disturbances presumably reflect, at least in part, the enduring effects of active mechanisms that act to terminate the ictal state.[16]

Interictal behavioral disturbances can represent the enduring consequences of repeated epileptic seizures or can be produced by the underlying brain disturbance/damage that is responsible for the seizures themselves. Underlying mechanisms that have been implicated in long-term effects of epilepsy include (a) specific structural damage, which might be the result, rather than the cause, of seizures; (b) transsynaptic functional changes, such as those modeled by kindling; and (c) side effects of natural seizure-suppressing mechanisms that are necessary to maintain the interictal state. Some animal research is being carried out to elucidate mechanisms of epilepsy induced interictal behavioral disturbances. However, given the degree of clinical disability that can be attributed to these disturbances, more effort in this area of research should be encouraged.[39]

Studies of Human Epilepsy

With the preceding dissection of epileptic phenomena as a framework for organizing the approaches to research into basic mechanisms of human epilepsy, the remainder of this chapter focuses on how the results of investigations of human epilepsy confirm or contradict concepts derived from the results of studies carried out on experimental animal models.

Epileptogenesis and the Interictal State

The primary (idiopathic) epilepsies are genetically transmitted, typically have an age-related onset, and may resolve spontaneously after several years. These disorders are presumably caused by defects that manifest themselves as epileptic seizures only at vulnerable periods during cerebral development. Epileptogenesis, or the active process of creating an epileptic condition, is therefore difficult to evaluate in these conditionsâ€"although it is certainly possible that genetically determined abnormalities may be elaborated as the brain matures, and thus a process of epileptogenesis is likely to also occur in these types of epilepsies. The secondary (symptomatic) epilepsies, however, usually result from structural disturbances that become epileptogenic lesions during some finite period. In patients with epilepsy caused by metabolic diseases, congenital malformations, or intrinsic substrates such as neoplasia, the timing of this process is undeterminable; however, in others (e.g., those in whom epilepsy develops following head trauma or a cerebrovascular accident), the existence of a well-defined â€œlatent periodâ€ is well documented. Presumably, the damaged brain reorganizes during this period in a manner that ultimately predisposes to the recurrence of detectable, spontaneous epileptic seizures.

Clinical data indicate that the likelihood that epilepsy will develop after an epileptogenic insult depends on the area of brain damaged, type of damage, age at which the damage occurred, and genetic predisposition.[70] It is clear from clinical experience that mechanisms accounting for the occurrence of acute seizures at the time of, or shortly after, an epileptogenic cerebral insult are different from those accounting for the development of a chronic epileptic condition many months or years later; that is, early seizures do not necessarily predict late seizures, and the risk factors for epileptic seizures occurring at the time of head trauma or stroke are not exactly the same as those for the development of late posttraumatic epilepsy[70] (Table 1), although early seizures may indicate an increased risk of later development of epilepsy.[70] Furthermore, whereas the immature brain is more susceptible to acute seizures than the mature brain, it is less likely than the mature brain to generate subsequent spontaneous recurrent seizures, given the same initial insult.[91,101] The clinical expression of the process of epileptogenesis in the human brain (e.g., clinical seizures) following injury-associated insult can require considerable time, although this is not well understood.[55] The anatomic reorganizations that are currently hypothesized to underlie the epileptogenic process, however, cannot be the only epileptogenic factors involved, because the latent period can be much longer than expected for such changes to take place; the increased risk for epilepsy after head trauma persists for well over 10 years,[70] even though chronic epilepsy develops in more than half of such cases within the first year.

Table 1 Risk factors for epileptic seizures and epilepsy after nonmissile head trauma

Early seizures
Intracranial hematoma
Focal neurologic signs
Posttraumatic amnesia >24 hours
Any neurologic signs
Depressed skull fracture
Subarachnoid hemorrhage
Injury before 5 years of age
Linear skull fracture

Late seizures
Intracranial hematoma
Early seizures
Depressed skull fracture
Posttraumatic amnesia >24 hours
Injury after 16 years of age

Adapted from Jennet B. *Epilepsy After Non-missile Head Injuries,* 2nd ed. Chicago: William Heinemann; 1975, with permission.

It is also important to note that the brain reorganization underlying epileptogenesis (see the next section) is not necessarily a product of an epileptogenic *insult*, but may be determined by genetic factors (i.e., aberrant brain developmental processes). At the very least, it is quite clear from studies of animal models that genetics contribute significantly to epilepsy predisposition.[118]

Our current understanding of the basic mechanisms of human epileptogenesis derives largely from studies of patients with mesial temporal lobe epilepsy (TLE), perhaps the most common human epileptic condition.[103] Because mesial TLE is often medically refractory and treated preferentially by surgical resection, extensive diagnostic testsâ€"at times involving in vivo invasive electrophysiologic recordingsâ€"are carried out, and excised tissue becomes available for in vitro investigations. The pathologic substrate that is most often associated with the clinical condition known as *mesial TLE* is hippocampal sclerosis.[6,23] Microscopic examination of mesial temporal structures has further defined the kinds of lesions seen in the parts of medial temporal lobe removed from patients with hippocampal sclerosis. These include losses of neurons in almost all hippocampal regions, with a heavier loss in the hilus, CA1, and CA3, and lesser losses in CA2 and dentate gyrus (DG) granule cell (GC) layer. In addition, clear synaptic reorganization is present, with collaterals of surviving DG granule cells reinnervating the inner molecular layer of DG GC dendrites, as well as inhibitory interneurons scattered throughout the DG (see Chapter 13). It is becoming increasingly apparent that patients with this condition also have much more widespread extrahippocampal pathological changes as well.[120]

The lesions seen in mesial TLE with hippocampal sclerosis in human brain have been modeled in the animal laboratory using a variety of techniques that cause hippocampal cell loss and neuronal reorganization.[9,75,111,113,115] Whereas the progression of epileptogenic changes can be examined in these animal models, studies of patients with medically refractory mesial TLE reveal only the end results of the epileptogenic process. The pathologic changes observed in these patients could be either the cause or the effect of recurrent epileptic seizures; if the latter, they could result in further epileptogenicity or reflect natural homeostatic mechanisms acting to suppress seizure occurrence. It is also important to note that the sclerotic hippocampus, despite all our attention, may not be the primary epileptogenic region in some patients with mesial TLE. Research results are confounded by the fact that there is no adequate control tissue for human studies, because epileptiform abnormalities can be widespread and often involve both temporal lobes; in addition, evaluations are complicated by the superimposed effects of antiepileptic drugs (AEDs), which have invariably been used.[38] Nevertheless, important insights have been derived from anatomic, neurochemical, electrophysiologic, and molecular investigations of this human condition.

Hippocampal sclerosis, induced in rats by intrahippocampal injection of KA, is characterized by general cell loss but more pronounced loss of specific neurons, relative preservation of some inhibitory interneurons, and axonal sprouting resulting in the creation of aberrant circuits, gliosis, neurogenesis, and laminar dispersions of the dentate gyrus.[9,64,78,92] All these pathologic changes have been demonstrated in surgically resected specimens of human hippocampal sclerosis, suggesting that the epileptogenic process in human mesial temporal lobe epilepsy resembles that of rats injected with KA.[5,23,67,110] In addition, amygdala sclerosis has been described,[65] and some animal models show evidence for selective entorhinal cell loss.[26] Inflammatory processes also play a role in epileptogenesis in some experimental models.[116] Mossy fiber sprouting could create powerful recurrent excitatory feedback that might contribute to the development of epileptiform potentials. Such an enhanced excitatory drive is suggested by the observation of increased extracellular levels of excitatory amino acids obtained during microdialysis of human epileptic brain[29] and chronic alteration in glutamate receptors in human epileptogenic tissue.[52,53,63] Conversely, there is also evidence that a significant number of aberrant mossy fibers terminate on interneurons, which increases inhibition.[106]

Investigations of human mesial TLE have yielded inconsistent results concerning inhibitory influences. Inhibitory interneurons appear to be preferentially preserved, and sprouting of inhibitory terminals may also occur.[8,22] The results of microdialysis studies are equivocal, with evidence for both increased and decreased release of Î³-aminobutyric acid (GABA).[27] Positron emission tomography (PET) consistently reveals a reduction in benzodiazepine receptor binding in human epileptogenic regions;[60,100] this may merely reflect cell loss, but it could also indicate a selective decrease in postsynaptic inhibitory mechanisms or a receptor downregulation resulting from enhanced presynaptic inhibitory neurotransmitter release.

In vitro electrophysiologic studies of human sclerotic hippocampal slices have been difficult to perform, but there is some suggestive evidence of increased membrane excitability,[78] which may be mediated by *N*-methyl-D-aspartate (NMDA) receptors;[66] parallel animal studies also show enhanced GABA-mediated inhibition,[90] and some studies on human tissue support this.[5,50] In vivo electrophysiologic studies also indicate enhanced inhibitory influences in some areas of the human epileptogenic hippocampus and enhanced excitatory influences in others.[19,47,122] Enhanced inhibition of the epileptic hippocampus could reflect natural protective mechanisms; however, it is intriguing to note that enhanced inhibition could also predispose to the appearance of epileptiform hypersynchronization.[36] Recordings from resected human tissue in a slice chamber have been somewhat disappointing with regard to recreating the epileptiform discharges often recorded in vivo from the same tissue. Spontaneous interictal discharges are usually lacking, and seizure-like discharges can only be elicited after threshold-lowering maneuvers such as reducing inhibition or raising extracellular potassium (K).[14] More recent work suggests that recordings from parahippocampal regions (subiculum and entorhinal cortex) may more closely mimic in vivo phenomena. It has also been suggested that the enhanced excitability and increased synchrony in these regions may be related to altered intracellular chloride concentrations, such that normally inhibitory synaptic actions may become excitatory.[18]

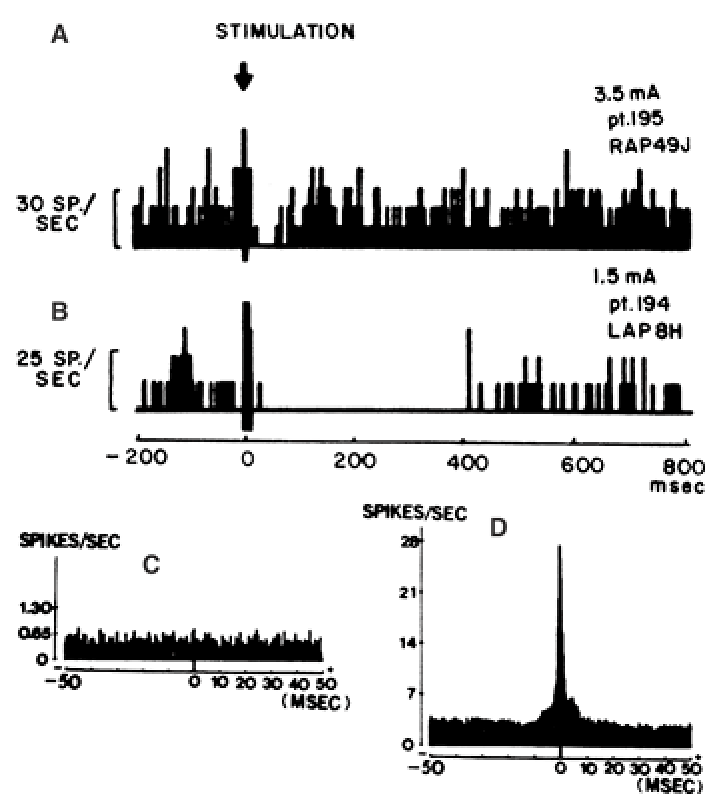

FIGURE 1. Unit histograms from human epileptic hippocampus show weak firing suppression (**A**) in

neurons that were not firing synchronously as determined by cross-correlation histograms (**C**), and strong firing suppression (**B**) in neurons that were firing synchronously (**D**). This provides indirect evidence for recurrent inhibitory circuits as a mechanism of hypersynchronization. From Isokawa-Akesson M, Wilson CL, Babb TL. Prolonged inhibition in synchronously firing human hippocampal neurons. *Epilepsy Res.* 1989;3:236â€"247, with permission.

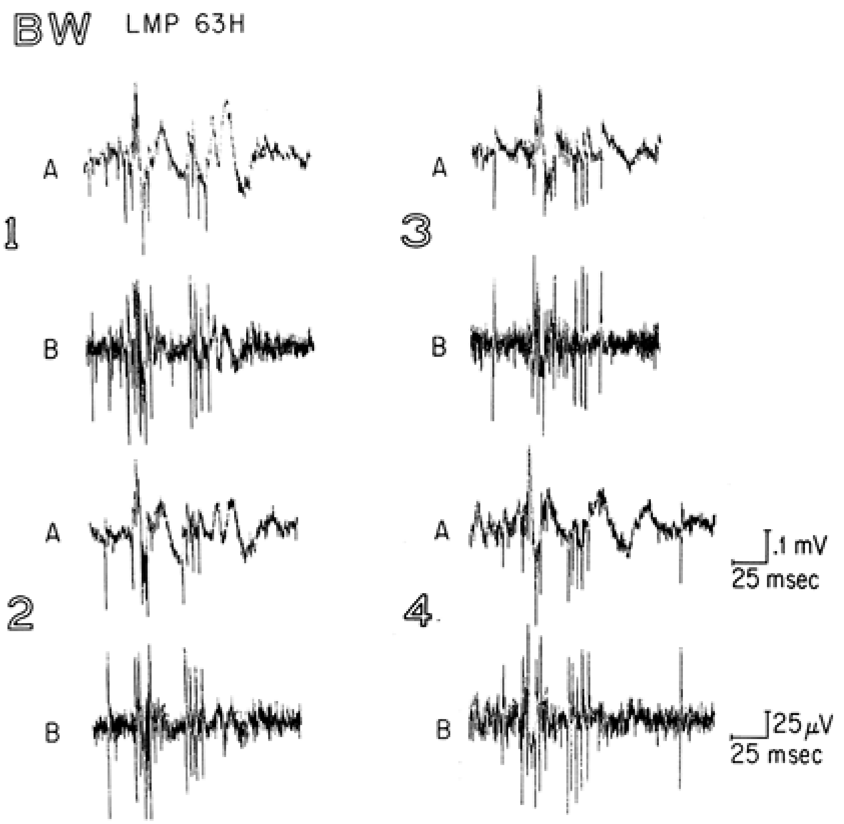

FIGURE 2. EEG spikes (**A**) and action potentials (**B**) recorded from the same microelectrode (*63H*) in the left midhippocampal pes (*LMP*) in a patient with clinical seizures originating in the LMP. *Tracings 1 through 4* were taken from the beginning to the end of the recording period and selected to have a similar EEG spike morphology, characterized by a fast rise time of the initial negative component. *Tracing A* is a wide-band recording to show the EEG spike-and-slow wave superimposed on the unit discharges. For *tracing B*, additional high-pass filtering was used to enhance the neuronal discharges. Note increased unit firing during EEG spike, and cessation of unit firing during EEG slow wave. From Babb TL, Crandall PH. Epileptogenesis of human limbic neurons in psychomotor epileptics. *Electroencephalogr Clin Neurophysiol.* 1976;40:225â€"243, with permission.

Unit recordings obtained from human epileptic hippocampus in vivo demonstrate that cells that receive strong inhibitory input are highly synchronized[68] (Fig. 1), suggesting that inhibition does play a role in the development of epileptiform hypersynchronization in TLE, just as it does in absence epilepsy[83] and in the promotion of normal rhythmic neuronal activity.[2]

The interictal state in human mesial TLE is characterized by the appearance of interictal electroencephalographic (EEG) spike-and-slow-wave discharges in the epileptogenic temporal lobe, and often independently in the contralateral temporal lobe as well. Microelectrode recordings demonstrate that the spike is associated with increased unit firing, and the slow wave with absence of unit firing (Fig. 2),[7] suggesting that this epileptiform transient reflects synchronous paroxysmal depolarization shifts and afterhyperpolarizations of neurons within the epileptogenic hippocampus, in much the same way as occurs in the experimental penicillin focus.[24] These abnormal excitatory and inhibitory events occur relatively infrequently, and the overall interictal state of the epileptogenic region in this disorder is one of relatively decreased activity, as reflected in the hypometabolism seen on PET using ^{18}F-fluorodeoxyglucose.[61] It would appear therefore that the synaptic reorganization observed in human hippocampal sclerosis are associated with a chronic state of relative quiescence, but a propensity for hypersynchronous excitatory and inhibitory discharges.

It has been suggested that hippocampal reorganization alone, and the resultant repetitive hypersynchronous ictal discharges limited to the hippocampus, is not sufficient for the clinical manifestation of epileptic seizures. In fact, these electrographic ictal phenomena can be recorded with depth

P.498

electrodes, unassociated with clinical signs or symptoms.[108] Complex partial, and perhaps even simple partial, seizures would seem to require propagation of ictal discharge to adjacent and distant structures, which might be facilitated if these structures were particularly receptive and themselves epileptogenic. Secondary epileptogenesis, as occurs with kindling and the mirror focus phenomenon,[88] could conceivably account for transsynaptic changes necessary for behaviorally apparent ictal events to ensue. In primates, bilateral hippocampal lesions may be necessary before temporal lobe seizures can be observed,[107] and in patients with medically refractory TLE, some degree of bilateral mesial temporal epileptogenicity is the rule rather than the exception.[119] Patients with mesial TLE and hippocampal sclerosis often experience the recurrence of auras after radical anterior temporal removal has succeeded in abolishing the habitual complex partial seizures. Perhaps the epileptiform region is widespread from the beginning, or perhaps secondary epileptogenicity results in extension to the ipsilateral posterior hippocampus, contralateral hippocampus, or wide areas of limbic cortex in either hemisphere.

There are reasons to believe that focal epileptic conditions caused by specific structural lesions, such as neoplasms, cortical dysplasias, vascular malformations, cysts, scars, or infectious processes (so-called lesional epilepsies), involve epileptogenic mechanisms that differ from those of hippocampal sclerosis.[58] Whereas mesial TLE is usually associated with diffuse interictal hypometabolism on fluorodeoxyglucose PET, this is a rare finding with neocortical lesional epilepsy.[62] Furthermore, surgical results for mesial TLE appear to depend on the amount of adjacent entorhinal cortex removed,[105] whereas surgical cures can occasionally be achieved in lesional epilepsy by removal of the lesion alone, with the adjacent cortex left intact.[17] Therefore, for some lesional epilepsies, the lesion might produce an epileptogenic irritation that does not require reorganization of adjacent cortical neurons. This is an area that has not been very well explored in the literature. It is important to note here, however, that even with apparent â€œcuresâ€ achieved by resection of specific lesions, other regions (or lesions) that had previously been electrically innocuous may

P.499

become â€œepileptogenicâ€â€”suggesting either some more diffuse abnormality and/or a subsequent epileptogenic process.[98] Focal epilepsies associated with localized areas of dysplastic cortex represent a unique category of disorder related to disturbances in neuronal migration and differentiation.[117] It is unclear whether the bizarre neurons and aberrant neuronal connections in these areas are directly responsible for seizure generation, or whether they merely represent a marker for a variety of less apparent disruptions in neuronal integration that are responsible for the appearance of spontaneous epileptic seizures (see Chapter 14). Certainly, children with extensive dysplasias also show evidence of hippocampal cell loss and abnormal axon sprouting similar to that of hippocampal sclerosis.[79] However, human[81] and animal[99] studies confirm that these dysplastic regions do have epileptogenic properties.

In a third group of secondary focal epilepsies, no association is found with a demonstrable structural lesion or hippocampal sclerosis. Presumably, these conditions are caused by structural lesions that cannot be seen using standard neuroimaging techniques or, in many cases, even using the pathologist's microscope after surgical resection of an electrophysiologically demonstrated epileptogenic region. These epilepsies might be caused by specific lesions identical to those of lesional focal epilepsies, but are too small or too disseminated to be detected; they could reflect neocortical cell loss and synaptic reorganization similar to what is seen in hippocampal sclerosis but that cannot be identified by present histopathologic technology; or they may reflect molecular changes (and related changes in gene expression) that are not manifest at the level of structural cell loss or reorganization. It is also conceivable that some forms of nonlesional neocortical focal epilepsy result from unique pathophysiologic substrates that have yet to be recognized and that might lead to entirely new concepts of human epileptogenesis.

Ictal Onset

Routine EEG recordings obtained from patients during epileptic seizures provide ample evidence of the existence of a variety of ictal phenomena. The classic *grand mal* convulsion, whether occurring spontaneously in an individual with primary generalized epilepsy or artificially induced (e.g., during electroconvulsive shock treatment for depression), typically begins with a widespread buildup of low-voltage fast activity referred to as a *recruiting rhythm*. This is distinctly different from the characteristic high-voltage, three-per-second, generalized spike-and-wave discharge seen at the onset of typical absence seizures in patients with childhood absence epilepsy and other forms of primary generalized epilepsy.[34] Although the actual generators for these ictal events have not been identified in patients, animal studies and responses of patients to various AEDs clearly indicate that they reflect different epileptogenic mechanisms. Recent studies have focused on attempting to recognize features of ictal onset so as to predict the approach of seizure activity well before the typical EEG and clinical/behavioral signs become apparent.[74] The difficulty of this enterprise, and the variable success of the different approaches (mostly based on nonlinear dynamic analysis of EEG) certainly confirm the feasibility of recognizing brain changes well before seizure onsetâ€”and also are consistent with the view that different seizures and/or seizure types are associated with significant variability (in form and underlying mechanisms) in ictal onset.

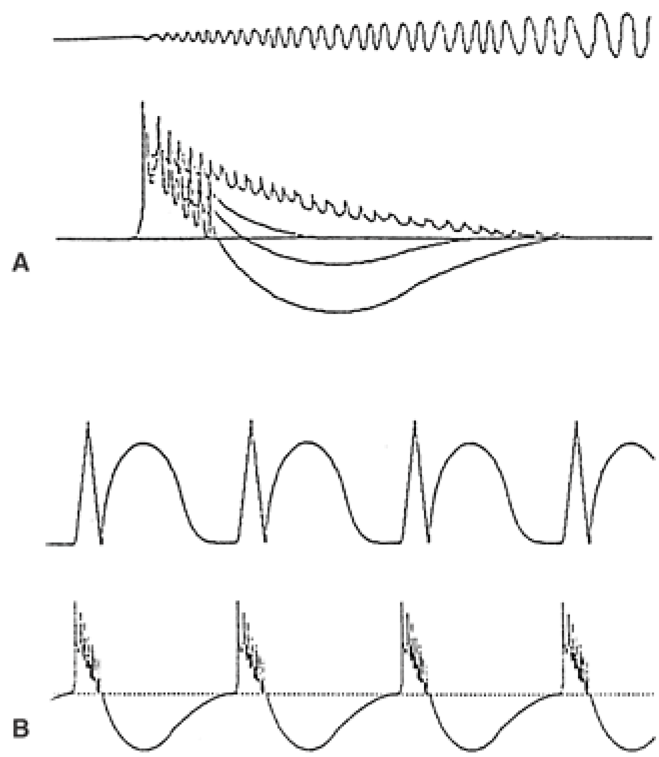

FIGURE 3. A: The neuronal mechanism of the recruiting rhythm is illustrated schematically here. The *lower trace* represents an intracellular recording of a paroxysmal depolarization shift (*PDS*); it demonstrates how the afterhyperpolarization gradually disappears to become an afterdepolarization, giving rise to continuous, high-frequency action potential discharge. The EEG in the *upper trace* increases in amplitude and slows in frequency as more and more neurons are recruited into this process and develop increasing synchrony. **B:** The neuronal mechanism of a hypersynchronous ictal discharge is schematically illustrated here. The *lower trace* shows an intracellular recording of recurrent depolarizations. As with the interictal spike-and-wave discharge, the EEG spike, seen in the *upper tracing*, represents a summation of depolarizations, whereas the EEG slow wave represents a summation of afterhyperpolarizations. In the ictal state, however, each hyperpolarization is followed immediately by another depolarization, creating a repetitive hypersynchronous discharge such as the classic three-

per-second spike-and-wave pattern of *petit mal* absences. A similar mechanism appears to underlie some partial ictal events as well. From Engel J Jr. Functional explorations of the human epileptic brain and their therapeutic implications. *Electroencephalogr Clin Neurophysiol.* 1990;76:296â€“316, with permission.

Intracellular investigations of membrane events occurring during the transition to ictus, as originally studied in the experimental penicillin focus, demonstrated a disappearance of the presumably protective afterhyperpolarization during the interictal spike-and-wave transient, and gradual appearance of an afterdepolarization accompanied by rapid action potential discharges.[24,80] These events were synchronized among many neurons in the epileptic focus and appeared in the field recordings as a transient high-frequency discharge. Therefore, such disinhibitory ictal membrane changes are consistent with the EEG recruiting rhythm of generalized convulsive seizures.

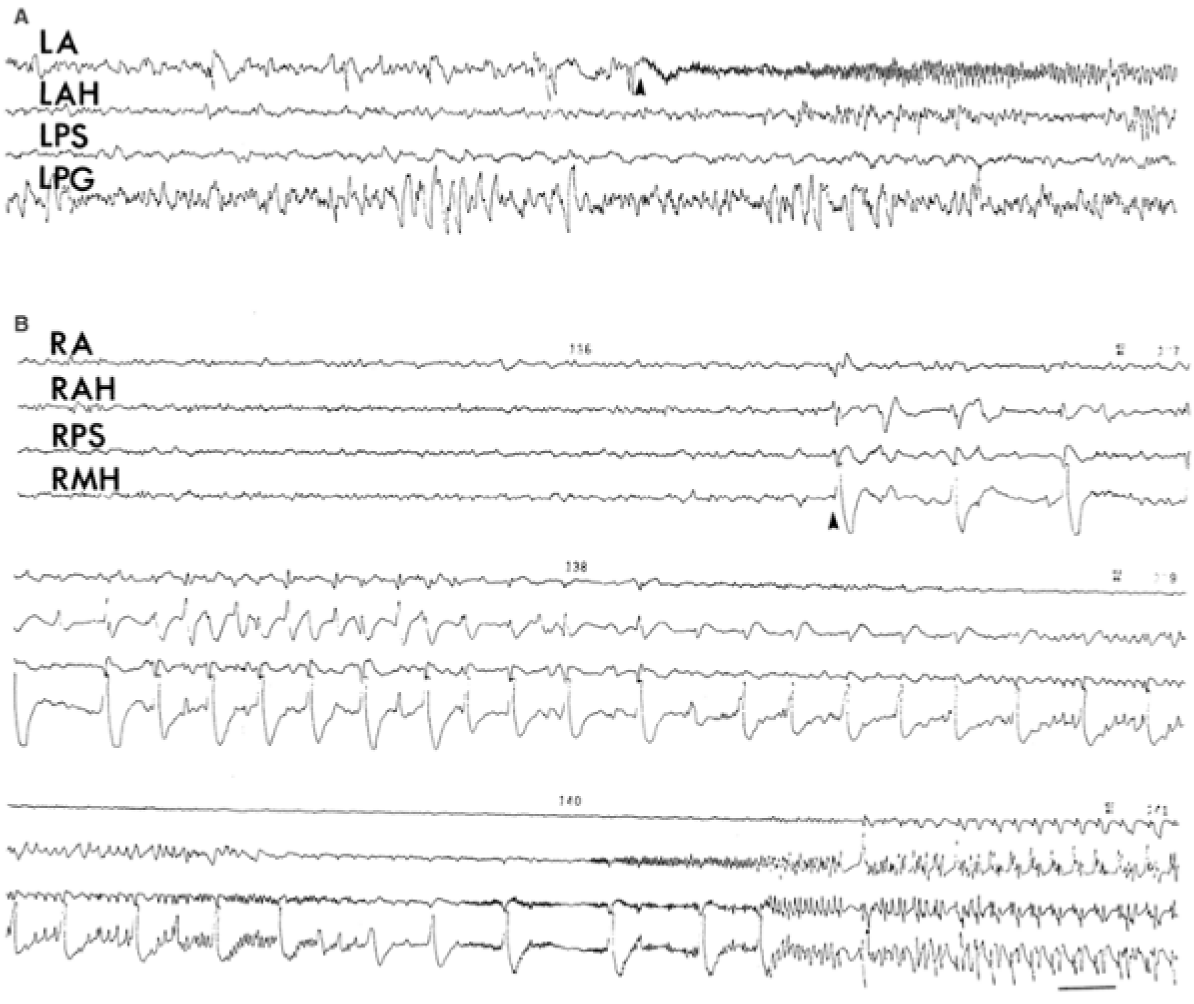

FIGURE 4. Segments of telemetry recordings from two patients showing EEG activity at selected depth electrode bipolar tips during the onset of complex partial seizures. **A:** The classic, depth electrodeâ€“recorded ictal onset consists of a buildup of low-voltage fast discharge, here beginning in a single channel (*arrow*). **B:** Three continuous segments show a more common ictal onset pattern, beginning with rhythmic, high-amplitude, sharp and slow transients (*arrow*), eventually giving way to a low-voltage fast discharge, which then evolves into higher-amplitude repetitive spikes or spikes-and-waves. *L*, left; *R*, right; *A*, amygdala; *AH*, anterior hippocampus; *MH*, midhippocampus; *PS*, presubiculum; *PG*, posterior hippocampal gyrus. FIGURE 5. Forty continuous seconds of an EEG recorded from depth, sphenoidal, and scalp electrodes during a simple partial seizure of the right temporal lobe. Ictal onset consists of an increase in interictal spike discharges, maximal at the right anterior hippocampal electrode (*left portion of upper panel*). After 8 to 9 seconds, these spikes become regular, eventually developing into a 3-Hz spike-and-wave pattern involving all derivations from the right mesial temporal lobe. Note that no low-voltage fast activity is seen, either initially or at any part of the ictal episode. The patient reached for the call button at the *arrow*, at which point regular slow activity is also seen in the left anterior hippocampus and in the right sphenoidal electrode. The patient then indicated an aura consisting of a sensation of fear in her stomach. Depth electrode locations indicated as in FIGURE 4. Superficial contacts from anterior (*A*), mid (*M*), and posterior (*P*) depth electrodes recorded from cortex of middle temporal gyrus (*MTG*). Calibration, 1 second. From Engel J Jr. Brain

Metabolism and Pathophysiology of Human Epilepsy. In: Dichter M, ed. *Mechanisms of Epileptogenesis: Transition to Seizure*. New York: Plenum Press; 1988:1â€"15, with permission.

By contrast, the transition between interictal and ictal states of primary generalized absence seizures, in which the prominent slow wave persists in the rhythmic spike-and-wave pattern, indicates preservation of the inhibitory afterhyperpolarization (Fig. 3). Studies of the generalized feline penicillin model, in which large doses of intramuscular penicillin in the cat produce absence-like seizures associated with rhythmic spike-and-wave discharges, demonstrate that the EEG slow wave in this animal model is a reflection of chloride-sensitive afterhyperpolarizing potentials, indicative of GABA-mediated inhibition.[54] In fact, some GABA agonists make absence seizures worse.[56] One conclusion drawn from these data is that at least some forms of human spike-and-wave absence seizures reflect abnormally enhanced inhibition, and that the enhanced inhibition helps to produce and maintain a state of epileptic hypersynchrony. Pharmacologic studies have implicated low-threshold calcium (Ca) currents in thalamic pacemaker neurons as being responsible for driving the

P.500

hypersynchronous spike-and-wave discharges of human absence epilepsy.[20] This pattern is activated by membrane hyperpolarization caused by $GABA_B$ receptor-mediated inhibitory input.[4] Typical absence seizures are associated with increased glucose metabolism, seen with ictal fluorodeoxyglucose PET,[44] consistent with evidence that GABA-mediated inhibition requires energy.[1] Furthermore, H_2O-PET studies show that thalamic blood flow is selectively increased, supporting a principal role for this structure in generating spike-and-wave discharges.[96] There are conflicting data in the literature, however, concerning the metabolic correlates of different types of human absence seizures,[45] as well as of putative experimental animal absence models, suggesting that more than one pathophysiologic mechanism likely underlies the various types of spike-and-wave ictal events.

In the past, it was widely assumed that human focal seizures were generated by neuronal mechanisms resembling the disinhibitory form of transition to ictus originally described in the experimental penicillin focus.[24,80] Indeed, EEG recordings during transition to seizures in patients with partial epilepsy often reveal a localized low-voltage fast rhythm or an attenuation of normal rhythmic activity, which presumably reflects a more distant manifestation of the same electrographic phenomenon. This buildup of low-voltage fast activity can be more readily appreciated with direct recording from the human brain, as is usually achieved with subdural grid or strip electrodes used to delineate neocortical epileptogenic regions in patients who are candidates for surgical treatment.[3] However, depth electrode recordings from human epileptic hippocampus in patients with mesial TLE undergoing evaluation for surgical therapy are more likely to reveal high-amplitude sharp, or sharp-and-slow, transients than a localized recruiting rhythm as the first electrographic ictal event[36,72] (Figs. 4 and 5). This ictal EEG pattern usually occurs during the simple partial seizure

P.501

(aura), and it can also be seen without any clinical correlate. Typically, propagation from the site of onset does not occur unless the hypersynchronous ictal discharge evolves into a recruiting rhythm.

These clinical observations suggest that there must be more than one form of transition to ictus in human partial epilepsy, and perhaps that the fundamental neuronal mechanisms underlying the generation of limbic seizures originating in sclerotic hippocampus might be different from those of some forms of neocortical epilepsy. Understanding of transition mechanisms, as indicated in the earlier discussion, requires an appreciation of the neuronal mechanisms that contribute to both excitability and synchronization. The hypersynchrony characteristic of ictal discharge can be generated by a variety of mechanisms, ranging from â€œconventionalâ€ connectivity associated with chemical synapses to less well understood interactions

P.502

based on electrical synaptic connection, changes in extracellular milieu, and abnormal reactions of local astrocytes.[11,71,89] These variables, along with differences in regional connectivities, undoubtedly can contribute in different ways to the transition to ictus. For example, connections between the two hippocampi in humans are functionally poor;[121] consequently, the fact that hippocampal hypersynchronous ictal discharges evolve into a low-voltage fast rhythm typical of some neocortical seizures before contralateral propagation could reflect a spread of activity from the hippocampus to adjacent neocortex, or it could represent a particular property of the low-voltage fast rhythm per se, which is necessary for projection along fiber tracts to distant areas of the brain. However, because hypersynchronous hippocampal ictal discharges also fail to propagate in the kainate rat model of mesial TLE, in the presence of a well-developed hippocampal commissure, it is likely that failure of this pattern to propagate reflects intrinsic properties of the involved structures that prevent spread, and not loss of commissural projections per se. It has been proposed that propagation is opposed by increased inhibition of the DG, the so-called dentate gate.[48]

If the hypersynchronous focal discharges associated with hippocampal sclerosis do require inhibitory mechanisms, then different types of inhibition with different spatial distributions would be both pro- and antiepileptogenic in the same structure. The implications of this interpretation are clear: Multiple fundamental epileptogenic disturbances can give rise not only to different types of focal seizures, but also to the different manifestations that characterize the evolution of a single focal seizure. Therefore, different therapeutic interventions may be required to prevent or terminate each of these phenomena. In fact, drugs that act to suppress one part of a seizure could conceivably exacerbate another.

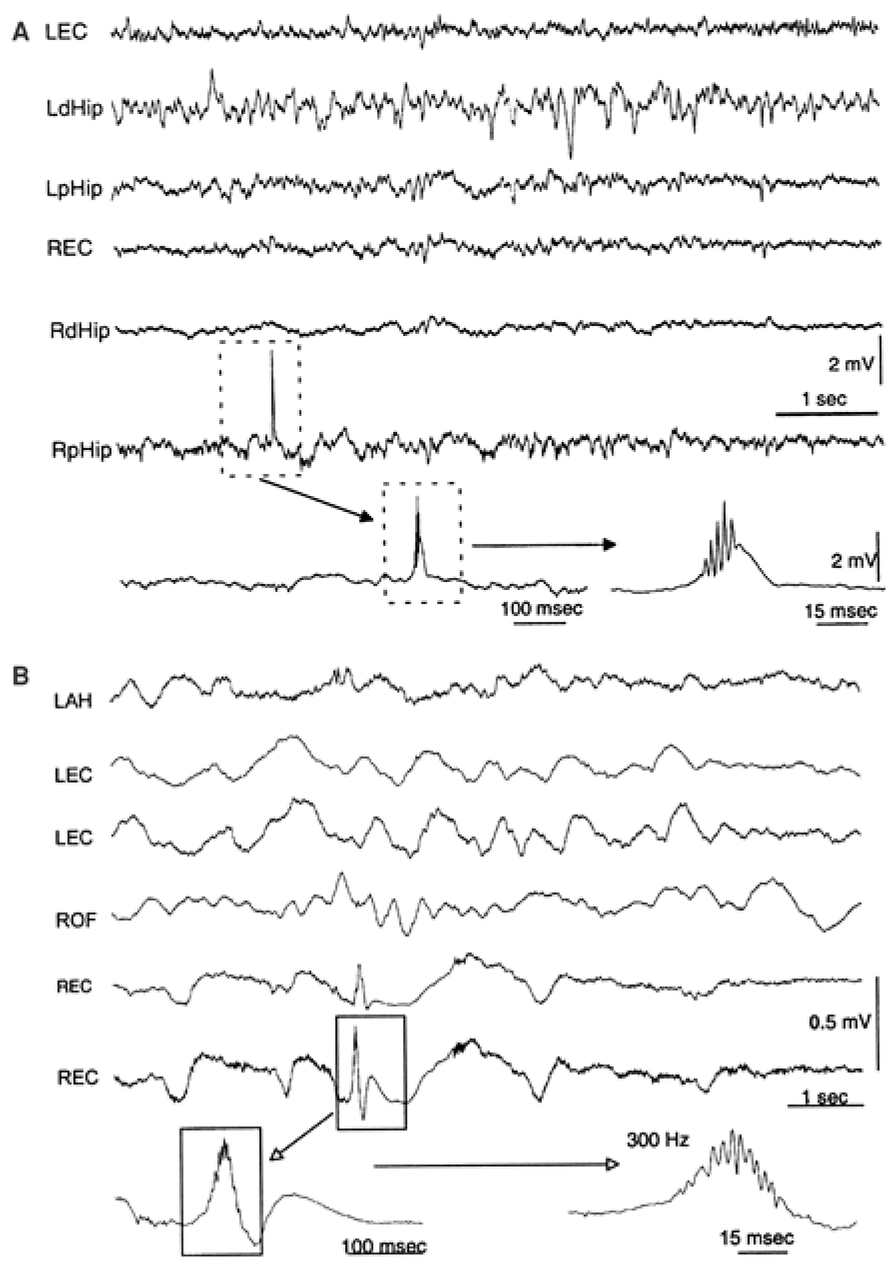

FIGURE 6. A: Example of KA-rat EEG with interictal spike with superimposed fast ripples. Abbreviations: LEC and REC left and right entorhinal cortex; LdHip and RdHip left and right dorsal hippocampus; LpHip and RpHip left and right posterior hippocampus. **B**: Interictal spike with superimposed fast ripples in the

entorhinal cortex of a patient with mesial temporal lobe epilepsy. *Arrows* indicate extension of electrical activity indicated in the box. Abbreviations: LAH, left anterior hippocampus; ROF, right orbitofrontal cortex; LEC and REC, left and right entorhinal cortex (two microelectrodes in each side). From Engel J Jr, Wilson C, Bragin A. Advances in understanding the process of epileptogenesis based on patient material: what can the patient tell us? *Epilepsia*. 2003;44(Suppl 12):60â€“71, with permission.

Although studies in patients with epilepsy and in experimental animal models have characterized disinhibitory and hypersynchronous types of ictal events, the mechanisms that precipitate these phenomena have yet to be elucidated adequately. In some types of epilepsy, sudden synchronizing influences, such as startling stimuli or repetitive photic stimulation, can induce seizures, presumably by producing synchronous neuronal discharges. Intrinsic pathways and conditions associated with synchrony, such as slow-wave sleep and activation of specific thalamic pacemakers, may also predispose to the appearance of seizures. Alternatively, convulsant drugs, withdrawal from sedative medications and alcohol, and intrinsic alterations in the extracellular ionic milieu can all result in a reduction of inhibitory influences and contribute to the precipitation of disinhibitory-type ictal events.

Recent parallel human and animal investigations have revealed the existence of abnormal high-frequency (200â€" 600 Hz) oscillations, termed fast ripples (FR), which appear to be unique to structures capable of generating spontaneous seizures[12,13] (Fig. 6). FR usually occur in association with interictal EEG spikes and are believed to reflect the field potentials of synchronously bursting neurons, perhaps the primary substrate of epileptogenicity. FR occur at the onset of both disinhibitory and hypersynchronous ictal onsets,[13] and features of the neuronal clusters that generate these high-frequency oscillations provide insight into possible mechanisms of transition to ictus. FR-generating neurons are not homogeneously distributed throughout epileptogenic mesial temporal structures, but are localized to discrete areas of hippocampus, DG, entorhinal cortex, and other parahippocampal structures embedded in tissue that does not generate FR.[14] In experimental animals, the location of these FR-generating neuronal clusters is spatially stable over time, and the frequency of spontaneous seizures is directly related to the density of these clusters.[15] Whereas surrounding nonâ€"FR-generating tissue is characterized by paired-pulse suppression indicating enhanced inhibition during the interictal state, the same afferent input results in paired-pulse facilitation within FR-generating clusters, and often the enhanced response of the second pulse is followed by an FR. Minimal disinhibition induced by small amounts of bicuculline can increase the size of these FR-generating areas.[14] It is conceivable, therefore, that minor alterations in inhibitory tone within an epileptogenic region results in an increase in size of FR-generating neuronal clusters, leading to coalescence and synchronization among them until the area involved in the hypersynchronous discharge is sufficiently large to permit propagation. This hypothetical mechanism of transition to ictus requires a reduction in some form of inhibition to expand the extent of the epileptogenic abnormality.

The currently available AEDs all appear to act on general mechanisms of excitation, inhibition, and synchronization that not only determine threshold for transition to ictus, but modulate important normal neuronal functions. Anticonvulsants such as carbamazepine and phenytoin reduce use-dependent neuronal firing, whereas others, like vigabatrin, enhance GABA-mediated inhibition. Antiâ€"petit mal drugs like ethosuximide reduce thalamically mediated hypersynchronization by blocking a specific form of the Ca channel that underlies low threshold Ca currents (T currents), whereas the GABA agonist benzodiazepines may abort absence seizures by inhibiting the synchronizing inhibitory activity of the thalamic reticular nucleus. With better understanding of the multifaceted specific epileptogenic mechanisms that predispose to the intermittent appearance of spontaneous epileptic seizures in each of the various forms of human epilepsy, additional unique interventions might be designed to reverse these primary abnormalities without interfering with normal brain function.

Ictal Termination and the Postictal State

As with EEG recordings obtained from patients during transition to ictus, recordings made during ictal termination show a number of patterns. Some generalized convulsions evolve through a clonic phase, with high-amplitude discharges interspersed with periods of suppression that increase in duration until the electrographic event ends abruptly, to be replaced by a diffusely depressed EEG pattern. This so-called â€œfit switchâ€ is by no means an invariable consequence of a generalized convulsion, however. Some convulsions have a much less prominent clonic EEG pattern, or no clonic phase at all, and the ictal discharge can gradually deteriorate with no clear delineation of the beginning of the postictal period. It is commonly assumed that generalized convulsions terminate as a result of active inhibitory processes as well as depolarization block, electrogenic pumps, or changes in the ionic environment, and that these mechanisms can account for both the intermittent EEG suppression during the clonic phase and the profound postictal EEG depression. Seizure-related pH changes (acidification) have also been proposed, as have increases in outward K currents triggered by the sodium (Na) and Ca influxes during repetitive neuronal discharge. However, very few reported studies in humans substantiate those theories, derived from research on experimental animal models, that GABA, K, opioid peptides, and adenosine are involved in ictal termination.[28,73,81,114] For example, whereas postictal EEG depression and behavioral disturbances following electroconvulsive shock and amygdaloid-kindled seizures in animals can be greatly enhanced by pretreatment with opiates and reduced by pretreatment with naloxone,[49] it has been difficult to repeat these studies in patients.[37] Studies with PET, however, have confirmed upregulation of the Âµ-opioid receptors in epileptogenic temporal lobe cortex.[51]

The hypersynchronous spike-and-wave ictal EEG discharge of absence seizures ends abruptly, with no postictal sequelae. Simple partial seizures that consist entirely of localized hypersynchronous discharges also usually are not followed by postictal EEG or behavioral disturbances. Furthermore, whereas generalized convulsions and complex partial seizures are associated with postictal hypometabolism on fluorodeoxyglucose PET, absences and simple partial seizures may not be.[42,43,44] Perhaps the termination of absence ictal events involves desynchronizing influences or the dissolution of synchronizing mechanisms, processes that do not require the release of neurotransmitters or neuromodulators that induce prolonged postictal neuronal dysfunction.

An obvious conclusion to be drawn from observations of human seizures is that many different mechanisms account for ictal termination, just as many different mechanisms underlie ictal onset and evolution. The clinical condition of epilepsia partialis continua is of interest because it illustrates that the mechanisms that act to limit the propagation of partial seizures from the primary epileptogenic region in this disorder are not the same as the mechanisms that terminate the ictal event, providing further evidence for multiple natural seizure-suppressing influences functioning in concert. Further research into the homeostatic mechanisms that limit and terminate ictal events is important, not only because these processes might be exploited to help control human epilepsy, but also because reversal of these phenomena might eliminate prolonged postictal deficits that can be an important disabling factor in some patients with epilepsy.

Research into seizure termination associated with SE must have high priority, because continuing seizure activity in this condition is associated with dramatic morbidity. Insights from clinical experience in terminating SE are at best confusing. GABA agonist approaches are often most effective in terminating SE, at least early in SE, thus suggesting that GABA-mediated inhibitory mechanisms are â€œintact.â€[76] However, as seizure activity continues, opportunities to stop seizures (short of coma induction) seem to decrease, perhaps reflecting loss (internalization) of $GABA_A$ receptors.[57] Interesting recent studies, showing that vagus nerve stimulation may sometimes be effective in terminating SE, provides a new window for developing nonpharmacological therapies.[93]

Enduring Consequences of Epilepsy

Controversy continues over the question of whether epilepsy is a progressive condition.[46,87,109] There seems to be little doubt from animal studies, such as those involving kindling and the mirror focus phenomenon, that the onset of spontaneous seizures is not necessarily the endpoint of epileptogenesis. In an acquired epileptic conditionâ€"for example, mesial TLE or posttraumatic epilepsyâ€"the epileptogenic mechanisms have presumably been under development for a period of time before the first signs of recurrent (epileptic) seizures appear. Many investigators have argued that this process continues after initiation of clinically evident ictal events, perhaps making seizures more severe or more difficult to treat, or perhaps leading to other aberrations in neuronal function that give rise to interictal behavioral disturbances. Conversely, some seizure disorders disappear with time, but the neuronal mechanisms of spontaneous reversal of the epileptogenic process have not been studied in animals or patients.

Unequivocal evidence suggests that the developmental delays associated with catastrophic childhood epilepsy can be prevented or reversed by surgical interventions that eliminate recurrent epileptic seizures.[104] Furthermore, some focal neurologic deficits, such as contralateral material-specific memory impairment, are greatly improved after successful localized resections.[97] These observations strongly suggest that some types of recurrent epileptic seizures can have an enduring deleterious effect on normal neuronal function *between* seizures, although distinguishing between postictal and truly interictal deficits in these situations can be difficult. Other clinical studies have reported an inverse relationship between the degree of seizure relief following surgical intervention and the duration of epilepsy before surgery, implying that secondary epileptogenesis can worsen the epileptic condition, or at least make it more difficult to treat surgically.[41,87]

Undoubtedly, some forms of epilepsy are more likely to be progressive than others, but it remains unclear what seizure-associated factors contribute to increasing seizure severity and related (e.g., cognitive, psychiatric) morbidity. Is it seizure severity per se (and if so, how does one measure â€œseverityâ€)? Is the key factor the occurrence of significant neuronal damage (and if so, how much damage is sufficient to lead to further seizure consequences)? Is the issue of â€œprogressionâ€ tied to the etiology of the seizure? To the age at which it appears? Benign forms of epilepsy, particularly the primary epilepsies that are age-related, may not be progressive at all and, indeed, many resolve spontaneously after several years. It is of great clinical importance to pursue research aimed at identifying the progressive aspects of human epilepsy that might be reversed or prevented, so as to determine which types of epilepsy are likely to progress and therefore require early aggressive treatment.

Future Directions

Reiterative parallel human and animal studies have been facilitated by the development of new neuroimaging techniques, such as (a) high-resolution structural magnetic resonance imaging (MRI), which has increasing capabilities for identifying small epileptogenic lesions such as migration defects in patients previously believed to have cryptogenic epileptic disorders;[10] (b) functional magnetic resonance imaging (fMRI), which has the spatial and temporal resolution to produce dynamic three-dimensional cerebral anatomic maps displaying ictal onset and propagation patterns;[69] (c) PET and single photon emission computed tomography (SPECT), which utilize a variety of tracers to localize biochemical abnormalities in the brain and characterize presynaptic and postsynaptic neurotransmitter functions;[82] (d) magnetic resonance spectroscopy (MRS), which can measure localized biochemical changes in the brain related to epilepsy;[94] and (e) magnetoencephalography (MEG), which, in association with EEG, can reliably localize current sources of interictal and ictal epileptiform events occurring deep within the brain.[30] A specific area in which these new imaging techniques may prove of extraordinary value is in the analysis of epileptogenesis in human patients. As has been discussed earlier, partial epilepsy often develops with a period of latency after some form of brain â€œinjury.â€ At the cellular and molecular level, the process of epileptogenesis is just beginning to be studied, and it is likely that observations in animal models will provide insight into comparable processes in humans. However, it is also possible, and quite desirable, to study these questions in humans, and this goal can now be approached using enhanced imaging techniques and MRS. Such studies will require detailed examination of subgroups of individuals identified with specific risksâ€”with the collaboration of population epidemiologists. Prospective studies of high-risk individuals should be developed, to look for the progression of hippocampal sclerosis and other changes in vulnerable structures that may correlate with development of the epileptic state and that may then become surrogate markers for any intervention strategy developed to suppress epileptogenesis. These studies will also benefit from the increasing resolution of novel imaging modalities that will soon provide cellular-level observations noninvasively.[85]

Another area of recent interest that also promises to produce a paradigm shift in our understanding of the development of seizures in the human brain relates to the burgeoning field of seizure prediction.[74] Recognizing that no one has yet developed an ideal model to accurately predict seizures before they occur, the demonstration that reproducible and detectable changes in brain electrophysiology occur hours, minutes, or many seconds before the ictal onset provides new sets of experimental mechanisms to investigate. Similarly, recent evidence indicating that some of these preseizure states can wax and wane without inevitably producing seizures also promises to alter the horizon for investigating seizure prediction and for understanding the network mechanisms that come into play when a chronically hyperexcitable (or perhaps â€œhyperirritableâ€) brain changes state from relatively normal, distributed activity to abnormal, hypersynchronous ictal activity. Of particular interest is that all of this work is occurring in human patients and not in animal modelsâ€"a reversal of the usual pattern of going from animal models to human studies.

There has been a growth of basic research activity in epilepsy surgery facilities, taking advantage of unique opportunities for invasive investigations utilizing in vitro microanatomy, neurochemistry, molecular biology, electrophysiology, direct brain recordings in vivo from macroelectrodes and microelectrodes,[38] microdialysis,[29] and, most recently, optical imaging.[59] All these available approaches now make it possible to design studies with patients that, in the not too distant past, were possible only in the animal laboratory.

There are several areas in which new initiatives in the analysis of human epileptic tissue promise to lead to new understanding of the pathobiology of the epileptic state and of the development of the epileptic state. The explosion of recent data regarding the molecular biology of the mammalian nervous system has defined a series of new questions that must be addressed in human epilepsy, and the development of new techniques in this field has allowed the detailed characterization of human tissue. For example, as discussed in Chapters 22 and 23, multiple subtypes of all of the neurotransmitter receptors in the central nervous system (CNS) exist, each with a specific anatomic localization and developmental pattern. Each also has a specific physiology and pharmacology, which can convey subtle, but quite important, differences in function to a given

P.505

synaptic interaction. Most receptor subtype distributions are altered after CNS injury, so it is possible, for example, that after injury to the hippocampus, a different expression pattern of NMDA receptors develops that alters the normal excitability of remaining circuits in ways that predispose to the development of epilepsy. Such altered receptors could become specific targets for new pharmacologic agents designed to dampen excess excitability while leaving normal excitability (occurring via other NMDA receptors) unaffected. Thus, tissue removed from patients with epilepsy that appears to contain the most hyperexcitable areas will need to be examined using such techniques as in situ hybridization, single-cell polymerase chain reaction,[31] or single-cell mRNA amplification[86] to analyze specific receptor changes at a cellular, as well as a network, level. Such analyses will need to be extended to many molecules involved in neuronal excitability, synaptic transmission, and neurotransmitter regulation. In addition, as is being discovered from the analysis of genetic models of both animal and human epilepsy, other molecules that are not traditionally thought to play major â€œneurobiologicâ€ roles may, when altered, produce seizures as a consequence. A new technique of single-cell mRNA amplification, which can be applied to both living and fixed human tissue,[21,31] will allow the simultaneous identification of many molecular species in identified single cells in epileptic tissue, so that coordinated changes in gene expression that may be involved in the development of the hyperexcitable state can be identified. The development of cDNA microarray technology provides a powerful tool for monitoring thousands of genes of potential interest. Recent studies suggest that one might even be able to carry out such â€œchipâ€ analyses using blood samples from patients of interest.[112]

The primary epilepsies remain an enigma with respect to basic mechanisms; invasive research on these disorders is usually not possible, because patients are not likely to be surgical candidates or to die of their disorder. Furthermore, none of the naturally occurring genetic animal models appears to reproduce human conditions adequately, although some, such as the genetic absence epilepsy rat of Strasbourg (GAERS),[77] come close. Genetic probes should provide opportunities in the future to identify the specific defects that give rise to these familial conditions and characterize their neuronal mechanisms. When specific gene defects are identified, it will be necessary to determine how these mutations affect function within neuronal circuits. It may be that this focus will require that transgenic mice be created with the mutated homolog of the human gene, so that the cellular pathophysiology of the human disease can be determined. With such transgenic models, it may be possible, by using either targeted drugs or some form of gene therapy, to rectify or correct the underlying defect. Initial attempts to modify gene expression in experimental animals, and/or to deliver genes of interest to brain regions responsible for seizure generation, are being described.[84]

Improved means of recognizing specific substrates of human epileptic disturbances should, in turn, lead to the development of better experimental animal models, particularly for those conditions that currently represent a therapeutic challenge, such as the cryptogenic partial epilepsies and the severe secondary generalized epilepsies (Lennox-Gastaut syndrome and infantile spasms), and also for specific seizure types that are difficult to treat, such as myoclonic seizures and atonic seizures. These animal models will then provide opportunities to develop and test new treatments, based on an understanding of the basic pathophysiology.

Summary and Conclusions

Many different types of human epilepsy exist, and these reflect a variety of underlying fundamental neuronal mechanisms. Even within a given epileptic disorder, there are many component parts for which unique mechanisms can be identified. Thus, basic research on a single type of epilepsy can be directed toward understanding the mechanisms of epileptogenesis, various interictal phenomena, ictal onset and spread, ictal termination, postictal disturbances, and more enduring behavioral consequences of chronic epilepsy. Although well-designed studies using experimental animal models can provide insights into the mechanisms of various epileptic conditions and their component parts, more direct research on patients can now also be carried out. In vivo studies utilize noninvasive functional and structural neuroimaging as well as invasive techniques, such as macroelectrode and microelectrode recordings and microdialysis; in vitro studies comprise electrophysiologic, neurochemical, morphologic, and molecular biologic analyses of surgically resected epileptic brain tissue. Investigations of patients with temporal lobe seizures who are candidates for surgical treatment have revealed evidence of neuronal reorganization in the epileptic hippocampus, with resultant disturbances in excitatory and inhibitory synaptic integration, leading not only to hyperexcitability but also to hypersynchronization. Inhibition as well as excitation is enhanced, which may represent natural mechanisms that maintain the interictal state and which may also contribute to certain epileptiform abnormalities and interictal behavioral disturbances. Tremendous recent technologic advances in neuroimaging and application of new concepts of molecular biology will undoubtedly lead to more direct research on patients, making possible an even greater understanding of the mechanisms underlying the various types of human epilepsy. This work should contribute to the development of better animal models designed to investigate more specifically questions that cannot be easily or ethically pursued in patients and, in turn, research in the animal laboratory will continue to yield new hypotheses, many of which can now be tested directly in human subjects.

Chapter 42

Overview: Phenomenology

Warren T. Blume

Introduction

Accurate and complete seizure descriptions will allow the reader to elicit maximum benefit from the information contained in the chapters of this section. Ictal semiology remains the most reliable guide to the classification of the seizure disorder, localization of onset of focal seizures, and pathways of propagation.

Such meticulous descriptions will either identify these aspects with certainty or suggest the most likely possibilities, so that cogent questions can be applied to further stages of enquiry such as the neurological examination, electroencephalogram (EEG), and other tests. Attack descriptions may even identify some or all events as nonepileptic.

Aura and *epilepsy*, the two most common terms applied to seizure disorders, are good examples of the importance of accurate seizure description. The term *aura*, meaning â€œbreezeâ€ in the Greek language, was apparently first applied to initial manifestations of focal seizures by Pelops, Master of Galen (AD130â€"210), who described a seizure onset as a â€œcold breeze.â€[16] Patients often describe the succeeding ictal phase as â€œgoing into it.â€ This sensation possibly resembles the meaning of *epilepsia*, also a Greek term, as â€œa taking hold of, something seizing the subject as though that â€˜somethingâ€™ were outside himself.â€[18]

The value of ictal features in localizing involved areas of the brain was first indicated by John Hughlings Jackson, who correlated semiology with sites of lesions disclosed at postmortem pathological examination.[12] Such associations were supplemented by those disclosed by electrical stimulation of the cortex by Fritsch and Hitzig in 1870.[13] A most comprehensive description of ictal semiology and its seizure-localizing value was achieved by Penfield and Jasper in authoring *Epilepsy and the Functional Anatomy of the Human Brain* in 1954 (see further).[21]

The physician should obtain as much of the seizure description from the child or adult patient as possible, because only he may possess a detailed description of the most localizing features early in the attack. Patients who initially deny having auras may change their response if asked â€œDo you ever think you are going to have a seizure, and you don't have it?â€ If affirmed, the physician then can ask, â€œDo some of your seizures begin like that?â€ Because symptoms such as an epigastric or cephalic sensation may reflect seizure origin from one of several regions, inquiring about symptoms or signs relative to neighboring regions may refine localization possibilities. Seizures involving primary motor or sensory regions may be easier for the patient to describe and localize than those from association areas such as the limbic system. Thus, vaguely described symptoms more likely reflect involvement of such regions, rather than simply a â€œpoor historian.â€ Observations by family or associates, although of considerable value, may pertain to phenomena occurring later in the ictal sequence and therefore may represent ictal spread rather than origin. Observers may mislateralize ictal phenomena, such as automatisms or dystonia. Once they are made more aware of its clinical value, observers' scrutiny of such subsequent seizures or in-hospital video monitoring may improve the lateralizing value of such data.

Ajmone Marsan and Ralston provided further data concerning the localizing value of ictal signs and symptoms through study of EEG- and video-recorded pentylenetetrazol (Metrazol)-induced seizures in patients with focal epilepsy. They cautioned that a given semiology may represent (a) various foci among patients and (b) ictal propagation as well as origin.[1]

Interpreting The Data

Focal Seizures

Through painstaking clinical analysis and systematic electrical stimulation of the exposed cortex at operation, Penfield and Jasper[21] charted the localizing value of human epileptic semiology in a work that remains the principal source of such information. These pioneers in epilepsy surgery possessed two vital qualities: (a) a substantial interest and background in all aspects of neuroscience as understood in that era and (b) a thorough knowledge and appreciation of antecedent observations and insights by Hippocrates, Herpin, Bravais, Jackson, and others[11] who correlated ictal semiology with lesion location and defined principles of cerebral localization using this information.

Although the initial clinical phenomenon most often reflects the site of seizure initiation,[18] Carreno and Luders[8] indicate that the epileptogenic â€œzoneâ€ may not be congruent with the symptomatogenic â€œzone.â€ Rapid propagation from a clinically silent region may create the discrepancy. Although such propagation may involve adjacent areas, longer trajectories occur, such as to the mesial temporal region from the occipital lobe[7] or from the orbital frontal lobe, to the supplementary motor region from occipital and parietal lobes.[7,25] Studying scalp and subdural focal frontal seizure propagation, Blume et al.[6] found wide ranges of latency to initial propagation and its extent. Because most frontal seizures began propagation between 5 and 20 seconds from onset and remained within the frontal lobe of origin in approximately 50% of seizures, ictal semiology for frontal lobe epilepsy has at least lateralizing value in many cases. Nonetheless, instantaneous propagation of frontally originating seizures may erase any clinical features localizing or even lateralizing ictal onset within a frontal lobe.[25] Rapidly developing bisynchronous discharge occurs particularly readily with a mesial frontal onset, thus producing a complex clinical semiology.[2]

Even without measurable propagation, complex local physiology may provide multiple semiologies from a given area. Sherrington[22] obtained inconsistent motor responses when stimulating the same region of the cat motor cortex. Although refinement of stimulation techniques have limited such variability, the complexity of regional representation in the motor cortex, for example, suggests that slight variations of seizure discharge pattern in the same location may elicit a variety of semiologies.[5] The several types of neurons in one region will respond differently to identical electrical stimuli: Connors and Telfeian[10] have shown that regular spiking neurons respond with high-frequency, regularly repetitive action potentials (APs), whereas intrinsically bursting neurons respond with clusters of APs. Such variability may influence clinical seizure phenomena.

Not only can cortical stimulation in the same region elicit a variety of response patterns, but the same symptom can represent stimulation to, or a seizure from, a variety of neuronal aggregates. This well applies to the temporal lobe in humans, in which none of the responses evoked by electrical stimulation that are identical to spontaneous clinical seizures demonstrates an â€œexclusive and consistent localization to a particular structure of the temporal lobe.â€[14] Similarly, somatosensory symptoms can represent seizures from the contralateral postcentral gyrus, the second sensory area, or the supplementary sensory area.[19,20]

The foregoing examples of sensory duplication and of pathways of ictal propagation lower somewhat the localizing specificity of most sensory phenomena taken in isolation.[4,17,23] Correlative data between auras and lobes of seizure onset are difficult to summate across studies because of methodology differences. However, auras such as epigastric, somatosensory, and visual sensations each initiate more commonly temporal, parietal, and occipital seizures (respectively) than do those arising from other lobes, but exceptions are not rare. For example, Bien et al.[4] found visual auras to occasionally represent seizures arising from the temporal lobe, although they arose more commonly from the occipital lobe.

A similar duplication (or complement) endows the motor system. Paralleling clinical observations, Bender[3] obtained contralateral eye movements by stimulating the monkey frontal, parietal, or occipital lobes. Additionally, the substantial overlap in activity between the primary and supplementary motor systems, and the complex physiologic interplay between them,[24] renders difficult the assignment of some ictal motor features exclusively to one system.

Nonetheless, ictal localization is accomplished by assessing the *constellation* of auras and motor/behavioral features of a given seizure. Thus, one can agree with So,[23] who stated, in supporting the substantial achievement of Penfield and Jasper,[21] that â€œauras have localizing significance.â€ By extension, so do motor and cognitive semiology. Although unique propagation patterns could theoretically create unfamiliar semiologic juxtapositions, usual associations represent traditional spread patterns. For example, each of several motor and linguistic features of temporal lobe seizures accurately predict the side of origin in 83% to 100% of patients.[9]

Generalized Seizures

Howell[15] described the substantial variety of motor and sensory phenomena that may accompany 3 Hz bisynchronous spike-wave sequences, the sensory phenomena appearing when some awareness is preserved. Similar semiologic variabilities are described in gelastic seizures by Freeman and Olofsson (Chapter 53), febrile seizures by the Camfields and Neville, (Chapter 57), and for myoclonic attacks by Ohtahara and Ohtsuka (Chapter 62).

Summary and Conclusions

This chapter intends to help the clinical epileptologist obtain a thorough and coherent seizure description from the patient, observers and video-telemetry. Such portrayals enable more precise questions to be posed to potentially confirmatory modalities such as EEG and neuroimaging. Any *apparent* incongruity of data from these sources will more confidently lead to new associations, thus enhancing our clinical and neurophysiological knowledge base.

Chapter 43

Classification of Epileptic Seizures

Jerome Engel Jr.

Peter D. Williamson

Anne T. Berg

Peter Wolf

Introduction

Writings about epileptic seizures date back 3,000 years to Mesopotamia and India.[18] In 400 BC, Hippocrates attributed epileptic seizures to disorders of the brain, rather than to supernatural forces and, 500 years later, Galen distinguished idiopathic seizures, which originated within the brain itself, from sympathetic seizures, which had external causes.[22] Nevertheless, throughout this time until the 19th century, very little was understood about the causes of epileptic seizures or, indeed, the variety of their manifestations. Until this time, for all intents and purposes, only generalized tonicâ€"clonic convulsions were considered to be epileptic seizures. Esquirol, in 1815, however, discriminated between grand mal and petit mal seizures[12] and, in 1827, Bravais described focal motor seizures.[5] Hughlings Jackson is credited with recognizing, in the 1860s, that a variety of focal symptomatology could be epileptic at a time when most workers considered only generalized convulsionsâ€"believed to originate in the medulla oblongataâ€"to be manifestations of epilepsy.[11,21] Jackson also recognized that it was easier to understand the mechanisms of epilepsy by studying focal ictal events, and his clinical pathologic correlations correctly established the cerebral cortex as the site of origin of focal epileptic seizures. This work helped define the location and function within the human cortex and led directly to the development of resective surgical therapy for epilepsy.[11]

With the advent of the electroencephalograph (EEG), characteristic electrographic ictal discharge patterns were identified to clearly distinguish among grand mal, petit mal, and psychomotor seizures.[14] Because linked-ear references were used, however, all these patterns were believed to be generalized until so-called *bipolar montages* revealed that the location, and not the pattern, of the electrographic discharge differentiated various focal ictal events.[16] Despite the description of hippocampal sclerosis in patients with epilepsy as early as 1826,[4] and Hughlings Jackson's observation that lesions in the hippocampal region occurred in patients with tasting movements and â€œdream state,â€[15] it wasn't until the mid-1900s that epileptologists began to accept the fact that most â€œpsychomotorâ€ seizures originated in mesial temporal structures.[17] This fact was further substantiated by the observation that psychomotor seizures could often be successfully treated by surgical resections of the temporal lobe.[2,20]

During this period, worldwide, multiple terminologies developed that made sensible discussions and communication increasingly difficult. In 1970, the International League Against Epilepsy (ILAE) created the first classifications of epileptic seizures and epilepsies.[13] They clearly distinguished ictal events from the disorders with which they were associated, and ictal and interictal EEG patterns, anatomic substrate, etiology, and age were included in this definition of seizures. Seizures were broadly divided into *partial*, beginning in a part of one hemisphere, and *generalized*, which were bilaterally symmetrical without local onset (Table 1). Partial seizures were further divided into those with *elementary* symptomatology, referring to signs and symptoms mediated by eloquent areas of neocortex, and *complex* symptomatology, referring to signs and symptoms mediated predominantly by mesial temporal limbic structures. The term â€œcomplex partial seizure,â€ therefore became synonymous with the older terms, â€œpsychomotor seizureâ€ and â€œtemporal lobe seizure.â€ This seizure classification was criticized because, at the time, insufficient anatomic and pathophysiologic information was available to provide a basis for classification, and there was controversy about some of the generalized seizure types. These perceived problems were rectified in 1981, with the second ILAE Classification of Epileptic Seizures (Table 2).[6]

1981 ILAE Classification of Epileptic Seizures

Despite persistent controversy, the 1981 Classification of Epileptic Seizures has gained general acceptance and is widely used. An ILAE Task Force has been reviewing this classification since 1997, but no new classification has yet been proposed.[7,9,10] Although flawed, it has been agreed that this useful construct should not be abandoned until a clearly better version can be devised.

The 1981 Classification of Epileptic Seizures was based on expert consensus, analyzing video-recorded seizures and considering their semiology as a sequence of ictal events developing in time. In addition to the clinical phenomenology, the ictal and interictal EEG was considered, but it was decided that there was still insufficient information about pathophysiologic mechanisms and anatomic substrates to warrant a more diagnostic approach.[6] The partial/generalized dichotomy was preserved, but the distinction between simple and complex partial seizures was based entirely on impairment of consciousness. Thus, the original intent of the concept of complex symptomatology indicating behaviors mediated predominantly by limbic structures was lost. Neocortical seizures with impaired consciousness became complex partial seizures, whereas limbic seizures without impaired consciousness became simple partial seizures. This was, and continues to be, a source of controversy and confusion. On the other hand, the 1981 classification acknowledged the evolution of partial signs and symptoms and recognized that simple partial seizures could evolve into complex partial seizures, and that both could evolve into secondarily generalized seizures. This classification also differed from the 1970 classification in that absences were divided into typical and atypical, infantile spasms were deleted because they were considered to be a syndrome and not a seizure type, and akinetic seizures were deleted because their existence was questioned.

P.512

Table 1 1970 ILAE CLASSIFICATION OF EPILEPTIC SEIZURES (defined by ictal + interictal EEG, anatomic substrate, etiology, and age)

I. Partial
   A. With elementary symptomatology
   B. With complex symptomatology
   C. Secondarily generalized
II. Generalized, bilaterally symmetrical or without local onset
   A. Absences
   B. Bilateral massive epileptic myoclonus
   C. Infantile spasms
   D. Clonic seizures
   E. Tonic seizures
   F. Tonicâ€“clonic seizures
   G. Atonic seizures
   H. Akinetic seizures
III. Unilateral or predominantly unilateral

From Gastaut H. Clinical and electroencephalographical classification of epileptic seizures. *Epilepsia.* 1970;11:102â€“113, with permission.

Table 2 1981 ILAE CLASSIFICATION OF EPILEPTIC SEIZURES

I. PARTIAL (FOCAL, LOCAL) SEIZURES

Partial seizures are those in which, in general, the first clinical and electroencephalographic changes indicate initial activation of a system of neurons limited to part of one cerebral hemisphere. A partial seizure is classified primarily on the basis of whether or not consciousness is impaired during the attack. When consciousness is not impaired, the seizure is classified as a simple partial seizure. When consciousness is impaired, the seizure is classified as a complex partial seizure. Impairment of consciousness may be the first clinical sign, or simple partial seizures may evolve into complex partial seizures. In patients with impaired consciousness, aberrations of behavior (automatisms) may occur. A partial seizure may not terminate, but instead progress to a generalized motor seizure. *Impaired consciousness* is defined as â€œthe inability to respond normally to exogenous stimuli by virtue of altered awareness and/or responsiveness.â€
There is considerable evidence that simple partial seizures usually have unilateral hemispheric involvement and only rarely have bilateral hemispheric involvement; complex partial seizures, however, frequently have bilateral hemispheric involvement.
Partial seizures can be classified into one of the following three fundamental groups:

A. Simple partial seizures
B. Complex partial seizures
   1. With impairment of consciousness at onset
   2. Simple partial onset followed by impairment of consciousness
C. Partial seizures evolving to generalized tonicâ€“clonic convulsions (GTC)
   1. Simple evolving to GTC
   2. Complex evolving to GTC (including those with simple partial onset)

Clinical seizure type	**EEG seizure type**
A. Simple partial seizures (consciousness not impaired)	Local contralateral discharge starting over the corresponding area of cortical representation (not always recorded on the scalp)

1. With motor symptoms
   a. Focal motor without march
   b. Focal motor with march (Jacksonian)
   c. Versive
   d. Postural
   e. Phonatory (vocalization or arrest of speech)
2. With somatosensory or special-sensory symptoms (simple hallucinations, e.g., tingling, light flashes, buzzing)
   a. Somatosensory
   b. Visual
   c. Auditory
   d. Olfactory
   e. Gustatory
   f. Vertiginous

3. With autonomic symptoms or signs (including epigastric sensation, pallor, sweating, flushing, piloerection, and pupillary dilatation)
4. With psychic symptoms (disturbance of higher cerebral function). These symptoms rarely occur without impairment of consciousness and are much more commonly experienced as complex partial seizures.
   a. Dysphasic
   b. Dysmnesic (e.g., dÃ©jÃ -vu)
   c. Cognitive (e.g., dreamy states, distortions of time sense)
   d. Affective (fear, anger, etc.)
   e. Illusions (e.g., macropsia)
   f. Structured hallucinations (e.g., music, scenes)

• B. Complex partial seizures (with impairment of consciousness: may sometimes begin with simple symptomatology)	Unilateral or, frequently, bilateral discharge, diffuse or focal in temporal or frontotemporal regions

- 1. Simple partial onset followed by impairment of consciousness
    a. With simple partial features as in A.1â€“4 (followed by impaired consciousness)
    b. Without automatisms
  2. With impairment of consciousness at onset
    a. With impairment of consciousness only
    b. With automatisms

• C. Partial seizures evolving to secondarily generalized seizures (This may be generalized tonic-clonic)	Above discharges become secondarily and rapidly generalized

- 1. Simple partial seizures (A) evolving to generalized seizures
  2. Complex partial seizures (B) evolving to generalized seizures
  3. Simple partial seizures evolving to complex partial seizures evolving to generalized seizures

---

II. GENERALIZED SEIZURES (CONVULSIVE OR NONCONVULSIVE)

Generalized seizures are those in which the first clinical changes indicate initial involvement of both hemispheres. Consciousness may be impaired, and this impairment may be the initial manifestation. Motor manifestations are bilateral. The ictal electroencephalographic patterns initially are bilateral and presumably reflect neuronal discharge, which is widespread in both hemispheres.

Clinical seizure type	EEG seizure type
A. Absence seizures	
• 1. Typical absence	Usually regular and symmetrical 3-Hz but may be 2- to 4-Hz spike-and-slow- wave complexes and may have multiple spike-and- slow-wave complexes. Abnormalities are bilateral
• a. Impairment of consciousness only[a] b. With mild clonic components[a] c. With atonic components[a] d. With tonic components[a] e. With automatisms[a] f. With autonomic components[a]	
• 2. Atypical absence	EEG more heterogeneous; may include irregular spike-and-slow-wave complexes, fast activity, or other paroxysmal activity. Abnormalities are bilateral but often irregular and asymmetrical.
• May have: a. Changes in tone that are more pronounced than in A.1 b. Onset and/or cessation that is not abrupt	
• B. Myoclonic seizures, myoclonic jerks (single or multiple)	Polyspike-and-wave or sometimes spike-and- wave or sharp and slow waves[b]
• C. Clonic seizures	Fast activity (10 c/sec or more) and slow waves; occasional spike-and- wave patterns[b]
• D. Tonic seizures	Low voltage, fast activity or a fast rhythm of 9â€“10 c/sec or more, decreasing in frequency and increasing in amplitude[b]
• E. Tonicâ€“clonic seizures	Rhythm at 10 or more c/sec, decreasing in frequency and increasing in ampli- tude during tonic phase, interrupted by slow waves during clonic phase[b]
• F. Atonic seizures (astatic)	Polyspike-and-wave or flattening or low-voltage fast activity[b]

III. UNCLASSIFIED EPILEPTIC SEIZURES

Includes all seizures that cannot be classified because of inadequate or incomplete data and some that defy classification in hitherto described categories. This includes some neonatal seizures, e.g., rhythmic eye movements, chewing, and swimming movements.

IV. ADDENDUM

Repeated epileptic seizures occur under a variety of circumstances:

1. As fortuitous attacks, coming unexpectedly and without any apparent provocation.
2. As cyclic attacks, at more or less regular intervals (e.g., in relation to the menstrual cycle or to the sleepâ€“waking cycle).
3. As attacks provoked by:
   a. Nonsensory factors (fatigue, alcohol, emotion, etc.)
   b. Sensory factors, sometimes referred to as *reflex seizures*

Prolonged or repetitive seizures (status epilepticus). The term *status epilepticus* is used whenever a seizure persists for sufficient length of time or is repeated frequently enough that recovery between attacks does not occur. Status epilepticus may be divided into partial (e.g., Jacksonian), or generalized (e.g., absence status or tonicâ€“clonic status). When very localized motor status occurs, it is referred to as *epilepsia partialis continua*.

[a]II.A.bâ€“f may be used alone or in combination.

[b]Combinations of II.Bâ€“F, e.g., B and F, B and D.

Table 3 PROPOSED DIAGNOSTIC SCHEME FOR PEOPLE WITH EPILEPTIC SEIZURES, AND WITH EPILEPSY

Epileptic seizures and epilepsy syndromes are to be described and categorized according to a system that utilizes standardized terminology and is sufficiently flexible to take into account the following practical and dynamic aspects of epilepsy diagnosis:

1. Some patients cannot be given a recognized syndromic diagnosis.
2. Seizure types and syndromes change as new information is obtained.
3. Complete and detailed descriptions of ictal phenomenology are not always necessary.
4. Multiple classification schemes can, and should, be designed for specific purposes (e.g., communication and teaching, therapeutic trials, epidemiologic investigations, selection of surgical candidates, basic research, genetic characterizations).

This diagnostic scheme is divided into five parts, or *Axes*, organized to facilitate a logical clinical approach to the development of hypotheses necessary to determine the diagnostic studies and therapeutic strategies to be undertaken in individual patients:

- Axis 1: Ictal phenomenologyâ€"from the Glossary of Descriptive Ictal Terminology, can be used to describe ictal events with any degree of detail needed.
- Axis 2: Seizure typeâ€"from the List of Epileptic Seizures. Localization within the brain and precipitating stimuli for reflex seizures should be specified when appropriate.
- Axis 3: Syndromeâ€"from the List of Epilepsy Syndromes, with the understanding that a syndromic diagnosis may not always be possible.
- Axis 4: Etiologyâ€"from a Classification of Diseases Frequently Associated with Epileptic Seizures or Epilepsy Syndromes when possible, genetic defects, or specific pathologic substrates for symptomatic focal epilepsies.
- Axis 5: Impairmentâ€"this optional, but often useful, additional diagnostic parameter can be derived from an impairment classification adapted from the World Health Organization (WHO) ICIDH-2.

From Engel J Jr. A proposed diagnostic scheme for people with epileptic seizures and with epilepsy: report of the ILAE Task Force on Classification and Terminology. *Epilepsia.* 2001;42:796â€"803, with permission.

Table 4 Seizure Types

Self-limited epileptic seizures

I. Generalized onset
    A. Seizures with tonic and/or clonic manifestations
        1. Tonicâ€"clonic seizures
        2. Clonic seizures
        3. Tonic seizures
    B. Absences
        1. Typical absences
        2. Atypical absences
        3. Myoclonic absences
    C. Myoclonic seizure types
        1. Myoclonic seizures
        2. Myoclonic astatic seizures
        3. Eyelid myoclonia
    D. Epileptic spasms
    E. Atonic seizures
II. Focal onset (partial)
    A. Local
        1. Neocortical
            a. Without local spread
                1. Focal clonic seizures
                2. Focal myoclonic seizures
                3. Inhibitory motor seizures
                4. Focal sensory seizures with elementary symptoms
                5. Aphasic seizures

b. With local spread
    1. Jacksonian march seizures
    2. Focal (asymmetrical) tonic seizures
    3. Focal sensory seizures with experiential symptoms
2. Hippocampal and parahippocampal

B. With ipsilateral propagation to:
    1. Neocortical areas (includes hemiclonic seizures)
    2. Limbic areas (includes gelastic seizures)

C. With contralateral spread to:
    1. Neocortical areas (hyperkinetic seizures)
    2. Limbic areas (dyscognitive seizures with or without automatisms [psychomotor])

D. Secondarily generalized
    1. Tonicâ€“clonic seizures
    2. Absence seizures
    3. Epileptic spasms (unverified)

III. Neonatal seizures

Status epilepticus

I. Epilepsia partialis continua (EPC)
    A. As occurs with Rasmussen syndrome
    B. As occurs with focal lesions
    C. As a component of inborn errors of metabolism

II. Supplementary motor area (SMA) status epilepticus

III. Aura continua

IV. Dyscognitive focal (psychomotor, complex partial) status epilepticus
    A. Mesial temporal
    B. Neocortical

V. Tonicâ€“clonic status epilepticus

VI. Absence status epilepticus
    A. Typical and atypical absence status epilepticus
    B. Myoclonic absence status epilepticus

VII. Myoclonic status epilepticus

VIII. Tonic status epilepticus

IX. Subtle status epilepticus

From Engel J Jr. Report of the ILAE Classification Core Group. *Epilepsia*. 2006;47:1558â€“1568, with permission.

Some workers have criticized the current classification for not being purely phenomenologic.[19] To give the correct diagnosis to individual patients, EEG and other clinical information may sometimes be necessary to determine whether a brief lapse of consciousness is an absence seizure or a complex partial seizure with impaired consciousness only. An alternative, purely phenomenologic approach to the classification of individuals with epilepsy has been proposed and is used in some epilepsy centers.[19] The detailed descriptive information is particularly useful, along with other diagnostic information, in localizing the epileptogenic region when resective surgery is being considered, but this type of descriptive detail is usually not necessary for determining diagnosis, treatment, or prognosis for most patients with epilepsy.[8] It should also be noted that the ILAE Classification is a taxonomy and not intended to be a diagnostic manual.[23] Although distinguishing between partial and generalized epileptic seizures has clinical value with respect to the differential diagnosis of underlying etiologies, this is not an absolute dichotomy. It can be difficult to determine whether some ictal phenomena are partial or generalized, or to account for the continuum from discrete focal, to diffuse hemispheric, to multifocal bilateral, to bilaterally symmetrical epileptogenic abnormalities.

Proposals for Improving the Classification

The ILAE Task Force has acknowledged the usefulness of a detailed description of ictal phenomenology under certain circumstances. Thus, the first axis of a proposed five-axis diagnostic scheme for describing individual patients (Table 3) consists of ictal phenomenology.[7] To standardize the use of this axis, a glossary of descriptive terminology has been published.[3] This axis, however, is considered optional, because the degree of detail needed for clinical purposes varies greatly from one patient to another.

The second axis of the diagnostic scheme introduces a new concept: a seizure type as a diagnostic entity.[7] The Task Force believes that sufficient information now is available about the pathophysiologic mechanisms and anatomic substrates of many ictal events to permit identification of epileptic seizure types that are unique diagnostic entities, having within

themselves etiologic, therapeutic, and prognostic implications. In any given patient, therefore, the diagnostic evaluation, treatment, and prognosis of these entities may be determined from the diagnosis of a specific seizure type, when a diagnosis of an epilepsy syndrome is not possible. The Task Force is currently attempting to establish scientifically rigorous criteria for the identification of specific epileptic seizure types that include not only pathophysiologic mechanisms and neuronal substrates, but also response to antiepileptic drugs (AEDs), ictal EEG patterns, propagation patterns, postictal features, and the epilepsy syndromes with which the seizure type is associated.[9] Clinical semiology is not a necessary criterion, nor is the anatomic location per se. For example, an epileptogenic abnormality due to a unique pathophysiologic mechanism could be considered a class of seizures regardless of whether the epileptogenic region were in the posterior frontal cortex (giving rise to motor signs), or in the occipital cortex (giving rise to visual symptoms). Conversely, similar ictal behaviors could reflect different classes of seizures; as noted earlier, a brief loss of consciousness could be a â€œgeneralizedâ€ absence, or a focal limbic seizure due to entirely different pathophysiologic mechanisms acting on entirely different anatomic substrates.

The ultimate objective is to pattern a new ILAE classification after other biologic classification systems; that is, to establish reasonable, rigorous objective criteria for recognizing epileptic seizure types as unique natural classes that can be reproducibly distinguished from all other natural classes.[1] This is an ambitious goal, but the field is just beginning to have the capacity to evaluate more than signs, symptoms, and EEG discharges, and to consider fundamental concepts of pathophysiology. A list of seizure types has been compiled (Table 4) and is discussed herein. Each type classification should be considered as a testable working hypothesis, subject to verification, falsification, and revision.[9] Evidence-based methodology can be used to reevaluate, revise, or discard seizure types, and changes are also anticipated as new information becomes available. The revision and refinement of this list of seizure types, as well as any future organization into one or more diagnostic manuals, is an ongoing dynamic process.

The Task Force has proposed replacing the term â€œpartial seizureâ€ with â€œfocal seizure,â€ which remains in common use, with the understanding that this does not imply a small, discrete area of epileptogenicity.[7] A description of focal-onset seizures has presented a particular problem for identifying unique diagnostic entities. They represent dynamic events, usually involving propagation, so that clinical manifestations do not necessarily reflect the site of onset. Focal seizures due to discretely localized lesions must be distinguished from focal seizures due to more distributed network disturbances, for example those occurring in patients with benign childhood epilepsy with centrotemporal spikes. Maturational factors, mode of precipitation, structural pathology, pathophysiologic mechanisms, location, and progressive disturbances all need to be taken into consideration. A suggested approach to defining focal seizures, therefore, is shown in Table 4[9] and discussed below. Although impairment of consciousness is a clinically important manifestation of some ictal events, this parameter is poorly defined and often difficult to determine. Aspects of altered consciousness, therefore, are not considered as a factor for defining *seizure types* here, but rather should be assessed as part of the *phenomenologic description* in individual patients. Finally, any new classification of epileptic seizures must take into account continuous epileptic seizure types or *status epilepticus*. As yet, no agreed-upon classification for status epilepticus exists, but a list of forms of status proposed by the ILAE Task

Force is shown in Table 4[9] and discussed below.

Discussion of ILAE-Recognized Seizure Types

The following discussion is adapted from the work of the ILAE classification committee, with permission.[11]

Self-Limited Epileptic Seizure Types

I. **GENERALIZED ONSET**

A. **Seizures with tonic and/or clonic manifestations**

1. *Tonic-clonic seizures*: involve brain stem, possibly prefrontal, and basal ganglia mechanisms. Ictal initiation of primarily bilateral events are predominantly disinhibitory, but other mechanisms are responsible for ictal evolution to the clonic phase, involving gradual periodic introduction of seizure-suppressing

mechanisms. Several discrete types might be identified: Future investigation is needed to determine which of these types represent unique phenomena.

- Reactive GTCS (acutely provoked seizures)
- GTCS of idiopathic generalized epilepsies
- GTCS of symptomatic generalized epilepsies
- GTCS evolving from myoclonic seizures (e.g., clonic-tonic-clonic seizures in Juvenile myoclonic epilepsy (JME) and Epilepsy with myoclonic astatic seizures)
- GTCS evolving from absence seizures

And several questions can be raised:

- Do patients with idiopathic focal epilepsies have primarily generalized as well as secondarily generalized seizures? Some data suggest that GTCS in Benign childhood epilepsy with centrotemporal spikes (BCECTS) are secondarily generalized, although some patients with this condition may have primarily generalized GTCS as well.
- What are clonic-tonic-clonic seizures? Are GTCS that evolve from myoclonic seizures the only form, or are there also true clonic-tonic-clonic seizures (as may be seen in forms of progressive myoclonus epilepsy [PME])?
- How should we regard hemi-generalized seizures which manifest unilaterally in the immature brain due to poor myelinization of the corpus callosum? In this case the disorder is bilateral, but the onset is clearly unilateral. Do these only occur in infants, or do they also occur in children and adults? In some infants, hemi-generalized seizures have focal onset.

Some experimental evidence suggests that the mechanisms of ictal initiation could be different for some or even all of these subtypes of GTCS, and that there may even be more than one mechanism of initiation within each of the subtypes.

2. *Clonic seizures*: Clonic seizures are fast rhythmic events (1â€“2 Hz), associated, or not, with impaired consciousness. Mechanisms are different from those of the clonic phase of GTCS. In the latter, the clonic phase represents the phasing in of seizure-suppressing mechanisms, whereas in clonic seizures, the repetitive discharges appear to be due primarily to rhythmic excitatory discharges. There may be several types of generalized clonic seizures.

3. *Tonic seizures*: The mechanism of tonic seizures is probably not the same as that of the tonic phase of GTCS. Generalized tonic seizures typically occur in Lennox-Gastaut syndrome and occasionally in Epilepsy with myoclonic astatic seizures.

B. **Absences**

1. *Typical absences*: Although the pyknoleptic manifestations of typical absences in Childhood absence epilepsy (CAE) have been suggested to differ by shorter duration from the longer-duration, less frequent absences of Juvenile absence epilepsy (JAE), based upon what we currently know, it seems likely that they do not represent two mechanisms, but merely the evolution of a single mechanism as the brain matures. Phantom absences also are likely to be a result of brain maturation. A working group will be convened to study whether absences of CAE and JAE represent two seizure types or a spectrum of the same seizure type, and to better define associated motor components.

2. *Atypical absences*: There are variable manifestations of this ictal event, some involving hypotonia and atonia. Better criteria for characterizing atypical absences will also be discussed by the working group on atonic seizures.

3. *Myoclonic absences*: The myoclonic components of these seizures are rhythmic (2Â½â€“4Â½ Hz) clonic rather than myoclonic and have a tonic component. The seizure type should be called something else, but there is no agreement on another name at this time.

C. **Myoclonic seizures types**

1. *Myoclonic seizures*: The distinction between myoclonic seizures and clonic seizures is not clear. Classically, clonic seizures are rapid rhythmically-recurrent events, whereas myoclonic seizures are single, or irregularly recurrent events. The prototype of generalized myoclonic seizures are those occurring with JME. These are typically bilateral and symmetrical, but localized reflex myoclonus can also occur. The slowly rhythmic events of Subacute sclerosing panencephalitis (SSPE) used to be considered epileptic myoclonus but are more accurately epileptic spasms, those with biPEDs (bilaterally synchronous PLEDs) in comatose patients also are not necessarily epileptic, and their cause is usually not clearly defined. Differential diagnosis between myoclonic and clonic seizures can be difficult because a single jerk can be a fragment of a clonic seizure.

   Working groups will be convened to specifically evaluate myoclonic epileptic phenomena, including negative myoclonus and atonic seizures, compare them with nonepileptic myoclonic phenomena, and develop uniform criteria and terminology for these diagnoses.

2. *Myoclonic astatic seizures*: These seizures occur typically in Epilepsy with myoclonic astatic seizures. There is a question as to whether the astatic component is an atonic seizure.

3. *Eyelid myoclonia*: The degree to which these recurrent events (5â€“6 Hz) are associated with impairment of consciousness has not been adequately documented, and should be. In some patients they can be provoked by eye closure. The seizure type, however, does exist as a unique entity.

D. **Epileptic spasms**: The mechanism of infantile spasms is unknown. The semiology and pathophysiology of epileptic spasms in the more mature brain need to be better defined.

E. **Atonic seizures**: A number of seizure types involve an atonic component, some of which may be variants of atypical absences, others of which can have an initial brief tonic or myoclonic component. When these events are very short, they have been referred to as negative myoclonus. A working group will be convened to review videotapes of various types of atonic seizures, and to develop criteria to distinguish between negative myoclonus, atonic seizures, and perhaps some atypical absences.

II. **FOCAL ONSET**

The anatomical substrates of a substantial number of focal seizure manifestations have now been sufficiently established to include this information in their description. Because focal seizures represent dynamic events that usually involve propagation, and clinical manifestations can reflect discharges at the site of ictal onset, and/or sites of propagation, the organization of focal seizures here takes into account the various patterns of ictal propagation. In addition, a number of factors will need to be investigated in order to develop more definitive criteria for distinguishing between different types of focal seizures. These include:

- Factors that might distinguish between focal seizures due to discretely localized lesions, as occur with focal symptomatic epilepsy, and focal seizures due to more distributed network disturbances, as might occur with some focal idiopathic epilepsies (e. g., those responsible for the transverse dipole of BCECTS), or even in idiopathic generalized epilepsies.

- Maturational factors
- Modes of precipitation, as in reflex seizures
- Pathology, i.e. focal seizures due to various malformations of cortical development may be different from each other and from those due to other lesions.
- Pathophysiologic mechanisms, e. g., hypersynchronous ictal onsets, which most commonly occur in hippocampus, vs. low voltage fast ictal onsets, which most commonly occur in neocortex. These electrophysiological features clearly reflect different pathophysiologic mechanisms of seizure initiation, which may not be absolutely correlated with location, and there may be other ictal onset patterns indicative of other initiating mechanisms that have not yet been well-described.
- Location, not with respect to differences in ictal semiology that reflect differences in the normal function of cortex, but to differences in neurophysiologic properties and anatomical connections unique to specific areas of cortex, e. g., those that cause brief and clustered seizures with little or no postictal disturbances and nocturnal predilection typical of some frontal areas, as compared to longer, less frequent events with profound postictal disturbances in other areas, and those that cause fast distant propagation from some areas and localized, slower propagation in others.

Factors influencing seizure-induced progressive disturbances in neuronal function and structure at the site of, and downstream from, ictal onset.

Local

1. *Neocortical*
   a. Without local spread
      1. *Focal clonic seizures* are brief focal motor events that are distinguished from focal myoclonic seizures by their rhythmic repetition. Localization to the primary motor cortex is implied.
      2. *Focal myoclonic seizures* most likely consist of many types. These events, including *multifocal myoclonus*, will be discussed by the working group on myoclonus. There is no unanimity of opinion as to whether the myoclonic events in PME which have no EEG correlate are epileptic. At least in Lafora, there is evidence to suggest a cortical site of initiation.
      3. *Inhibitory motor seizures* are not a unique seizure type. The clinical manifestation merely represents the function of the involved cortex, just as focal motor seizures and unformed visual hallucinations reflect seizures in precentral gyrus and calcarine cortex.
      4. *Focal sensory seizures with elementary visual, somatosensory, vestibular, olfactory, gustatory, or auditory symptoms* manifest themselves as a variety of sensory phenomena that can be produced by activation of primary sensory cortices.
      5. *Aphasic seizures* can consist of inability to speak when Broca's area is principally involved, or more complex disturbances of

P.517

speech production or reception when other language cortical areas are principally involved.
   b. With local spread
      1. *Jacksonian march seizures* refers to the clinical manifestations of the slow ephaptic propagation of epileptic discharge along the motor cortex, although similar progression can sometimes be seen in other primary cortical areas as well.
      2. *Focal (asymmetric) tonic seizures* can be associated with seizure origin from practically anywhere in the neocortex. In their purest form, focal tonic seizures are seen in the

explosive motor seizures of supplementary motor area origin.

3. *Focal sensory seizures with experiential symptoms* are those with complex, usually formed, distorted and/or multimodal, sensory symptoms implying seizure initiation in association cortices, such as the temporo-parieto-occipital junction, with connections to multiple sensory areas.

2. *Hippocampal and parahippocampal seizures* almost always require local spread for clinical manifestation, which may involve insula, amygdala, hypothalamus, and other limbic structures. Autonomic features such as a sensation of epigastric rising is common, as well as emotional experiences such as fear, dysmnesias, focal sensory seizures with olfactory or gustatory symptoms, and vague bilateral sensory phenomena such as tingling.

With ipsilateral propagation to:

1. *Neocortical areas*
   a. Same manifestations as II.A.1.a. and b.
   b. *Hemiclonic seizures* occur early in development before myelinization of the corpus callosum and do not necessarily have localizing value. They can alternately affect both hemispheres, as in Dravet syndrome and ischemic encephalopathy, or only one hemisphere in the case of focal disturbances.
2. *Limbic areas*
   a. Same manifestations as II.A.2.
   b. *Gelastic seizures* are clearly unique ictal events when they are initiated in relation to structural abnormalities of the hypothalamus, which are usually hamartomas. The mechanism is unknown, but initiation, at least, is distinct from gelastic seizures arising from other areas, such as mesial temporal lobe and cingulate.

With contralateral spread to:

1. *Neocortical areas*

   Hyperkinetic seizures, also referred to by some as *hypermotor seizures*, involve bilateral forceful limb movements, sometimes with vocalizations. Frontal lobes are implicated in these behaviors.

2. *Limbic areas*

   Dyscognitive seizures with or without automatisms (psychomotor) are not exactly synonymous with the current term â€œcomplex partial seizures,â€ which were defined on the basis of impaired consciousness only and do not necessarily involve limbic areas. This new term, as well as the term â€œpsychomotor,â€ conforms more to the original intent of the term â€œcomplex partial seizuresâ€ in the 1970 ILAE Classification of Epileptic Seizures.â€[13] It is implied that mesial temporal limbic areas and their immediate connections are involved in the clinical manifestations, although seizures may have been initiated elsewhere.

Secondarily generalized

1. *Tonic-clonic seizures* that are secondarily generalized probably consist of multiple types and may involve different pathophysiologic mechanisms and anatomical substrates, at least initially, than generalized tonic-clonic seizures with generalized onset.
2. *Absence seizures* can rarely represent propagation from localized cortical areas, usually in the frontal lobe. There may be a continuum between these events and generalized atypical absences.
3. Although *epileptic spasms* can occur in infants with focal lesions, the mechanism by which these generalized events are generated is unknown.

III. **NEONATAL SEIZURES**

Neonatal seizures: Although the components of neonatal seizures can be described in terms of the seizure types itemized above, they often display unique organizational features. Therefore, a study group will be created to more completely define and characterize the various types of neonatal seizures.

Status Epilepticus

Mechanistically, status epilepticus represents the failure of the natural homeostatic seizure-suppressing mechanisms responsible for seizure termination. Although an operational definition of status epilepticus has been proposed and is in common use in the clinical and epidemiological literature, it does not adequately reflect the underlying mechanisms involved in status epilepticus, nor is it always useful for clinical purposes. Regardless of the specific operationalized definition, however, the mechanisms involved in initiation and spread of the various types of status epilepticus are, in general, similar to those of self-limited ictal events, but additional factors that need to be considered in determining criteria for classification include:

- Different mechanisms that can prevent seizure termination, e.g., mechanisms that prevent active inhibition, desynchronization of hypersynchronous discharges, and depolarization block.
- Progressive features that contribute to subsequent functional and structural brain disturbances.
- Maturational factors

I. **EPILEPSIA PARTIALIS CONTINUA (EPC) OF KOJE- VNIKOV**

This is a combination of focal seizures with continuous twitching in the same area. The clinical and EEG features permit distinction of 3 conditions that correlate with etiology.

As occurs with Rasmussen syndrome. EPC in this subacute lateralized encephalitis of unknown cause (half the cases show the clinical expression of this encephalitis) combines focal myoclonus and focal seizures affecting various areas of the same hemisphere, with or without clear EEG correlation of the myoclonic jerks, and at times persistence of the jerks in sleep. There is progressive slowing of the background EEG activity on the affected side.

As occurs with focal lesions. Various dysplastic, vascular or tumor lesions produce EPC lasting a few days, weeks or months before the patient returns to baseline. EPC is also seen with nonketotic hyperglycemia. The jerks affect the same area as the focal seizures, and have an EEG correlate; they do not persist in sleep.

EPC is also a component of several inborn errors of metabolism. Various conditions affecting energy metabolism, namely Alpers disease or Myoclonus

epilepsy with ragged red fibers (MERRF), produce uni- and then bilateral rhythmic jerks that persist in sleep, with EEG correlates.

II. **SUPPLEMENTARY MOTOR AREA (SMA) STATUS EPILEPTICUS:** Frequently repeated seizures from the SMA usually present as a type of focal status epilepticus with preserved consciousness and individual tonic motor seizures occurring every few minutes all night long. Another type of SMA status epilepticus consists of secondarily generalized seizures that evolve into repetitive asymmetrical tonic motor seizures with profound impairment of consciousness.

III. **AURA CONTINUA:** Aura continua is a rare but well described manifestation of focal epilepsy. The symptoms depend on the localization. The attacks are usually without impairment of consciousness. The symptoms wax and wane, often for hours, and may be associated with a motor component, depending on the spread. Dysesthesia, painful sensations and visual changes are examples. Limbic aura continua is the most common clinical pattern. Fear, an epigastric rising sensation, or other features may recur every few minutes for many hours, or more than a day without going on to seizures with impairment of awareness. Electrographic correlation is variable. Diagnosis must be entertained, particularly in patients with well-established epilepsy.

IV. **DYSCOGNITIVE FOCAL (PSYCHOMOTOR, COMPLEX PARTIAL) STATUS EPILEPTICUS**

Mesial temporal: Focal status epilepticus predominantly involving mesial limbic structures consists of serial dyscognitive focal ictal events without return of clear consciousness in-between. Onset can be limited to one side, or can alternate between hemispheres.

Neocortical: Focal status epilepticus originating in various neocortical regions can present with a wide variety of unpredictable clinical patterns. Status epilepticus from some frontal foci can resemble absence status or generalized tonic-clonic status. It can present as repetitive descrete behavioral seizures. To some extent, this type of status epilepticus can reflect the neocortical region of origin. For example, occipital status epilepticus might present with unexplained blindness while dysphasia or aphasia could represent focal status in language cortex.

V. **TONIC-CLONIC STATUS EPILEPTICUS:** Generalized tonic-clonic status epilepticus can be an acute symptomatic event; it can be primarily generalized in idiopathic and symptomatic generalized epilepsies; and it is commonly secondarily generalized from focal epilepsies. Occasionally the manifestations can be unilateral.

VI. **ABSENCE STATUS EPILEPTICUS**

Typical and atypical absence status epilepticus: When absence status epilepticus occurs in the idiopathic epilepsies, it has features similar to atypical absence and can be terminated by antiepileptic drugs. In the generalized symptomatic epilepsies, there is overlap with focal status epilepticus due to lesions of certain frontal lobe areas. The absence status epilepticus occurring in elderly patients without a prior history of epilepsy, as well as drug-induced and drug-withdrawal absence status epilepticus, have been characterized and most likely represent similar mechanisms; however, there may be several different types of typical and/or atypical absence status epilepticus.

Myoclonic absence status epilepticus: Myoclonic absence status epilepticus consists of proximal, predominantly upper extremity myoclonic jerks corresponding with 3 Hz spike-wave discharges in the EEG. It can last hours or even days and is usually very resistant to therapy.

VII. **MYOCLONIC STATUS EPILEPTICUS:** Myoclonic status epilepticus consists of irregular, usually bilateral or generalized myoclonic jerking without interference with consciousness. Duration may be up to hours. It is most often seen in patients with insufficiently controlled JME, Dravet syndrome, and in non progressive myoclonic epilepsy in infancy, particularly Angelman syndrome. In myoclonic-astatic epilepsy, it predominates in the extremities of the upper limbs and around the mouth, the areas most represented in the precentral gyrus.

VIII. **TONIC STATUS EPILEPTICUS:** Tonic status epilepticus most commonly occurs in patients with symptomatic generalized epilepsy, but may occur in patients with idiopathic generalized epilepsy. In some of these patients, there appears to be an overlap of symptoms of idiopathic and symptomatic generalized epilepsy. Characteristically, when the patient is lying down, the neck is flexed, the arms are flexed at the elbow, and slightly elevated. The tonic spasms are brief and can continue at brief intervals for hours. In symptomatic generalized epilepsy the duration of the status epilepticus can be much longer.

IX. **SUBTLE STATUS EPILEPTICUS:** This has become an accepted concept, although its accurate diagnosis is often controversial. It refers to an end stage of prolonged generalized tonic-clonic status epilepticus characterized by focal or multifocal myoclonic movements, coma, and pseudoperiodic lateralized epileptiform discharges (PLEDs) against a slow low-voltage background on EEG. The myoclonic movements reflect severe brain damage caused by prolonged status epilepticus and may not be epileptic in nature.

Summary and Conclusions

The 1981 International Classification of Epileptic Seizures has been under review by the ILAE for the past 8 years. A diagnostic scheme for describing individual patients has been proposed that treats epileptic seizure types as diagnostic entities with etiologic, therapeutic, and prognostic implications. This concept is particularly useful when syndromic diagnoses cannot be made. This diagnostic scheme also recognizes the need for a separate detailed phenomenologic description of epileptic seizures in some patients. Although minor changes in the 1981 classification have been recommendedâ€"most importantly replacement of the term â€œpartial seizureâ€ with â€œfocal seizureâ€â€"no new classification has been proposed. As a first step, however, a list has been prepared of recognized epileptic seizure types that are currently believed to be unique diagnostic entities based on knowledge of pathophysiologic mechanisms, anatomic substrates, response to AEDs, ictal EEG patterns, provocative factors, postictal features, and epilepsy syndromes with which the seizure types are associated. Impairment of consciousness should be noted as part of the clinical description of individual patients' seizures, but is not a factor for defining unique seizure types as diagnostic entities. Scientific principles and hypothesis testing will be applied to the process of classification of these seizure types. Each will be subject to evidence-based verification, falsification, and revision, as new information becomes available. Experience with the application of these seizure types and their subsequent classification will also lead to modifications. Continuous review and revision of seizure types will be needed to ensure that they adequately and accurately reflect current knowledge, as well as the needs of clinicians and scientists working in the field of epilepsy.

Chapter 44

Simple Motor Seizures

Prakash Kotagal

Hans O. LÃ¼ders

Introduction

Focal motor seizures have been recognized since Hippocrates first noted them, beginning contralateral to the side of head injury. Hemiplegic epilepsy was first actually described by Bravais in 1827.[62] Jackson pointed out that focal epileptic seizures were due to a â€œsudden and excessive discharge of gray matter in some part of the brainâ€ and that the symptoms of the seizure depended on the â€œseat of the discharging lesion.â€ Fritsch and Hitzig demonstrated that electrical stimulation of the motor cortex in animals gave rise to focal muscular contractions in the contralateral limb.[38] In 1887, Charcot proposed the term *jacksonian epilepsy* to describe seizures with a â€œmarchâ€ of symptoms.[59] Another term â€œBravais-jacksonian seizuresâ€ has been used by some to indicate a similar march of symptoms. The term *aura* has been in use since Galen's time; its literal meaning â€œbreeze of airâ€ refers to the altered sensations experienced by the patient with epilepsy at the start of a seizure. Erastus pointed out that an aura was the start of the seizure itself.[48] Electrical stimulation of the brain[100] and detailed observations of spontaneous and metrazol-induced seizures[3] have provided much of the basis for our current knowledge of focal motor seizures.

Definitions

The International Classification of Epileptic Seizures divides simple partial motor seizures into those with or without a march, versive, postural, and phonatory seizures.[30,31] Consciousness is retained during these seizures; however, occasionally, a seizure discharge may remain localized and still produce alterations of consciousness.[46] The epileptogenic zone in the involved hemisphere may be very restricted or quite large, even though terms such as â€œpartialâ€ or â€œfocalâ€ are employed. A more recent seizure classification is based on clinical symptomatology and is independent of electroencephalographic (EEG), neuroimaging, and historical information. In this classification, terms such as *focal clonic, focal tonic,* or *versive* are used, and evolution during the course of the seizure is indicated by arrows, for example somatosensory aura â†' left arm clonic seizure â†' left versive seizure.[8,81,82]

Epidemiology

In a series of 8,938 patients admitted to the University Hospital of Lyon over a 10-year period from 1965 to 1975, 1,158 (12.9%) patients had focal motor seizures without march, 199 (2.2%) patients had focal motor seizures with march, 582 (6.5%) had hemiconvulsions, and 461 (5.2%) had adversive seizures.[89] In a population-based study of 1,054 patients from Denmark, Wagner found that 17% of epileptic patients had simple partial seizures.[124] Loiseau reported that out of 200 patients with partial seizures, 71 (35.5%) had partial motor symptoms, of whom 10 patients exhibited a march.[76]

Anatomic Pathways and Pathophysiology

Simple partial seizures with motor manifestations are due to ictal onset within or near the pre- and postcentral gyri of the contralateral hemisphere. The somatotopic motor and sensory representation of various regions of the body has been documented by the pioneering work of Penfield and Jasper[100] and others[75] (Fig. 1). It is believed that the relatively large representation of the face and fingers is accounted for by the majority of focal motor seizures starting in those brain regions. Holowach noted that 25 of 50 jacksonian seizures in children began in the face, 17 from the hand, 7 from the arm, and 9 from the leg.[60] Penfield and Jasper also noted that the angle of the mouth was involved first in seizures affecting the face; upper-extremity seizures began in the thumb and index finger, whereas lower-extremity seizures often began in the great toe.[100] Another factor is the seizure threshold of various regions of the homunculusâ€"the trunk not only has the smallest cortical representation[87] but also a higher threshold to electrical stimulation.[37] Jacksonian seizures show an orderly â€œmarch,â€ beginning, for example, in the thumb, then involving other fingers, the wrist, forearm, proximal arm, shoulder, and then the face (usually the orbicularis region first). At times, the march may skip certain areas, perhaps because of different seizure thresholds in various regions.[4] Sensory phenomena may occur in about one third of patients with focal motor seizures;[27] this may be caused by involvement of pre- and postcentral regions by the epileptogenic lesion or preferential pathways for spread of the ictal discharge.[36,112] Clonic seizures were reported in 29% of 24 patients with frontal lobe epilepsy.[113] Noachtar and colleagues examined seizure phenomena preceding and following clonic movements in a group of patients with frontal lobe epilepsy: Clonic seizures were usually preceded by behavioral arrest or tonic movements and were the initial manifestation in one third.[93] Motor symptoms also occur in seizures starting elsewhere and spreading to the sensorimotor cortex, such as the parietal lobe,[114,126] occipital lobe,[83,127] or even the temporal lobe.[17]

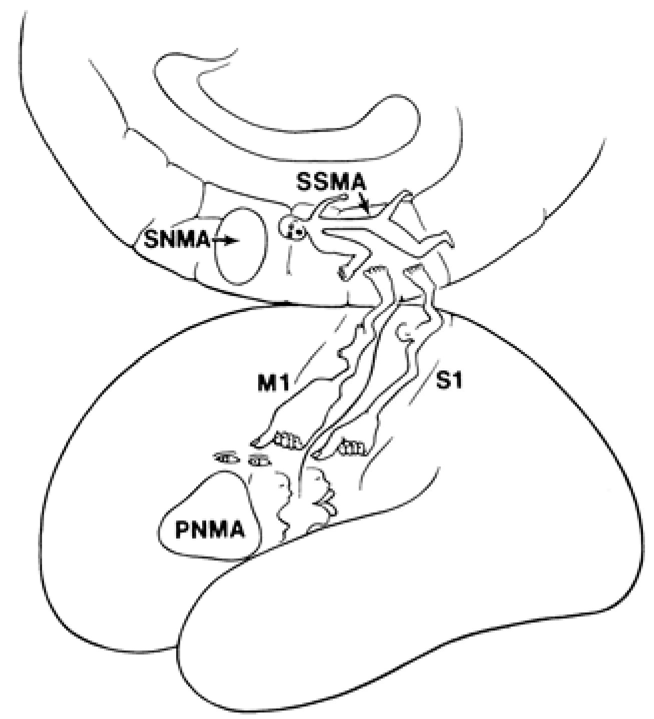

FIGURE 1. Motor and sensory homunculi. The lateral convexity homunculus was simplified from Penfield and Jasper (1954); the supplementary sensorimotor area (SSMA) homunculus was prepared based on stimulation findings by Lim et. al (1994).

The output of the primary motor area (PMA) goes to the corticospinal and corticobulbar tracts, as well as to the supplementary motor area and homologous areas in the opposite hemisphere via the corpus callosum. The PMA gives rise to only one third of the corticospinal and corticobulbar tract fibers, another third come from the premotor cortex and supplementary motor area (SMA), while another third arise from the parietal lobe.[5] Ictal single photon emission computed tomography (SPECT) scan findings in patients with frontal and parietal lobe epilepsy show good agreement with data from electrical brain stimulation studies and invasive EEG recordings.[28,54,58,84,92]

Very rarely, focal seizures have been reported in patients with cerebellar, brainstem, or spinal lesions.[52,55] In

Harvey's patient, localized hyperperfusion on ictal SPECT and ictal discharges were noted in the vicinity of the lesion, and the seizures disappeared after surgical removal of the lesion.

Clinical Features

Ictal

The hallmark of simple motor seizures is focal motor activity that may be expressed as clonic, tonic, postural, or phonatory activity. The international classification of seizures divides simple partial motor seizures into clonic, tonic, postural, and phonatory seizures.[30,31]

Clonic seizures consist of jerky, usually rhythmic movements and are usually seen with seizures starting from the sensorimotor cortex. The clonic movements may remain restricted to one region or spread in a jacksonian manner. As mentioned earlier, jacksonian seizures begin and spread in characteristic ways. Hemiconvulsions are clonic seizures affecting one side of the body. These often occur in the setting of infantile hemiplegia.[2,19,43,47] Most clonic seizures are brief, lasting less than 1 or 2 minutes. Focal myoclonus has also been reported in infants and young children with dysplastic lesions of the motor cortex.[71]

Persistent, stereotyped, periodic, or quasi-periodic clonic activity may occur, and different types are described.[42] Kojevnikov gave the label *epilepsia partialis continua* (EPC) to repeated jacksonian seizures characterized by a march of clonic seizures. Between such attacks, patients have persistent, stereotyped focal myoclonic episodes.[67] The twitching typically affects the thumb or big toe, and individual jerks occur no more than 10 seconds apart.[119] Another type consists of repeated, stereotyped clonic seizures without a march. The usual etiology for EPC is a lesion involving the sensorimotor cortex resulting from stroke, tumor, trauma, metastasis, or hypoxic ischemic encephalopathy.[98,119] EPC is frequently seen in the setting of Rasmussen encephalitis, in the subacute type of measles encephalitis, and in mitochondrial disorders such as mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS).[22] EPC cases have also been reported in nonketotic hyperglycinemia affecting adults and in some patients with subcortical lesions.[24]

Tonic motor seizures produce sustained contraction of a limb and result in assumption of various postures. Tonic motor seizures are believed to implicate a wider area of cortex including the SMA and premotor region.[34,44,100,128] The M2e posture described by Ajmone-Marsan is seen in seizures arising from the SMA region. It consists of abduction, elevation, and external rotation of the contralateral arm with the elbow slightly flexed; the head and eyes deviated as if to look at that arm, while both lower extremities may be slightly flexed at the hips and knees or extended. Even in patients where tonic posturing appears unilateral, a bilateral increase or decrease of tone occurs.[1]

Postural seizures refer to tonic contraction affecting more than one limb and the trunk or headâ€"typically these are bilateral tonic movements affecting the proximal muscles more than the distal muscles. Rarely, motor seizures are manifested by focal weakness instead of tonic or clonic activity.[45,51,100,122] Consciousness is retained during SMA seizures in 72% of attacks.[3] A prolonged continuous or interrupted vocalization may occur in seizures involving the supplementary motor or lower rolandic area from either hemisphere.

Versive seizures are characterized by predominantly tonic contraction of head and eye muscles resulting in sustained, forceful deviation to one side (invariably contralateral).

Consciousness is often lost by the time a patient experiences version; at other times, however, patients are conscious of forced eye and head deviation;[26,90] often the angle of the mouth is also deviated to the same side, and the neck is extended.[63] In Wyllie's study, version was accompanied by clonic or posturing arm movements or facial clonic movements on the side of contraversion. The versive movement was smooth in 65% and jerky in 35% of seizures.[129] Rasmussen and Penfield found that stimulation of the precentral gyrus immediately anterior to the central sulcus (area 8) resulted in contralateral eye deviation;[107] less often ipsilateral deviation or upward deviation and convergence occurred. However, stimulation of more anterior sites always resulted in contraversion.[117] Version may also occur upon stimulation of the occipital lobe.[10,104,120,129] Version occurs on the same side as dystonic posturing[68] and is usually but not always followed by a secondarily generalized tonicâ€"clonic seizure.[13,21,68,129] Version occurs in partial onset seizures originating from a number of different locations that spread to the premotor cortex. Chee et al. found that version occurred earlier than 18 seconds in extratemporal seizures and later than 18 seconds in the vast majority of temporal lobe seizures.[21] This is, of course, due to more rapid spread to the prefrontal cortex in extratemporal seizures (the majority starting from the frontal lobe). Ipsilateral forced eye and head deviation occurs in frontal lobe seizures; later in the seizure, contralateral version occurs just prior to secondary generalization. Some authors reported forceful head turning occurring ipsilaterally to the focus;[44,95,109] these could be due to (a) seizures beginning in the area where Penfield and Rasmussen found ipsiversive movements, (b) rapid contralateral spread to homotopic frontal eye fields, or (c) disruption of normal pathways due to structural lesions.[16] In our experience, version occurring just prior to a secondary generalization has always been correct in lateralizing the side of ictal onset.[13,21] At the end of the generalized convulsion, Wyllie et al. have noted ipsilateral head and eye deviation (ipsiversion), which is presumed to reflect activation of the opposite hemisphere and neuronal exhaustion on the side of seizure onset.[130] Ictal SPECT scans in versive seizures show localized hyperperfusion in the region of the sensorimotor cortex.[54,92,125] Asymmetric tonic limb posturing, sometimes referred to as the â€œFigure 4 sign,â€ occurs in the course of secondarily generalized tonicâ€"clonic seizures, and is usually contralateral to the side of ictal onset.[69]

Phonatory seizures are thought to result from activation by the ictal discharge of the primary motor cortex or the SMA. Phonatory movements have been elicited upon stimulation of the SMA or the primary motor cortex below the tongue or lip area.[100] Vocalization in SMA seizures is more often sustained than interrupted,[64] whereas seizures involving the primary motor area tend to produce interrupted sounds. Speech arrest (inability to speak during the seizure in spite of conscious attempts by the patient) may result from involvement of the primary motor cortex on either the dominant or nondominant hemisphere.[40] Conversely, Broca aphasia results from involvement by the ictal discharge of the Broca area immediately anterior to the face area in the dominant hemisphere. This can be reproduced by electrical brain stimulation.[40,56,80,116]

Interictal

In the interictal state, patients who have structural lesions involving the sensorimotor cortex may exhibit contralateral hemiparesis or sensory disturbances on that side of the body, for example in the setting of Rasmussen encephalitis, infantile hemiplegia, or the hemiconvulsions, hemiplegia, epilepsy (HHE) syndrome. In the HHE syndrome, infants between 6 months to 2 years of age develop prolonged unilateral convulsions in the setting of a febrile illness. The convulsions last from an hour to several days, and are followed by the onset of hemiparesis and jacksonian motor, complex partial seizures or secondarily generalized tonicâ€"clonic seizures arising from the contralateral rolandic region or the temporal lobe.[43] Cases of HHE syndrome are much less common these days since the introduction of effective medications to terminate status epilepticus.

Postictal

Postictally, a functional neurologic deficit that lasts from minutes to as long as 48 hours may be seen.[122] This may be a worsening of a previous focal deficit, or a new one may appear. Todd paralysis, as it is commonly referred to, is related to the duration of the seizure, and is thought to represent postictal neuronal hyperpolarization,[85,86] the inhibitory effect of ictally released endogenous peptides, or cortical ischemia resulting from functional arteriovenous shunting.[131] It may be accompanied by postictal slowing on the EEG, contralateral to the side of weakness. Computed tomography (CT) and magnetic resonance imaging (MRI) scans may show transient cerebral edema.[29,115] The side of Todd paralysis is useful in lateralizing the hemisphere of seizure origin in over 90% of patients, especially when it can be documented in the epilepsy monitoring unit.[65]

Electroencephalographic FINDINGS

Interictal

Detection of interictal spikes by scalp EEG electrodes depends on the extent of the epileptogenic zone as well as the orientation of the dipole. A critical area of 6 cm^2 must be involved before changes can be detected at the scalp.[39] Quesney et al. examined surface and subdural recordings from 34 patients with frontal lobe epilepsy rendered seizure-free after resection of the epileptogenic focus. Focal spiking was noted in 9% of patients, whereas nearly 60% had more widespread or generalized spiking. Nearly 12% had no detectable spikes on scalp recordings. Subdural recordings revealed either regional spiking over two or three gyri, extensive spiking all over the grid electrodes, or less often, an absence of interictal spikes.[103]

Ictal

Scalp recordings of ictal onsets may disclose regional seizure patterns; however, the patterns are more extensive or difficult to lateralize compared to temporal lobeâ€"onset seizures. From subdural electrode recordings, evidence for a focal onset is found in a relatively small number of patients; more often a diffuse regional onset is seen.[103] Devinsky et al. reported good correlation between the localization of the ictal onset with semiology. Furthermore, subdural electrodes detected ictal changes that were not apparent at the scalp in some cases.[28] In epilepsia partialis continua, irregular 0.5- to 3-Hz slowing is seen in the frontocentral region, along with a reduction in the Î²-activity. If progression to a more involved seizure occurs, a well-defined seizure pattern may become evident. Interictal epileptiform discharges were noted in only 8 of 36 (22%) of patients with EPC[24] (Fig. 2).

Diagnostic Considerations

Simple motor seizures are usually easily diagnosed by history alone. The history of focal tonic or clonic features is usually unmistakable. Seizures arising from the SMA however, can sometimes be mistaken for generalized tonicâ€"clonic seizure or psychogenic seizures. SMA seizures are brief, stereotyped seizures with variable responsiveness, which often involve the proximal limbs bilaterally. Video-EEG (V-EEG) monitoring is helpful in ambiguous cases; after reducing or stopping the patient's antiepileptic medications one may note a progression to focal clonic activity, version, or secondary gene- ralization.

Differential Diagnosis

The differential diagnosis of simple motor seizures includes nonepileptic myoclonus,[101] tic disorders, tremor, myokymia, and paroxysmal dystonic and kinesogenic choreoathetosis; a normal outpatient routine EEG does not exclude the possibility of simple motor seizures. Home videotape recordings, when available, are extremely helpful; otherwise, prolonged V-EEG monitoring may be indicated if the attacks are occurring with some frequency. In this setting, ambulatory EEG is not particularly helpful, especially if no ictal changes are seen. Good-quality videotape recordings of the events are essential in making a diagnosis.

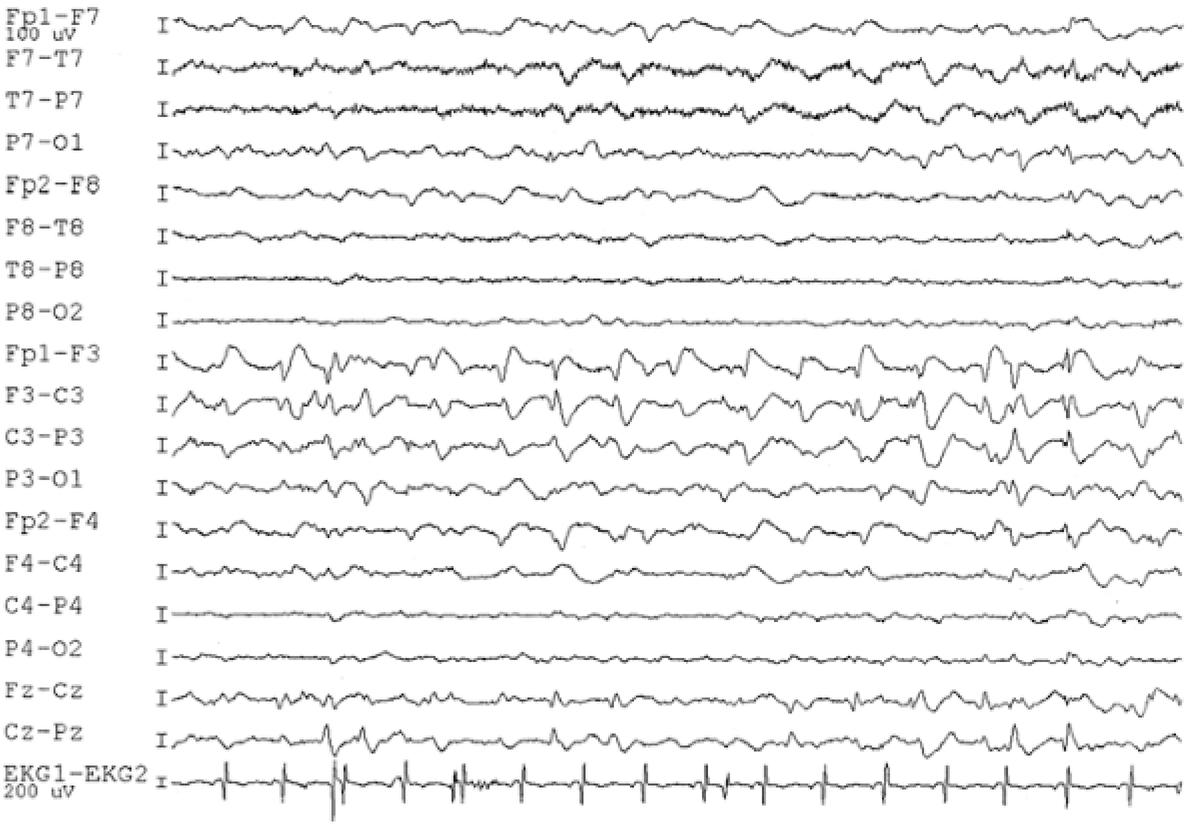

FIGURE 2. EEG recording in a 12-year-old girl with epilepsia partialis continua affecting the right hand secondary to Rasmussen encephalitis. Repetitive sharp waves and continuous slowing are noted in the left frontocentral region; these were noted to coincide with the jerks.

Specific Syndromes

Rasmussen Encephalitis

In Rasmussen encephalitis, young children, usually between 6 and 10 years of age, develop intractable focal motor seizures with frequent bouts of focal status or epilepsia partialis continua on one side of the body. Within months of onset, the child develops a progressive hemiparesis, hemisensory loss, or even hemianopsia, as the involved hemisphere undergoes progressive neuronal cell loss, gliosis, and atrophy. This is accompanied by intellectual decline and behavior disturbances. The course is progressively worsening, with death occurring in most of the children within a decade; a few patients appear to stabilize over time, a condition known as â€œburnt-out Rasmussen.â€[96,105]

P.524

CT and MRI scans show progressive atrophy starting in the region of the sylvian fissure and slowly affecting other areas of that hemisphere. Changes in signal intensity may also be seen in the deep gray and white matter.[118] Pathologic examination shows signs of inflammation, with glial nodules and perivascular infiltrates containing plasmocytes, lymphocytes, and glial cells.[49,61,110] Diagnostic criteria for making the diagnosis of Rasmussen syndrome were recently published.[12] In situ hybridization techniques were reported to show most Rasmussen patients to have neurons with cytomegalic inclusion virus;[102] this, however, has not been confirmed by others.[7] Autoantibodies to the glutamate receptor GluR3, functioning as a glutamate agonist, have been reported in some patients.[111] T-cellâ€“mediated cytotoxicity may also play a role.[35] Following cleavage of the GluR3 protein by granzyme B, the immunogenic section of the GluR3 protein becomes exposed to the immune system.[41] For reasons that are not yet known, Rasmussen encephalitis is essentially a unilateral disease. Because the seizures do not respond to medical treatment, surgical removal of the epileptogenic cortex is done when hemiparesis has resulted (usually when useful finger movement has been lost). This consists of a functional or complete hemispherectomy. The surgical procedure should be done relatively early in the course, prior to involvement of the opposite hemisphere. Some authors have recommended intravenous immunoglobulins, high-dose steroids, or plasmapheresis; patients with recent onset of the disease showed a significant improvement.[6,23,32,53] However, medical treatment does not appear to produce a lasting improvement. A trial of tacrolimus was found to slow the rate of neurologic deterioration, but it did not improve seizure frequency.[11]

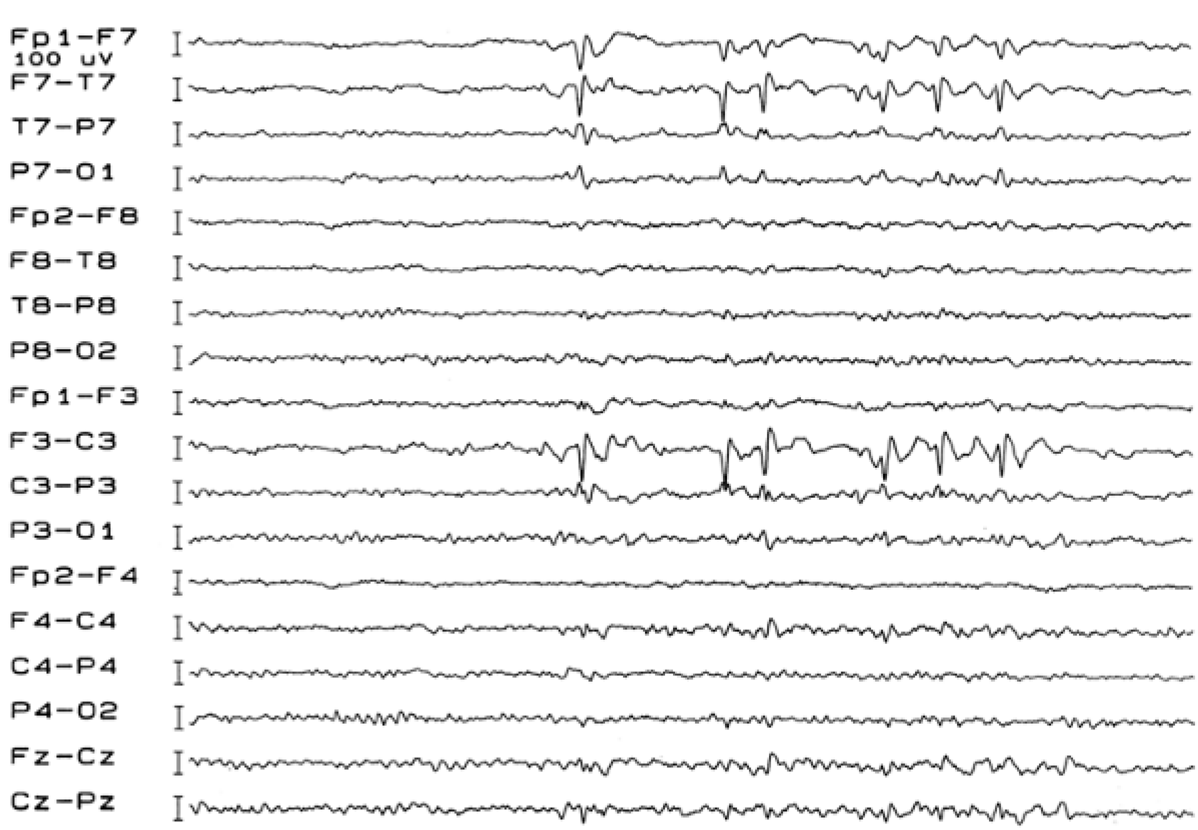

FIGURE 3. Typical benign focal epileptiform discharges of childhood in the left central-temporal distribution.

Benign Focal Epilepsy of Childhood

Also known as *benign rolandic epilepsy* or *benign epilepsy with centrotemporal spikes*, benign focal epilepsy of childhood (BFEC) is the commonest epilepsy in children, accounting for 15% to 25% of childhood epilepsies.[57,73] Its usual age of onset is between 2 and 12 years, followed by eventual remission in all typical cases before the age of 16.[77] Genetic factors are believed to play a role; it is thought to be autosomal dominant with variable penetrance.[18,57] It has been calculated that only about 8% to 10% of children with the typical EEG picture will actually manifest seizures.[79] It is thought to have a diffuse epileptogenicity affecting the brain in an age-dependent expression.[79] Children typically present with simple motor seizures affecting the face and arm (sometimes accompanied or preceded by somatosensory auras) that occur shortly after falling asleep or upon awakening. Younger children may instead have secondarily generalized tonicâ€“clonic or hemiclonic seizures. The EEG findings in this syndrome are diagnostic.[9,15,57,73,79,91] Sharp waves with a characteristic morphology and polarity occur in the centrotemporal region; at times multifocal sharp waves are seen in other areas as well (Fig. 3). The typical sharp waves may not be seen on awake recordings, but are abundant, sometimes in long runs as soon

P.525

as the child falls asleep. Seizures in BFEC are readily controlled by most antiepileptic medications. Approximately half the children will have fewer than five seizures; the remainder can be readily controlled by medications such as oxcarbazepine, carbamazepine, phenytoin, or gabapentin.[9,15,73,78] After a seizure-free period of 2 or 3 years, children can be successfully tapered off medications. Another syndrome of benign partial seizures affecting adolescents has been reported; however, the epileptiform discharges do not have a typical morphology.[66]

Partial seizures during the first 2 years of life often manifest tonic posturing (either symmetric or asymmetric), eye deviation, and asymmetric clonic jerking. This contrasts with auras, restricted clonic movements, automatisms, and dystonic posturing that become increasingly frequent after the age of 6 years.[94] Some of these infants will also develop infantile spasms following or preceding the partial seizures.[97] The entity of *malignant migrating partial seizures of infancy* begins before the age of 6 months, with nearly continuous focal seizures arising independently from shifting foci in both hemispheres. These seizures may be clonic, tonic, versive, or autonomic. Interictal EEG shows multifocal sharp waves and background slowing, whereas ictal recordings demonstrate monomorphic rhythmic Î¸-discharges arising from shifting foci. These infants show developmental regression and have high morbidity and mortality risk.[25,50]

Response to Treatment

After the occurrence of several partial or secondarily generalized tonicâ€“clonic seizures, the need for treatment with antiepileptic medications becomes evident. Sodium channel blocking agents such as oxcarbazepine, carbamazepine, and phenytoin are most often used. Other antiepileptic drugs (AEDs) that are also effective include levetiracetam, topiramate, zonisamide, lamotrigine, gabapentin, pregabalin, vigabatrin, and primidone. The response to treatment becomes clear by the end of the first year in most cases, provided that the seizure type and medication used are correct.[33] Elwes found that approximately 73% of those with partial seizures had a 1-year seizure-free period during 5 years of follow-up; the remaining patients have medically intractable seizures.[33,108] Recent studies indicate that failure to respond to two or three AEDs is a very strong indicator of medical intractability.[72] Such patients may benefit from a presurgical evaluation to determine if they can benefit from focal cortical resection.[70] Partial onset seizures occurring in association with periodic lateralized epileptiform discharges (PLEDS) may be more difficult to control; however, few of these patients go on to develop chronic epilepsy.[74] Seizures occurring in the setting of focal lesions, such as focal dysplasia or tumor, seem more resistant to therapy. Patients with medically intractable seizures should be evaluated for epilepsy surgery. Results after focal cortical resection are much better for those with localized lesions than for those without.[123] Unless evidence shows the epileptogenic focus to be far removed from functional areas, invasive EEG recording and electrical brain stimulation are necessary in most patients. Children with Rasmussen chronic encephalitis almost always have a progressively worsening course. Functional hemispherectomy should be considered when useful finger movements have been lost in the affected hand. Hemispherectomy is also useful in

patients with chronic epilepsy and infantile hemiplegia.[19] In the case of BFEC, in which some children have only occasional simple motor seizures at night, the child's physician and parents may decide not to use daily antiepileptic medications, which may have potential side effects.

Summary and Conclusions

The study of simple partial seizures has provided us with valuable insights into the organization of the sensorimotor cortex. BFEC, the most common epilepsy in children, is easily recognized thanks to its typical presentation; seizures are infrequent and readily controlled with antiepileptic medications. At the other end of the spectrum, Rasmussen encephalitis is an infrequent but catastrophic disease with inexorable progression. Medical treatment offers no lasting benefit, and hemispherectomy is usually necessary. Approximately 25% of patients with simple partial seizures become medically intractable and may need evaluation for epilepsy surgery.

Chapter 45

Neocortical Sensory Seizures

Paul C. Van Ness

Ronald P. Lesser

Michael S. Duchowny

Introduction

Simple sensory seizures represent challenging clinical phenomena. Neurologists readily accept that a patient's sensory symptoms prior to the appearance of motor symptoms or alteration of consciousness represent part of the patient's clinical seizure semiology and provide valuable localizing information. A challenge appears when a patient has only simple partial sensory seizures. Simple partial seizures are a relatively common seizure presentation among the childhood epilepsies, but motor seizures are predominant.[47] The paucity of psychic or sensory symptoms may reflect the child's inability to describe internal experiences in a way that is easily interpretable to adult observers. Since simple sensory seizures have no overt ictal behavior, the subjective description of the seizure symptomatology is the only clue that can lead to a proper clinical evaluation and treatment. Some patients react to sensory seizures in a stereotypic fashion. For example, a painful simple partial sensory seizure of the hand may result in hand rubbing or vocalization about the pain. Occasionally, physicians encounter patients who have simple partial seizures for many years prior to the appearance of more clinically apparent seizures. When patients with pure sensory seizures also have psychiatric complaints, the chances for misdiagnosis or delay of diagnosis are high.[121]

Simple sensory seizures were originally underrecognized as epilepsy.[35] While auras were known in ancient times as an event preceding seizures,[122] it was not until the early 19th century that partial seizures were clearly related to localized brain disease. Fritsch and Hitzig described localization of function in 1870, which led to modern concepts of cortical specification.[38]

Jackson also promoted the hypothesis that abnormal electrical activity in a localized region of cortex could cause symptoms such as those seen in epilepsy.[51,52] In the early 1900s, the work by Brodmann[18] and other neuroanatomists showed that the cerebral cortex had regional histologic variations often corresponding to different cerebral functions. Penfield, Jasper, and others made major contributions to mapping the localization of cerebral function and defining motor and sensory areas of the brain, as well as areas without obvious effect on sensory, motor, or speech activity.[83,85]

Definitions

Sensory seizures were defined by Penfield and Jasper separately from simple seizures with autonomic symptoms or psychic symptoms:[85]

â€œSensory seizures. Discharge in an area of sensory representation produces a sensation that may serve as a warning (aura) of a motor or psychical seizure. Actually, the sensation constitutes, in itself, a seizure. Under this heading we have taken up the sensory attacks that involve the trunk, head, and extremities (somatosensory), and the special senses (visual, auditory, vertiginous, gustatory, and olfactory).

1. Somatosensory seizures. Sensation of this type may be transient, or it may be continuous over a considerable period of time. The quality of sensation is tingling, numbness, sense of movement, desire to move, or, very occasionally, pain. A detailed march of sensation may occur from one somatic part to the

next in a manner similar to the Jacksonian motor march. The discharge, which produces this, usually occurs in the postcentral gyrus. There is a tendency for the sensory march to stop and to spread across the Rolandic fissure so as to produce movement in the same member. Spread in the reverse direction from motor to sensory representation, thus producing sensation after movement, is quite rare.

A somatosensory seizure may also be produced by discharge in the second sensory area on the upper bank of the fissure of Sylvius. Furthermore, peculiar body sensations may result from discharge in the supplementary motor area within midsagittal fissure.

2. Visual seizures result from discharge in one or the other occipital lobe. Lights, which may be colored, appear before the patient, or there may be dimming of vision and complete blindness even though the discharge originates in one occipital lobe. Complicated visual hallucinations and alterations in the interpretation of things seen are not included in this group, but are discussed under the heading of psychical seizures.
3. Auditory seizures are characterized by a simple sound, usually described as buzzing or drumming, and often referred by the patient to the opposite ear, or opposite side of the head. Like a visual seizure, there is nothing elaborate about it. Hallucinations of music, for example, are classified as dreamy states or psychical seizures and are discussed below.
4. Vertiginous seizures. What is called by the patient dizziness or unsteadiness is frequently reported, but there is rarely any recollection of direction of rotation as there is in the sudden dizziness of Meniere syndrome.
5. Olfactory seizures have been called uncinate fits because of the demonstration by Jackson of involvement of the uncinate gyrus in cases in which an aura of disagreeable odor constituted the initial feature. The localization of discharge is doubtless in or near the uncinate gyrus.â€

Penfield and Jasper's classification of simple partial sensory seizures has withstood the test of time since the international classification[26] of simple partial seizures with somatosensory or special sensory symptoms is nearly identical to the original description except for lack of description of gustatory seizures (Table 1). It is unlikely that another sensory modality will be discovered and change the classification further.

Table 1 Simple Partial Seizures with Somatosensory or Special Sensory Symptoms[a]

Somatosensory
Visual
Auditory
Olfactory
Gustatory
Vertiginous

[a]Simple hallucinations (e.g., tingling, light flashes, buzzing).

Penfield and Jasper recognized the difficulty of separating a simple sensation from a more complicated hallucination, for example, separating simple visual hallucinations from more complicated formed illusions. Occasionally one finds more complicated hallucinations with intraoperative stimulation, but more reliably localizing are the simple hallucinations of rather elementary sensory perceptions. A conscious patient may attach many complex descriptions to simple

P.530

hallucinations, and since we observers have nothing to observe other than the patient's subjective description, sometimes there may be a fine line between a classification of simple partial sensory seizure and a simple partial psychic seizure with prominent sensory complaints.

Epidemiology

Ideally, understanding the epidemiology of simple partial seizures would require evaluation of a large population in which patients with epilepsy are identified accurately and their seizures and epilepsies are classified based on a thorough clinical and laboratory investigation. Such studies are usually based on patients referred to specialized epilepsy centers. Focal epilepsy occurs in approximately 60% of patients with epilepsy, and 10% to 21% of these patients have simple partial seizures alone.[40] Detection of simple partial seizures can be difficult. Some patients with simple partial sensory seizures may be undiagnosed or unaware that their symptom represents epilepsy unless the seizure progresses into a more disabling seizure type. In patients with obvious epilepsy and more severe types of seizures, only a careful history will elicit remote sensory complaints that may no longer occur, as in several cases reported by Williamson et al.[123]

Isolated simple partial sensory seizures are uncommon in patients referred to major epilepsy centers. Among the focal epilepsies, temporal lobe and frontal lobe foci predominate in surgical series.[119] Parietal and occipital cases are rare because those epilepsies are either rare, rarely intractable, or rarely brought to surgery. For example, occipital epilepsy was identified in only 12 of 502 nontumoral epilepsy cases by Bidzinski et al.[12] Williamson et al. reviewed reports of occipital lobe epilepsy in the literature and found that <2% of focal epilepsy is occipital.[124] They found only sporadic reports when they reviewed parietal lobe epilepsy.[123]

These surgical data are typically grouped by lobe, not seizure type. It is likely that the epidemiology of simple partial sensory seizures differs from the lobar distribution of surgical cases. A review of the initial signs of seizure onset in data adapted from Penfield and Kristiansen showed that in 222 patients, 55 had somatosensory auras, 11 had visual auras, three had auditory auras, one had an olfactory aura, and two had gustatory auras.[62] Penfield and Perot noted visual hallucinations in 41 of 1,132 (3.6%) patients with focal epilepsy; 21 had only visual hallucinations.[87] Mauguiere and Courjon found somatosensory epilepsy in 127 of 8,938 (1.4%) patients with epilepsy when evaluated after age 3 years.[72] Young and Blume reported painful seizures in 24 of 858 (3%) epileptic patients[129] and Hausser-Hauw and Bancaud noted that 30 of 718 (4%) intractable epileptics had gustatory hallucinations.[43] West and Doty reviewed olfactory auras in epilepsy and concluded that prevalence is unknown but published estimates ranged from <1% to >30% depending on the epilepsy syndrome and pathology.[122]

The advent of magnetic resonance imaging (MRI) technology has further complicated matters. Patients with lesions identified in known sensory cortical regions may not volunteer information on sensory symptoms until thoroughly interrogated about an aura. At times, only with inpatient video-electroencephalography (V-EEG) and MRI can sensory symptoms be suspected and assessed. This is especially true in patients with sensory symptomatology at seizure onset that progresses to loss of consciousness and amnesia for the aura. These patients often have more intense seizures and EEG changes are usually bilateral.[103] Additionally, sensory symptoms may result from spread of a seizure from an unexpected location; for example, many patients with supplementary motor seizures complain of a somatosensory aura even when lesions are not near the sensory cortex.[106] Gustatory hallucinations may also represent seizure spread.[43] Visual hallucinations have been reported with frontal lesions,[102] as have jacksonian sensory seizures from a prefrontal lesion.[118] Thus, at this time, there is still need for adequate epidemiologic studies of localization-related epilepsies and partial sensory seizures using modern technology and appropriate clinical information.

Anatomic Pathways and Pathophysiology

Understanding neocortical anatomy and regional interconnections has led to a better understanding of seizure semiology and evolution. The neocortex is a repository for all primary sensory input for somatosensory, visual, auditory, and gustatory senses, while olfaction mostly utilizes portions of the limbic system and is the only special sense without thalamic relays.[21] Within the cerebral cortex, sensory functions are not so discreetly organized that there are sharp boundaries; for example, the sensory responses obtained by Penfield and Rasmussen[88] and Uematsu et al.[116,117] showed that sensory responses could be recorded from the precentral gyrus (see reference 85, p. 58, Fig III-12). Motor responses show similar dispersion. Penfield reported that removal of the precentral gyrus did not prevent motor responses from the postcentral gyrus, suggesting that activation of the postcentral gyrus alone could result in movements during seizures.

The sensory homunculus (see reference 85, p. 70, Fig III-15) must be considered as an artist's schematic diagram of data obtained by Penfield and Jasper on many patients; it is not entirely accurate for each patient. However, the homunculus does show significant organization of the cerebral cortex in an anatomically meaningful way (see reference 85, p. 71, Fig. III-17).

Some body parts (e.g., the tongue and hand) have large cortical sensory areas. Picard and Olivier have extensively reviewed the anatomy of the sensory tongue cortex in humans. The language-dominant hemisphere had a larger sensory cortical tongue representation and the tip of the tongue had more extensive representation than the middle or back portions of the tongue.[89] Most cortical representation was contralateral to somatic localization, but ipsilateral and bilateral responses to stimulation were reported, suggesting possible stimulation of the secondary sensory area, located at the base of the perirolandic cortex.

Penfield and Rasmussen[88] found a human second sensory area in the region of the termination of the motor strip in the frontoparietal operculum (see reference 85, p. 79, Fig III-21). When stimulated, the second sensory area on the superior bank of the frontoparietal sylvian fissure produces bilateral, contralateral, or ipsilateral sensations, often of the perioral regions (see reference 85, p. 79, Fig III-21). Ipsilateral inputs are less numerous as shown by Adrian in cats.[1] LÃ¼ders et al. recorded evoked potentials from the second sensory area that were of lower amplitude than primary sensory potentials.[67]

P.531

Other primary sensory cortices show highly organized anatomy; for example, the visual cortex deep within the calcarine fissure is organized so that the occipital pole is innervated polysynaptically by the macula and therefore is activated by the central visual field, whereas more rostral portions of the calcarine cortex contain representations of more peripheral visual fields.

The auditory cortex in the Heschl gyrus of the temporal lobe is tonotopically organized as shown by evoked potential mapping of longer-latency responses with magnetoencephal- ography.[82,115,119,120] Vestibular cortex is also in the superior temporal gyrus rostral to the auditory cortex, but stimulation does not produce anatomically specific symptoms, just mild vertigo.[85]

Taste is represented in the parietal operculum and possibly near the insula,[85] though Hausser-Hauw and Bancaud's detailed depth electrode studies point primarily to the parietal operculum.[43] Olfaction initially involves pathways from the olfactory epithelium through the cribriform plate to the olfactory bulbs, olfactory tracts, and lateral stria. These areas project to the anterior perforated space, prepiriform cortex, lateral olfactory gyrus, periamygdaloid cortex, entorhinal cortex, amygdala, septal nuclei, and hypothalamus.[122] Thus, most olfactory centers are located in the mesial temporal region and adjacent structures.

While a description of epileptogenesis is beyond the scope of this chapter, clearly any structural lesion, whether seen by MRI or not, involving a sensory cortex or adjacent area may provide the necessary and sufficient changes for chronic localization-related epilepsy to develop. The concept of the epileptogenic zone, as interpreted by Penfield and Jasper[85] and Ajmone-Marsan[4] and reviewed by LÃ¼ders and Awad,[65] implies that the locations in the cortex where symptoms are produced, where seizures are generated, where interictal spikes occur, and of any structural lesions all may contribute to epileptogenesis or to the symptom expression during seizures. It is certainly possible for sensory cortex to become activated late in a seizure and thus produce symptoms after the actual EEG onset in a silent cortical area. To experience somatosensory, visual, or auditory symptoms, white matter pathways, association cortices, and brain structures regulating attention and consciousness all play a role.

Epileptogenesis producing sensory seizures and focal epilepsy may occur without brain lesion or injury from peripheral nervous system injury. Spiller et al. reported three cases with soft tissue injuries to the hand where sensory seizures developed within months in the injured limb and all cases eventually had secondarily generalized tonicâ€“clonic seizures. The authors postulated that the injury resulted in cortical reorganization that was epileptogenic.[109]

Clinical Features

Simple sensory seizures show a wide variety of phenomenology and represent some of the most interesting seizures reported. Patients can have prolonged symptoms[70] and can relate elaborate descriptions of their seizure. Since sensory cortices are located in adjacent lobes, it is not surprising that multimodality sensory seizures are frequently reported in addition to sensory seizures from one modality.[72]

Seizures of the primary sensory cortex typically produce contralateral positive or negative symptomatology. Unilateral symptoms thought to originate in or near the contralateral postcentral gyrus include tingling, numbness, sense of movement, desire to move, somatic pain, heat or cold, electric shock sensations, agnosia for a body part, and phantom sensations.[60,72,85,99,123,129] The hand and fingers are most often involved initially.[72] Symptoms may be stationary or have a sensory march. Somatosensory seizures may be interpreted as motor activity by the patient, even when there is no visible movement seen. This can often lead to misinterpretation of seizure localization by a physician taking the history. Cephalic pain, occasionally migrainous in nature,[19] even if unilateral, may not have localizing value, while abdominal pain usually originates from the temporal lobe.[129] Genital pain probably originates at the mesial parietal termination of the sensory strip and is not necessarily associated with orgasmic seizures.[98,110,128] Attacks of limb agnosia (sudden loss of sensation for a body part) and phantom limb sensations (sense that the limb is in a position that is not the true position) probably originate in the posterior parietal region.[41,72,99] Ajmone-Marsan gives Foerster credit for pointing out that a postcentral-area seizure can be distinguished from the precentral seizure since motor symptoms stop earlier when the seizure originates in the postcentral gyrus and that the convulsing muscles are often more limited in distribution than when the primary motor cortex is seizing. Additionally, when a motor seizure occurs after activation of the sensory cortex, a tremor may be seen before true clonic spasms, if clonic spasms occur.[4] Russell and Whitty observed that somatosensory auras often spread quickly to involve at least the entire limb and that prolonged sensory seizures, comparable to the epilepsia partialis continua of motor seizures, were not observed in their 85 cases. Motor seizures rarely progress to a simple somatosensory seizure, while the reverse is common. Sensory seizures often end abruptly, unlike the gradual cessation typical of focal motor attacks.[99]

Seizures from the second sensory area may produce ipsilateral or bilateral symptoms that are identical in character to symptoms occurring in the primary sensory cortex (e.g., numbness and tingling). Affected body parts can be diffuse or axial but often symptoms localize to the fingertips, feet, lips, or tongue.[2,6,11,13,61,85,93,123] Second sensory-area seizures can arise from the frontoparietal operculum or the inferior parietal lobule.[126] It is also possible to have ipsilateral sensations with seizures originating near the supplementary motor area since there may be a corresponding supplementary sensory region adjacent to the primary sensory foot area.[85] Arseni and Maretsis' case 3 may have had ipsilateral seizures from this location.[6]

Somatosensory auras have been reported in temporal lobe epilepsy, usually with bilateral or unilateral tingling. Pain and numbness were also noted in Erickson et al.'s report and most symptoms were in the limbs but could involve the head or trunk.[36]

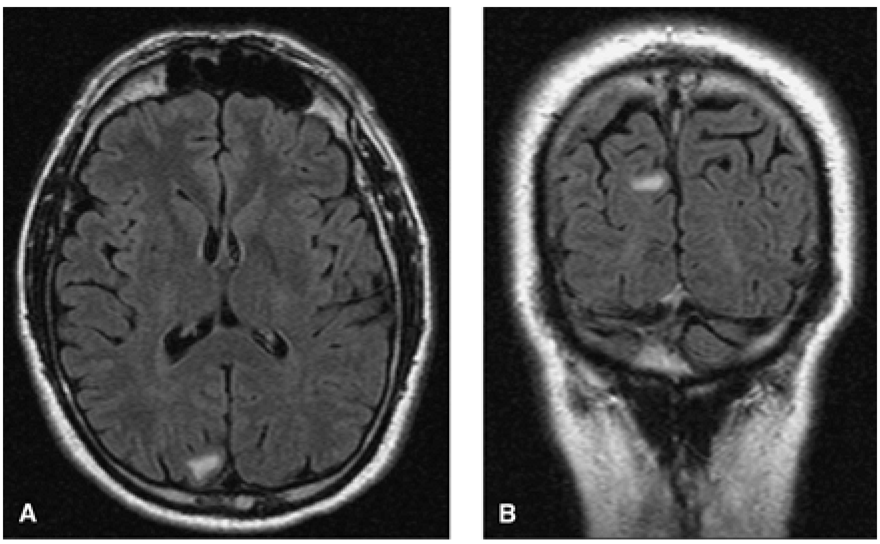

FIGURE 1. Poststroke occipital epilepsy. **A, B:** This is a magnetic resonance image of the brain in a 53-year-old male smoker and drinker with a right occipital infarct, mild left homonymous visual scotoma, and complex partial seizures with an aura of autonomic symptoms of epigastric sensation, facial flushing, and dizziness associated with â€œgraying outâ€ of his vision prior to loss of consciousness. Routine electroencephalography was normal and seizures are controlled by carbamazepine.

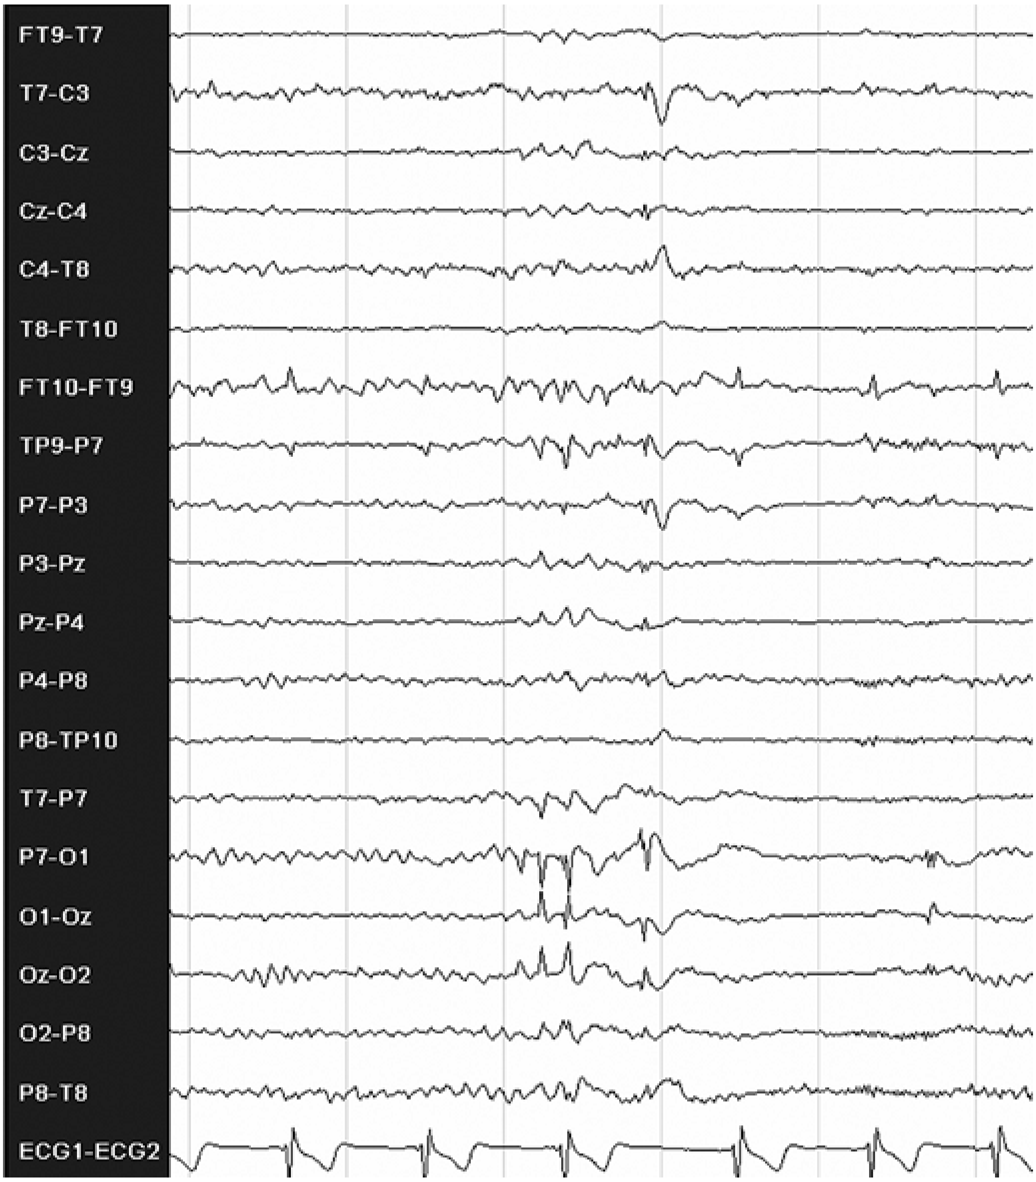

FIGURE 2. Interictal electroencephalogram showing left occipital spikes in an 18-year-old, right-handed male patient with a history of seizures since age 5, starting 3 months after a mild head trauma. He has an aura of right-sided flashing lights, then vertigo, followed by a subjective feeling of right arm twitching and then loss of consciousness. After that he turns his head to the right, raises his right arm, and progresses into a secondarily generalized tonicâ€"clonic seizure. Magnetic resonance imaging of the brain was normal. The patient became seizure free after adding levetiracetam to his monotherapy carbamazepine regimen.

FIGURE 3. A: Same patient as in FIGURE 2, 16 seconds after ictal onset showing the electroencephalographic onset of a left occipital seizure. Patient reported seeing flashing lights to his mother prior to this time. **B:** Left occipital seizure 28 seconds after clinical onset showing O1 spikes and later rhythmic fast activity. **C:** Same seizure, 40 seconds after clinical onset. Note the rhythmic sharp waves maximally over the left occipital region. The seizure subsequently spread and secondarily generalized, not ending until 88 seconds after clinical onset.

Simple sensory visual seizures' semiology includes positive symptoms and unilateral or bilateral negative symptoms.[49,101] Seizures of the calcarine cortex produce elementary visual hallucinations such as flashing or flickering lights, spots, colored lights, weaving patterns, zigzag lights, or visual field deficits such as scotoma or ictal amaurosis.[85,100,101,124] Other seizure symptoms attributed to the occipital lobe include eye movement sensations, sensations of object movement, ictal nystagmus, eye deviation, early forced blinking, and inversion of the visual field.[57,93,101,124] Some cases with autoscopic hallucinations where a person sees him- or herself without a mirror may be due to epilepsy.[63,100] Eye movements can complicate the clinical picture; for example, if a patient sees a bright light, he or she may look toward that light and yet the light continues to move away as his or her eyes deviate, giving a sensation of movement. Nystagmus may also occur and complicate the symptomatology. The patient may see colored lights. Negative symptoms can include loss of a visual field or quadrant; some patients complain of transient blindness. Ictal blindness probably results from seizure spread to the contralateral occipital lobe.[9] The visual symptoms often occur in areas of scotoma or other visual field defect.[58,100] While the simplest visual phenomena probably relate to involvement of the calcarine cortex,

adjacent areas may also participate, and occasionally patients with posterior temporal lesions or parietal lesions may report a visual aura with or without other disturbances. Formed or complex visual hallucinations, including remembered scenes[95] or distortions such as micropsia, macropsia, or changes in object shape, and blindness or hemianopia probably originate in the visual association cortex or adjacent parietal or temporal lobe[100] and are more often seen from the right or nondominant posterior temporal region.[87]

Auditory seizures were reported by Holmes as early as 1927.[46] Penfield and Kristiansen found only three patients, suggesting that this condition is rare.[86] The auditory symptoms can occur without dizziness. Certainly more complicated auditory hallucinations can occur, such as hearing words or music, but these seizures usually are classified as psychic, rather than just as sensory seizures, because of accompanying experiential phenomena. Simple sounds such as buzzing, drumming, or single tones, often contralateral, are typical of seizures from the auditory cortex.[85] One localizing sign noted occasionally with an auditory seizure consists of plugging an ear or placing the hand over the ear. This seems to correlate with an auditory aura that originates contralateral to the plugged ear in the auditory cortex.[25]

Simple partial olfactory sensory seizures (uncinate seizures) are relatively infrequent considering the large number of patients with temporal lobe epilepsy seen at most centers. These seizures may originate from the orbitofrontal cortex as well as the mesial temporal region. Howe and Gibson reported that there is not an increased incidence of tumors in patients with olfactory aura,[48] contrary to reports in other series (see reference 122 for review). Olfactory symptoms have also been reported in occipital- or central-area epilepsy by King and Ajmone-Marsan,[55] but seizure spread may explain at least some of the more unusual localizations. The odor is often but not exclusively unpleasant or disagreeable.[28,85,122] Daly described two types of olfactory phenomena. Hallucinations may be crude or elaborate with other sensory modalities involved, while illusions distort or alter the character of normal olfactory stimuli. Illusions were also noted interictally or postictally.[28]

Gustatory seizures are usually associated with temporal lobe epilepsy, often due to tumors. Daly reported that the sensations, though often unpleasant, can be acidic, bitter, salty, or sweet. Often a metallic taste is experienced.[28,29] The taste of bile or cigarette smoke has been reported.[43] Penfield and Jasper believed that gustatory symptoms result from seizures originating in or near the insula,[85] although Bornstein believed that the parietal operculum may also produce these seizures.[15] Rosetti et al. reported a case with dysgeusia and contralateral sensory symptoms from the insula in a case well documented with subdural ictal EEG recordings.[97] Hausser-Hauw and Bancaud reviewed their experience with gustatory hallucinations. Seizures originated in the parietal and temporal lobes in 20 of 30 patients with adequate ictal localization. Electrical stimulation of the parietal and/or rolandic operculum produced gustatory hallucinations and spontaneous seizures produced symptoms by spread to the opercular region.[43]

Seizures with vestibular symptoms, or vertigo, when isolated, are notoriously difficult to diagnose since these patients are often initially evaluated and treated for peripheral vestibular dysfunction. Symptoms include true vertigo, vague dizziness, or unsteadiness, with spinning most common.[56,85,86,105] Smith's study of 120 cases described rotation around the vertical or sagittal axis but not the coronal axis. Horizontal and vertical movements and also a sense of body or room tilting were described.[105] Lesions have been reported near the temporal parietal occipital junction as well as the superior temporal gyrus by Penfield and Kristiansen,[86] and Eviatar and Eviatar[37] have shown vertiginous symptoms in patients with frontal lobe epilepsy. Kogeorgos et al. found that 7 of 30 cases also had generalized tonicâ€"clonic seizures and 15 of 30 had absencelike episodes, while only two had auditory hallucinations with vertigo.[56]

Postictally, a variety of neurologic deficits can occur analogously to the classical Todd paralysis or postictal amaurosis or visual field deficits.[34,101] Patients with central-area epilepsy may have sensory deficits postictally that gradually improve, and these may only affect higher cortical sensory functions, such as graphesthesia or two-point discrimination. Olfactory sensitivity decreases postictally for several hours.[122] A severe seizure is not necessary to produce Todd paralysis and the process probably involves active inhibition of function rather than neuronal exhaustion.[34] Holmes found prominent postictal impairment infrequently in children with simple partial seizures.[47]

Electroencephalographic Findings and Clinical Correlations

Since sensory seizures can originate in a variety of brain regions, it is not surprising that a variety of interictal EEG abnormalities can be seen (Figs. 1, 2, and 3). Interictal changes could include changes in amplitude or frequency (e.g., focal slowing), particularly if there is a known structural lesion. Focal fast activity is less commonly seen with lesions. Interictal spikes may occur, but should be interpreted cautiously.

P.533

Blume et al. reported that 4 of 44 focal epilepsy cases that localized with ictal EEG had ictal onset clearly distant from the area of principal interictal spiking.[14] Temporal lobe spiking can occur in cingulate, frontal, parietal, and occipital lobe epilepsy.[107] Some authors report that ictal patterns are occasionally difficult to interpret in patients with seizures originating in the parietal or occipital region.[123,124] This is certainly true when seizures rapidly generalize and obscure the EEG record or muscle and movement artifact prevail. However, it is also recognized that some patients will have well-defined interictal spikes or ictal onsets from the occipital,[49,69] parietal, or central area[72] while clinical symptoms are recorded. Activation procedures can increase focal spiking and occipital spikes may be enhanced by eye closure or darkness.[69] Kogeorgos et al. found 28 of 30 patients with epileptic dizziness had abnormal interictal EEG, and localization was in the posterior temporal lobe unilaterally or bilaterally with sharp waves or focal slowing.[56]

Devinsky et al. studied the prevalence of scalp EEG changes in patients with simple partial seizures and found that when sensory symptoms alone predominate, only 15% of patients have EEG changes, whereas if motor symptoms are present, 33% will have EEG changes.[30] However, Bare et al. found that extra scalp electrodes improved the EEG yield in sensory seizures to 27%.[8] Sperling et al. reported that EEG changes may be absent in patients with simple partial seizures in presumed temporal lobe epilepsy when recording with bitemporal depth electrodes, and even in patients where postoperative seizure outcome was excellent.[108] The limited neocortical coverage with bitemporal depth electrodes may miss simple partial seizure ictal patterns from neocortex.

Kaibara and Blume studied postictal EEG changes.[53] Thirty-seven percent of cases had polymorphic delta, 29% had attenuation of background, 31% had immediate return to normal background, and 25% had spike activation. Some patients had more than one postictal pattern. All 51 patients in the study had focal seizures. The changes seen could be prolonged. When postictal EEG changes occur, one may appreciate postictal spiking or slowing that was not evident before the seizure occurred, and these findings may have some localizing value.

Diagnostic Considerations

As with any focal epilepsy, the history from the patient or reliable observer is very important for proper diagnosis. It may be helpful to ask the patient to watch for certain symptoms during subsequent seizures so that a more detailed description can be obtained later. Onset, evolution, postictal features, postictal deficits, patterns of occurrence, and precipitating factors should be thoroughly explored. The stereotypic nature of a seizure is also helpful in confirming a diagnosis of epilepsy.

MRI and routine EEG will often support a diagnosis of epilepsy, but negative initial MRI studies may require alternative MRI scanning protocols tailored for specific clinical situations such as cortical dysplasia or other neocortical lesions. Initially, nondiagnostic EEG studies should be repeated with prolonged recordings, or with sleep and other appropriate activation procedures. V-EEG monitoring may be quite helpful in patients when the diagnosis of epilepsy is uncertain or when seizures are medically intractable.[62] Other medical or neurologic disorders can result in epilepsy and should be considered during the evaluation process. Several genetic forms of focal epilepsy have been characterized, including autosomal dominant partial epilepsy with auditory features,[80] so it is likely that commercial testing for these syndromes will become available.

Differential Diagnosis

As alluded to earlier, pure sensory seizures can occasionally be confused with other nonepileptic conditions, such as cerebrovascular disease or psychiatric disorders.[61,121] Sensory symptoms due to ophthalmologic, otolaryngologic, or vestibulocochlear disease or to peripheral neuropathy need to be excluded. A thorough evaluation is warranted to avoid missing a more serious medical problem that is leading to the symptoms.

Specific Syndromes Incorporating the Seizure Type as an Integral Feature

In the 1989 proposed classification of the epilepsies,[27] one can identify a variety of epilepsy syndromes in which sensory seizures may occur; for example, in benign childhood epilepsy with centrotemporal spikes, sensory symptoms may be noted when partial seizures occur.[64] Seizures involving the central area may exhibit somatosensory symptomatology. Seizures of the temporal lobe can present with auditory or vertiginous sensations, as well as olfactory sensations.

The International Classification does not significantly address the issue of parietal lobe epilepsies. Seizures are clinically diverse and do not always include sensory auras.[123] Recently, Ho et al., using ictal single photon emission computed tomography (SPECT) and MRI, have described an anterior parietal syndrome with sensory symptomatology being quite prominent, whereas a more posterior parietal syndrome was characterized by psychoparetic complex partial seizures.[45]

Occipital lobe epilepsies can be divided into those with symptoms that are supracalcarine or infracalcarine, depending on the location of the visual hallucinations. Depth electrode studies have documented specific seizure spread patterns. Infracalcarine seizures, for example, more often manifest with a temporal lobe seizure spread pattern, whereas supracalcarine occipital lobe seizures may spread to the parietal and central area producing focal motor or even generalized seizure activity.[7,112] Not all occipital epilepsies produce appropriate visual auras.[68,124] Williamson et al. reported that 88% of their series of 25 occipital epilepsy patients had visual symptoms,[124] while only 73% of the Montreal series of 42 patients reported by Salanova et al. had a visual aura.[101] Childhood epilepsy with occipital paroxysms and the syndrome of migraine and seizures are often manifested by seizures that have visual symptomatology, simple or more complex.[27,39,78]

Some reflex epilepsies are associated with partial seizures rather than generalized seizures. Partial seizures of various

types are reportedly induced by startle, somatosensory input, proprioception, music, sounds, voices, hot water immersion, eating, reading, and other language functions.[94] Simple sensory seizures are infrequent manifestations of reflex epilepsy and usually develop after similar seizures develop spontaneously. Ritaccio believed that this represents postafferential facilitation of a preexisting condition.[94] Reading epilepsy can have seizures with a sensation of jaw movement, though often jaw clonic movements predominate.[94] Sutherling reported sensorimotor seizures triggered by music.[111] Caloric vestibular stimulation can produce temporal lobe seizures with auras of tinnitus and vertigo.[10,20] Ricci and Vigevano described stroboscopic provocation of occipital seizures with simple visual hallucinations in four cases and complex hallucinations in one patient;[92] however, most patients with photosensitive epilepsy have generalized seizures.[17,94] Brinciotti et al. found that pattern (checks or stripes)-sensitive seizures were more often associated with localization-related epilepsies.[17] Duncan et al. reported a case with gaze-evoked seizures in nonketotic hyperglycemia.[32] Reder and Wright described a 13-year-old boy whose seizures included ictal sensory loss in one arm provoked by using cutlery while eating. Accidental finger amputation resulted in seizure control.[91]

A wide variety of childhood epilepsy syndromes may exhibit simple sensory seizures, though motor seizures dominate the clinical picture. For example, cortical dysplasia can cause simple partial seizures with motor symptomatology that is extremely resistant to medical therapy.[81] Just as with motor seizures, status epileptics may present with sensory symptomatology. Chronic focal encephalitis typically presents with epilepsia partialis continua in association with unilateral progressive cortical atrophy.[5] Mitochondrial encephalopathy with lactic acidosis and strokelike episodes (MELAS)[74] has a similar, but more acute presentation. Epilepsia partialis continua is common in children with Alper disease[16] and focal cerebral vasculitis. In all these syndromes, sensory seizures, if present, are often relegated to a minor role in the complete clinical syndrome.

Responses to Treatment

A thorough discussion of medical and surgical management of epilepsy is beyond the scope of this chapter. However, if the epilepsy syndrome is focal, drugs used for partial seizures should be used first. These include carbamazepine, phenytoin, gabapentin, lamotrigine, topiramate, tiagabine, oxcarbazepine, levetiracetam, zonisamide, pregabalin, primidone, and phenobarbital. In suspected cases of pure sensory simple partial seizures without EEG changes, a blind trial of antiepileptic drugs may support the diagnosis;[127] however, a definitive treatment end-point is necessary to avoid prolonged unnecessary therapy.

The success of pharmacotherapy for simple sensory seizures is not well described in the literature, though some patients do respond well to medical therapy. At times, more severe seizure types will be eliminated by antiepileptic drugs but simple sensory seizures will persist as auras with minimal disability. Often patients will choose occasional auras over antiepileptic drug toxicity when higher doses are tried. Still, some patients claim severe disability from sensory seizures, resulting in medication changes and dose escalation until intolerable dose-related toxicity develops. These cases may benefit from counseling, treatment of comorbid underlying depression, and consideration for a surgical procedure.

The benign childhood epilepsy syndromes may resolve spontaneously, so lifelong therapy is unwarranted. When seizures persist in benign focal epilepsies, particularly benign rolandic epilepsy, one should consider alternative diagnoses.

If neuroimaging studies have shown specific lesions, such as tumor or vascular malformation, particularly when there is a risk of progression, specific surgical or nonsurgical therapy may help seizures, particularly in cases where the lesion is adjacent to important sensory cortex, rather than in the functional zone.

Surgery for patients with sensory seizures should proceed with caution to avoid significant postoperative deficits. Sufficient disability from seizures should exist. For example, careful thought should be given before suggesting surgery in an individual with sensory seizures alone, unless an underlying lesion was serious enough to require surgical intervention in any case. Careful mapping of ictal foci and cerebral function may be needed to plan a safe resection.[12,22,42,71,75,76,77,79,96,113,114,119,125] Functional MRI offers hope for noninvasive functional mapping.[50] Subdural electrodes[66] are preferred by most epilepsy centers because of potentially better localization and less risk of hemorrhage compared to depth electrodes[113,114] or epidural electrodes.[42] Still, selected cases with subcortical lesions, such as a cortical dysplasia case reported by Privitera et al., are better evaluated with intracerebral depth electrodes.[90] Subdural electrodes are more convenient for functional mapping by direct cortical stimulation or with evoked responses for various sensory modalities. Additionally, the use of subdural electrode recordings can help with decisions on the need for intraoperative electrocorticography and cortical mapping during awake craniotomies.

The role of magnetoencephalography is controversial, since the technique is better for interictal epileptiform discharge localization. Magnetoencephalography data should be considered complementary to scalp EEG. No randomized controlled studies exist to show superior surgical outcomes with the use of magnetoencephalography.

Subpial transection gained favor as more reports appeared in the literature demonstrating safety and efficacy.[31,76,77,104] Theoretically, subpial transection can spare sensory cortex and function, yet still help relieve seizures. However, deficits have been reported after this technique and a pathologic study suggested that subpial transection may produce small confluent lesions rather than disconnection.[54]

Lesionectomy can also decrease risks of sensory deficits and help seizures long term in about half of the cases.[23,24] Gamma Knife radiosurgery may be appropriate in selected patients.[44]

At times, resection of primary cortex is needed for seizure control and the sensory deficits may be acceptable to the patient. It is possible to remove portions of primary sensory or motor neocortex without producing a lasting neurologic deficit.[73] Lehman et al. reported that the disability was quite limited with resection of the sensorimotor face region in the lower central area.[59]

With reflex seizures, avoidance of the stimulus can play a role in management. In some patients, biofeedback or sensory input may also reduce seizures, as in Efron's remarkable case.[33] Aird reviewed alternative epilepsy therapies in 500 refractory patients with various forms of epilepsy and found that 43% benefited from lifestyle modification in areas such as hydration, central nervous system excitation, sleep habits, and anxiety.[3]

Safety concerns should also be considered if the seizures produce any disability. While most simple partial seizures with sensory symptomatology alone may not be very disabling, many have complex partial or secondarily generalized seizures also. Safety concerns are justified if a patient has a job where sudden, complete or partial loss of vision or disturbance of sensation could result in injury. Each case must be assessed individually for safety concerns.

Summary and Conclusions

Simple sensory seizures can occur in a variety of epileptic syndromes. Many patients have other seizure types that make

the diagnosis more obvious. Caution is recommended in those patients with subjective sensory symptoms alone, particularly without supportive EEG or neuroimaging findings. The chances for misdiagnosis are high, and these patients may require a more thorough investigation before nonepileptic, medical, or psychiatric conditions are diagnosed.

The epidemiology of simple partial seizures is incomplete. Evidently, these seizures are seen in a minority of patients with epilepsy. Identifying patients with simple sensory seizures can help localize structural lesions. Prolonged clinical manifestations are occasionally reported by patients. Postictal neurologic abnormalities should be sought in the history and examination. Scalp EEG, while not highly sensitive, can be diagnostic. Treatment is similar to treatment in other localization-related epilepsies.

The possibility of developing treatment strategies that could specifically inactivate seizures by altering sensory function transiently requires further exploration. Additionally, patients with well-defined sensory phenomena may be good candidates for studying treatment methods that rely on advance warning of an impending seizure. Since consciousness is maintained, at least during the patient's simple partial seizure, these patients would make ideal study subjects.

Chapter 46

Limbic Seizures

Jerome Engel Jr.

Peter D. Williamson

Introduction

In 1970, after a 4-year effort, the Commission on Classification and Terminology of the International League Against Epilepsy (ILAE) presented a scheme for classifying epileptic seizures, in which the term â€œpartial seizures with complex symptomatologyâ€ was introduced.[54] This term was used to denote a type of seizure that was clearly described almost 100 years earlier by Hughlings Jackson,[74] who noted a relationship between lesions in the mesial temporal lobe and seizures characterized by olfactory hallucinations and a â€œdreamy state,â€ which he referred to as â€œuncinate fits.â€ Since then, myriad signs and symptoms, both psychic and motor, have been identified with this seizure type. In 1937, Gibbs et al.[56] proposed the term â€œpsychomotorâ€ to define these phenomena. Subsequently, the Montreal school, through their pioneering invasive recording and surgical treatment efforts, repeatedly demonstrated the clear association between psychomotor seizures and temporal lobe pathology, changing the terminology to â€œtemporal lobe seizures,â€ as part of a condition known as *temporal lobe epilepsy* (TLE).[75,104] Because the limbic system primarily involves mesial temporal lobe structures, the specific condition is now known as *mesial temporal lobe epilepsy* (MTLE).[140]

The advent of long-term video electroencephalographic (video-EEG) recording allowed routine electroclinical correlation and documentation of habitual seizures, permitting detailed analysis of ictal semiology. It became recognized that not all seizures of temporal lobe origin have psychomotor features; some seizures have psychic symptoms without motor signs, and others have motor signs without psychic symptoms; seizures originating outside the temporal lobe can propagate into limbic areas, producing ictal events that are indistinguishable from temporal lobe onset seizures; and seizures originating outside the temporal lobe could have complex symptomatology without involving temporal limbic structures. Whereas the 1970 International Classification essentially used the term *complex partial seizure* (CPS) as synonymous with â€œpsychomotor seizureâ€ or â€œtemporal lobe seizure,â€[54] the revised 1981 Classification[21] chose to define terms purely on the basis of phenomenology and to avoid any implication of anatomic substrate. Consequently, CPSs were defined as partial seizures associated with impairment of consciousness, as opposed to *simple partial seizures* (SPSs), which are partial seizures with preserved consciousness.

Now that more is known about the pathophysiologic mechanisms and anatomic substrates of various epileptic seizure types, it is recognized that classical temporal lobe seizures, beginning in mesial temporal limbic structures, can be simple or complex partial, whereas ictal impairment of consciousness can occur during partial seizures that arise from the neocortex and never involve mesial temporal limbic structures.[147] Because modern electrophysiologic and neuroimaging technology now permit accurate anatomic localization of ictal events in many patients under evaluation for surgical treatment, it has become common to distinguish between limbic partial seizures and neocortical partial seizures based on their characteristic ictal semiology. Consequently, the ILAE has now recommended that SPS and CPS not be used in a future classification, but have accepted the term â€œlimbic seizuresâ€ to describe ictal clinical manifestations of epileptic activity in mesial temporal limbic areas and their efferent projections.[37,39]

Definitions

Although the current 1981 International Classification of Epileptic Seizures appeared to satisfy many of the needs of the epileptology community, confusion and lack of acceptance persisted among some practicing neurologists because highly complicated and sometimes bizarre seizures in which consciousness was not impaired were, by definition, simple partial seizures. Conversely, patients with partial seizures who have only a motor arrest with impaired consciousness, by definition, have CPS, which can be mislabeled as petit mal. Finally, although the term â€œcomplex partial seizuresâ€ has been universally accepted, it continues to be abused by reversal to the meaningless term â€œpartial complex seizure.â€[3,44,71,72,103]

Defining consciousness is difficult.[11,57,58] For example, seizures can present with a relatively pure reversible Wernicke aphasia. In this situation, the patient would appear alert and awake. Speech would be jargon, and commands would not be followed. On the other hand, patients can present with seizures consisting of pure word muteness or aphemia,[146] during which the patient would be able to follow commands and perform all other language-related functions, but simply could not speak. Are these examples of CPS or SPS? The latter should be considered simple partial seizures, but the former could be difficult to classify when impairment of receptive language function complicates testing consciousness. Amnesia for the ictal event is another criterion that can be used to define CPS.[33] Amnesia, however, whether complete or partial, can be as difficult to document as altered consciousness. Careful testing by trained observers during and after seizures is the only method that can define these issues,[141] but in practice, this has not been standardized, nor is it universally performed in all centers where seizures are recorded. Although recognition of whether consciousness is impaired is of clinical importance in individual patients, the ILAE has recommended that this difficult-to-assess clinical manifestation not be used as a criterion for classifying seizure types in the future.[37,39] For purposes of describing the ictal manifestation of cognitive dysfunction, the ILAE has now recommended the term â€œdyscognitive.â€[11]

The term â€œlimbic seizureâ€ is used in this chapter to describe ictal events in which the clinical manifestations result from epileptic activity within the mesial temporal limbic network and structures to which it projects. Limbic seizures can be initiated by epileptogenic regions within this limbic network, or from epileptogenic regions in any neocortical area that projects to it and gives rise to the same clinical manifestations. Epileptic activity will preferentially propagate to mesial temporal limbic structures from the temporal neocortex, orbital frontal cortex, mesial frontal regions such as the anterior cingulate, and

P.542

occipital cortex ventral to the calcarine fissure. Certain sensory, psychic, and autonomic manifestations of limbic seizures do not usually involve impairment of consciousness, and so would currently be classified as SPS.

Epidemiology

Most prevalence studies estimate that approximately 60% of the adult population with epilepsy and 40% to 50% of children with epilepsy have focal seizures.[18,24,25,50,55,68,79,80,89,103] The earlier Rochester study by Hauser and Kurland reported that CPS were the most prevalent of any single type of seizure, constituting 42% of focal seizures and 26% of all seizures. Another earlier study reported that 40% of patients with epilepsy had CPS as the predominant seizure type.[55] Epidemiologic studies from developing countries usually report much lower percentages of patients with CPS.[2,28,47,64,77,118,126] The reasons for this discrepancy are not entirely clear but probably reflect such factors as diminished diagnostic accuracy and different etiologies. However, the inherent difficulties of seizure classification exist at any level of societal development.[92,102,132]

CPS are not all limbic seizures and not all limbic seizures are CPS; therefore, attempts to further subclassify focal seizures based on limbic system involvement are at best an estimate. By necessity, such approximations come from epilepsy surgery centers, where ictal substrates are most thoroughly and precisely evaluated and where surgical results give credence to the localization of seizure origin. This introduces an undeniable referral bias that cannot be avoided. Of those patients referred for surgical consideration, patients with limbic seizures of temporal lobe origin are by far the most common, constituting approximately 70% of the referrals.[138,151] Of the other 30%, approximately two thirds are patients with different varieties of frontal lobe seizures, with the remaining 10% divided among seizures originating in other lobes of the brain.[107,139,143,150] Some of these patients also have seizures generated by the limbic system, even though they do not originate in limbic structures.

Many pathologic conditions, idiopathic as well as symptomatic, primarily involving limbic structures or occurring in distant neocortex, can be associated with limbic seizures as the predominant ictal features. These conditions are discussed in detail in Chapters 246 and 247. The most common pathologic substrate associated with limbic seizures is hippocampal sclerosis (HS) (Chapter 13), which can now be detected in most patients using high-resolution magnetic resonance imaging (MRI).[73,83] Another indication of the prevalence of limbic seizures, therefore, can be derived from two large longitudinal outpatient studies, one in Paris that included tertiary referrals,[116] and the other at a primary clinic in Glasgow.[128] In the Paris study, half the patients had a diagnosis of TLE and, in both studies, approximately a quarter of the patients had hippocampal atrophy documented by MRI. In both studies, the seizures in patients with hippocampal atrophy were the most refractory. In the Paris study, only 11% were seizure-free in the previous year, and with dual pathology (hippocampal atrophy plus another MRI abnormality), only 3% were seizure free in the preceding year.[117] Although there is no way to accurately assess the true prevalence of limbic seizures and the burden of disability due to epilepsy that limbic seizures represent, it is reasonable to assume that they are the most common, and are certainly among the most refractory epileptic seizure types.

Anatomic Pathways and Pathophysiology

Because patients with TLE are the most common candidates for surgical treatment,[45,46] and often require invasive V-EEG monitoring, many more limbic seizures have been explored with stereotactically implanted depth electrodes in TLE than any other seizure type. It is clear from these recordings that ictal activity that remains confined to hippocampus and parahippocampal structures can have no clinical manifestations at all,[125] and that the classical signs and symptoms of limbic ictal events reflect propagation, both ipsilaterally and contralaterally, to frontal and temporal neocortex, insula, hypothalamus, basal ganglia, and other subcortical structures. Although limbic and neocortical propagation patterns have been explored with depth electrodes,[81,85,87,124] and thalamic and basal ganglia involvement has been inferred from ictal behavior as well as structural and functional neuroimaging,[8,13,70,101] the contribution of other subcortical structures to the typical signs and symptoms of limbic seizures in the human cannot be directly studied.

Both animal and human investigations suggest that the pathophysiologic mechanisms responsible for seizure initiation in the hippocampus, and perhaps parahippocampal structures, may be different from those of seizures originating in neocortex;[16,114,133] this is discussed in Chapter 41.

The limbic anatomy and physiology responsible for the elaboration of clinical signs and symptoms of limbic seizures are described in Chapter 30. As previously mentioned, ictal discharges restricted to hippocampus alone are often devoid of noticeable clinical manifestations.[125] Ictal symptoms that occur in clear consciousnessâ€"the typical limbic aurasâ€"result from usually ipsilateral projections. Autonomic symptoms and emotions such as fear most likely reflect propagation to hypothalamus and insula, whereas complex multimodal sensory psychic experiences result from neocortical projection, particularly the temporal parietal occipital junction.[59,129] Limbic structures responsible for memory, as well as taste and smell appreciation, give rise to dysmnesias and olfactory and gustatory auras. More complex motor symptomatology, characteristic of limbic automatisms, however, is almost always associated with impaired consciousness and usually involves contralateral propagation. Bilateral hippocampal involvement accounts for ictal amnesia, although unilateral ictal discharge can produce amnesia when the contralateral hippocampus is severely dysfunctional. Oroalimentary automatisms derive from the temporal and frontal operculum but the specific origin of more complicated gestural automatisms has not been clearly defined.

Studies in animal models of MTLE with HS reveal strong inhibitory mechanisms within the hippocampus that suppress contralateral propagation.[91] A similar resistance to contralateral propagation exists in patients, as evidenced by the common observation that depth-recorded limbic ictal discharges remain unilateral for long periods of time and may never involve the contralateral side.[85,87] The existence of intrinsic mechanisms that permit ictal discharges within the limbic system to remain unilateral for extended periods of time without propagation likely accounts for the clinical observation that auras in patients with limbic seizures of mesial temporal origin commonly occur in isolation; these patients typically experience auras that do not progress to behavioral seizures. In contrast, neocortical auras rarely occur in isolation because of the propensity for neocortical discharges to rapidly project contralaterally across the corpus callosum. When contralateral propagation occurs, it is usually indirect via either temporal or frontal ipsilateral neocortex.[81,85,86,87,124] Because ictal discharges can be seen in contralateral mesial temporal limbic structures before involvement of contralateral neocortex, the route of contralateral propagation may not be callosal. Furthermore, it is not possible to explain how bilateral automatisms can occasionally occur in clear consciousness without amnesia.

The neuronal networks responsible for the manifestations of limbic seizures involve neocortical and subcortical areas.

Extensive extrahippocampal cortical and subcortical gray matter atrophy may be apparent on MRI,[8,13] and positron emission tomography (PET) often reveals unilateral thalamic and basal ganglia hypometabolism ipsilateral to the side of ictal onset in patients with limbic seizures.[70] Unilateral basal ganglia hyperperfusion on single-photon emission computed tomography (SPECT) is associated with contralateral ictal dystonic posturing, suggesting that the basal ganglia are involved in this clinical behavior.[101]

Impairment of consciousness, which is a feature of bilateral limbic seizures and the hallmark of CPS, is difficult to define, and can also be difficult to document in individual patients. Consciousness is a multidimensional phenomenon. The ILAE has recommended referring to *cognition* rather than *consciousness,* and has defined *dyscognitive seizures* as involving at least two of five components of cognition: perception, attention, emotion, memory, and executive function.[11] Consequently, it is unlikely that a single pathophysiologic mechanism or anatomic substrate is responsible for dyscognitive ictal manifestations. Unilateral electrical stimulation of human limbic structures can produce signs and symptoms of limbic seizures that typically occur in clear consciousness, but impairment of consciousness does not occur in the absence of contralateral discharge.[59,66] Although this suggests that at least some dyscognitive features of limbic seizures require bilateral hippocampal or other limbic involvement in the epileptic discharge, it does not rule out the possibility that certain unilateral subcortical structures that receive preferential input from the limbic system mediate other aspects of dyscognitive behavior.[149] Accurate descriptions of the various types of cognitive dysfunction that occur during limbic seizures, and their neurobiologic basis, cannot be elucidated from research with animal models of MTLE and will require further studies in patients.

The evolution of epileptogenesis in the limbic system, as well as propagation patterns during individual limbic seizures, have been studied in detail in animals using procedures such as amygdala kindling[22,23,60,106] or chronic models of hippocampal sclerosis following status epilepticus induced by neurotoxins or electrical stimulation.[105] In these models, the limbic ictal manifestations often secondarily generalize, and in amygdala-kindled animals, once the initial stages of limbic ictal manifestations progress to involve the generalized stages of rearing and falling, subsequent stimulation almost always results in the fully developed kindled seizure.[106] In contrast, limbic seizures only relatively rarely secondarily generalize in patients, despite the fact that ictal discharges often commonly become bilateral. This could possibly be attributed to the fact that patients are treated with antiepileptic drugs (AEDs), which are much more effective at preventing secondarily generalized seizures than they are at preventing limbic ictal events, or inherent protective mechanisms could account for failure of propagation to brainstem structures responsible for more generalized ictal manifestations. The latter interpretation is consistent with the observation that some rat models of MTLE with HS (that are not treated with AEDs) continue to have frequent localized limbic seizures that only rarely progress to involve more generalized ictal semiology.[15] When limbic seizures secondarily generalize, the motor manifestations are usually asymmetrical.[93] Increasing evidence suggests that the responsible subcortical mechanisms are not exactly the same as those that give rise to primarily generalized tonicâ€"clonic seizures, which are invariably symmetrical.[76]

Recent studies provide converging evidence that the clinical expression of limbic seizures involves large neural networks with both inhibitory and excitatory functions.[5,12,34,35,135] Understanding these networks might provide new targets for AEDs.[48] Also, careful network analysis might explain some of the reasons for surgical failures in limbic epilepsy.[115] This, in turn, could lead to more effective surgical approaches.

A final consideration with respect to the ictal network responsible for the manifestations of limbic seizures concerns the unlikelihood that this will be clearly defined as a group of interrelated structures that are necessary and sufficient for limbic seizures to occur. The central nervous system is extremely redundant, and decades of animal research with limbic kindling has revealed that no forebrain lesions, including destruction of the amygdala itself,[78] can completely prevent the progression of limbic epileptogenesis.[22,23,97] Although these studies have identified specific structures that undoubtedly are important in limbic epileptogenesis, because specific lesions can delay the progression of ictal manifestations, eventually alternate pathways are found and kindling proceeds to completion. Given the fact that the human nervous system is much more complex than that of the lower animals used for kindling experiments, it is reasonable to assume that there are multiple overlapping neuronal networks capable of mediating the clinical behaviors characteristic of limbic ictal events. On the other hand, animal experiments suggest that some areas of the limbic system, apart from the hippocampus, are exquisitely epileptogenic and may be more important than others in promoting limbic epileptogenesis and epileptogenicity, such as the prepiriform, perirhinal, and entorhinal cortices.[53,67,98] In fact, a postoperative MRI study of patients who underwent amygdalohippocampectomy for MTLE demonstrated that seizure freedom is related specifically to the amount of entorhinal cortex, not hippocampus, removed.[119]

Clinical Features

Clinical features of limbic seizures encompass a rich and diverse spectrum of signs and symptoms. Some of these reflect the region of seizure origin, some reflect spread patterns, whereas others are nonspecific. Although many of the clinical characteristics of limbic seizures have been recognized for over 100 years,[63,74,130] the advent of closed-circuit video and EEG monitoring has allowed repeated detailed studies of many seizures from large numbers of patients.[61,65]

This section briefly describes the classical clinical features of limbic seizures that occur with MTLE. Limbic seizures that result from propagation of epileptic discharges originating in neocortical epileptogenic regions outside the mesial temporal lobe area often, but not always, begin with signs or symptoms that reflect the unique functioning of the cortex of origin. These variations are described in detail in Chapter 246.

Early attempts to subclassify limbic seizures based on anatomic substrates have not stood the test of time,[29,137] although they did help direct attention to different clinical manifestations. Nevertheless, it is now recognized that most limbic seizures begin in mesial temporal structures.[33,138,150] This observation, combined with specific clinical features and a distinctive hippocampal pathology, serves to define a syndrome of MTLE with HS,[140] the subject of Chapter 247. A generic description of a typical mesial temporal lobe seizure (MTLS) is included here.

Table 1 Clinical Features of Simple Autonomic Seizures

Abdominal sensations
Apnea
Arrhythmias/bradyarrhythmias
Chest pain
Cyanosis
Erythema
Flushing
Genital sensations/orgasm
Hyperventilation
Lacrimation
Miosis/mydriasis/hippus
Palpitations
Perspiration
Pilomotor excitation
Tachycardia
Urinary urgency/incontinence
Vomiting

Most, but not all, MTLS begin with an aura, which is an SPS. The most common limbic aura is a visceral sensation of gastric rising, although a wide variety of autonomic signs and symptoms, complex multimodality psychic experiences, dysmnesias, emotions (fear being particularly frequent), and gustatory, olfactory, or nonspecific somatosensory symptoms occur. Clinical features of simple autonomic seizures are listed in Table 1,[88] and principal ictal psychic phenomena are listed in Table 2.[49] Olfactory and gustatory auras are typically, but not always, unpleasant. Limbic somatosensory seizures have nonspecific anatomic localization, such as tingling or paresthesias, that are bilaterally diffuse, perioral, or at the bridge of the nose. Experiential phenomena involve multiple sensory modalities as well as appropriate emotions and can be quite vivid.[59]

Sensory distortions and bizarre hallucinations are also encountered, all of which reflect propagation from mesial temporal structures to neocortex, particularly the temporal parietal occipital junction.[59,66,129] Although limbic auras can evolve from one type to another, they are almost always stereotyped, with the same static or evolving pattern appearing with each occurrence. A characteristic feature of limbic auras, when they occur, is that they occur in isolation, and they precede the typical limbic seizure with impaired consciousness and automatisms. Auras in isolation typically occur more frequently than do behavioral limbic seizures, and they can persist after surgical resection that eliminates disabling seizures.

The behavioral limbic seizure begins with impaired consciousness, widened palpebral fissures (fixed stare), and dilated pupils. Early in the seizure, oral-alimentary automatisms occur consisting of lip smacking, chewing, tooth grinding, or swallowing. Patients can continue with ongoing motor activity, react to their surroundings in a semiappropriate fashion (reactive automatisms), or develop repetitive motor behavior that is similar during each seizure in a given patient (stereotyped automatisms). Ictal head and eye deviations, tonic/dystonic postures, unilateral automatisms, and hemiparesis have lateralizing significance that is discussed further in Chapters 246 and 247. MTLSs rarely last longer than 1 to 2 minutes and have a definite postictal period of variable duration, with longer durations associated with seizure origin on the language-dominant side. Ictal automatisms can stop abruptly at the end of the ictus and the beginning of the postictal period, or they can persist for variable lengths of time into the postictal stage. Clear postictal aphasia is seen after seizures beginning in the language-dominant temporal lobe.

EEG Manifestations and Clinical Correlation

EEG findings in patients with limbic seizures are highly variable. Routine recordings often are normal or display nonspecific findings.[82] Continuous monitoring of the EEG when the patient is awake and through all stages of sleep increases the yield of abnormal findings.[30] AED reduction during continuous monitoring further increases detection of both ictal and interictal events.[65,94]

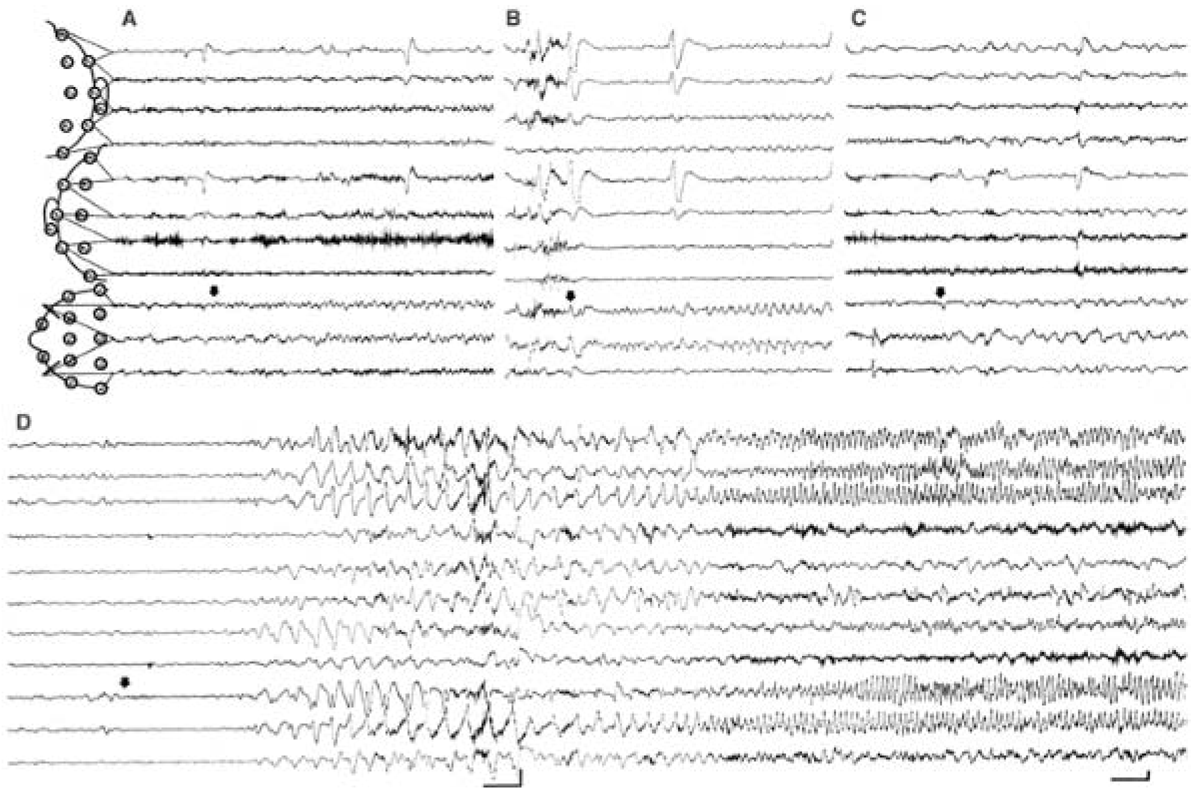

FIGURE 1. Examples of EEG telemetry-recorded ictal onsets from four patients with complex partial seizures. **A:** Low-voltage 5- to 7-c/sec rhythmic activity appears at the right sphenoidal electrode (*arrow*) 5 seconds before it is seen over the right temporal convexity. **B:** After a diffuse burst of muscle and eye movement artifact, low-voltage fast activity is recorded by the right sphenoidal electrode (*arrow*). This becomes progressively slower, and the amplitude increases; 5 seconds later, it is seen diffusely over the right hemisphere. **C:** Irregular, sharply contoured slow waves demonstrate phase reversal at the right sphenoidal electrode (*arrow*) and are reflected as low-amplitude Î´-waves, without phase reversal, over the right hemisphere. **D:** In this lateralized but not localized ictal onset, voltage suppression and low-voltage fast activity occur over the right frontotemporal area and are best seen at the right sphenoidal electrode (*arrow*). This precedes by 3 seconds the appearance of diffuse 3-c/sec spike-and-wave discharges, which are prominent from the right frontotemporal and sphenoidal derivations. After 10 seconds, this latter activity evolves into high-voltage 7-c/sec rhythmic activity, which phase reverses at the right sphenoidal electrode and laterally at the right anterior to midtemporal region. Patterns shown in **A** and **B** (initial focal onsets) and **D** (delayed focal onset) have more reliable localizing significance than the irregular Î´-pattern shown in **C**. Calibration: 1

second, 100 ÂµV. Note that sensitivity is the same for **A, B**, and **C** and the first half of **D**, but decreased to half in **D** at the first calibration mark. New York: Churchill Livingstone, 1983:1349â€“1380, with permission.

Interictal

Depth electrode studies show that hippocampal interictal spikes cannot usually be seen on scalp or sphenoidal EEG recordings unless they have propagated to neocortex. Therefore, interictal EEG abnormalities in patients with focal epilepsy do not necessarily reflect either maximum interictal spike activity, or the region of seizure origin. In a series of surgically verified patients with MTLS origin, the vast majority had interictal epileptiform abnormalities on scalp EEG monitoring.[145] The interictal abnormalities consisting of spike, sharp, and slow complexes were usually located in the anterior temporal derivations, but some were not; one third had bilateral, independent, anterotemporal, paroxysmal findings, results consistent with other studies.[4,9,20] Bilaterally synchronous temporal paroxysmal activity was conspicuously absent. Rarely occurring frontopolar sharp waves in patients with temporal lobe seizures are considered clinically insignificant.[111] There is general agreement that lateralized anterior temporal or sphenoidal interictal spikes in patients thought to have temporal lobe seizures are relatively reliable indicators of side and site of seizure origin.[4,9,10,20,82,100] Investigations of mesial versus lateral interictal spike relationships have shown latency changes in either direction.[6,127] Reconciliation of these different mesialâ€“lateral interictal findings from extracranial studies and intracranial data is difficult considering the common observations that abundant interictal paroxysmal activity occurs independently and dependently in mesial and lateral temporal structures during invasive monitoring.[120,122]

Patients with extratemporal limbic seizure origin often have unreliable interictal EEG findings. Frontal lobe onset limbic seizures can be associated with normal or nonspecific interictal EEGs.[142,147] When epileptiform abnormalities occur, they

P.545

can be bilateral or temporal.[147] Absent or temporal interictal EEG findings are common in patients with parietal and occipital lobe seizure origin.[14,17,112,144,148] Typical anterior temporal interictal spikes, therefore, do not rule out an extratemporal origin of limbic seizures.

Ictal

Limbic seizures without impairment of consciousness typically are unassociated with ictal EEG changes, although interictal spikes can disappear. This phenomenon is usually not appreciated unless interictal spikes are frequent. The classical ictal EEG onset pattern begins at the time consciousness becomes impaired and is a 5- to 7-Hz rhythmic discharge, maximal in basal electrodes over the side of seizure origin[42,43,109,145] (Fig. 1). Although correlation between simultaneous depth and sphenoidal electrode recordings revealed that this unilateral ictal-onset EEG pattern does not usually appear until the electrographic discharge in deep mesial temporal structures is bilateral, it indicates the side of hippocampal onset in 83% of seizures.[109] This is true regardless of whether the 5- to 7-Hz pattern is the initial ictal EEG change, or whether it follows another ipsilateral or bilateral ictal pattern within 30 seconds.[109] This pattern is not lateralizing, however, if the initial ictal changes occur contralaterally. Nonspecific ictal onset patterns include unilateral or bilateral slowing, rhythmic Î´-waves, loss of ongoing activity including interictal spikes, low-voltage fast, and no discernible change other than muscle artifact.

No systematic studies of ictal scalp EEG have been performed in extratemporal onset seizures. Most reports comment on the nonspecificity or paucity of ictal findings, particularly in frontal lobe seizures.[17,134,142,143,147,150,151]

P.546

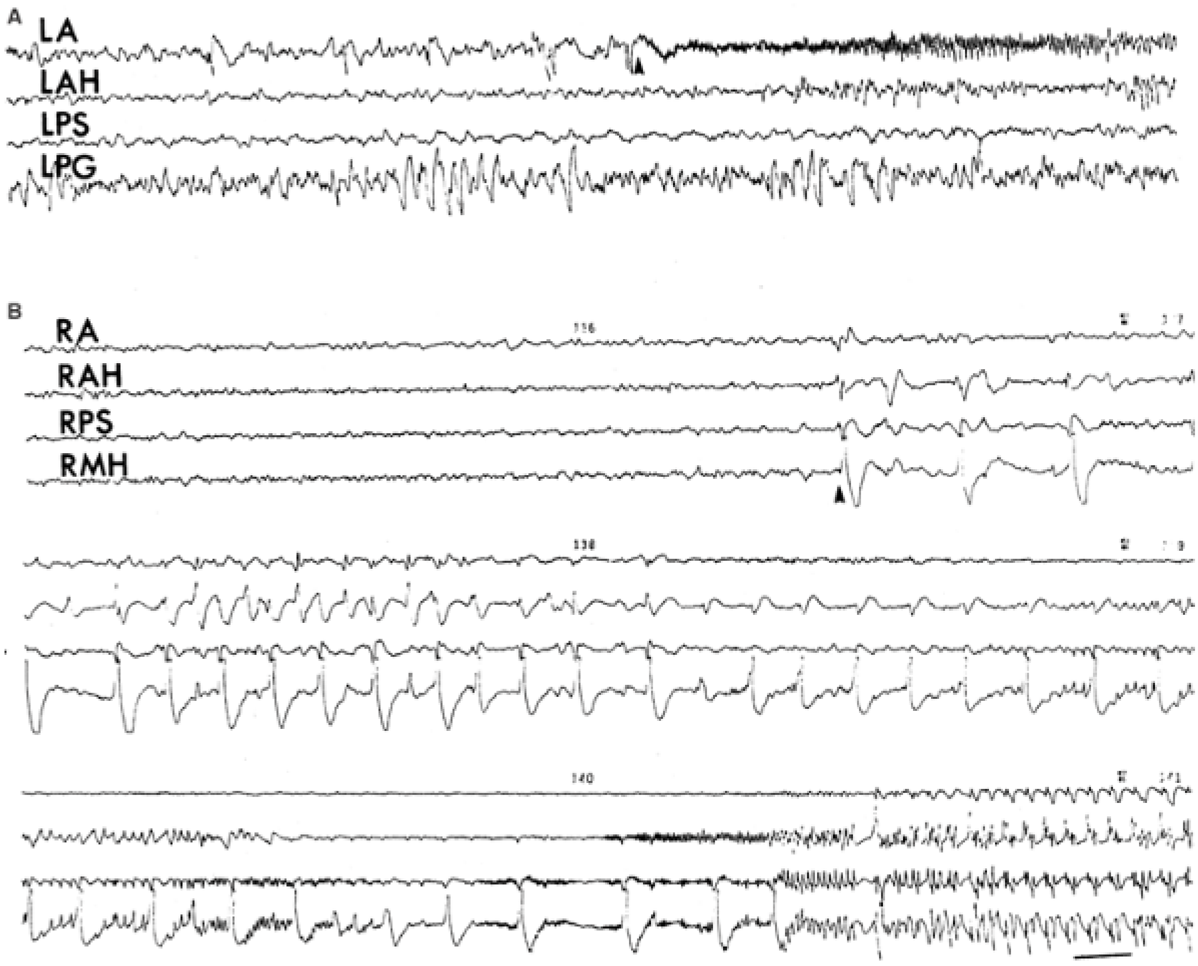

FIGURE 2. Segments of telemetry recordings from two patients showing EEG activity at selected depth electrode bipolar tips during the onset of complex partial seizures. **A:** The classic, depth electrodeâ€"recorded ictal onset consists of a buildup of low-voltage fast discharge, here beginning in a single channel (*arrow*). **B:** Three continuous segments show a more common ictal onset pattern, beginning with rhythmic, high-amplitude, sharp and slow transients (*arrow*), eventually giving way to a low-voltage fast discharge, which then evolves into higher-amplitude repetitive spikes or spikes-and-waves. *L*, left; *R*, right; *A*, amygdala; *AH*, anterior hippocampus; *MH*, midhippocampus; *PS*, presubiculum; *PG*, posterior hippocampal gyrus. Postictal

Postictal EEG changes have rarely been specifically examined. In documented temporal lobe seizures, lateralized postictal slowing, when present, could be a lateralizing finding.[145] Localized interictal spiking often increases in the postictal period[62] and, in some patients, this may be the only localized EEG abnormality.

Intracranial EEG

A variety of ictal onset patterns can be recorded using depth electrodes from hippocampal and parahippocampal struc- tures;[32,34,121,131] these have implications for basic mechanisms, which are discussed in Chapter 41. Limbic seizures of hippocampal origin typically begin with hypersynchronous discharges that remain relatively restricted; they may be associated with an aura or have no associated behavioral signs or symptoms.[34,131] If this ictal activity progresses to a behavioral limbic seizure with impairment of consciousness, it typically converts to a low-voltage fast pattern before propagation to contralateral mesial temporal structures (Figs. 2 and 3).[32] Contralateral propagation, when it occurs, usually is slow (>5 seconds), whereas contralateral propagation of neocortical onset seizures is usually rapid.[85,87] MTLS can also begin with low-voltage fast activity, but this is more likely to be diffuse than focal, and could indicate that the initial site of ictal origin is not within the range of the recording elec- trodes.[32,34,131]

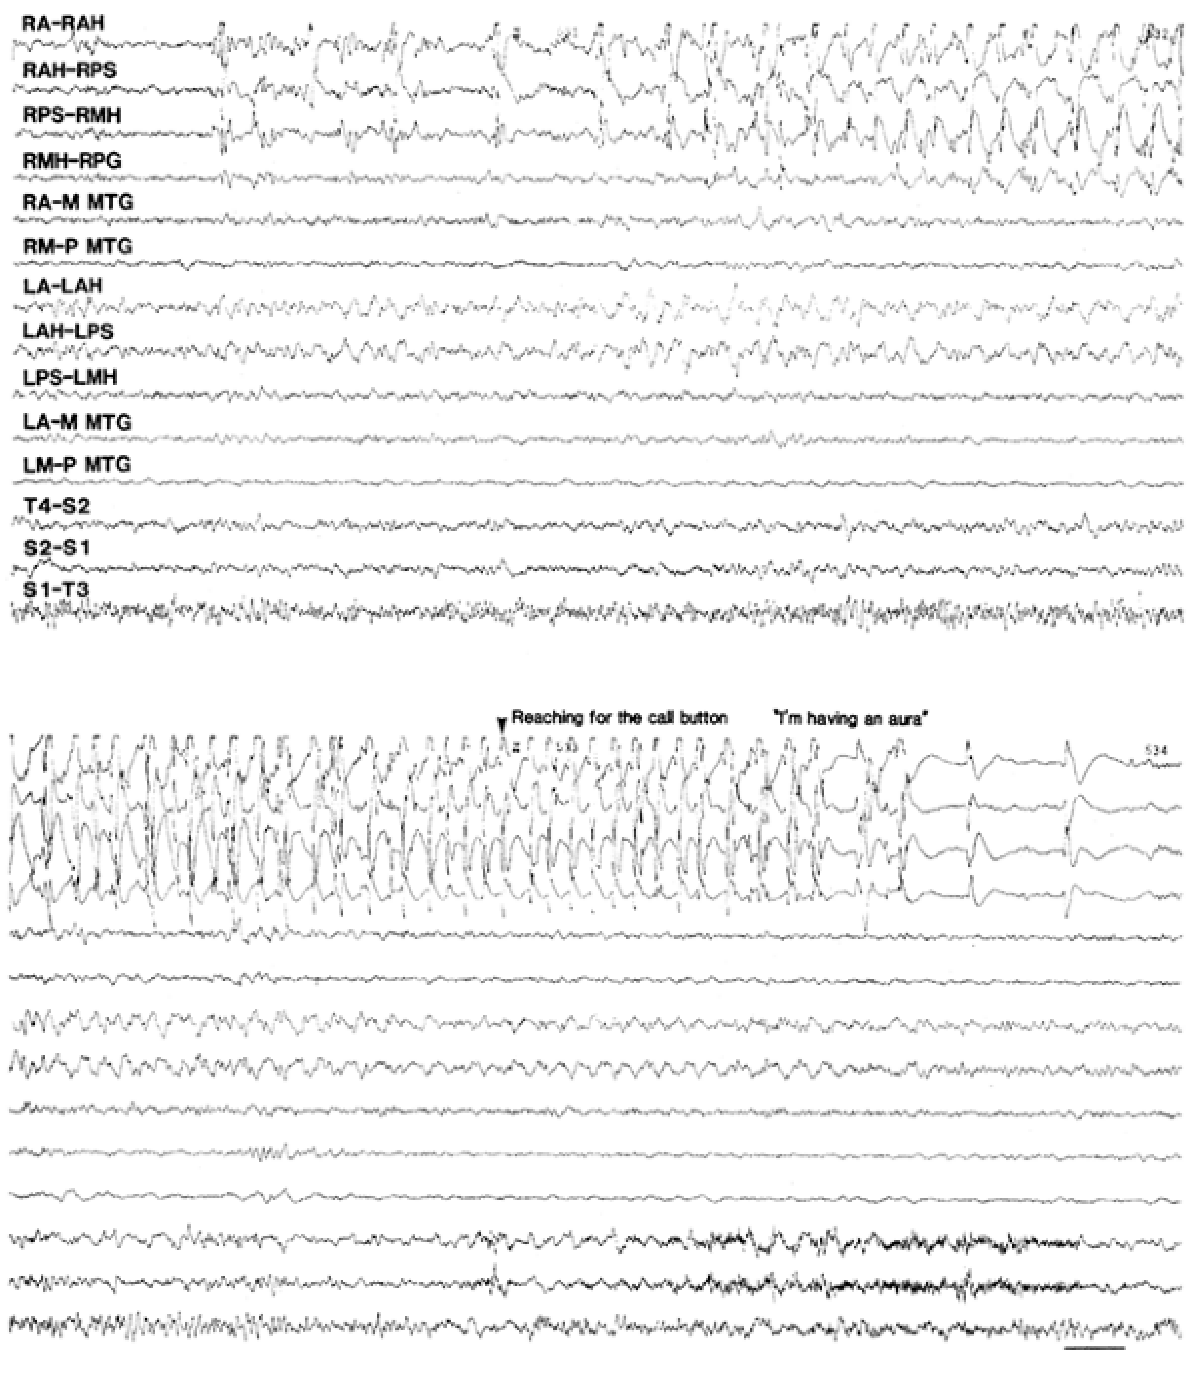

FIGURE 3. Forty continuous seconds of an EEG recorded from depth, sphenoidal, and scalp electrodes during a simple partial seizure of the right temporal lobe. Ictal onset consists of an increase in interictal spike discharges, maximal at the right anterior hippocampal electrode (*left portion of the upper panel*). After 8 to 9 seconds, these spikes become regular, eventually developing into a 3-Hz spike-and-wave pattern involving all derivations from the right mesial temporal lobe. Note that no low-voltage fast activity is seen, either initially or at any part of the ictal episode. The patient reached for the call button at the arrow, at which point regular slow activity is also seen in the left anterior hippocampus and in the right sphenoidal electrode.

The patient then indicated an aura consisting of a sensation of fear in her stomach. Depth electrode locations indicated as in Fig. 1. Superficial contacts from anterior (*A*), mid (*M*), and posterior (*P*) depth electrodes recorded from cortex of middle temporal gyrus (*MTG*). Calibration 1 sec. From Engel J Jr. Brain metabolism and pathophysiology of human epilepsy. In: Dichter M, ed. Mechanisms of epileptogenesis: transition to seizure. New York: Plenum Press, 1988: 1â€“15, with permission.

Considerable experience has been gained over many decades from ictal depth electrode recordings of limbic seizures from

patients who have been evaluated for surgical treatment.[35,38] Data are not only important for devising more effective surgical therapies (see Chapters 166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181,182,183,184,185), but for investigating the pathophysiologic mechanisms and anatomic substrates of limbic system epileptogenicity (see Chapters 30 and 41). A detailed description of indications and uses of invasive monitoring, however, is beyond the scope of this discussion. Suffice to say that these techniques are justified only during evaluation for possible resective epilepsy surgery. The distinction between limbic seizures that originate within those mesial temporal structures that are removed in a standardized anteromesial temporal resection, and those that originate

from temporal or extratemporal neocortex, can be exceedingly difficult.[1,84,120,122,123,142,143,152,153,154]

Diagnostic Considerations

As with the diagnostic approach to any patient with intermittent behaviors that could represent epileptic seizures, the primary concerns are to determine whether the events in question are epileptic, whether they constitute a chronic condition justifying the diagnosis of epilepsy, and whether a treatable underlying cause exists. A description of the ictal semiology by the patient and reliable observer is extremely important for classifying ictal events as limbic seizures. A description of the typical auras, oroalimentary and other automatisms, and postictal features discussed earlier in this chapter, and elicitation that auras, when present, commonly occur in isolation, makes a diagnosis of mesial temporal onset limbic seizures highly likely. This diagnosis of seizure type is further supported when (a) the history yields information typical of MTLE with HS, such as a family history of epilepsy, prolonged febrile seizures, or initial precipitating insults early in life; (b) neurologic examination is normal with the exception of verbal or nonverbal memory deficit; (c) and other features discussed in Chapter 247 are present. When a history suggestive of MTLE with HS is missing, limbic seizures could still reflect MTLE due to another type of mesial temporal lesion, or an epileptogenic abnormality in an area of neocortex that preferentially projects to mesial temporal limbic structures. Features of the history, neurologic exam, and initial ictal signs and symptoms then help to localize the neocortical epileptogenic region (see Chapter 246), although the limbic seizure itself, including the aura, can be identical to one originating in mesial temporal limbic structures.

Routine EEG is an essential part of the diagnostic evaluation, and the presence of unilateral or bilateral independent anterior temporal interictal spikes supports a diagnosis of limbic seizures. Although an interictal EEG spike focus outside the temporal lobe suggests that the limbic seizures do not originate within mesial temporal structures, the absence of such findings does not rule out this possibility.

High-resolution MRI is now the most effective diagnostic test for identifying the structural epileptogenic lesions responsible for limbic seizures, and the most common finding is unilateral hippocampal atrophy and increased T2 signal, including fluid-attenuated inversion recovery (FLAIR).[83] Other lesions can also be seen in mesial temporal structures, and neocortical lesions outside this area suggest that limbic seizures represent propagation from neocortex. Many patients with limbic seizures have normal MRI scans. Structural imaging is normal when lesions are below the resolution of MRI, as occurs early in MTLE with HS,[113] and in most patients with idiopathic familial MTLE.[19]

Neurocognitive testing often documents material-specific memory and learning deficits in association with limbic seizures due to mesial temporal lesions,[108] but memory also can be secondarily impaired when frequent limbic seizures result from neocortical projections. FDG-PET has been used to study patients with limbic seizures for over 25 years.[41] Ictal SPECT, functional MRI (fMRI), magnetic resonance spectroscopy, and magnetoencephalography (MEG) are increasingly employed to localize the epileptogenic lesion in patients with limbic seizures, as discussed in Chapters 246 and 247.

Differential Diagnosis

Limbic auras and seizures can be confused with a variety of psychiatric conditions, including nonepileptic psychogenic events. Clinically, the former can usually be easily diagnosed by their stereotypical features, whereas psychiatric experiences (Chapters 284, 285, 286), and nonepileptic psychogenic seizures (Chapter 283) are less likely to be stereotyped and can continue for prolonged periods. Other nonepileptic events that might be confused with limbic seizures include sleep disorders, particularly the parasomnias (Chapter 277) and migraine phenomena (Chapter 275). A differential diagnosis of limbic seizures from nonepileptic seizures that is not obvious by careful description of the ictal events can usually be achieved by routine EEG showing interictal spikes, and/or demonstration on MRI of structural abnormalities that are likely to be epileptogenic. It is important to bear in mind, however, that epileptiform-appearing transients on EEG or structural abnormalities on MRI, in themselves, do not make a diagnosis of epilepsy, and inpatient video-EEG monitoring may be necessary to make a definitive diagnosis.

Differential diagnosis between limbic seizures and other seizure types that involve bizarre behaviors with and without impaired consciousness is important only when diagnosis affects management. A typical situation would be the differential diagnosis between a limbic seizure consisting of impairment of consciousness only and the typical absence seizures seen with idiopathic generalized epilepsies. This distinction is usually easily made based on the clearly different clinical contexts of these two conditions, as well as the fact that patients with typical absence have bilaterally synchronous spike-and-wave on EEG and normal MRIs. Differential diagnosis between the seizures described here that utilize the mesial temporal ictal limbic network and certain frontal lobe seizures can be more difficult. Frontal lobe seizures tend to be more frequent, briefer, occur in clusters, and have a nocturnal preponderance. Supplementary motor area seizures can be confused with limbic seizures because they are bilateral and do not always show the classical tonic posturing, but consciousness is usually preserved. Hyperkinetic seizures mediated by frontal lobe structures, but at times originating in other neocortical areas, have sudden onset and offset without postictal confusion, and are characterized by vocalization, marked bilateral motor manifestations with a bizarre hysterical appearance and, occasionally, sexual automatisms. Differential diagnosis in these situations is important when seizures are refractory to medication and surgical treatment is being considered. In this situation, ictal EEG, neuroimaging, and characteristics of the ictal behavior are all important for localization, as discussed in Chapter 246.

Specific Syndromes Incorporating the Seizure Type as an Integral Feature

Limbic seizures are the predominant seizure type associated with MTLE with HS (Chapter 247), but are also the predominant seizure type of MTLE caused by other mesial temporal lesions, as well as other symptomatic focal epilepsies caused by neocortical lesions that preferentially propagate to mesial temporal limbic structures (Chapter 246). They also occur in association with gelastic seizures with hypothalamic hamartoma (Chapter 250), and in familial TLEs (Chapter 248).

Responses to Treatment

Any discussion of the medical management of limbic seizures must recognize that there are no population studies using currently available diagnostic methods to document pharmacoresistance of specific seizure types. Furthermore, no such studies are likely to occur because the vast majority of extensive evaluations are conducted in specialized epilepsy units as part of a presurgical investigation in patients who are deemed medically intractable. Whereas most large drug trials are carried out on patients with CPS, not all of these meet the criteria

P.549

discussed here for a diagnosis of limbic seizuresâ€"that is, seizures for which the ictal manifestations reflect activity in the limbic system and its efferent projections.

One comprehensive double-blinded study has compared the efficacy of four major AEDs (phenytoin, carbamazepine, primidone, and phenobarbital) on CPS and, secondarily, on generalization convulsions.[95] This multicenter cooperative study found phenytoin and carbamazepine to be superior, with the latter having a statistically insignificant edge. What was not intuitively obvious was that all drugs were equally efficacious once established. The problem with primidone and phenobarbital was intolerance to side effects at the time of drug initiation. In a similar study comparing carbamazepine and valproate, carbamazepine was found superior for controlling CPS, whereas both were equally efficacious for treating secondarily generalized seizures.[96] New AEDs are typically given as add-on trials in patients who are refractory to standard medications. In this situation, antiepileptic potency can easily be obscured. No data suggest that any of the new AEDs is more efficient against limbic seizures than carbamazepine or phenytoin, although their side-effect profiles are different and in some cases more acceptable to many patients.[26,27,51,52]

Numerous studies have documented that CPSs are not satisfactorily controlled with AEDs.[26,27,31,68,95,99,110,116] When these are limbic seizures associated with MRI-documented MTLE with HS, only 11% were adequately controlled in one study in a tertiary outpatient clinic,[117] and 46% in a primary outpatient clinic.[128] In both cases, this was the most pharmacoresistant condition. In the latter case, most of the patients were new onset, and recent evidence confirms the clinical impression that MTLE has a â€œstutteringâ€ course; limbic seizures are initially easily controlled, and it may take many years before they become pharmacoresistant.[7] This suggests that limbic ictal events could have progressive structural or functional consequences that make seizures more severe, or more difficult to treat. Indeed, evidence suggests that these ictal events could also be responsible for long-term interictal behavioral dysfunction, including progressive memory impairment and even psychiatric disturbances such as depression.[40]

One explanation for the relative refractoriness of limbic seizures, compared to primary generalized tonicâ€“clonic and absence seizures, is that virtually all potential AEDs, until recently, were screened against experimental models of the latter seizure types: maximal electroshock and subcutaneous metrazol. Consequently, many pharmacologic compounds that might have been highly effective against limbic seizures could have been discarded because they did not have anticonvulsant or antiabsence properties. One of the newer AEDs, levetiracetam, did fail these two screening tests, but was brought to market because it was found to be effective against amygdala-kindled seizures, a model of human limbic seizures.[90] Levetiracetam has proved to be highly effective clinically against limbic seizures, although not necessarily more effective than several other AEDs.[26,27,51,52] Although this proves that compounds without anticonvulsant or antiabsence properties can have clinical efficacy against limbic seizures, and that animal models of limbic seizures should be employed when routinely screening potential antiepileptic compounds, it does not provide evidence that such screening will significantly reduce the percentage of patients with limbic seizures who are currently pharmacoresistant.

Fortunately, most patients with limbic seizures have surgically remediable epilepsy disorders, such as MTLE, that can be effectively treated with excellent results.[36,46,136] Surgery, therefore, should not be considered a last resort; rather, patients with surgically remediable syndromesâ€”those conditions with seizures resulting from a known pathophysiologic disturbance and that have a high likelihood of being pharmacoresistant and progressiveâ€”should be referred for surgical treatment early, before the disabling social and psychological consequences of recurrent seizures become irreversible.[36,46]

Summary and Conclusions

Limbic seizures are ictal manifestations resulting from epileptic discharges within a specified neuronal network consisting of the limbic system and its efferent projections. Limbic seizures can be caused by epileptogenic abnormalities within this mesial temporal limbic network, such as occurs with MTLE with HS, MTLE due to other structural lesions, or idiopathic familial MTLE, or they can be the predominant seizure type in patients with epileptogenic regions in areas of neocortex that preferentially project to mesial temporal limbic structures. Limbic seizures are the single most common type of seizure and among the most pharmacoresistant. They present with a wide variety of signs and symptoms, most of which, alone or in combination, can reliably localize and, in some instances, lateralize the region of seizure origin. However, numerous exceptions exist. When accurate seizure onset localization is required before planned surgical intervention, the clinical characteristics of a patient's limbic seizures should never be examined in isolation, but only as one important part of the data in a comprehensive evaluation. However, the concept that clinical seizure characteristics are not useful for localization is not valid.

Chapter 47

Generalized Tonicâ€"Clonic Seizures

Benjamin G. Zifkin

Charlotte Dravet

Introduction

The generalized tonicâ€"clonic seizure (GTCS) has been known since antiquity. The earliest descriptions appear in Egyptian hieroglyphics before 700 B.C.[99] From the mid-19th century, when notions of cerebrovisceral sympathy were discarded and all epilepsy was recognized as originating in the brain, the GTCS was considered the cardinal manifestation of genuine or idiopathic epilepsy due to a predisposition to have seizures. GTCS was described as *grand mal,*[49] a term that is still encountered. This predisposition was, in turn, believed to be associated only with generalized seizures (reviewed in Gastaut[42]). Although the history of clinical epileptology has been marked by the differentiation of nonconvulsive seizures as epileptic events, progressively more exact descriptions of seizure types and epileptic syndromes, the development of surgery (usually for intractable partial seizures), and progress in childhood seizure disorders, the GTCS is still the hallmark of epilepsy for the general public. It remains a dramatic and often frightening event for patients, families, and onlookers. For most neurologists, however, the generalized convulsion is a rarely witnessed clinical event, albeit a common reason for consultation the history of which can be frustratingly difficult to obtain. It may be an isolated event in the setting of an acute encephalopathy, a symptom of serious brain disease, or a manifestation of several epilepsy syndromes of generally good prognosis.

Definitions

The current International Classification of Epileptic Seizures[23,30] defines GTCS within the group of generalized convulsive or nonconvulsive seizures. Unlike the conceptual approach of the classification of epileptic syndromes,[24] this classification of seizures is based on observed events, specifically, the seizures themselves as documented during intensive monitoring, and the electroencephalogram (EEG). As a group, in generalized seizures, â€œThe first clinical changes indicate initial involvement of both hemispheresâ€¦. Motor manifestations are bilateral. The ictal electroencephalographic patterns initially are bilateral, and presumably reflect neuronal discharge which is widespread in both hemispheres.â€ The classification, however, treats the term *tonicâ€"clonic seizures* as self-explanatory. In the last proposal by the International League Against Epilepsy (ILAE) Task Force,[33] the Glossary of descriptive terminology for ictal semiology describes a tonicâ€"clonic seizure as â€œa sequence consisting of a tonic followed by a clonic phase. Variants such as clonicâ€"tonicâ€"clonic may be seen.â€ Dreifuss[29] provides a useful description:

â€œThe majority lose consciousness without any premonitory symptoms. There is a sudden sharp tonic contraction of muscles; when this involves respiratory muscles, there is a cry or moan. The patient falls to the ground â€¦tonic contraction inhibits respiration.â€¦ The tongue may be bitten.â€¦ This tonic stage then gives way to clonic convulsive movements that last for a variable period of time.â€

Cyanosis, salivation, tongue biting, and incontinence are frequent, and the postictal state includes a variable period of unconsciousness.

There is at present no provision in the international classification for subclassifying GTCS with preceding bilateral myoclonic jerks or absence attacks. Sequences such as a brief clonic attack before the tonic phase (clonicâ€"tonicâ€"clonic seizure) are also well known to epileptologists, and the glossary indicates this possibility. The classification makes it clear, however, that the term *generalized convulsive seizure* is restricted to convulsive seizures that are generalized from the start and excludes partial seizures that may become secondarily generalized so quickly as to look like GTCS, as is seen in some frontal lobe seizures.[93] Generalized tonicâ€"clonic (convulsive) seizures are manifestations of idiopathic generalized epilepsies (IGEs) and epilepsy syndromes, as these have been defined and, in the most recent proposed classification of epileptic syndromes,[33] would be associated with the generalized epilepsies with variable phenotypes: These are discussed in detail elsewhere in this book.

Seizures that often differ from classic tonicâ€"clonic convulsions can occur when partial seizures become generalized. Distinguishing these from GTCS due to an IGE syndrome is a common problem of vital importance in daily practice. Especially in seizures arising in the temporal lobe, clinical spread is not immediate, and the complete seizure pattern (see â€œDiagnosis,â€ below) may aid in diagnosis. These seizures are classified under partial seizures as partial seizures evolving to GTCS, although the seizure pattern is often different from that of GTCS. An isolated seizure or brief flurry of seizures clinically indistinguishable from GTCS may occur with an acute diffuse encephalopathy. These are classified as situation-related seizures in the classification of epilepsies, because they do not constitute a separate seizure type. Childhood febrile convulsions, probably the most common form of convulsion, are similarly classified.

It is important to emphasize that, although generalized convulsions may occur in the generalized cryptogenic and symptomatic epilepsies and syndromes, they are not the predominant or defining seizure type and usually happen relatively late in the course of the disease. Generalized seizures manifested only by a tonic phase are, however, quite different from GTCS and are common and often intractable in these syndromes. True GTCSs are not frequent in young children but can occur, particularly in epilepsy with myoclonicâ€"astatic seizures,[27] severe myoclonic epilepsy of infancy (Dravet syndrome),[28] and in some progressive myoclonic epilepsy varieties in children and adults, such as Jansky-Bielschowsky disease[94] and Unverricht-LÃ¼ndborg disease.[68]

P.554

Epidemiology

Tonicâ€"clonic seizures may be the most common afebrile seizure type in the general population. However, until recently, epidemiologic studies included patients with clinically generalized seizures of partial onset and did not specify the epilepsy syndromes in which GTCSs occur. The occurrence of GTCS is also age-related. Although epilepsy begins much more commonly in infants, children, and the elderly than in middle life, other seizure types are more common in young children, related in part to incomplete synaptic development and myelination, especially of interhemispheric connections.[2] Generalized convulsive seizures are uncommon in infants and rarely, if ever, occur in neonates. In the elderly, seizures usually reflect localized brain lesions. Thus, GTCSs are rare in the first few years of life, although myoclonic and tonic seizures are not, whereas partial seizures with secondary generalization are common in the elderly. Typical GTCSs are common, however, in later childhood, adolescence, and young adult life, with the onset of IGEs. Studies based on seizure descriptions without EEG or imaging results or which refer to GTCS in very young children will, thus, overestimate their occurrence. Studies from specialized epilepsy centers that concentrate on patients with intractable seizures and candidates for epilepsy surgery risk underestimating the prevalence of GTCS. It should also be noted that not every subject with a generalized epilepsy syndrome has GTCSs.

Hauser and Kurland,[56] using the unique medical records system in Rochester, Minnesota, reported that the prevalence of patients with only GTCS was 20.6% of patients with epilepsy. Patients with GTCS also accounted for 23%[54] of the incidence of epilepsy. Incidence estimates for all recurrent afebrile seizures in children and adolescents are roughly similar in different studies, from 50 to 100 new cases per 100,000 per year.[55] A study of clinical and EEG data[61] estimated that about 39% of patients with epilepsy have a generalized epilepsy syndrome. As discussed later, GTCSs occur in several of these syndromes. Patients with absences commonly develop GTCS, particularly if absences begin relatively late, in preadolescent years: This occurs in about 35% of patients with absences in general, but in 90% of patients with later-onset absences (reviewed in Aicardi[3]).

A genetic component is evident in many different types of epilepsy. However, the common epilepsies do not usually behave as simple Mendelian disorders, and several lines of evidence suggest multifactorial inheritance.[5] The genetics of juvenile myoclonic epilepsy (JME), in which GTCSs often occur, have been recently reviewed.[110] Relatives of patients with idiopathic epilepsy have a higher risk for epilepsy than do those of patients with symptomatic epilepsy.[86] Population studies show an increased risk of unprovoked seizures in close relatives of patients with idiopathic age-related epilepsy syndromes of childhood. The relative risk ranges from 2.5 (95% confidence interval [CI] 1.3â€"4.4] for siblings to 3.4 (95% CI 2.1â€"5.1) for offspring. However, the risk for offspring of parents with GTCS, about 5%, is not higher than that for offspring of parents with partial seizures, the difference being accounted for by the much higher risk to offspring if a parent has absences.[7,86] Twin studies in IGEs, reviewed by Berkovic et al.,[12] provide further evidence for a large inherited component and show a high rate of concordance in monozygous twins for specific syndromes, including those with GTCS as a major feature. Other risk factors[80,92] include a history of febrile convulsions (odds ratio 13.75, 95% CI 3.49â€"54): This may indicate a lower convulsive threshold and cannot be taken as the cause of later GTCS. Some familial epilepsies are associated with specific ion channel defects (Chapter 18), but single gene defects are a rare cause of common epilepsies. This information is, however, in keeping with a polygenic inheritance for common epilepsies.

Anatomic Pathways and Pathophysiology

Different forms of convulsive seizures in animals depend on independent anatomic regions and pathways. Models of convulsive seizures using drugs such as bicuculline and pentylenetetrazol, kindling studies, and animals genetically prone to generalized epilepsy at times with reflex triggers, have implicated brainstem structures (reviewed by Browning[19] and Moraes[82]) in the genesis and, clearly, in the modulation of convulsive seizures; including the lateral geniculate body, which produces GTCS when kindled in the cat[96]; ascending pathways through the mamillary bodies and anterior thalamus; the substantia nigra, including a nigrotectal Î³-aminobutyric acid (GABA)ergic projection[38]; and diffuse increased noradrenergic innervation of the cortex from the locus coeruleus.[84] The three principal concepts of generalized epilepsy, thus, each implicate a different mechanism: an abnormal response of hyperexcitable cortex to initially normal thalamic input, a primary subcortical trigger, and abnormal cortical innervation from subcortical structures. Subcortical mechanisms would play at least a modulating role. Any or several of these may operate in the clinically and genetically different syndromes with GTCS in humans (for a review with EEG emphasis, see Binnie[14]). It should be emphasized that GTCS models in rodents and fowl are clinically quite different from human epilepsy; feline, canine, and primate models may be closer approximations.

Studies in the Senegalese baboon *Papio papio*, which has both photosensitive and spontaneous generalized motor seizures, suggest that the substantia innominata participates in the mechanism of generalized convulsions by modulating excitability of the hemispheric motor mechanisms. In partial seizures that spread from limbic structures, the claustrum participates in activating the ipsilateral hemispheric motor mechanisms. Bilateral spread of partial motor seizures requires the anterior two-thirds of the corpus callosum. These studies (reviewed in Wada[103]) are of particular interest because, despite some important differences, the photosensitive baboon is believed to be a closer model of human epilepsy than are lower animals such as rodents and fowl.

Regulation of the seizure threshold and of seizure spread in different animal seizure types depends on seizure-gating pathways, which themselves are not pathways for seizure spread. Gating mechanisms include the substantia nigra and related circuits, ascending noradrenergic pathways, thalamic circuits, and some arising in the cerebellum (for a review see Gale[37]).

Intracellular events during GTCS have not been studied extensively, but neocortical neurons recorded during convulsive seizures induced by focal penicillin application show prolonged depolarization coinciding with the tonic phase, followed by sequential rhythmic depolarization and repolarization during the clonic phase. Gloor[46] noted that GTCSs are associated with activation of *N*-methyl-D-aspartate (NMDA) receptors, which would permit calcium (Ca^{2+}) influx into the neuron, and that many deleterious intracellular events follow the massive Ca^{2+} influx associated with convulsive seizures, some of which depend on activation of second messengers and some of which are direct. These can be transitory and manifested clinically by symptoms such as postictal stupor or Todd paralysis. However, irreversible cell damage or cell death may occur, especially with prolonged seizures or with status epilepticus (SE).[57]

P.555

Clinical Features

Ictal

Generalized convulsive seizures occur in several distinct epilepsy syndromes. Although the convulsion seems stereotyped, details of the seizure onset are important in the diagnosis of the related epilepsy syndrome. These may not be obtained from witnesses: video-EEG monitoring may be needed to document clinically relevant features, such as partial onset of a secondarily generalized event. Frontal lobe seizures particularly may imitate GTCSs (see the next section), and GTCSs may imitate focal seizures.[36]

Some patients reliably report a *prodrome*, premonitory symptoms hours or days before a seizure. It is surmised that these represent changes in cortical excitability or manifestations of some factor that also alters the seizure threshold. These are not auras; that is, they are not simple partial seizures that come immediately before more elaborate partial seizures, and they do not indicate a focal seizure onset. Common prodromes include mood changes, sleep disturbances, lightheadedness, anxiety, difficulty concentrating, and irritability.

GTCSs may begin with myoclonic jerks (Fig. 1) or, rarely, with absences.[78,83] Before the tonicâ€"clonic phase, versive movements of the head and eyes may occur. Although controversial and usually considered typical of partial seizures, versive movements clearly occur at or near the onset of some seizures which, as far as can be known, are generalized from the start.[21,85,91] More complex circling behavior has also been documented.[39,70] GTCSs can also occur at the onset, in the midst of, or at the end of absence status.[6]

The tonic phase[40] begins with a brief flexor spasm of axial muscles that spreads quickly to the arms and legs, accompanied by loss of consciousness. The eyes deviate upward, the pupils dilate, and the jaw is rigid and partly open. This is followed by more prolonged tonic extension, spreading from axial muscles to the limbs. The initial closing of the mouth often results in tongue biting or other trauma, and the strong tonic contraction of respiratory muscles results in the characteristic cry. Apnea begins at the very onset of the tonic phase and can cause progressive cyanosis. Autonomic signs are prominent: Pulse and blood pressure rise, and profuse sweating and tracheobronchial hypersecretion are common. Although urinary bladder pressure rises, voiding does not occur because of sphincter muscle contraction.

The clonic phase begins gradually as a diffuse tremor (European authors often refer to this as *vibratory*), which slows from 8 to 4 Hz. It then emerges with cycles of inhibition interrupted by reappearance of the tonic contraction, producing atonia alternating with repeated violent flexor spasms. Each spasm is accompanied by pupillary contraction and dilation. The atonic periods gradually become longer until the last spasm. Voiding may occur at the end of the clonic phase as sphincter muscles relax. The convulsion typically lasts 1 to 2 minutes.

Postictal

Respiration returns almost at once after the last clonic jerk. Usually, the muscles are relaxed postictally, but a diffuse tonic state may return, resembling decerebrate rigidity and possibly causing further injury. The patient gradually awakens, often after a period of stupor or sleep, and is often confused, with some automatic behavior. Headache and muscle pain are common. The patient does not recall the seizure itself.

Complications of GTCS include trauma to the tongue, lips, and cheeks from trismus; head trauma due to a fall or to repeated banging of the head against hard surfaces during the clonic phase; vertebral compression fractures (usually asymptomatic); aspiration pneumonia; and, infrequently, neurogenic pulmonary edema, which may be related to the intense autonomic activity during the seizure. Sudden death in epilepsy, an uncommon but well-known event, may be related to an immediately preceding seizure. A GTCS can, rarely, be lethal[74] (this topic is extensively reviewed in Lathers[72]). Langan et al.[71] found that sudden death was more likely if GTCS had occurred in the previous 3 months (odds ratio 13.8, 95% CI: 6.6â€"29.1) (see Chapter 189). Pulmonary edema, apnea, cardiac arrhythmia, and aspiration with asphyxia have been proposed as mechanisms (see Chapter 10). Transitory metabolic changes after GTCS are usual. Changes in circulating hormone levels are also common.[90] They are summarized in Tables 1 and 2. The elevation of plasma prolactin reaches its zenith of 5 to 30 times the upper limit of normal about 20 minutes after the seizure and, if present, almost certainly excludes pseudoseizure as the cause of a clinical episode. The postictal value should be compared to a control value obtained 24 hours later with no intervening seizure. Other hormone levels also rise after a seizure, but the relatively minor diurnal variation of prolactin levels and the relative ease of measuring them make this a practical test for clinical use. A prolonged convulsion may be associated with a minimal increase in the cerebrospinal fluid (CSF) cell count of 1 to 2 cells/mm^3 and SE with a greater pleocytosis, but whatever the number of seizures, a cell count of more than 10 cells/mm^3 should be taken as evidence of intracranial inflammation until proven otherwise.[32]

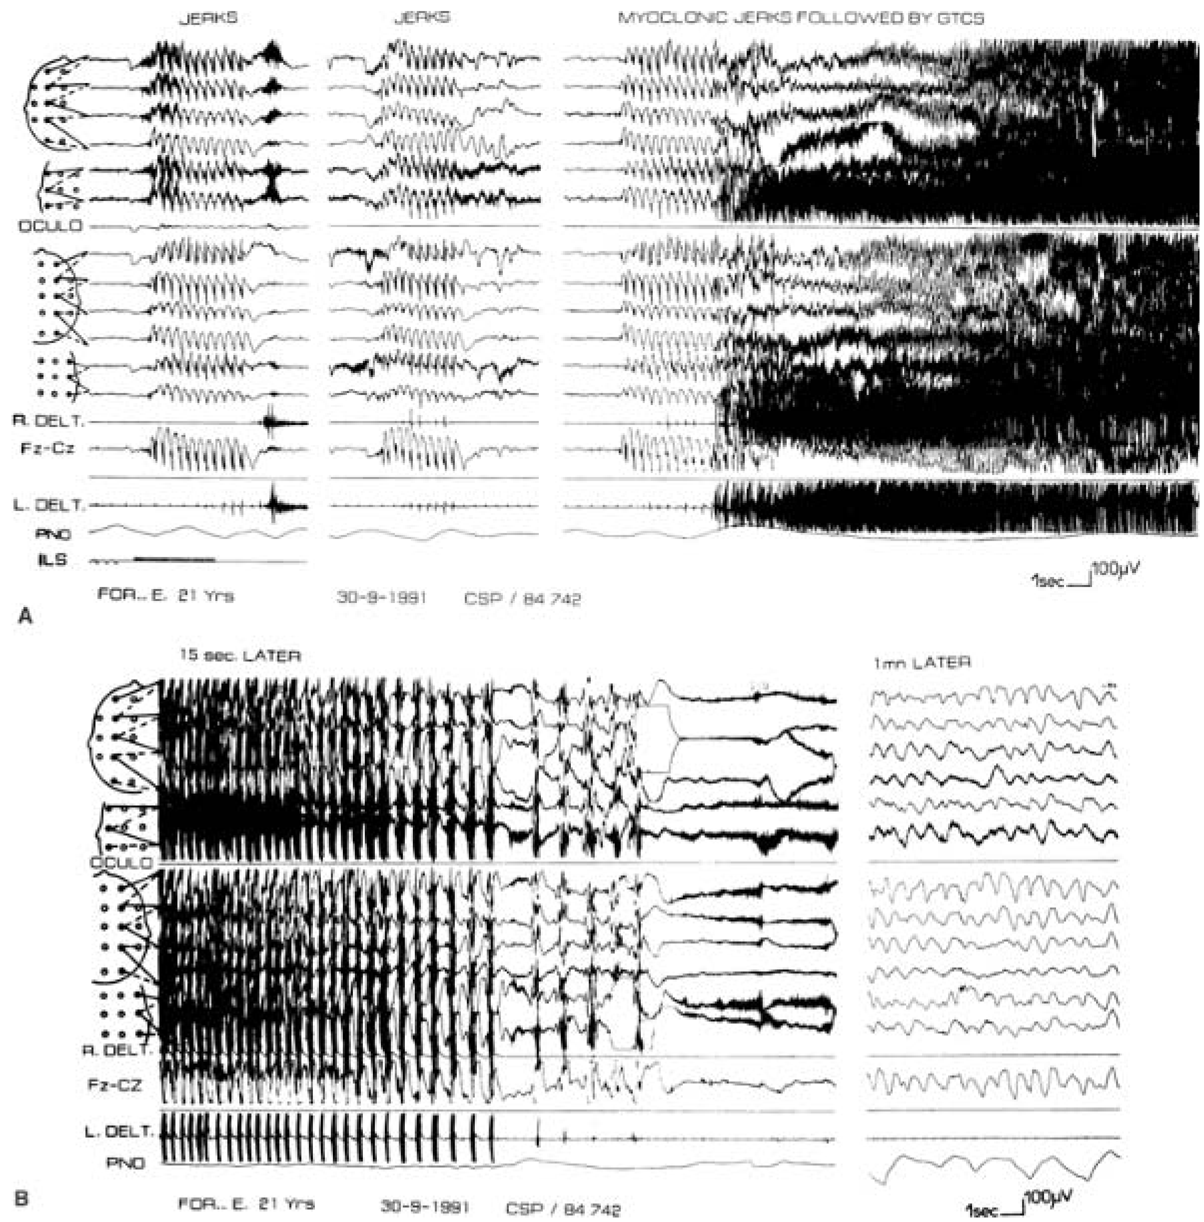

FIGURE 1. A generalized tonicâ€"clonic seizure preceded by myoclonic jerks in a 21-year-old with juvenile myoclonic epilepsy. **A:** Three salvos of myoclonic jerks on awakening, the first elicited by intermittent photic stimulation. The others occur spontaneously, and the third is followed immediately by the tonic phase of the generalized convulsion. **B:** Clonic phase and end of the convulsion. Bilaterally synchronous jerks of decreasing frequency are recorded in the deltoid muscle EMG, followed by relative flattening of the EEG, partly masked by EMG artifact caused by postictal tonic spasm. Diffuse delta activity is recorded 1 minute later. The respiratory monitor records apnea during both the tonic and clonic phases of the seizure. R. delt, right deltoid; L. delt, left deltoid; PNO, pneumogram; ILS, intermittent light (photic) stimulation.

EEG Manifestations and Clinical Correlations

Interictal

The waking EEG of patients with only GTCS is often normal.[17] Slight nonspecific abnormalities of background activity may occur, and antiepileptic drugs (AEDs) may cause mild diffuse slow activity, especially at high levels. Barbiturates and benzodiazepines commonly cause diffuse increased Î²-wave activity. Some patients, especially those with a history of absences, may have some paroxysmal frontal intermittent rhythmic delta activity. Although abnormal in the EEG of the awake adult, this pattern reflects only a nonspecific disturbance of cerebral activity and is not considered epileptiform (reviewed in Zifkin[109]).

Generalized EEG interictal epileptiform abnormalities consist of spikes, sharp waves, polyspikes, and polyspike or spike-and-wave complexes (SWCs). Hyperventilation is often effective in bringing out generalized epileptiform activity, especially typical SWCs. Sleep recordings, ideally obtained without sedation, often increase the yield of epileptiform activity. Epileptiform activity may be reduced or abolished by chronic treatment with certain AEDs, especially valproate and the benzodiazepines. The type of interictal epileptiform activity can be related to the syndrome in which GTCS occurs:

- Typical generalized bilaterally synchronous 3-Hz SWCs are associated with typical absence attacks: Whether this is really interictal is a subject of debate.
- Irregular bilateral SWCs may be seen with IGE and GTCS but may also be recorded in different metabolic encephalopathies and drug withdrawal.
- Fast spike-and-wave activity at 4 to 5 Hz is most often associated with GTCS. In the resting EEG in wakefulness, this is typical of JME and can also be seen with

epilepsy with myoclonic absences, in which subjects are also typically photosensitive.
- Polyspikes or polyspike-and-slow-wave complexes are usually seen with JME, often on eye closure.[8]

All these are usually predominant over anterior head regions; they may be seen only over these areas but may occasionally be predominant posteriorly in children. They are commonly asymmetric: This should not be interpreted to indicate a focal or regional seizure onset without additional evidence such as convincing local or regional nonspecific abnormalities. During non-REM sleep, the epileptiform bursts are usually more frequent but briefer and fragmented. They become much less frequent in REM sleep.[95] Patients with GTCS are more likely to have an epileptiform response to intermittent photic stimulation than are those with partial seizures. Routine photic

stimulation may induce generalized epileptiform activity in about 25% of patients with IGE and, if strictly defined, this activity is rare without a personal or family history of epilepsy.[14]

Table 1 Transitory changes following a generalized convulsive seizure

Tissue	Value	Change
Arterial blood	pH	Decrease (usually >7.0)
Serum	Glucose	Increased up to 12 mmol/L (decreases in status epilepticus)
Serum	Creatine kinase	Increased

Serum	Lactate	Increased
CSF	Cell count	Usually normal. Consider inflammation if elevated after a single seizure or >10 cells/mm^3 after any number of seizures.

Table 2 Circulating hormone changes following GCS

Hormone	Change
Prolactin	Increased
ACTH	Increased
Cortisol	Increased
Vasopressin	Increased
Growth hormone	Increased
Î²-Endorphin	Increased
TSH	Inconsistent change

Ictal

Much of the ictal EEG of a GTCS is usually obscured by muscle and movement artifact. Computer analysis shows that the EEG seizure onset is usually asynchronous, with small time differences between the hemispheres (Figs. 1, 2). These are minor and usually inconsistent,[48] and if there is no focal interictal epileptiform activity, the current classification of seizures treats such attacks as generalized, although this is now a subject of debate. Certain stereotyped patterns of seizure onset have been observed. Some patients have one or a few bilateral myoclonic jerks before the tonic phase begins, usually associated with EEG artifact, although individual high-amplitude bilateral anterior predominant spikes may be recorded with each jerk. Absences may progress to GTCS[78,83]: The ictal EEG shows a transition from the spike-and-wave activity of the absence through a sudden bilateral relative flattening of the EEG with low-amplitude Î²-wave activity, followed by the GTCS. Perioral myoclonia with absences may also be accompanied by GTCS.[9]

The convulsion itself is characterized during the tonic phase by progressively higher amplitude and lower frequency ictal epileptiform activity, reaching about 10 Hz, which is the epileptic recruiting rhythm.[41] This then becomes slower, mixed with bilateral high-amplitude spikes, and a progressively greater amount of high-amplitude rhythmic Î´-wave activity. These are slow, progressively developing into repetitive complexes of high-amplitude spike-and-slow-wave activity associated first with the tremor, then, with further slowing of the repetitions, with the violent jerks of the clonic phase. This pattern is held to be the result of progressively greater inhibition.

The postictal EEG may be briefly isoelectric at routine gains or may show diffuse, very low-amplitude slow Î´-wave activity. This corresponds to sustained hyperpolarization.[105] The seizure ends not by exhausting the brain but by an active mechanism. Baseline activity returns in minutes to hours, but a mild, nonspecific postictal disturbance may persist for a day or more in adults and longer in children. The postictal EEG may occasionally show only subtle nonspecific change; this appears to represent different mechanisms of ictal termination, but the basis for it is unknown.

Diagnostic Considerations

The diagnosis of GTCS requires first establishing that a seizure, not usually observed by the physician, is indeed an epileptic event, then whether it is a manifestation of an IGE, another form of epilepsy or epileptic syndrome, or an isolated seizure. The rarity of true GTCS in very young children should not be forgotten, nor should the likelihood that a first generalized convulsion in middle adult life and later is much more likely to be due to a symptomatic focal brain lesion or other encephalopathy than to an IGE syndrome. Even with an apparent cause such as alcohol withdrawal, full investigation of a first seizure is required. The patient does not remember the seizure, so the history should also be obtained from witnesses whenever possible. Factors such as sleep deprivation, alcohol withdrawal, and nonmedical drug use should be explored, as well as more specific triggers such as television or cognitive performance. Eliciting a history of the sequence of the tonicâ€“clonic convulsion without leading the witness is important. Family members can also often provide details of prenatal, perinatal, developmental, and family history. A GTCS is not usually captured during routine EEG recording, and the interictal EEG, even if it contains epileptiform activity, provides only suggestive evidence for the diagnosis of a given event. Patients with GTCS and IGE typically have no evidence for any localized, regional, or diffuse brain abnormality on history, physical, or neurologic examination; clinical laboratory testing; EEG; or imaging studies. Focal or asymmetric regional EEG epileptiform abnormalities are not rare, especially in JME.[110] A history of simple febrile convulsions or of familial epilepsy may be obtained: These are recognized risk factors for the development of GTCS.

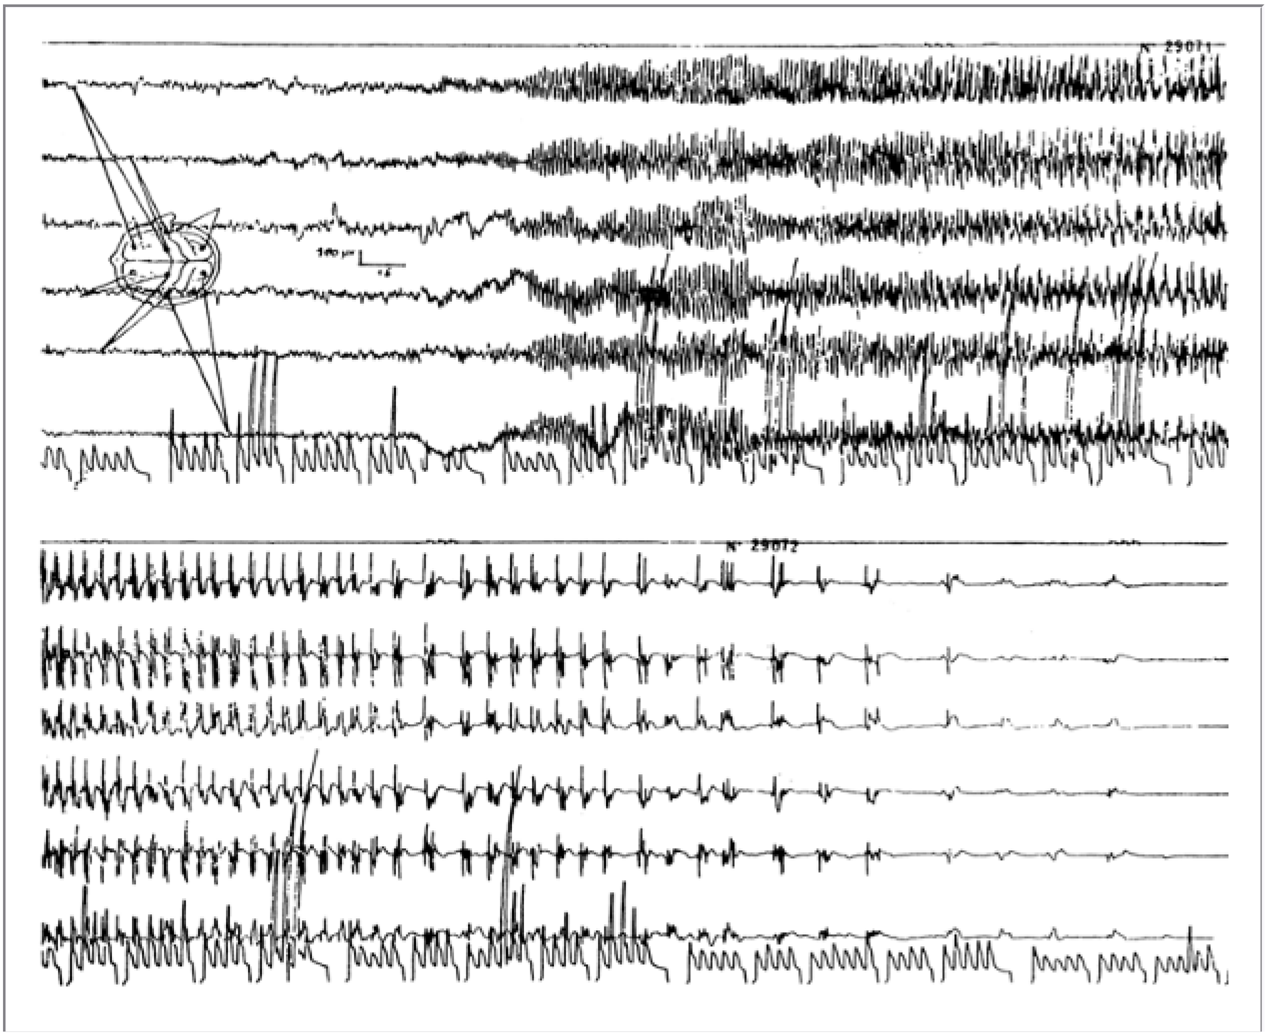

FIGURE 2. The first 10 seconds of EEG are recorded prior to the clinical seizure. The seventh channel (*bottom*) is the output of a Grey-Walter frequency analyzer. The recording was obtained with partial muscle relaxation after injection of curare and is less contaminated by muscle artifact than are present-day ictal scalp EEGs. The second 10 seconds corresponds to the tonic phase, with prominent 9- to 10-Hz rhythmic activity throughout, the epileptic recruiting rhythm. Note the increase in amplitude, followed by the vibratory period of transition to the clonic phase with the development of increasing theta activity. The lower fragment of the tracing shows the clonic phase. The repetitive and rhythmic 3-Hz polyspike and slow-wave complexes slow progressively and are followed by periods of relative flattening, between which bursts of polyspikes appear. From Gastaut H, Broughton R. *Epileptic Seizures. Clinical and Electrographic Features, Diagnosis and Treatment*. Springfield, IL: Charles C. Thomas, 1972, with permission.

Evidence that the generalized convulsion may have been secondarily generalized and a manifestation of a symptomatic localization-related epilepsy must be carefully sought. Suggestive historic elements of possible importance include prenatal, perinatal, and neonatal difficulties; prolonged or

atypical febrile convulsions; partial seizures at an early age; head trauma; intracranial infection; and developmental or physical disability. Examination between seizures may reveal subtle lateralized or bilateral motor disturbances or asymmetries of the face, hands, or feet. Detailed sensory testing may also show asymmetry of two-point discrimination over the face or hands. The seizure pattern can also be highly suggestive. Whereas the initial history from a frightened witness may suggest a seizure generalized from the start, a detailed history may disclose an aura that may lateralize or localize the clinical seizure onset or deviations from the very stereotyped pattern of the typical GTCS described earlier. Intensive monitoring of patients with intractable partial seizures shows that, when these seizures generalize, especially from the temporal lobe, the result is not a typical GTCS. Seizures arising in the temporal lobe often follow various sequences of lateralized dystonic posturing or adversion before generalization (extensively discussed in Kotagal[67]). The generalized seizure in these cases occurs late in the sequence of ictal events and usually in the longer seizures observed during monitoring. Kirton et al.[65] reviewed some of the clinical differences between primary and secondarily generalized seizures in childhood. In all cases with focal onset, the mouth either remained open or repeatedly opened and closed rather than slamming shut. In 77% of cases with focal onset, late motor activities were seen after the clinical and EEG seizure was over.

Partial seizures arising in the frontal lobe, although of several clinical types, are notorious for their rapid onset, prominent motor activity, and tendency to generalize rapidly (see Kellinghaus and LÃ¼ders[64] for review). Such patients often have apparently generalized convulsions, but the focal onset may be apparent on history or video monitoring. The posturing of supplementary motor area attacks may be disclosed by informed questioning of witnesses or by video monitoring. Similarly,

transient postictal findings, such as hemiparesis or dysphasia, are of diagnostic importance. Whereas patients with frontal seizure onset often have supporting clinical and paraclinical evidence, the differentiation of their attacks from generalized seizures can be extremely difficult and can require extensive and, at times, invasive monitoring. Nocturnal paroxysmal dystonias are unusual events that, although not GTCS, are usually frontal lobe epileptic seizures, but monitoring may be required to make the diagnosis.[98]

The typical childhood seizure patterns of idiopathic localization-related epilepsies with rolandic or occipital spikes may not be elicited, and these may present as apparently generalized convulsions in sleep. History and examination are normal, but the EEG is characteristic (see Chapters 73, 236, and 238). Reports differ as to the frequency with which rolandic epilepsy is manifested by generalized convulsions, but at least a quarter of affected children are reported to show this,[77] possibly because the seizure onset was not observed by sleeping parents. Benign epilepsy of childhood with occipital spikes and other occipital epilepsies of childhood (reviewed in Aicardi[4] and Gastaut[43]) may also generalize, but these typically progress from the characteristic visual aura, and postictal migraine symptoms are common.

Generalized tonic seizures typically occur in patients with diffuse encephalopathies and developmental delay, as part of symptomatic generalized epilepsy syndromes. These may occur in prolonged sequences during sleep,[40] which might be confused with GTCS, but the clinical context is different. Brief tonic seizures in wakefulness, responsible for disabling drop attacks,[31] are not usually associated with GTCS. A sleep video recording may help diagnosis if doubt persists. Some GTCSs with a very brief tonic phase could be confused with purely generalized clonic seizures. The use of the EEG and of imaging in differential diagnosis is discussed elsewhere in this book.

Historic, laboratory, and EEG data may help in the diagnosis of an isolated GTCS related to acute or chronic metabolic encephalopathies, an event not considered diagnostic of epilepsy, although the seizure itself is clinically not different from an epileptic event. Common causes include alcohol and other drug withdrawal, hyponatremia, hypoglycemia, and drug toxicity.

Differential Diagnosis

Nonepileptic Conditions

The differential diagnosis of GTCS from nonepileptic conditions is different in children and adults. In infants, apneic syndromes including gastroesophageal reflux, jitteriness of the newborn with various encephalopathies and metabolic disorders, and paroxysmal abnormalities of tone such as opisthotonic posturing and clonus, can be mistaken for GTCSs, which are very rare in early childhood. In toddlers and young school-age children with paroxysmal disorders during wakefulness, simple faints, breath-holding spells, and pallid syncope are common causes of diagnostic confusion, especially if brief convulsive movements occur (convulsive syncope is reviewed by Lin[76]). Syncope of various types is probably the most common source of diagnostic error in older children and adults. Elements suggesting syncope include the typical precipitating factors such as pain, fear, prolonged standing, or heat; the presyncopal, gradually increasing feeling of lightheadedness, blurred vision, and clamminess over several seconds; and pallor followed by collapse. EEG and imaging studies are normal or noncontributory. The diagnosis of syncope should not be taken lightly, and potentially life-threatening cardiac disease such as cardiomyopathy, prolonged QT syndrome, and other arrhythmias should be considered in children and adults.[73,87,97] Hyperventilation and electrolyte imbalances may cause tetanic attacks that could also be confused with GTCS.

Nocturnal paroxysmal events in adults and children include sleep apnea, night terrors, and nocturnal paroxysmal dystonias. Cardiac arrhythmia and resulting brain ischemia followed by a seizure can occur with severe sleep apnea. This seizure is not diagnostic of epilepsy but reflects the acute encephalopathy. Night terrors are stereotyped and unlikely to be confused with GTCS. Nocturnal paroxysmal dystonic attacks are often frontal lobe seizures.

Psychogenic nonepileptic seizures are unusual in young children but are a common diagnosis among patients referred to epilepsy centers for intractable seizures. The belief that many such patients also have epileptic seizures has not been confirmed.[75] Whereas routine clinical evaluation can usually distinguish among the disorders described here, especially if an adequate history can be obtained, the diagnosis of psychogenic nonepileptic seizures is often difficult and may require intensive monitoring, particularly when there has been strong iatrogenic reinforcement of the diagnosis of epilepsy. Measurement of serum prolactin[90] and creatine kinase[108] levels following a seizure can be helpful but also requires a hospital setting to collect blood at the appropriate time. Vinton et al.[101] suggest that detailed evaluation of the rhythmic muscle artifact can distinguish GTCS from convulsive nonepileptic events: The nonepileptic attacks showed a stable, nonevolving frequency that is different from the evolving pattern seen during an epileptic seizure.

Specific Syndromes Incorporating the Seizure Type as an Integral Feature

A further step in differential diagnosis is determining whether the GTCS forms part of a defined epilepsy syndrome. This has implications for the prognosis and response to medication. Different syndromes also have different genetic substrates. Generalized convulsive seizures, strictly defined as a manifestation of IGE, occur in these syndromes, which are described in detail elsewhere in this book.

Febrile Convulsions

This syndrome is classified as situation-related seizures, rather than as epilepsy (see Chapter 57).

Juvenile Myoclonic Epilepsy

JME[50,88,110] is discussed in Chapter 244.

Epilepsy with Generalized Tonicâ€“Clonic Seizures on Awakening

The diagnosis of this syndrome is usually made by specialist epileptologists, and there are disagreements as to its frequency and nosologic usefulness as a separate syndrome distinct from JME (compare reports by Berkovic[13] and Janz[59]). The current proposal would include it under generalized epilepsy syndromes with variable phenotypes.

Juvenile Absence Epilepsy

Juvenile absence epilepsy, beginning around puberty or shortly before, is characterized by absence attacks that are clinically similar to, although less frequent than, those of childhood onset (pyknoleptic) absence epilepsy. The juvenile onset syndrome is much more often associated with GTCS than is childhood-onset absence epilepsy, and the EEG spike-and-wave activity may be slightly faster (see Chapter 239).

P.560

Reflex-Induced GTCS

Individual patients with reflex-induced GTCS are sensitive to different epileptogenic stimuli. Those with only reflex seizures are considered to have reflex epileptic syndromes. Certain stimuli affect specific cortical regions but induce attacks that are clinically and electroencephalographically generalized from their onset. These are typically absences or GTCSs, and the patients may also have spontaneous generalized seizures: They are often considered to have an IGE. The prototype for this phenomenon is pattern-sensitive epilepsy, in which a localized occipital trigger is responsible for the apparently generalized or bilateral EEG abnormality and generalized seizures.[106] It is also observed in seizures induced by thinking[47] and by reading.[10] These uncommon but well-defined clinical events raise essential questions about the underlying nature of apparently generalized epilepsy and GTCS (reviewed in Ferlazzo et al.[35]).

Responses to Treatment

GTCSs respond to most AEDsâ€"except ethosuximideâ€"at least partially. However, GTCSs are part of different syndromes in which other seizure types may occur, and we must emphasize that some AEDs can aggravate other seizure types such as myoclonus and absences that may occur in patients with GTCSs. Therefore, it is also necessary when deciding on treatment to consider the syndrome diagnosis. Treatment will not be the same for an IGE and a focal epilepsy. This is, for example, particularly so for carbamazepine and lamotrigine, which should be avoided in some syndromes.[100]

Valproate is the first-line drug for GTCS. It can be used in every idiopathic generalized syndrome because it is effective against GTCS, myoclonus, and absences, isolated or repeated in status.[11,107] In JME, it is effective in up to 90% of patients.[60,89] Side effects such as weight gain can limit its use, particularly in adolescents and in women. Endocrine adverse effects and an association with polycystic ovaries are currently under study. Teratogenicity (neural tube defects[22]) must be considered in women of child-bearing age. In these patients, it can be replaced by another AED. However, the teratogenic potential of newer appropriate drugs is not yet clear, and it is also possible to give valproate at the lowest effective dose of the sustained release formulation, with folate supplementation before conception and detailed ultrasound monitoring during pregnancy. Valproate is also indicated in secondary generalized GTCS after a focal onset.

Lamotrigine,[18,102,104] topiramate,[1] and levetiracetam[69] are useful alternatives with broad efficacy for the other seizure types often associated with GTCSs. However, several cases of JME worsened by lamotrigine have been reported,[15,20,79] as well as deterioration in IGE patients with only GTCSs.[25] Lamotrigine can aggravate myoclonus in other situations, particularly in severe myoclonic epilepsy in children.[53] Thus, we consider lamotrigine indicated for GTCS, but we prefer to avoid it for JME when possible. Topiramate is useful for GTCS in both primarily and secondarily generalized seizures.[1,51,81] However, in JME, results obtained are good for GTCS but less so for myoclonic and absence seizures.[16] Although rare, the possible occurrence of ophthalmologic side effects (eye pain, redness, glaucoma) needs close monitoring because they are reversible after topiramate withdrawal.[8] Other side effects are more frequent and may require discontinuation (language and cognitive disturbance, psychotic episodes, weight loss, nephrolithiasis, dehydration). Paresthesia is usual and transient when starting treatment. Thus, we prefer TPM for refractory secondarily GTCSs rather than idiopathic GTCSs.

Levetiracetam is a promising drug for GTCS, whatever the associated seizure type and syndrome.[63] It may thus be a very useful alternative drug for JME. Even if there are no randomized controlled studies of patients with GTCS, small open-label studies and case reports provide preliminary information suggesting efficacy in both secondarily and idiopathic GTCS and myoclonic seizures.[45,69] The drug is usually well-tolerated, but behavioral toxicity such as aggressiveness and psychosis, usually in patients with known psychiatric symptoms, are reported.[66]

Carbamazepine or oxcarbazepine may be used if absences or myoclonus have not occurred, but there are different practices in different countries. These two drugs have been proved to aggravate every type of epilepsy with myoclonic components, including JME.[62,44] Thus, in Europe, experts believe that an accurate syndromic diagnosis must be established to exclude syndromes such as JME before prescribing them in patients with GTCS, and they should be restricted to patients who have secondary GTCS and given in the sustained-release formulation whenever possible to minimize side effects and improve compliance. Moreover, carbamazepine should also be avoided in GTCSs related to idiopathic rolandic (mid-temporal) epilepsy in children, because it could be responsible for a worsening of epilepsy, triggering negative myoclonus[52] and, exceptionally, continuous spike-and-wave activity during slow-wave sleep.[26,34] Patients may be referred for IGE syndromes with GTCS and already are taking such drugs that are not recommended for these conditions. If seizure control is complete and without side effects, we would not change drugs at once in these patients, although it would be useful to verify with detailed questioning and EEG that no myoclonic seizures are present. Outside Europe, carbamazepine and oxcarbazepine are more widely used, even for GTCS with IGE syndromes.

In patients with generalized or partial seizures, the side effects, interactions, and complex pharmacokinetics of phenytoin make it a second- or third-choice monotherapy drug except for parenteral use in convulsive SE or when enteral administration is temporarily impossible, and it should be avoided in JME.

Phenobarbital is an effective drug whose usefulness is limited by side effects, which may be inapparent, and by drug interactions. Its long half-life can be an advantage in cases of poor compliance, as in young adults, for example. The same considerations are valid for primidone, which was previously the treatment of choice in JME.[58] Phenobarbital remains popular, especially in developing countries, because it is very inexpensive and because it is believed to be relatively innocuousâ€"comment on these issues would be beyond the scope of this chapter. In IGEs with absences, it must be used with ethosuximide because it does not control absence seizures.

Benzodiazepines, mainly clobazam, are popular outside the United States as add-on treatment active against all seizure types, and they sometimes achieve complete seizure control. Clobazam is effective against photosensitivity. Unfortunately, many patients develop tolerance after a delay of weeks or months, with seizure reappearance. Clobazam can be given intermittently in cases of periodic seizure exacerbations as in catamenial epilepsy, in case of clusters and threatening SE, or in triggering situations (sleep deprivation, stress, etc.).

GTCSs usually occur in idiopathic syndromes with a generally good prognosis for seizure control and normal development, and adequate seizure control should mean *no seizures at all* in most cases, although very long-term treatment, possibly lifelong, is needed in JME and in seizures upon awakening. If an IGE syndrome with inadequate seizure control is diagnosed, and the patient is not taking valproate, it should be added if there are no contraindications, and a switch to valproate monotherapy should be considered. Although refractory cases exist, the diagnosis should be reevaluated if seizures persist despite optimal medical management. The possibility of rapidly generalized seizures arising in one frontal lobe should also be considered in these patients (see earlier discussion).

P.561

Because GTCSs can be triggered by factors such as sleep deprivation and alcohol withdrawal, and because patients are often adolescents or young adults, comprehensive treatment involves not only the right diagnosis and choice of AED, but also explanation and encouragement of the changes in habits that may be necessary.

Summary and Conclusions

Generalized convulsive seizures are common and dramatic manifestations of common IGE syndromes. It is very important to identify patients whose apparently generalized seizures arise from secondary generalization of a partial seizure. Idiopathic generalized convulsive seizures typically begin in later childhood, adolescence, and early adult life in otherwise normal subjects, but a history of febrile convulsions and a family history of epilepsy are risk factors. Interictal EEG abnormalities may be scanty, especially in treated patients, but generalized polyspike or spike-and-wave activity is typical, and many patients may be photosensitive. Recognition and appropriate treatment of idiopathic GTCSs offer a good prognosis for seizure control and intellectual development. Many patients with idiopathic GTCS have myoclonic jerks or absence attacks, and valproate used alone is the drug of choice. Successful treatment also requires attention to factors that may provoke the seizures, notably, sleep deprivation and alcohol withdrawal.

Chapter 48

Generalized Clonic and Hemiclonic Seizures

Charlotte Dravet

Masakazu Seino

Introduction

The generalized convulsive seizure has been known since antiquity, and the earliest descriptions appear in Egyptian hieroglyphics before 700 BC.[48] From the mid-19th century, the generalized convulsive seizure was considered the cardinal manifestation of genuine or idiopathic epilepsy caused by a predisposition to have seizures. The generalized convulsive seizure was described as *grand mal,*[26] a term that is still encountered. Whereas a great amount of literature has been dedicated to this seizure type, which corresponds to the generalized tonic-clonic seizure (GTCS), the distinction between GTCS and purely generalized clonic seizure (GCS) did not appear clearly before the mid-20th century. The first use of this distinction was in the original international classification of epileptic seizures proposed by the International League Against Epilepsy (ILAE),[23] in which they were a type of generalized convulsive seizure different from the tonicâ€"clonic, myoclonic, and tonic seizures. They were considered as observed especially in children.

In the same classification, the authors described a category of unilateral seizure including unilateral clonic seizures, also known as hemiclonic seizures (HCS), occurring almost exclusively in very young children. The existence of unilateral motor seizures with possible permanent hemiplegic sequelae, if the seizures are prolonged, has long been recognized.[4,17,26,37,47,51] However, the combination of seizure observation and recording and the study of a large series of cases with status epilepticus (SE), with or without hemiplegia and/or permanent epilepsy, enabled Gastaut et al.[22] to define precisely the electroclinical details of these unilateral seizures.

Definitions

These two seizure types, GCS and HCS, were better defined in the 1970 proposal.[19] The generalized seizures were â€œthose in which the clinical features do not include any sign or symptom referable to an anatomical and/or functional system localized in one hemisphere and usually consist of initial impairment of consciousness, motor changes which are generalized or at least bilateral and more or less symmetrical and may be accompanied by â€˜en masseâ€™ autonomic discharge; in which the electroencephalographic patterns from the start are bilateral, grossly synchronous and symmetrical over the two hemispheres; and in which the responsible neuronal discharge takes place, if not throughout the entire grey matter, then at least in the greater part of it and simultaneously in both sides.â€[19]

The unilateral seizures were â€œthose in which the clinical and electroencephalographic aspects are analogous to those of the generalized group, except that the clinical signs are restricted principally, if not exclusively, to one side of the body and the electroencephalographic discharges are recorded over the contralateral hemisphere. Such seizures apparently depend upon a generalized or at least very diffuse neuronal discharge which predominates in, or is restricted to, a single hemisphere and its subcortical connections. They are characterized by clonic, tonic or tonicâ€"clonic convulsions, with or without an impairment of consciousness, expressed only or predominantly in one side. Such seizures sometimes shift from one side to the other but usually do not become symmetrical.â€[19]

One epileptic clonic seizure is a form of generalized seizure peculiar to early childhood and characterized by (a) clinical loss of consciousness, one massive autonomic discharge, and more or less rhythmically repeated, bilateral clonic contractions, distributed more or less regularly throughout the entire body; (b) an associated mixture of rapid rhythms and slow waves realizing more or less regular images of spike-and-waves and polyspike waves in the electroencephalogram (EEG).[20]

However, 11 years later, the ILAE commission, in a new proposal, maintained the category of GCS, but withdrew that of unilateral clonic seizures (as well as all other unilateral seizure types), deeming them â€œputative syndromic seizures.â€[8] The definition of generalized seizure has changed. These seizures are now defined as â€œthose in which the first clinical changes indicate bilateral involvement of both hemispheres. Consciousness may be impaired and this impairment may be the initial manifestation. Motor manifestations are bilateral. The ictal electroencephalographic patterns initially are bilateral, and presumably reflect neuronal discharge which is widespread in both hemispheres.â€[8]

Finally, the last ILAE commission has proposed a completely new approach to the seizure classification, which can be found at its Web site (www.ilae-epilepsy.org). The glossary now defines *generalized seizure* to mean â€œa seizure whose initial semiology indicates or is consistent with more than minimal involvement of both cerebral hemispheres.â€ In the list of seizure types, generalized clonic seizures are not described, and the hemiclonic seizures are placed among focal seizures with no additional description.

In the semiologic classification proposed by LÃ¼ders et al.,[30] based on a purely clinical description of the seizures, the definitions are the same but expressed differently. Clonic seizures are simple motor seizures, consisting of a series of myoclonic contractions that regularly recur at a rate of 0.2 to 5 per second. Their different subtypes are indicated by the use of â€œmodifiers.â€ These seizures are *generalized* when the manifestations occur over a relatively widespread distribution, with approximately equal involvement of both sides and of the distal and proximal segments of the brain. These seizures may also be *localized*; in that case, different modifiers are used according to the somatotype localization, such as â€œleft-hand clonic seizure.â€ Unilateral seizures are not considered in this classification. Hemiclonic seizures may be described as â€œunilateral, left or right clonic seizuresâ€ or â€œleft or right hemibody clonic seizures.â€

P.564

These variations reflect our lack of knowledge of the true physiopathology of generalized and unilateral seizures, despite the progress in technical advances in all fields of investigation. In practice, no clear-cut borderline exists between generalized and unilateral clonic seizures in many cases, making it difficult, if not impossible, to classify them. Moreover, the two types can have a focal onset that is often hidden because of the rapid secondary generalization. Sometimes the generalized clonic seizure can begin with a very short tonic phase, but continue with all the characteristics of the purely clonic seizure. Outside of cases of SE, these seizures are not usually observed by the clinician, and most onlooker descriptions are not detailed enough to definitively classify them as generalized or unilateral in an infant or a young child. The observation of a postictal hemiparesis is in favor of ictal unilaterality.

As in GTCS, clonic and hemiclonic seizures may be an isolated event in the setting of an acute encephalopathy, a symptom of serious brain disease, or a manifestation of several epilepsy syndromes of differing prognoses.

Epidemiology

GCSs and unilateral clonic seizures or HCSs are rarely described in the literature, and they are not considered apart from GTCSs in epidemiologic studies. However, GCSs are probably rare, unlike HCSs, which are reported primarily in papers concerning the pediatric population because of their relative frequency in infancy and childhood.

In one single Spanish study,[36] GCSs are not specified, but the following data were reported for unilateral seizures, without distinction between HCSs and the other types: Among 5,000 patients consecutively recruited between1966 and 1990, 346 (6.92%) presented with unilateral seizures; 13.29% of them were febrile seizures and 18.21% developed during status; 53.17% started before 2 years, 80% before 6 years and only 2.02% after 18 years. The unilateral seizures were the initial seizures of generalized epilepsies in 7.5% of the patients, of focal epilepsies in 23.4%, and of undetermined epilepsy if generalized or focal in 65.9% (the majority).

In a previous series of 3,000 patients,[35] the same author found 151 patients (5%) with HCSs, separated into four groups. In the first group, 39 patients went on to a diagnosis of temporal lobe epilepsy (TLE). In the second group, 32 patients had Lennox-Gastaut syndrome (it is important to note that severe myoclonic epilepsy was not recognized as an epilepsy type in this study). In the third group, six patients had an idiopathic generalized epilepsy. In the fourth group, 74 patients had only HCSs.

In a pediatric French regional population-based study,[31] GCS had an incidence of 5.8 per 100,000 children younger than 10 years, in comparison with 8 per 100,000 with GTCS. HCSs were not counted because they did not appear in the 1981 international classification. Conversely, HCSs appeared in a pediatric Yugoslavian regional population-based study[42] in which they represented 6% of patients born between January 1, 1967 and December 31, 1984, aged less than 18 years, versus 0.3% for GCS and 38.8% for GTCS.

One could also indicate that, due to their propensity manifest during SE, HCSs have been often considered within epidemiologic studies of SE, whereas generalized clonic statuses are rarely separated from generalized tonicâ€“clonic seizures. Thus, Aicardi and Chevrie,[1] among 239 cases of SE, reported 102 cases with GCS status and 94 with HCS status. Congdon and Forsythe[9] reported 17 cases of SE treated by clonazepam, in which 14 were GCS status but none HCS status.

Clinical Features

Generalized Clonic Seizures

All authors recognize that clonic seizures are predominantly observed in infants and children, and very often tend to be lateralized. So, the descriptions usually given correspond to HCSs or GCSs evolving to HCSs or vice versa. We did not find many descriptions of seizures that were only generalized. In 1973, Gastaut[20] defined their characteristics: â€œLoss of consciousness, massive autonomic discharge, and bilateral clonic contractions more or less rhythmically repeated and more or less irregularly distributed in all the body parts. The ictal EEG shows a mixture of rapid rhythms and slow waves realizing more or less regular images of spike-waves and polyspike-waves.â€

A good description was reported by Gastaut and Broughton.[21] The attacks begin with loss of consciousness associated either with sudden hypotonia or, conversely, with a brief generalized tonic spasm, sometimes so abbreviated that it could be considered as massive bilateral myoclonus. Either causes falling. The child then remains on the floor for 1 minute or longer and is seized by a series of bilateral myoclonus, usually generalized, although often asymmetrical and predominating on one side or in one limb. Subsequently, the variability of amplitude, frequency, and spatial distribution of these jerks from one moment to the next may become quite extraordinary. The most unlikely combinations are observed. Rapid low-amplitude twitching of facial muscles, for example, may be associated with infrequent but very intense jerks of the upper limbs and with such rapid myoclonus of the lower limbs that virtual tetanic contraction results. In some children, particularly those 3 years of age or younger, the myoclonus remains bilaterally synchronous and massive throughout the attack, rather than showing such complex and unstable patterns. The autonomic changes are relatively unimportant, except during very prolonged seizures in which accumulated bronchial secretions may cause respiratory distress. Resumption of consciousness is rapid after brief seizures. Those of long duration, however, may be followed by a confusional or even comatose state with generalized muscular hypotonia and areflexia.

Other forms of clonic seizures, seen in older subjects, are more properly considered as absence status with marked myoclonus, often rhythmic, or prolonged myoclonic absences with the jerks repeated at 3 Hz.

Hemiclonic Seizures

Conversely, HCSs have been well studied. Here we report their description by Roger et al.,[43] completed by our own observations.

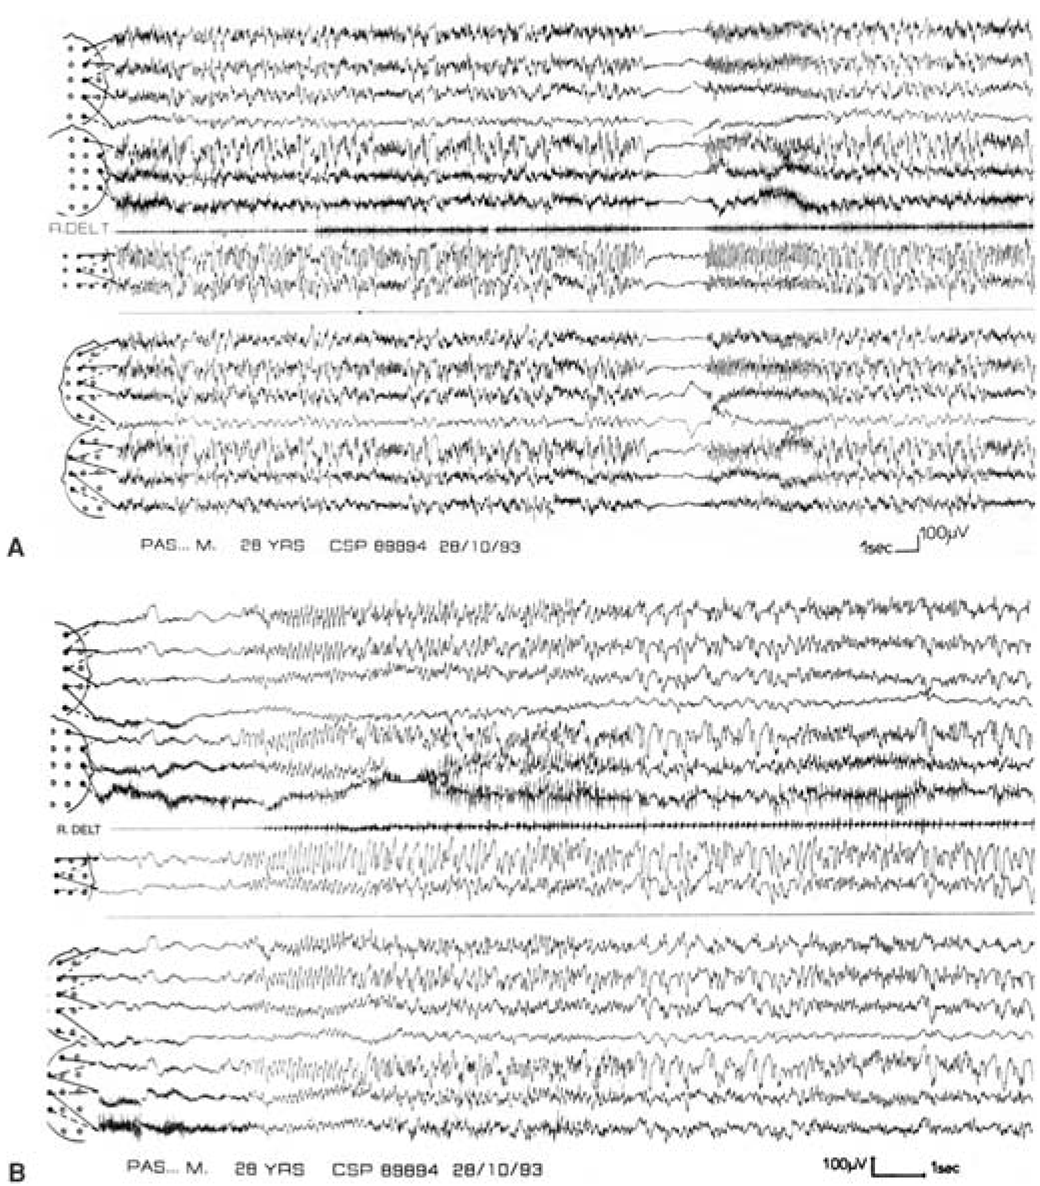

FIGURE 1. A: Generalized clonic seizure recorded in a 28-year-old woman suffering from an Angelman syndrome. Onset occurred 20 minutes before start of EEG. The irregular mixture of bilateral spikes and slow waves is well visible. The myoclonic jerks recorded in the right deltoid are extremely rapid. During a 2-second interruption of the jerks, a flattening of the EEG occurs. **B:** Another fragment of the same seizure recorded at 30 cm/sec. This better illustrates the variations of EEG patterns and myoclonus.

When observed, the onset is variable. Sometimes HCSs present as repeated clonic jerks or twitching of the eyeballs, followed by a deviation of the head to the same side. These are followed rapidly by hemifacial myoclonus that spreads to the upper and lower limbs. In other cases, the clonic jerks involve the entire side from the onset. In some cases, the clonic phase is preceded by a general discomfort, with abdominal pain, pallor, and loss of contact. Many children are discovered while already convulsing. More often, the seizures are of long duration (minutes, hours, even days). In such cases, the jerks show continuous changes in frequency, rhythm, and amplitude in the different body areas involved. This gives a pattern of erratic seizures. They may, for instance, disappear in the lower limb while continuing in the upper limb or the face, and then spread to the entire side of the body again, thereby

P.565

creating patterns of considerable complexity. At times they affect both sides of the body, either simultaneously as generalized seizures, or successively, as alternating epileptic seizures, so-called â€œsee-saw epileptic seizuresâ€ or *crises Ã bascule*. They also can affect one upper limb and the opposite lower limb together, as *crossed seizures*. Another eventuality consists of a seizure reduced for some minutes to the loss of consciousness with only slight jerks localized to a small muscular segment or with lateral deviation and slight clonic jerks of the eyeballs. The state of consciousness is variable and often difficult to assess. Either initial complete loss of consciousness occurs, or consciousness is little, if at all, impaired and may fluctuate while the seizure develops. Most often, there is a loss of contact, and the clouding of consciousness increases with the duration of the seizure, as do the autonomic manifestations (hypersalivation, pallor, cyanosis, vomiting). The end of the seizure usually is sudden, immediately followed by a flaccid hemiplegia, with or without Babinski sign, in the side involved; this is of variable duration, depending in part on the duration of the seizure. This aspect is difficult to determine in a child in coma with unilateral SE. The side of the hemiplegia gives a good indication for the lateralization of the seizure, which is not always easy to define in small infants, particularly when the seizure is not directly observed by a doctor. Spontaneous postictal recovery is progressive with an agitation phase whereas, after seizure interruption by a drug injection, the child may sleep quietly. However, when the seizure has been protracted (>1 hour) there is a risk for a definitive hemiplegia, first flaccid then spastic; this sequence constitutes the hemiconvulsion-hemiplegia (HH) syndrome, usually followed by epilepsy and manifesting as hemiconvulsion-hemiplegia-epilepsy (HHE) syndrome.[6] This syndrome has become rare with the advent of prompt, efficient treatment that shortens the duration of febrile seizures. The risk remains, however, for the development of later mesial TLE. It has been established by various authors that patients with mesial TLE often have had a long febrile seizure in early childhood.[5] The exact type of this seizure is generally not indicated by the authors, but we think a high probability exists for HCS, because this seizure type is most prone to be of very long duration, and we have found it in the history of our own patients.

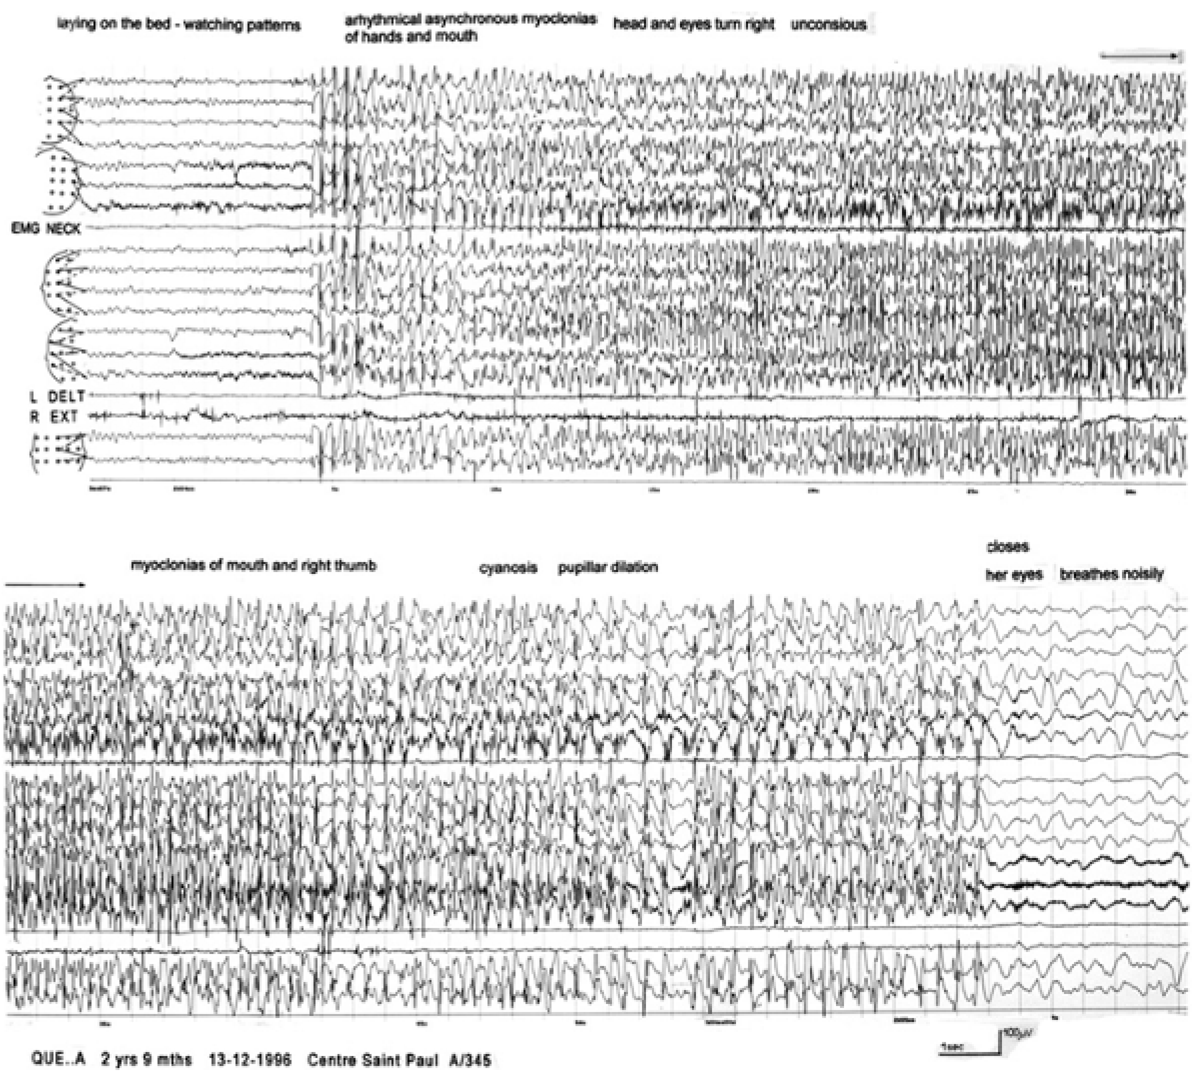

FIGURE 2. Right hemiclonic seizure recorded in a 33-month-old girl suffering from severe myoclonic epilepsy

in infancy. EEG shows an onset of a burst of generalized spike-and-wave discharges (6 sec), progressively mixed with bilateral rapid activities prominent in the left hemisphere (30 sec), and followed by bilateral rhythmic spike-and-wave discharges of higher voltage in the left. After the end, bilateral Î´-waves and relative left depression are noted. Clinically the child presents with, unconsciousness, small myoclonic jerks that are arrhythmic in the hands and the mouth but rhythmic in the head (EMG), eyes and head deviation to the right, cyanosis, and brief postictal right motor deficit.

EEG Features

In GCSs, the ictal EEG patterns are generalized over the entire scalp and are often of considerable complexity (FIGURE 1). An epileptic recruiting rhythm at 10 Hz is intermingled with slower activity of changing frequency. The two activities are mixed from the start, giving a very complex discharge of

irregular spike-and-wave type. As in myoclonus, the EEG pattern can be extremely variable in time, with the relative predominance of rapid or slow activity over a given region of the scalp usually fluctuating from moment to moment. Simultaneous recording of EEG and electromyogram (EMG) shows no constant relationship between the hypersynchronous muscular potentials of a given body region and the presence of spikes (i.e., the sharp waves of the recruiting rhythm) over the contralateral scalp region. After the seizure, a transient period of diffuse slow-wave activity occurs without the phase of postictal electrical silence after a GTCS.

The interictal EEG can be normal or show only generalized discharges with normal background. More often, the interictal EEG findings depend on the etiology (discussed in the next section). In some cases, these findings are highly characteristic for a metabolic (hepatic, renal, hypoglycemic encephalopathy) or a degenerative disease (Lafora disease).

In HCSs, the clinical phenomena are concomitant with an ictal EEG discharge of bilateral slow waves, at around 2 to 3 Hz, greater in amplitude over the hemisphere contralateral to the seizure and associated there with a rapid recruiting rhythm discharge that generally predominates in the posterior scalp regions (FIGURE 2). Complex EEG patterns occur due to the unceasing changes in phase, frequency, and topography of the two components, such as rhythmic slow waves, or spike-and-wave, or polyspike-and-wave discharges, variable in frequency and distribution. At times, the discharge and myoclonus are interrupted for several seconds. The polygraphic recording shows no constant correlation between the muscular and the EEG phenomena. Immediately after the seizure, depression

of electrogenesis is noted over the contralateral scalp regions, followed by slow-wave activity of variable duration. The latter is not always correlated with the duration of the seizure. No depression occurs in the hemisphere ipsilateral to the attack, and normal EEG patterns are rapidly restored.

The interictal EEG findings vary according to the mechanism of the seizures. In infants and young children, when HCSs are the peculiar expression of a generalized epileptic process, the EEG shows only generalized discharges and a more or less normal background. In patients who have HCSs due to a symptomatic focal epilepsy, the EEG can show focal interictal anomalies corresponding to the underlying lesion. Sometimes it shows only an asymmetric background, for example, in patients who have a hemiplegia due to HHE syndrome. In other patients, EEG anomalies are multifocal, associated or not with generalized discharges, as in severe myoclonic epilepsy.

Anatomic Pathways and Pathophysiology

There are no specific studies separating GCSs from GTCSs, and mechanisms are probably the same as discussed in Chapter 47.

According to Gastaut and Broughton,[21] HCSs result from an excessive neuronal discharge limited to or predominating in a single hemisphere. The attacks either may originate in brainstem structures and be *unilateral from the start* or result from propagation of a local cortical discharge to brainstem structures and so be *unilateral of local onset or secondarily hemigeneralized.*

As with generalized seizures, unilateral attacks may be categorized into two groups depending on whether they result from a primary discharge involving the brainstem and its cortical connections, or from a distant focus propagating secondarily to the brainstem structures. In the latter group, the discharge is first localized in one hyperexcitable intrahemispheric neuronal population but then spreads very quickly to involve the entire ipsilateral hemisphere. Such an attack consists of a partial (focal) seizure with *secondary hemigeneralization* or a *unilateral seizure of local (focal, partial) onset*.

Why HCSs only or predominantly involve one hemisphere is not well known. In the first group, it is apparently due to asymmetries of neuronal excitability resulting from physiologic and pathologic factors still poorly understood.[2,52] In the second group, it could be due to an insufficiency of commissural transmission. Because they occur almost exclusively in early infancy, this insufficiency has been related to the structural and functional immaturity of the corpus callosum. This hypothesis is supported by the results of experimental animal studies that have demonstrated the role of the corpus callosum in the synchronization of ictal discharges in feline generalized epilepsy[33] and in Senegalese photosensitive epileptic baboons (*Papio papio*).[34]

Diagnostic Considerations

Obviously, the first step is to determine the epileptic nature of the paroxysmal event. Rarely, as regard to other seizure types, nonepileptic manifestations can mimic GCSs and HCSs. However, when the seizure has not been directly observed, it is mandatory to have a precise description of the symptoms from the onset to the end of the event, of the circumstances, the triggering factors, the previous history of the patient, and other pertinent details. In young children, for example, a febrile context is highly suggestive of an epileptic event. The diagnosis may be uncertain between repeated myoclonic jerks, either physiologic during drowsiness or pathologic, and a GCS in neonates, or between a syncope followed by a brief clonic phase and a GCS in infants, children and adults.

Concerning the diagnosis of the seizure type, we would like to underline a terminology problem raised by Porter,[41] who wrote that â€œmyoclonic is often used interchangeably with â€˜clonic,â€™ especially when used to describe fragments or â€˜myoclonic componentsâ€™ of a seizure.â€ Thus, it is sometimes difficult to differentiate between a long myoclonic absence with strong myoclonic jerks and a GCS. Indeed, the duration of the event is much shorter in absences, rarely exceeding 1 minute, and the rate of repetition is much higher (several a day). The same criteria can be applied to those cases in which myoclonic jerks are grouped in bursts and repeated at brief intervals, with full consciousness (as in juvenile myoclonic epilepsy), often early in the morning.

According to Treiman et al.,[49] a generalized convulsive SE that either has not been treated or has been treated inadequately evolves to one phase they have named â€œsubtle generalized convulsive status,â€ in which the clinical manifestations are reduced to loss of consciousness and subtle twitching of the fingers, abdominal muscles, or face, or nystagmoid jerks of the eyes while the ictal EEG discharges persist. This electroclinical picture could be diagnosed as a purely clonic or myoclonic status.

The *differential diagnosis* between GCS and HCS should be easy in adulthood. At this age, GCSs are more frequent than HCSs, and the semiology is clear enough to be described without ambiguity. The main question is whether the seizure is primarily or secondarily generalized. That information is obtained from eyewitness accounts of seizure onset. A careful neurologic examination may find interictal signs of localization, actually rarely present. The interictal EEG may also give good information when asymmetry or focal anomalies are present.

In infants and young children, we have seen that GCSs and HCSs are not well differentiated, sometimes having the same generalized basis, as in severe myoclonic epilepsy. The best way to understand the ictal semiology is to use video-EEG and polygraphic recordings, rarely available in a clinical situation. If this is not possible, the diagnosis can be aided by the search for a transitory postictal lateralized motor deficit, which can be obvious after one diazepam injection. A postictal recording is still useful in demonstrating the presence (or absence) of a clear asymmetry of the background activity. In that case, the etiologic workup will be orientated toward a localized origin, even if it is known that a diffuse pathologic process (e.g., metabolic disease) cannot be eliminated a priori.

Specific Syndromes Incorporating the Seizure Type as an Integral

Feature

GCSs and HCSs are the expression of either primarily generalized seizures or generalized seizures secondary to a focal onset, and they may occur in many various clinical situations.

Simple febrile seizures more often manifest as tonic and tonicâ€"clonic in nature, but they sometimes present a GCSs.[15,16] It is important to differentiate them from massive myoclonias because they do not have the same meaning. In *complex febrile seizures*, HCSs occupy a predominant place and constitute a situation of emergency due to the risk of occurrence of HH syndrome, which occurs in about 4% of patients.

Pyridoxine dependency in infants causes various seizure types, including GCSs and HCSs, which are severe and often result in SE. Antiepileptic drugs (AEDs) are not efficacious, and only pyridoxine, first given intravenously then orally, allows recovery.

In our own experience, GCSs are observed in various *metabolic disturbances*, and *anoxic and toxic encephalopathies* in children as well as adults.[38,44] In one study, PoirÃ©[40] reported an extensive and deep analysis of hypoglycemia-induced epileptic seizures in a psychiatric ward where Sakel's cure was regularly applied. He showed the seizures could feature all the different aspects of generalized convulsive seizures, from isolated myoclonic jerks, grouping of massive myoclonias, and purely clonic fits to, more rarely, full tonicâ€"clonic seizure. Data are scanty in the recent literature, but Dulac,[15] in one review, confirmed that GCSs sometimes occur in children in hyponatremia, hypoglycemia, or hypocalcemia. The report by Dalla Bernardina et al.[10] on hypernatremia give additional details. Other authors who have reported seizures in metabolic encephalopathies in adults mentioned generalized seizures only, and it was impossible to know if they were GTCSs or GCSs.[18,45]

GCSs are one of the seizure types observed in most of the *progressive myoclonus epilepsies*.[24] In Unverricht-Lundborg disease, they often present as a sequence of clustered massive myoclonic jerks triggered by voluntary movement. They may develop into full GCS with impairment of consciousness. A brief tonic component may be inserted between the two phases, producing a clonicâ€"tonicâ€"clonic seizure.

GCSs and HCSs are also a part of the epilepsy present in some *chromosomal disorders*. Although in Angelman syndrome the most typical seizures are long myoclonic status, we have observed true generalized clonic seizures, sometimes evolving to SE, in patients presenting with this syndrome, in accordance with other authors.[10,28] HCSs are rarely signaled in this syndrome.[32] GCSs and HCSs were also reported in patients with 4p-syndrome.[3,25]

GCS can occur in *epilepsy with myoclonic astatic seizures (Doose syndrome)*, in association with generalized tonicâ€"clonic seizures and drop attacks.

HCSs are observed in *idiopathic focal epilepsies* in childhood. They appear in *benign epilepsy with centrotemporal spikes* in children aged 2 to 5 years. These seizures sometimes last more than 30 to 60 minutes and are followed by a transient homolateral deficit, generally not including the face.[12]

In *early-onset benign childhood occipital epilepsy (Panayiotopoulos syndrome)*, HCSs occur in 25% of patients in a context of behavioral (irritability) and autonomic symptoms (pallor, sweating, nausea, vomiting), usually with impairment of consciousness.[39] They are only nocturnal in 66% of patients. Their duration is variable, from minutes to hours. When prolonged, they are followed by a transient hemiparesia.[50] HCSs may also occur in 43% of patients presenting with *late-onset childhood occipital epilepsy (Gastaut type)*, in which the visual symptoms and headache are more characteristic.

Rare cases of idiopathic generalized epilepsy with hemiconvulsive seizures within the framework of *juvenile myoclonic epilepsy* have been reported.[29] These patients presented with bouts of grouping myoclonic jerks lateralized on one hemibody; these seizures were of brief duration (from seconds to few minutes), occurring without loss of consciousness and repeated several times a day. Ictal and interictal EEGs showed generalized 3-Hz spike-and-wave discharges, asymmetrical during the attack. This type of seizure seems to be myoclonic rather than truly hemiclonic. HCSs have been reported as initial seizures in the syndrome of *electrical status epilepticus during slow sleep (ESES or CSWS)*,[46] related to a focal epilepsy preceding the syndrome.

HCSs are the hallmark of *HH syndrome*, occurring mostly in young children, and they may continue later in life, during the course of HHE syndrome. They are more extensively described in Chapter 233 (Arzimanoglou et al.). It is noteworthy that, in developed nations, this situation has dramatically declined over the last quarter century, and is either exceptional or absent in the recent series of SE studies[27]; it persists, however, in developing countries where prompt control of SE may be lacking.

We have observed a HHE syndrome in one diabetic patient presenting with undiagnosed hypoglycemic coma and followed by focal epilepsy. Three children presenting with HHE syndrome due to hypoglycemia were reported by Christiaens et al.[7] HCS in hypoglycemia and hypocalcemia are also mentioned by Dalla Bernardina et al.[11]

Hemispheric brain malformations are a relatively frequent etiology of HCS, as it is observed in corpus callosum agenesia, hemimegalencephaly, or Sturge-Weber disease. In the latter, repeated and prolonged HCSs lead to the risk of a permanent hemiplegia and represent a strong indication for an early pharmacologic treatment and, if not efficacious, early surgery.

HCSs of focal onset can occur in *many other situations* that provoke epileptogenic lesions (e.g., head trauma, subdural hematoma, intracerebral hemorrhages, meningitis, ischemia). They are more frequently due to lesions in the frontal lobe, but they can originate in the occipital or parietal lobe by spreading of the discharge above the sylvian fissure. This evolution is less frequent for the temporal localization of the lesion.

We have described a group of patients[13] whose epilepsy began in childhood (between 1 and 5 years) and was always characterized by HCSs during its course, with a strong tendency to evolve into SE. It included subjects with and without signs of brain damage. It represented a peculiar type of focal epilepsy, which should be acknowledged because its treatment raises specific problems.

GCSs and HCSs are also the hallmark of *severe myoclonic epilepsy in infancy (Dravet syndrome)*, which begins in the first year of life with the occurrence of these seizures, with or without fever, in a previously normal infant. They were fully described by Dravet et al.[14] (see Chapter 231). We would like to underline their variable aspects in this syndrome. The clinical phenomena can be generalized from the onset and remain during the entire seizure event. At other times, they can be initially localized, mainly in the facial muscles, before becoming unilateral or generalized. In other seizures, a fluctuation occurs from one side to the other, and from one body part to another. The clonic jerks can be associated with a tonic muscular contraction of variable intensity during the event. The EEG abnormalities correlate with these fluctuations, giving the impression of â€œfalsely generalized seizures.â€ We have postulated that these seizures were the expression of multifocality in infants having a very low epileptic threshold. True HCSs may also occur in this syndrome, often with a tonic component (FIGURE 3). They can affect both sides of the body successively in the same seizure and from one seizure to another one, this variability being a strong argument for the diagnosis of Dravet syndrome.

Responses to Treatment

GCSs and HCSs are often prolonged seizures, with a risk of SE, and they require rapid and vigorous treatment. They respond well to rectal or intravenous benzodiazepines. If seizures continue or cease only transiently, treatment for SE should be started. A diagnostic workup for etiology (EEG, biology, CT scan) must be started simultaneously in the emergency ward, in order to treat the immediate cause when possible (e.g., hyperthermia, infection, metabolic disturbance).

After the episode ends, treatment depends on the circumstances and etiology. Except in case of simple febrile seizures, usually an antiepileptic treatment must be initiated and continued as long as the diagnosis remains uncertain. When the seizure is symptomatic of an acute disease, treatment is adapted to the nature of this disease and, sometimes, rapidly

P.569

interrupted. In other situations, treatment must be tailored in accordance with the electroclinical picture.

FIGURE 3. A right hemiclonic seizure recorded during SE in a 30-month-old boy suffering from severe myoclonic epilepsy in infancy. **A:** The EEG shows onset with a bilateral burst of slow and sharp waves, beginning in the left frontocentral channels; after 7 seconds, a discharge of fast, high-voltage activity develops on the left hemisphere for about 30 sec. **B:** This activity then is mixed with slow waves, which become rhythmic at 2 to 2.5 Hz at the end of the seizure. (**C**): All these activities are present on the right hemisphere with a much lower amplitude. The EMG shows brief bilateral tonic contraction (6 sec), followed by extremely rapid myoclonic jerks on the right muscles associated with a slight tonic muscular background; at the end (**C**), the jerks slow down and stop abruptly while the EEG discharge persists. Myoclonic jerks of very low amplitude are also present on the left quadriceps (**B**). A right hemiparesis is observed after the end of the seizure.

As indicated earlier, GCSs and HCSs are related to many various epilepsy types, more often symptomatic than idiopathic, and the treatment will be established for every specific syndrome. All classical and modern AEDs active against generalized convulsive and focal epilepsies can be used, none being more efficacious than another in this seizure type. Their indication depends on the generalized or focal nature of the seizure. Only the AEDs specifically used against absences should be avoided, unless the patient has absences associated with convulsive seizures.

When febrile or afebrile GCSs or HCSs occur in an apparently normal infant and are repeated during the first year of life without known reason, the diagnosis of severe myoclonic epilepsy may be suggested, and it is reasonable to quickly institute a chronic treatment to minimize the risk of SE and delayed psychomotor development.

Summary and Conclusions

GCSs are a type of generalized convulsive seizures that present at every age in different etiologic contexts. In adults, they are often observed within the framework of acute metabolic pathologies and in progressive myoclonic epilepsies. They have a trend to be prolonged and to develop into SE. In childhood, they occur also in various situations, such as febrile seizures, metabolic diseases, and generalized epilepsies (Doose and Dravet syndromes).

HCSs are a particular seizure type, much more frequent in children than in adults. They can be related to either a generalized or focal epilepsy. They have a strong tendency to be prolonged and to produce SE, which can be followed by a definitive hemiplegia and further epilepsy (HHE syndrome). When they occur in a febrile context, they can be responsible for later TLE. Thus, these seizures represent a pediatric emergency, and they must be treated as soon as possible using intrarectal or intravenous diazepam, to avoid hemiplegia and TLE. They also can be the first manifestation of Dravet syndrome, especially when their lateralization changes during the seizure and from one seizure to another one.

Chapter 49

Typical and Atypical Absence Seizures, Myoclonic Absences, and Eyelid Myoclonia

Hermann Stefan

O. Carter Snead III

Orvar Eeg-Olofsson

Introduction

The first clinical description of generalized absence seizures was by Poupart, in a report to the Académie Royale des Sciences in 1705: "At the approach of an attack the patient would sit down in a chair, her eyes open, and would remain there immobile and would not afterward remember falling into this state. If she had begun to talk and the attack interrupted her, she took it up again at precisely the point at which she stopped and she believed she had talked continuously." Later in the eighteenth century, Tissot used the terms *grands accès* ("great attacks") and *petits accès* in describing a 14-year-old child whose intervals between generalized convulsive seizures were punctuated with "a movement of the eyelids which at first seemed to be a tic, but which was soon recognized as convulsive."[15,115] Adie[1] later described the characteristic features of a form of epilepsy with a good prognosis occurring in children. Neurophysiologic investigations in patients with epilepsies and impairment of consciousness by Gibbs and Gibbs[42] proved for the first time that spike-and-wave paroxysms were the electroencephalographic (EEG) correlate of absence seizures. The clinical correlates of absence seizures during spike-and-wave paroxysms in the EEG also were described by Lennox and Davis.[65] Although the terms *petit mal* and *absence* have been used interchangeably to describe this distinctive seizure type since the early part of the nineteenth century, it has been only with the advent of video-EEG (V-EEG) monitoring and careful studies utilizing that technique[87] that the clinical spectrum of the absence seizure has come to be understood.

Definitions

Generalized absence seizures may be defined as a paroxysmal loss of consciousness of sudden onset and sudden end that is associated with bursts of bilaterally synchronous spike-and-wave discharges recorded on the EEG. Behaviorally, absence seizures are characterized by a sudden clouding of consciousness, usually associated with a motionless stare and cessation of ongoing activities. The beginning and end of the seizure are abrupt, and no aura or postictal state is observed. In addition to the clouding of consciousness, mild motor and automatic symptoms may occur. Brief absences may be detected only by cognitive testing during the seizure itself. Frequency of seizures in absence epilepsy varies from daily to weekly.

Absence seizures may be "typical" or "atypical." Typical absence seizures are the most common, and are characterized by a loss of consciousness that is time-locked with bursts of bilaterally synchronous 3 cycles per second spike-and-wave discharges (SWD). Little if any cognitive impairment is observed with typical absence seizures, which generally respond well to pharmacologic treatments. This is in contrast to atypical absence seizures, which are less common, respond poorly to treatment, and are often associated with severe neurologic impairment.[7,16] Although the pharmacologic profile of the two absence types is the same,[25] four features may be used to distinguish typical from atypical absence seizures. The first is the neural circuitry involved in the

SWD. In typical absence seizures, the epileptiform activity is constrained within thalamocortical circuitry.[6,101] In contrast, there are experimental,[21] clinical,[41,53,91] behavioral,[19] and neuroimaging[36] data for the involvement of both thalamocortical and limbic circuitry in atypical absence seizures.

The second defining feature relates to the frequency of the spike-and-wave discharge. In typical human absence epilepsy, the frequency of the SWD is 3 Hz, while in atypical absence epilepsy the frequency is typically 1- to 2-Hz, and the background rhythms are slow for age.[81] In rodent experimental models of typical and atypical absence epilepsy, the SWD frequency is similarly disparate, being 7- to 9-, and 4- to 6-Hz, respectively.[20,21,22,101]

The third major difference concerns voluntary behavior during the ictus. The ictal behavior in typical absence has an abrupt onset and offset that is time-locked with the spike-wave discharges. In contrast, voluntary movement and at least partial consciousness is maintained during the ictus in atypical absence seizures, in which the ictal behavior is gradual in onset and offset and is not time-locked to the spike-wave discharge.[7,16,21,39,53,68,81,101]

The final distinguishing feature is that a major difference in outcome occurs between children with typical versus atypical absence seizures. Children with typical absence seizures generally have a good outcome and are spared major cognitive deficits. This may relate to the restriction of the SWD to the thalamocortical circuitry in typical absence epilepsy. In distinct contrast, atypical absence seizures are associated with a severely abnormal cognitive and neurodevelopmental outcome in children.[35,81] Similar cognitive deficits are observed in experimental models of atypical absence seizures.[19] Therefore, whether absence seizures are typical or atypical is often used as a predictor of outcome in children with absence epilepsy.

Epidemiology

The annual incidence rate of absence seizures has been estimated to be 1/10,000.[49] The estimation of the prevalence of absence seizures varies from 2.3%[65] to 37.7%.[64] Cavazzuti[17] observed absence seizures in about 8% of epileptic children of school age. In absence epilepsies among children, absences are more frequent in girls than in boys. Absence seizures are

P.574

more often seen in childhood epilepsy, and predominantly occur in children of school age;[84] however, absence seizures also are seen in adults,[32] albeit less commonly.

A family history of epilepsy is found in 15% to 44% of patients with generalized absence seizures,[65] and an inherited factor in human absence seizures was first recognized by Metrakos and Metrakos.[77] Genetic factors play a predominant role in the etiology of idiopathic generalized epilepsies with typical absence seizures.[11,66,67] Because the concordance for absence seizures in monozygotic twins does not reach 100%, acquired factors also probably play a role in the causation of this type of seizure.[10,11] Myoclonic absence is a rare seizure type with a male preponderance. The mean age of onset is 7 years (range: 9 months to 12 years).

Recently, the γ-aminobutyric acid $(GABA)_A$ receptor γ-2 subunit mutation R43Q has been reported to be an autosomal dominant mutation associated with childhood absence epilepsy and febrile seizures.[62,71] This mutation appears to impair $GABA_A$ receptor function by compromising $GABA_A$ receptor trafficking and reducing surface expression.[62]

Anatomic Pathways and Pathophysiology

The current thinking about the pathogenesis of absence seizures dates to the landmark experiments of Jasper and Droogleever-Fortuyn,[58] who demonstrated that electrical stimulation of the midline and intralaminar nuclei of the thalamus in cats at a frequency of 3 cycles per second could produce bilaterally synchronous spike-and-wave discharges in the cortical EEG of those animals. The relevance of this finding to human epilepsy was demonstrated in 1953, when Williams,[120] utilizing depth-electrode recordings from the thalamus of a child with absence seizures, demonstrated that bilaterally synchronous spike-and-wave discharges with a frequency of 3 cycles per second arose from that structure. During the next 20 years, a debate ensued in the literature as to which region was preeminent in controlling the bilaterally synchronous spike-and-wave discharges characteristic of absence seizures: the cortex,[3,70,116] the thalamus,[88] or both.[43] During the last 10 years, studies using several available animal models of generalized absence seizures coupled with sophisticated in vitro electrophysiologic techniques that allow investigation of cortical and thalamic networks have begun to shed light on the basic neurobiologic mechanisms of generalized absence seizures.

In 2002, Mereen et al., using the WAG/Rij rodent model of typical absence seizures, showed that a functionally intact thalamocortical network is required for the generation of spike-and-wave discharges.[75] By investigating the corticothalamic interrelationships in this model with nonlinear association signal analyses of multiple SWDs, those authors showed a consistent focus within the perioral region of the somatosensory cortex. From this focal activity, generalization took place rapidly over the cortex. During the first cycles of the seizure, the cortex appears to drive the thalamus, followed by the cortex and thalamus driving each other, thus amplifying and maintaining the rhythmic discharge.[76]

The fundamental underlying mechanism of absence seizures involves thalamocortical circuitry and the generation of abnormal oscillatory rhythms from that particular neuronal network.[28,29,38,73,74,77] Biochemical mechanisms operative within thalamocortical circuitry during this neuronal oscillation seem to entail phase-locked inhibition mediated by $GABA_B$ (γ-aminobutyric acid) alternating with glutamate-mediated excitation. The basic cellular mechanism operative within this tension between excitation and inhibition appears to involve low-voltage activated or T-type calcium (Ca^{2+}) currents, activation of which within thalamocortical circuitry plays a critical role in the development of the thalamocortical network oscillations that underlie absence seizures.[23,73] Of the three α1-subunits of the T-type Ca^{2+} channels, the α1G-subunit is critical to the genesis of spontaneous absence seizures.[102,122]

Local circuitry within the thalamus may influence the oscillatory rhythms that characterize absence seizures by $GABA_A$-mediated inhibition.[55] Pharmacologic factors that play a role external to the thalamocortical circuitry in the genesis of absence seizures include cholinergic, dopaminergic, and nor-adrenergic mechanisms.[72] Pathways utilizing these various neurotransmitters project onto the thalamus, cortex, or both from sites distant to those structures and may modulate the process either up or down. Perturbation of one or more of these neuronal networks, particularly those involving the basal ganglia[27,99] and the superior colliculus,[79] may lead to abnormal neuronal oscillatory rhythms within the thalamocortical circuitry, with resultant generation of the bilaterally synchronous SWDs that characterize generalized absence seizures.[100]

Although these mechanisms may explain the alteration of consciousness that occurs with absence seizures, the pathophysiologic mechanisms of the motor symptoms that so often accompany absence seizures are not as clear. Many of the mild motor phenomena of absences consist of turning and rotating movements around the vertical body axis, raising and lowering of extremities, or even episodes of decreased tone. These movements belong to the motor activity controlled by the phylogenetically old system that mediates posture and locomotion, the so-called *eneirismatic motor system.*[51] Hassler[48,49] has shown that different brainstem structures are involved in the performance of this kind of motor activity. The brainstem, truncothalamic projecting pathways and extrapyramidal cortical areas, supplementary motor area, and anterior part of the gyrus cinguli are all known to play a major role in inciting and coordinating complex movements such as those seen in some types of absence seizures.[3,112]

Table 1 Clinical features of absence seizures

Cognitive impairment: staring gaze, change of facial expression: 94%

Type 1: **ocular motor productive (89%)**	*Type 2:* **nonocular sporadic motor (11%)**
Rhythmic lid/eye clonic tonic retropulsive predominance oral and nonoral automatisms (march)	Sporadic myoclonic tonic without oral automatism

EEG: background normal generalized >>>regional ictal: fast rhythmic SW duration long (often 5–15 s or even longer)	Slowing focal abnormalities generalized>regional slow rhythmic SW duration low (often <10s)

SW, spikes and waves.

Clinical Features

Ictal

V-EEG split-screen studies of generalized absence seizures show that, in addition to cognitive impairment, staring and a change of facial expression occur in 94% of investigated absence seizures[108] (Table 1). Therefore, cognitive impairment, staring, and a change of facial expression represent the most common and important signs of absence and are common to all types of this seizure disorder (Table 1). In an attempt to differentiate absence seizures based on ictal clinical symptomatology, two types have been suggested: type 1 (*ocular motor productive*) was described in 89% of all absence seizures, and type 2 (*nonocular sporadic motor absence*) in 11%. The typical ocular motor productive absence seizure was characterized by predominantly ocular motor activity at the beginning of or during the seizure. The motor activity consisted of mild, rhythmic lid or eye clonic activity, tonic retropulsion of the eyes and head, or both. Oral automatisms were often combined with the ocular activity, and if the duration of the absence seizure was prolonged, nonoral (gestural) automatisms sometimes occurred. The motor activity often showed a "march" from ocular or facial regions to the extremities (Fig. 4). The atypical nonocular sporadic motor absence seizure was associated with sporadic myoclonic jerks, primarily of the head and extremities, and occasional oral automatisms.[108]

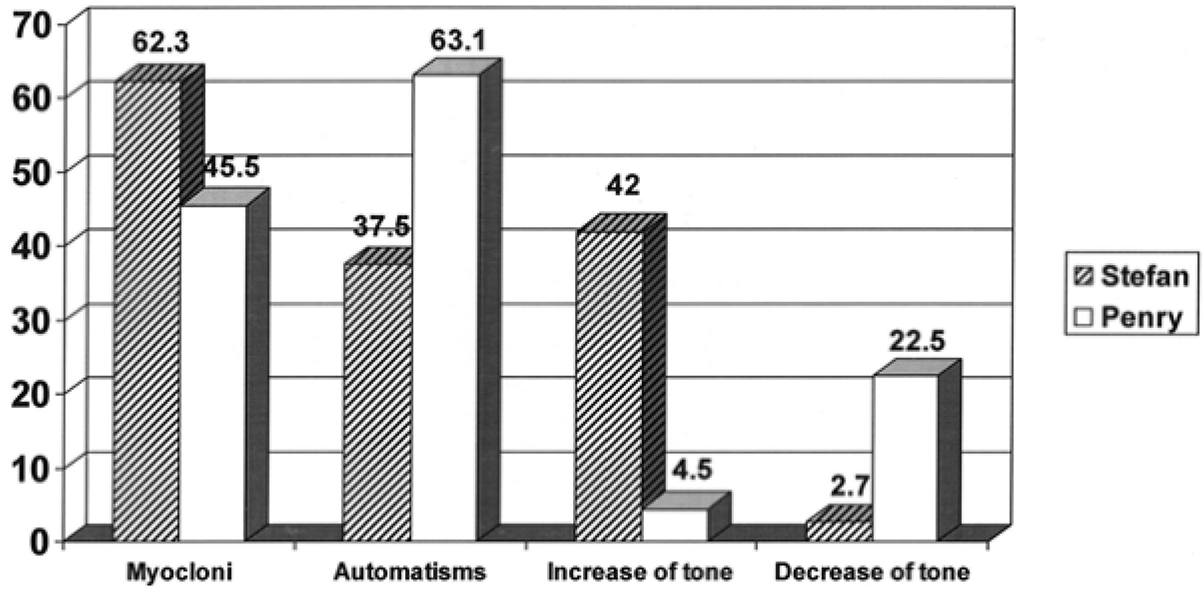

FIGURE 1. Comparison of frequency of different mild motor symptoms during absence seizures as documented by V-EEG recordings. From Stefan H, Burr W, Hildenbrand K, et al. Computer-supported documentation in the video analysis of absences. Preictal-ictal phenomena: Polygraphic findings. In: Dam M, Gram L, Penry JK, eds. *Advances in Epileptology: the XIIth Epilepsy International Symposium*. New York: Raven Press, 1981, with permission.

In addition to the phenomenologic description of clouding of consciousness during absence seizures, Janz[57] described subtle motor symptoms and differentiated absences according

to the direction in which these motor symptoms progressed: retropulsive, propulsive, and adversive absences; those with no predominant direction; and those with no motor symptoms. Up to this time, automatisms had rarely been noted. However, subsequent investigations[8,24,40,87,90,103] showed that automatisms were not an uncommon occurrence in absence seizures. Penry et al.[87] took a further important step by using V-EEG monitoring to analyze the frequency of different absence components according to the criteria of the International Classification of Epileptic Seizures. V-EEG analysis of absence seizures showed clearly that absences with impairment of consciousness only, so-called *simple absences*, were rare.[53,86,87,107] For example, in 59 patients with 528 absences, only two cases of simple absence were recognized.[107] During a simple absence seizure, no ocular movements occur. Absences with ocular movements show mild tonic or clonic movements. In addition to upward ocular movements during an absence seizure, adversive movements of the eyes may occur (mild tonic, clonic, or both). An analysis of ictal signs in typical absence seizures has shown that mild myoclonic or clonic phenomena and automatisms are a common adjunct to clouding of consciousness. The studies of Penry et al. and Stefan et al. are compared in FIGURE 1.

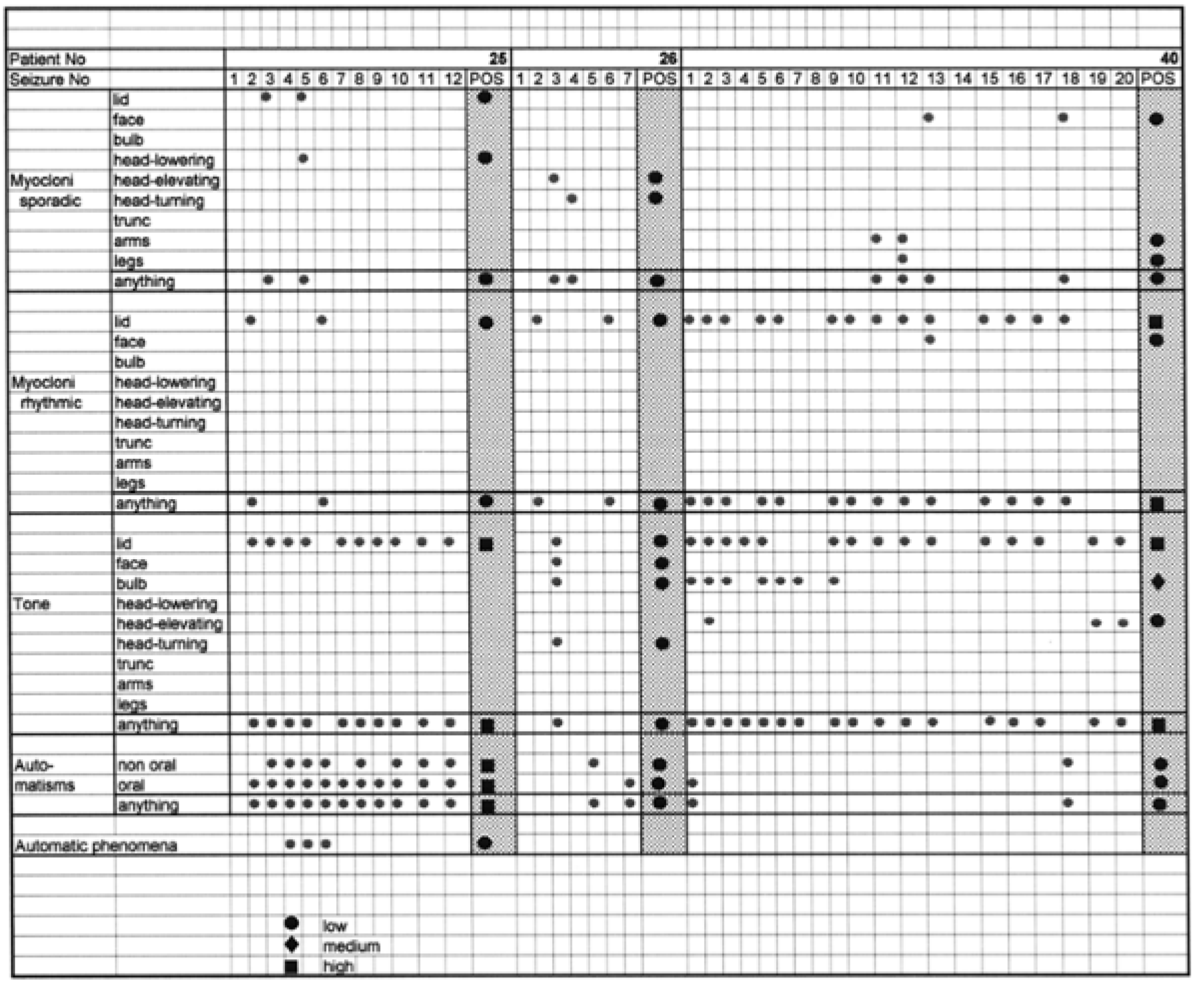

FIGURE 2. Profile of symptom activity of mixed absences (POS). Left side of figure shows different absence components. The first row contains the patient number, the second row the absence number. Vertically, the occurrence of symptom in each absence is marked by a *star*. All absences of one patient are combined as an aggregate of the seizures of that patient. The results are shown in the *shaded columns*, the "profile of symptoms." Patients 25, 26, and 40 have mixed absences with myoclonic, tonic, and automatic components. The activity of components occurring in not more than 33% of the absences of a patient is defined as low (marked on the graph by a *point*), between 33% and 66% as medium (marked by a *rhomboid*), and above 66% as high (marked by a *rectangle*). The POS of patient 26, for example, shows a low level of all the components;

the POS of patient 25 shows a high level of the combination of light myoclonus and increase of tone. Cluster analysis of the motor symptom activity of all V-EEG–documented absences indicates a continuum from low to high activity. From Stefan H, Burr W, Hildenbrand K, et al. Computer-supported documentation in the video analysis of absences. Preictal-ictal phenomena: Polygraphic findings. In: Dam M, Gram L, Penry JK, eds. *Advances in Epileptology: the XIIth Epilepsy International Symposium*. New York: Raven Press, 1981, with permission.

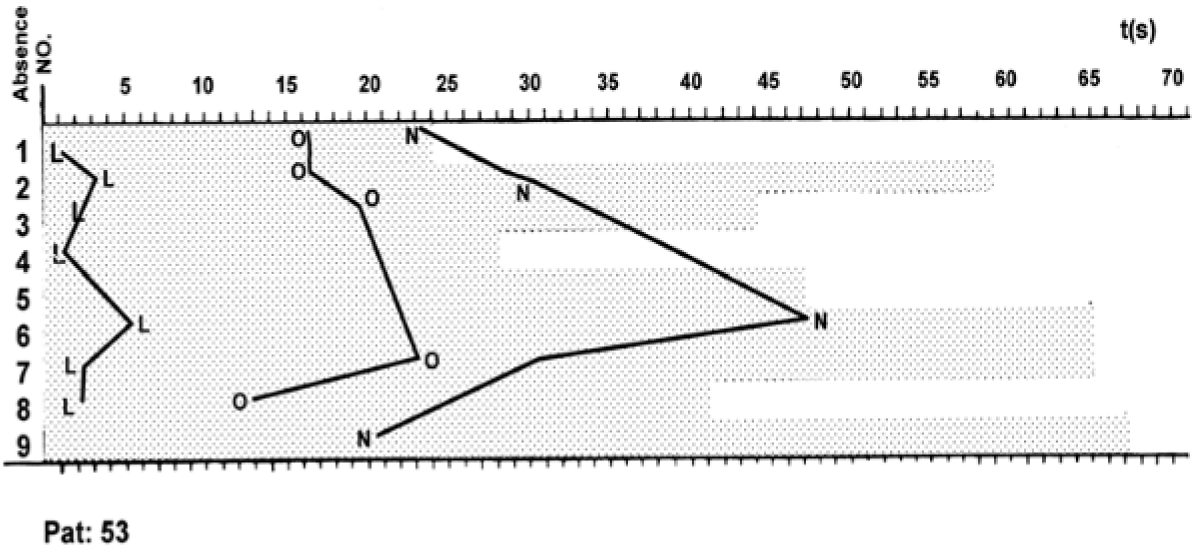

FIGURE 3. Correlation of mild motor signs and spike-and-wave duration in absences. Onset of lid activity and oral and nonoral automatisms in nine absences in one patient. *L*, myoclonic or tonic activity of lids, eyes, or both; *O*, oral automatism; *N*, nonoral automatisms; *dotted vertical lines*, end of EEG paroxysm. From Stefan H, Burr W, Hildenbrand K, et al. Basic temporal structure of absence symptoms. In: Akimoto H, Kazamatsuri H, Seino MD, et al., eds. *Advances in Epileptology: the XIIIth Epilepsy International Symposium*. New York: Raven Press; 1982:55–60, with permission.

The high percentage of patients with mixed absences in these studies indicates that many combinations of components are found in each patient. These data suggest that the existing classification of absence seizures is perhaps oversimplified. The simple enumeration of the various components without emphasizing one of them does not suffice to characterize absences precisely. The proposed criteria of the International Classification should therefore be more detailed, with other components added. Absences are characterized not only by myoclonic, tonic, or automatic events, but also by the directions of ictal movements and their lateral symmetry. For example, a profile of symptom activity (POS) of patients with mixed absences is shown in FIGURE 2. Various types of absences can be better differentiated phenomenologically if symptoms are weighted by defining accompanying behavior using the POS. In this way, even mixed absence seizure types can be differentiated by an analysis of the predominance of ictal behaviors. In the experience of Stefan et al.,[107] 74% of absence seizures are associated with two or more ictal signs in combination.

P.576

The recognition of this phenomenon and the subclassification of absence seizures according to the predominance of characteristic motor symptoms would seem reasonable in lieu of the current classification system, which provides for a somewhat static description of absence seizures with multiple clinical presentations and fails to weigh the predominant motor symptom activity. Myoclonic absences are characterized by:

- Impairment of consciousness, which varies from mild, in which the patient can continue with normal activities such as playing with toys, to severe.

- Motor manifestations consisting in rhythmic myoclonic jerks, primarily of the the shoulders and arms, and occasionally of the legs.
- In connection with shoulder symptoms, simultaneous jerks of the head can be seen.
- Eyelid twitching is absent or rare, whereas perioral myoclonias may be frequent.
- Due to coinciding tonic contractions, the arms can be lightly elevated.
- The jerks and tonic contractions are usually bilateral but may be unilateral or asymmetric.

- In about two-third of cases, other seizures such as simple absences and generalized tonic–clonic seizures can be seen.
- Autonomic manifestations may occur as arrest or as change of respiration and urinary incontinence.
- The seizures are usually extremely therapy resistant.

A further analytical approach to analysis of the phenomenologic structure of absences may be found in studies of time course. Based on the results of Rabending,[90] who described a succession of rhythmic myoclonic adversive symptoms and automatisms, Stefan[103,109] investigated the time course of the progression of myoclonic and tonic motor phenomena, automatisms, and autonomic changes during absence seizures by means of V-EEG monitoring. This dynamic approach seemed necessary to understand better the mosaic of events that characterize generalized absence seizures. Analysis of time course revealed the presence of a complex sequence of behaviors during absence seizures. For example, in some patients the absence was heralded by initial elevation of the eyelids. This was followed by eye deviation, chewing and licking, subtle tonic spasms of the extremities, and discrete automatic movements of the hand. In other absence seizures in the same patient, only single elements of the complex movement pattern occurred. In other words, the different elements of the whole complex movement pattern, which were completely visualized in one absence seizure, were only incompletely present (like fragments of motor pattern) in other absence seizures in the same patient.

A constant latency was found for each patient from the beginning of the spike-and-wave paroxysms to movements of the eyelids, eye deviation, chewing, and perioral myoclonus (Fig. 3). The latency for automatisms of the arms and legs was generally longer from onset of the SWDs. Studies of ocular lid movement (L activity), oral automatisms (O activity), and nonoral activity (N activity) in different absences often revealed a highly constant relation between the onset of an EEG paroxysm and the onset of L, O, and N symptoms (Fig. 4). It is of interest that the time interval between the L, O, and N symptoms during long-lasting seizures was prolonged compared with that in absences of shorter duration, indicating a compressed or prolonged time course of the same ictal complex of motor behaviors, depending on the duration of the ictal event.[108] Different types of oral automatic phenomena (swallowing, licking, smacking) could be recognized during the time course of an absence seizure, occurring most often during the earlier part of a seizure, whereas simple movements of the mouth (mouth opening, or "carp mouth phenomenon") were more evenly distributed throughout the course of the seizure. Ictal motor patterns correspond to archetypal elements of movement.[61] They are contained in normal motor schemes and are controlled by higher coordinating mechanisms. Their occurrence is possibly related to an isolated demand of stored elementary motor acts of a complex motor behavior. At the beginning of the seizures, staring gaze, change of facial expression (such as an anatomic facial palsy), and stopping of the rhythmic motor movement may be related to negative motor mechanisms. After this, the proximal-axial sequence of time-ordered involuntary motor events may indicate a disturbance of initiation and programming of motor activity.[37,92]

The V-EEG analysis also showed an interesting time course for autonomic phenomena during absence seizures. These include a change of respiratory rate at the onset of spike-and-wave paroxysms, followed by a reduction of heart rate and skin resistance response (see Fig. 4).

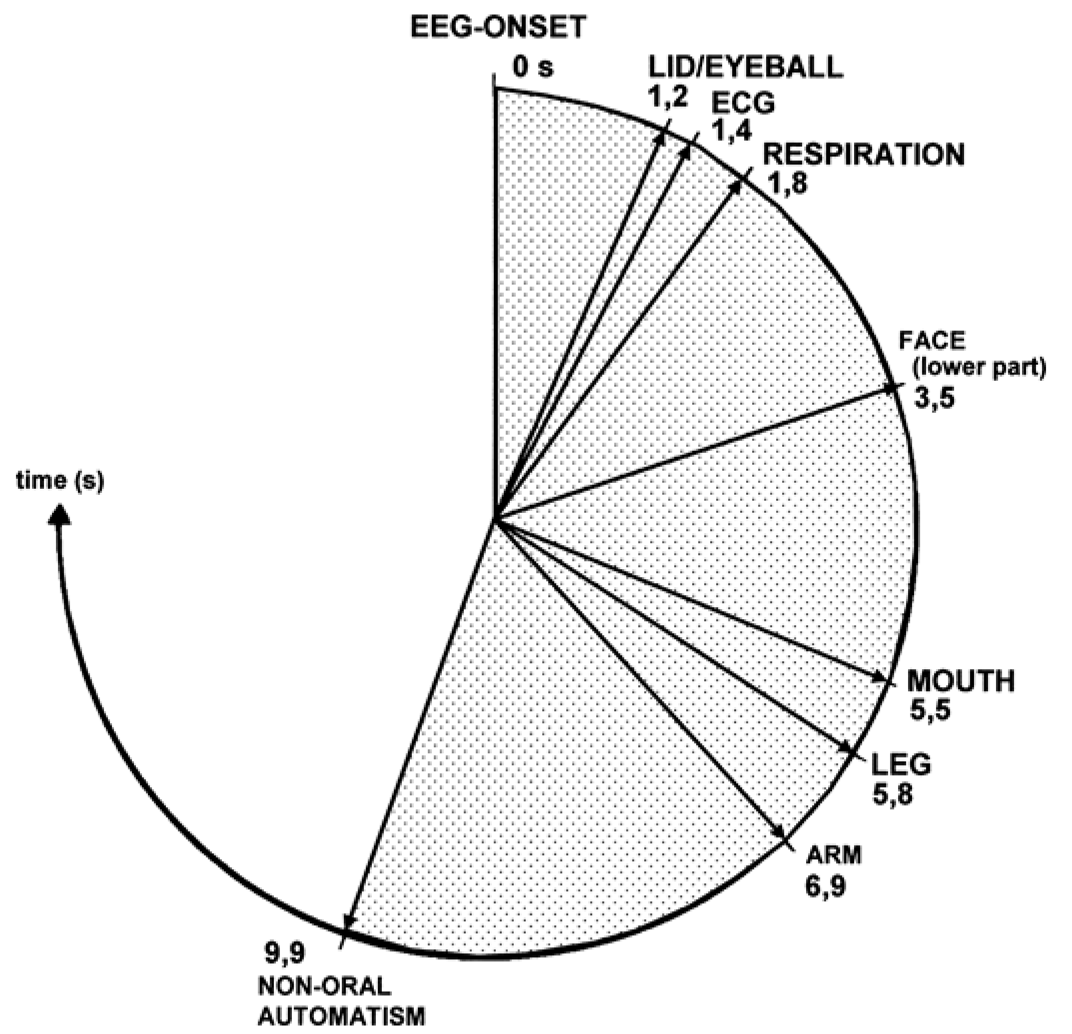

FIGURE 4. Temporal occurrence of motor and autonomic symptoms during absence seizures related to the beginning of generalized spike-and-wave paroxysms in the EEG. From Stefan H, Burr W, Hildenbrand K, et al. Basic temporal structure of absence symptoms. In: Akimoto H, Kazamatsuri H, Seino MD, et al., eds. *Advances in Epileptology: the XIIIth Epilepsy International Symposium*. New York: Raven Press; 1982:55–60, with permission.

Analysis of the time course of behaviors during generalized absence seizures suggests a spread of motor involvement in a craniocaudal direction, from the ocular region to the perioral area, thence to the upper and lower extremities, which is somehow analogous to the jacksonian march of partial elementary motor seizures. However, in absences variations occur as far as a somatotopic predominance of the ocular region is concerned in the case of craniocaudal descent to the extremities.

P.578

Frequently, after initial activity of the head and ocular region, the lower extremities show discrete myoclonic or tonic motor signs, but also motor pattern fragments occur. The craniocaudal march may indicate the involvement of frontolateral as well as frontomesial regions (e.g., premotor region, supplementary motor area, or gyrus cinguli) with excitatory and inhibitory interactions. These data support the suggestion of Berkovic et al.[9,10,89] that extremely careful analysis of ictal V-EEG recordings is necessary to classify absence seizures correctly, because of the continuum that exists between partial and generalized epilepsy.

Cluster analyses of motor symptomatology of absence seizures[103] have shown no clearly defined separation of seizure types with regard to the motor signs of absence. These findings support the hypothesis of Gloor[43,44,45] and Gloor et al.[46,47] concerning a continuum of absence seizure signs that are manifested in both genetic and diffuse symptomatic epilepsies. Along these lines, Gloor has suggested that, in absence seizures, there exists a spectrum of pathophysiologic disturbances that may involve the cortex, reticular projection system, or thalamus, with the primary abnormality not originating in any single structure. At one end of this spectrum are the frequently observed ocular motor productive absences, which might also be considered typical absences, with normal interictal EEG findings, no neurologic findings, and no demonstrable pathologic process; at the other end of the spectrum are the ocular motor unproductive absences, often associated with abnormal interictal EEG patterns, neurologic findings, and hints of diffuse central nervous system pathology. Holmes et al.[53] have suggested that the most likely causes of absence seizures of the first type are genetically determined, whereas in the second type, the seizures are likely to be a consequence of diffuse cerebral pathology. The normal interaction between cortex and subcortical projection mechanisms of reticular origin is probably disturbed in both types of absence.

Postictal

Generalized absence seizures usually stop abruptly. The patient immediately recovers mental function and can resume ongoing activities with no appreciable delay. The accumulation of a series of absences can cause a so-called *discontinuous nonconvulsive status*, or a prolonged absence can result in a continuous nonconvulsive absence status. Impairment of consciousness can vary quantitatively from slight dizziness to stupor.

EEG Manifestations and Clinical Correlations

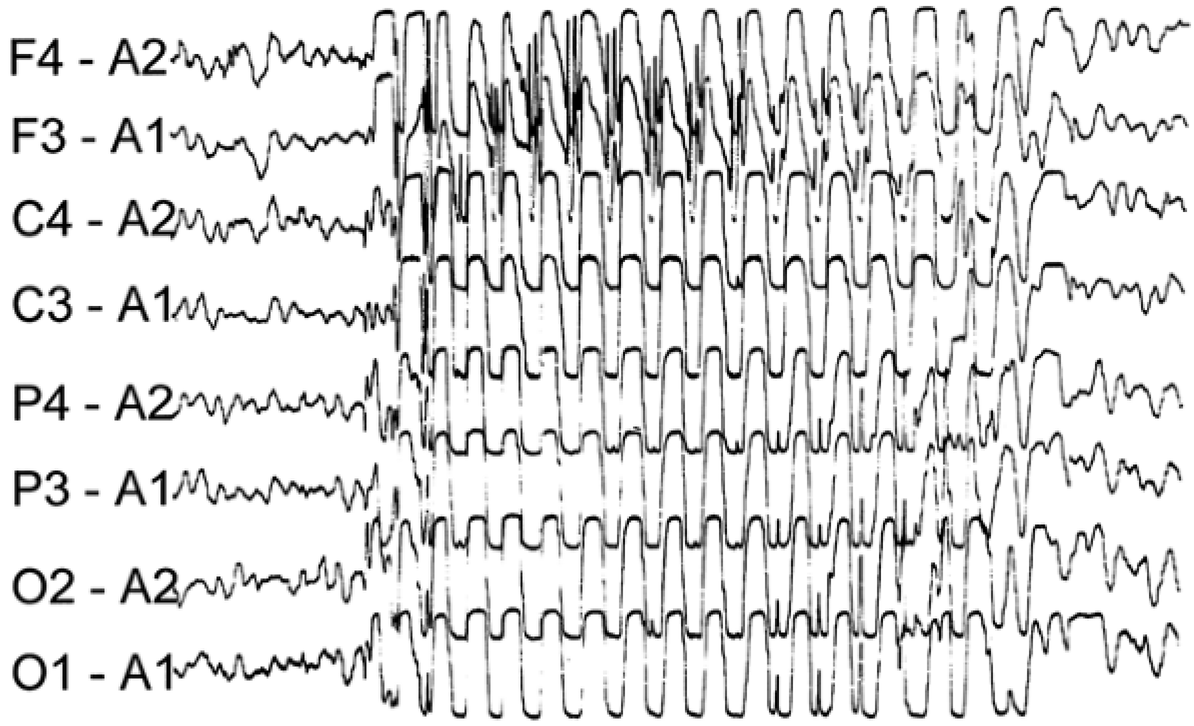

FIGURE 5. Generalized 3-cycle per second spike-and-wave paroxysms during an absence seizure with discrete accentuation in frontal brain regions. From Stefan H. *Epilepsien—Diagnose und Behandlung*. New York: Chapman & Hall, 1995, with permission.

Interictal

In patients with typical absences, the EEG demonstrates bilaterally synchronous and symmetric SWDs at 3 cycles per second, with normal background activity. The EEG for ocular motor productive absence seizures shows normal background activity with predominantly generalized spike-and-wave or polyspike-and-wave discharges, sometimes also mixed with focal or predominantly regional activity. Even bilateral independent interictal focal frontal spikes can occur in typical

P.579

absence epilepsy.[103] This may be caused by accentuated projection in the thalamocortical network system or by a focal frontal onset, such as in the frontobasal or mesial regions.[54] Encephalographic and magnetoencephalographic (MEG) recordings show an early MEG spike component and a later EEG negative spike element. By means of dipolar analysis, the main sources were shown to be in the frontopolar, premotor, or mesiobasal regions.[82,93] The coregistration of EEG and functional MRI indicates functional activation of the anterior or posterior cingulate cortex during generalized spike-and-wave paroxysms.[2,117] This result raises questions concerning the source of discharges in presumptive generalized epilepsies. The electro-clinical findings suggest that absence seizures may not be truly generalized but rather involve selective cortical networks,[54] as do the regional epilepsies, with participation of thalamocortical networks. In atypical absences, the background activity frequently shows abnormal findings (diffuse slowing, interictal spikes), and the SWDs are irregular, with a frequency below 2.5 cycles per second or above 3.5 cycles per second. The reason for the slower rhythms in this disorder is not clear, but in atypical absence seizures the bilaterally synchronous activity is not constrained by thalamocortical circuitry, but involves in all likelihood thalamocortical hippocampal circuitry.[19,21,118]

Ictal

Absence seizures are usually characterized by generalized, bilaterally synchronous, predominantly frontal SWDs having a frequency of 3 to 4 cycles per second and lasting less than 30 seconds[53,87](Fig. 5). Statistically, clinical manifestations are more likely to occur with spike-and-wave paroxysms lasting longer than 3 seconds. However, cognitive functional disturbances may occur during shorter spike-and-wave paroxysms. These cognitive lapses may be measured by means of neuropsychologic testing during the absence seizure by V-EEG monitoring.[13,78] Initial SWDs faster than 3.5-seconds occur more frequently in absence seizures accompanied by complex motor phenomena. In addition, regional frontal ictal onsets may sometimes occur.[103]

The ictal EEG for atypical nonocular sporadic motor absence seizures shows a tendency toward slower spike-and-wave rhythms of 2.5 to 3 cycles per second duration, often lasting less than 10 seconds.

The ictal EEG in myoclonic absences comprises rhythmic generalized and bilateral synchronous and symmetric 3 cycle per second spike-and-wave activity as can be seen in typical absence seizures. Occasionally, these classic discharges may be intermingled with polyspikes.

Postictal

In typical absences, the postictal EEG usually is normal. Single or brief discharges of bilateral SWDs are frequent, especially during non-REM sleep.

Diagnostic Considerations

For an accurate diagnosis of generalized absence seizures to be made, a careful description of the seizure is very important. This should include the presence or absence of an aura, the clinical events that transpire during the seizure itself, the presence or absence of a postictal event, and the duration and frequency of the seizure. In addition, EEG findings, family history of epilepsy, and developmental history are important.

EEG recordings should be recorded predominantly in the morning, between 8 and 10 AM. In previously untreated

P.580

patients with typical absences, generalized SWDs are most often seen at that time of day. If the routine EEG fails to detect SWDs, sleep deprivation, hyperventilation, and photic stimulation may activate them. The results of the neurologic examination and neuroimaging studies usually are normal in generalized absence epilepsy. Myoclonic absences are usually typical, and the diagnosis is mainly based on careful clinical observations and V-EEG studies with polygraphic recording (electromyelography [EMG] of various shoulder and arm muscles).

Differential Diagnosis

Absence seizures may sometimes be misdiagnosed as nonepileptic disturbances of behavior and concentration in school. In addition, clouding of consciousness with ocular and oromotor automatisms may occur in partial seizure disorders and generalized epilepsies other than absence epilepsy. The “absence” is no more than a short description of a clinical condition that evolves from physiologically different mechanisms. Thus, a careful history of the seizure is very important. A generalized absence seizure is characterized by an abrupt onset with no aura, a short duration of less than 30 seconds, and no postictal state. The appearance of a patient having a complex partial seizure may be similar, with staring, lip smacking, and motor automatisms of varying complexity. However, complex partial seizures are frequently heralded by an aura, usually last longer than a minute, and are commonly followed by postictal confusion.

Seizures arising from the frontal lobe may be more difficult to differentiate from absence seizures, because they appear to be nonfocal. Bancaud et al.[4,5] showed that mild stimulation of the frontal cortex produced absence-like seizures, and stimulation with higher intensity produced tonic–clonic seizures. Therefore, absence seizures might represent a minimal expression of epileptogenicity in the frontal lobe. Frontal lobe seizures generalize extremely rapidly, which may lead to the impression of a primary generalized epilepsy. Seizures originating in the frontal lobe are characterized by short duration and abrupt onset and termination of clouding of consciousness, in approximately the same time span as absences in generalized spike-and-wave epilepsy. In addition, seizures of frontal lobe origin occur rather frequently. Therefore, the differentiation of frontal lobe epilepsy from primary generalized absence epilepsy may prove very difficult in clinical practice.

The EEG findings are helpful in differentiating generalized absence seizures from complex partial and frontal lobe seizures only if they are abnormal. Normal EEG findings are not helpful. If the index of suspicion is high for an epileptic event, and the behaviors are frequent, V-EEG monitoring with capture of the event in question is the gold standard for differentiation of an epileptic from a nonepileptic event and for precise clinical definition of the type of seizure involved. In generalized absence epilepsy, the presence of generalized, bilaterally synchronous SWDs or of photosensitivity indicates the diagnosis of absence seizures. Focal spikes suggest complex partial seizures. The ictal EEG in frontal lobe epilepsy may show nothing but bilateral slowing if the frontal lobe onset is deep.

The rhythmic myoclonic movements in myoclonic absences can be overlooked due to tonic contraction of arm, or if the intensity of the myoclonias can be reduced through treatment. In such cases, simple absences may be suspected. When the motor manifestations are asymmetric, focal seizures may be considered. It has been proposed that resistance to conventional treatment for simple absences with a 3 cycle per second spike-and-wave activity is an indication of myoclonic absences, and adequate investigation should be performed.

Specific Syndromes Incorporating Absence Seizures as an Integral Feature

The term *absence* refers to seizures, not epilepsies; however, several epilepsies or epileptic syndromes incorporate absence seizures as a major feature and are commonly referred to as *absence epilepsies*.

Many genetic, pharmacologic, and semiologic data suggest that epilepsy with typical absences is not a homogeneous entity.[52,83,90] Animal studies support this hypothesis, because they suggest that chromosomal mutations may correlate with phenotypic variations of seizures, particularly in regard to frequency and duration.[80] The heterogeneity of the absence epilepsies has been recognized by the Commission on Classification of the International League Against Epilepsy, which describes four epileptic syndromes with typical absences: childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, and myoclonic absence epilepsy. To this list has been added eyelid myoclonus with absences; perioral myoclonus with absences; absences with single, nonrhythmic myoclonus; late-onset absence status and phantom absences; reflex absences; and symptomatic and secondarily generalized typical absences.[83]

Childhood Absence Epilepsy

This is an idiopathic generalized epileptic syndrome with onset of simple and complex absence seizures at 4 to 8 years of age. The seizures may be accompanied by upward deviation of the eyes and retropulsion of the head and trunk. Generalized tonic–clonic seizures develop in 30% to 40% of the cases.[69]

Juvenile Absence Epilepsy

The age of onset is around the time of puberty, and the absences are the same as those observed in childhood absence epilepsy, except that retropulsive movements are less common. Seizure frequency is lower than in childhood absence epilepsy. Generalized tonic–clonic seizures are common; they usually occur on awakening and may precede the appearance of absences. The patients may also have myoclonic jerks, and the prognosis for seizure control is said to be poorer than in childhood absence epilepsy.

Juvenile Myoclonic Epilepsy

Absence seizures occur in one third of patients with juvenile myoclonic epilepsy. Early-onset absence seizures may predate myoclonic jerks, generalized tonic–clonic seizures, or both by many years in this disorder, which requires lifelong treatment with antiepileptic drugs.

Myoclonic Absence Epilepsy

Absence seizures associated with rhythmic myoclonic jerking of the shoulders, arms, and legs and tonic contractions around the shoulders were first described as a specific syndrome by Tassinari et al.[113] and reviewed by Tassinari and Bureau.[114] The rhythmic (clonic) jerking is stronger in intensity than that seen in typical absence seizures. The duration of the myoclonic absence varies between 10 and 60 seconds. EMG activity during

the myoclonus correlates with the 3-cycle per second spike-and-wave bursts. The prognosis for seizure control in myoclonic absence seizures is less favorable than that in typical absences. Moreover, myoclonic absence epilepsy may be associated with an encephalopathy.

Eyelid Myoclonus with Absences or Jeavons Syndrome

The characteristic seizure, mainly occurring after eye closure, is a brief episode of marked jerking of the eyelids, often associated with jerky upward deviation of the eyeballs and sometimes associated with retropulsion of the head. The EEG shows generalized SWDs, which are inhibited by total darkness. All patients are photosensitive. Impairment of consciousness may occur. Sometimes, generalized tonic–clonic seizures in connection with sleep deprivation or fatigue have been reported. The prognosis for seizure control is poor. The seizure manifestations can initially be misinterpreted as a behavior disturbance with tics. The clinical manifestations were originally described by Jeavons.[59,60] The syndrome was recognized by Duncan and Panayiotopoulos.[34] This type of absence epilepsy has also been called *eye-closing seizures.*[12,119] Some patients may precipitate nonconvulsive status epilepticus with eye closure.[110]

Perioral Myoclonus with Absences

This is a syndrome with onset in childhood or adolescence, characterized by frequent typical absences associated with jaw and lip myoclonus. These patients are said to be at high risk for absence status. Moreover, generalized tonic–clonic seizures usually occur in conjunction with this type of absence epilepsy. The disease is said to be lifelong, like juvenile myoclonic epilepsy. There is no photosensitivity.

Other Classification Schemes

Hirsch et al.[52] analyzed 570 absences in 43 patients and were able to differentiate four groups of patients on the basis of clinical presentation and response to treatment, coexistence of generalized tonic–clonic seizures, and the nature of precipitating events.

Based on their experience, Hirsch et al.[52] have suggested that the only reliable clinical criteria by which one may predict the course of absence epilepsy are the early onset of generalized tonic–clonic seizures and the nature of the precipitating factors, that is, hyperventilation or intermittent photic stimulation. Moreover, these authors have questioned the usefulness of more and more syndromic subcategories of absence seizures, either in guiding treatment or establishing prognosis. Further, it is the belief of this group that the terms *childhood absence epilepsy*, *juvenile absence epilepsy*, and *eyelid myoclonus with absence* are misleading. Rather, they propose a simplification of the classification scheme for absence epilepsy with just three categories: (a) “pure” absence epilepsy, (b) generalized epilepsy with absences and tonic–clonic seizures, and (c) generalized epilepsy with photosensitive absences and tonic–clonic seizures.

Doose[30] described absences in patients with myoclonic astatic epilepsies of early childhood. If generalized tonic–clonic seizures occurred before the fourth year of life, and absences were also later observed, the prognosis for control of absences with drug treatment was poor.

There is strong evidence of causal heterogeneity within the disorder. Polygenic inheritance and multifactorial influences may explain the wide range of manifestations.[31,32]

Responses to Treatment

The drugs of choice for typical absence seizures are ethosuximide, valproate, or lamotrigine. Ethosuximide has been successful in controlling seizures in 70% of patients with absence seizures who are drug-naïve.[94] The initial dosage is 15 mg/kg/day. This dose can be gradually increased to a daily maintenance dose of 20 to 40 mg/kg.

If the patient continues to have absence attacks, has atypical absence seizures, or absence seizures with generalized tonic–clonic seizures or other seizure types, valproic acid or lamotrigine should be used; these broad-spectrum anticonvulsant agents are expected to be effective against both absence and generalized convulsive seizures.

The maintenance dose of valproic acid in children is 20 to 40 mg/kg/day in two divided doses. The enteric-coated formulation of valproic acid reduces the frequency of gastrointestinal complaints, but it does not lessen the fluctuations in serum concentrations.[18] If the sprinkle formulation is used in monotherapy, however, the drug may be given every 12 hours in children.[18] To avoid side effects in children given valproic acid, the initial dose is usually one third of the maintenance dose; this is increased by one third every 4 to 5 days until the full maintenance dose is reached. Some exceptional patients who do not respond to doses of 60 mg/kg may respond to doses as high as 80 to 100 mg/kg/day. These "supramaximal" doses of valproic acid are most effective when given as monotherapy.

In previously untreated adult patients, a dose of valproic acid of 15 to 20 mg/kg/day may be sufficient for seizure control. In these cases, a once-daily administration in the evening is often effective and well tolerated.[14,106] Dosing more than twice a day is rarely necessary.

Lamotrigine can be a choice in especially older girls and women. The initial dose in children under 12 years is 0.6 mg/kg/day in two divided doses for the first 2 weeks, and for the next 2 weeks 1.2 mg/kg/day. The dose is titrated with 1.2 mg/kg every or every second week up to a maintenance dose of 5 to 15 mg/kg/day or a maximum of 400 mg daily. If the child also is treated with valproic acid, the titrating doses are 50% of those mentioned, and the maintenance dose is 1 to 5 mg/kg/day or a maximal daily dose of 200 mg.

In children over 12 years and in adults, the dose is 25 mg/day during the first 2 weeks and 50 mg/day during the next 2 weeks. The dose is increased by 50 mg/week or every second week up to a maintenance dose of 200 to 400 mg/day. In combination with valproic acid, the corresponding doses are 25 mg every second day, 25 mg/day, and the increasing dose 25 to 50 mg/week or every second week with a maintenance dose of 200 mg/day.

If no therapeutic response to monotherapy occurs with either ethosuximide or valproic acid, a combination therapy, such as that already described for valproic acid and lamotrigine, may be of benefit.

For intractable absence seizures unresponsive to a combination of the mentioned drugs, other drugs may be tried (e.g., topiramate, lamotrigine, clobazam or, zonisamide, if there is no seizure control). Further details concerning side effects of treatment are discussed in the special literature.[26,33,56,60,63,85,89,95,96,97,98,104,111,121,123]

Summary and Conclusions

Absence seizures are primarily a disorder of childhood. They are neurophysiologically and pharmacologically unique and comprise the primary seizure type in a number of different

P.582

absence epilepsy syndromes. The underlying mechanism of SWD bursts that characterize generalized absence seizures involves thalamocortical modulation of spindles and recruiting responses of the cerebral cortex. Generalized absence seizures represent a perturbation of neocortical rhythmicity in favor of the rhythmic burst firing mode.

Although they are a seemingly heterogeneous group of disorders, all absence seizures have an abrupt, brief loss of consciousness without an aura or postictal state, and with or without motor or autonomic automatisms; all are associated with a burst of bilaterally synchronous SWDs, usually at a frequency of 2.5 to 3.5 cycles per second. No universal agreement exists regarding the best way to characterize the absence epilepsies; however, it is generally accepted that the coexistence of generalized tonic–clonic seizures, myoclonic jerks, or both with absence is considered unfavorable for ultimate seizure control. Clinical genetics may, in the future, hold the key to syndrome classification.

The drug of choice for typical absence seizures is ethosuximide and valproate. Valproic acid is the drug of choice for all other types of absence seizures, absence seizures with proven intractability to ethosuximide therapy, or absence seizures that occur in association with generalized tonic–clonic seizures. For lamotrigine and topiramate evidence class 2 for treatment efficacy exists in addition. From experience, drugs like carbamazepine and phenytoin should be avoided.

Signa epilepsiae remotoria sunt jactatio et cetera. (Heberden, 1804)

Introduction

"The term and concept of myoclonus have been a longstanding source of confusion and debate. Myoclonus should be used in its strictly etymological sense, referring to any brief muscular contraction, as would have been wished by Muskens, the first neurologist to do detailed clinical and experimental studies of it."[42]

The development of the concept of myoclonus and its application to epileptic seizures is closely connected with the history of description and conceptualization of progressive myoclonus epilepsy (PME) and other myoclonic epilepsies. Dubini (1846)[35] described a cohort of patients with possibly different conditions who had involuntary jerky movements that he named *electric chorea*. Delasiauve (1854), Reynolds (1861), Féré (1890), Binswanger (1899), and Gowers (1902) described sudden starts or jerks as expressions of motor prodromes, auras, or abortive seizures (*petit mal moteur*) in their monographs on epilepsy. They did not, however, differentiate them semiologically or nosologically. Credit for the first exact and comparable description of these phenomena belongs to Herpin (1867),[59] who described them as: "this variety of [seizure] prelude is a jerk [*secousse*] which runs through the entire body like an electric current." His twenty-fourth observation was the first description of juvenile myoclonic epilepsy (JME), in a 14-year-old child, the son of a doctor. His jerks were called *commotions* or *impulsions*.

"At the beginning of the seizure, the movements or jerks were limited to the upper part of his body; they later became generalized. If the boy were to stand or walk, he might fall, although this is rare. He stands up again immediately [after the seizure]. He throws or drops what he is holding, particularly if he is holding it with his right hand. He says that he cannot see at the moment of the movement, but that he recovers immediately afterwards. His mother called these events (*accidents*) shakes (*tremblement*) and the father jerks (*secousses*)."

In 1881, Friedreich[40] described a case, the diagnosis of which has remained unclear until today, and named it *paramyoclonus multiplex*. Many publications followed his observation, but they were comparable only in that they were dealing with involuntary jerks. From the "chaos of motor neuroses and from the cloudy pool of many publications," Unverricht[116] crystallized a unique disease entity from his 1895 study of members of two families and named it *familiäre myoclonie*. This disease started between the ages of 7 and 15 years, and consisted of a combination of nocturnal convulsive seizures and "lightning-like, arrhythmic, isolated jerks of individual, functionally unrelated muscles of both sides of the body. The jerks occurred less frequently when strained, but more frequently during psychic excitement, and stopped completely during sleep." Unverricht seemed to have not observed any relationship between the phenomena he named *myoclonie* and the preparoxysmal or interval jerks of epileptic patients that, at that time, were still called *secousses*.

In 1899, both Dide[27] and Rabot,[90] at almost the same time, introduced the concept of *myoclonie* to the vocabulary of epilepsy—Dide from a semiologic viewpoint ("La myoclonie dans l'épilepsie") and Rabot from a nosologic view ("De la myoclonie épileptique"). Rabot confirmed Herpin's observation and emphasized that the "jerks" might precede major convulsive seizures for many years, usually occur in the morning after awakening, are prone to recur in series, and occur more frequently days before major convulsive seizures and disappear thereafter for a while, as if switched off.

Some years later, Clark and Prout[19] proposed the concept of myoclonus epilepsy for their cases of Unverricht myoclonie, which they had described as *paramyoclonus multiplex associated with epilepsy* in 1900. When, in 1903, Lundborg[76] sought an appropriate term for the disease he observed in 18 members of a Swedish farm family, he noticed the same nomenclature for two different diseases. He then proposed to describe one, which was "identical with the Unverricht's myoclonie," as *progressive familial myoclonus epilepsy*—from which later the term Unverricht-Lundborg myoclonus epilepsy developed—and the other, which was "standing near the essential epilepsy," as *intermittent sporadic myoclonus epilepsy* (Rabot's type). This was described by Lecasble in 1958 as "épilepsie generaliseé avec des myoclonies intermittentes et sporadiques" and by Castells and Mendilaharsu[18] in the same year as "la epilepsia mióelonia bilaterally cosciente" to differentiate it from the epilepsy beginning with partial myoclonus. Janz[66,67] as well as Lennox[73] tried to replace the vague but accepted concept of myoclonus with the descriptive terms—at least for the jerks of JME—*impulsive-petit mal*[67] (from the Latin impulsio, "jerk") and jerk epilepsy.[73] During the 1970s, a syndromic approach to the problems of myoclonic epilepsies occurred, with a new importance given to electroencephalographic (EEG) findings and to elements of etiology and prognosis. The Marseille school, among others, established several well-accepted syndromic entities using the adjective myoclonic, such as *benign* and *severe myoclonic epilepsy in infancy*, and *epilepsy with myoclonic absences.*[44]

Recently, myoclonus has been the subject of intensive research using advanced technologies. Electrophysiologic studies, especially, have brought new insights into the pathophysiomechanism of myoclonus.[102] The recent advances in molecular genetics have also helped achieve an understanding of the different conditions that cause myoclonus.

P.586

Clinical Manifestations

Myoclonus consists of involuntary, quick movements distinctive for their abrupt, lightning-like character, occurring in a mild or vehement manner, spontaneously or in stimulus-sensitive conditions, affecting the entire body or in regional or localized distal or proximal parts of the body. It may be diffuse, predominating symmetrically in the axial muscles and the upper limb (*massive myoclonus*), or segmental, affecting randomly the different parts of the body, although the most involved muscles are those of the extremities, face, and trunk (*erratic myoclonus*); if the legs are involved, the person may be thrown to the ground. Myoclonus can be asymmetrical or even focal, limited to a restricted part of one limb or the face (*epilepsia partialis continua*).[36] It may occur at random over time, or at more or less fixed interval, and in sporadic or rhythmic fashion. Most myoclonia are caused by abrupt muscle contraction (positive myoclonus); rarely, a brief interruption of ongoing activity may be observed (negative myoclonus, previously named *asterixis*).[1] No distinguishable, even momentary, loss of consciousness occurs with single jerks, but if jerks occur in rapid succession or in the form of myoclonic status epilepticus, there may be a blurring of awareness.

Phenomenologically, epileptic myoclonus cannot be distinguished from the brisk, nonepileptic movements associated with physiologic or pathologic conditions. The classification of seizures as an epileptic manifestation requires knowledge of the clinical context and/or electrophysiologic confirmation, although physiologic correlates are not always demonstrable. Hallett[54] proposed to define epileptic myoclonus as an elementary electroclinical manifestation of epilepsy involving descending neurons, whose spatial or temporal amplification can trigger overt epileptic activity.

In this chapter, we use the term *myoclonic seizure* as synonymous with epileptic myoclonus. The term *myoclonus* was coined by Friedreich.[55] *Myos* means muscles, *clonus* means tumult or a quick movement, and (myo)clonia is the plural. Because a myoclonic movement is a jerk, the term myoclonic jerk is redundant.[42]

Stimulus Sensitivity

Myoclonus is often stimulus-sensitive, being elicited by stimuli of a single or multiple modalities. Tendon tap, posturing, passive or voluntary movement, visual and acoustic stimuli, and cognitive and emotional experiences may precipitate myoclonus. Myoclonus can also be facilitated by various physiologic factors such as the sleep–wake cycle and fatigue.

Rhythmicity/Periodicity

Myoclonus usually occurs irregularly; however, it occasionally appears to be rhythmic. Bilateral, rhythmic, virtually continuous myoclonus can be observed in Angelman syndrome. Guerrini et al.[46] suggested that small areas within the motor cortex are able to independently produce hypersynchronous, rhythmic neuronal discharges recruiting muscle activity similar to tremor. Cortical tremor, in the form of postural or action tremor, and showing the neurophysiologic characteristics of reflex cortical myoclonus, can be observed in patients with PME and with benign adult familial myoclonic epilepsy (BAFME).[60,111]

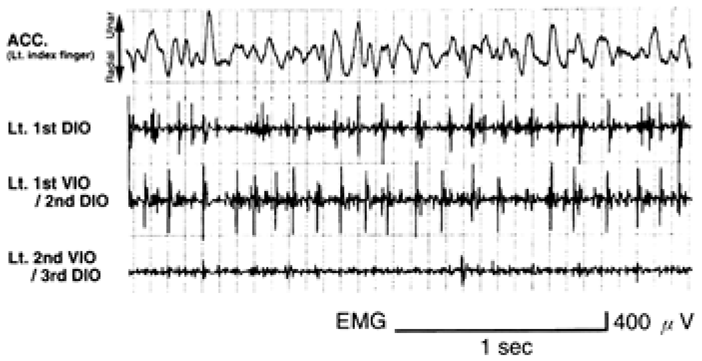

FIGURE 1. Polygraphic EMG records and accelerogram (ACC) in a patient with cortical myoclonus, obtained while the patient maintained the posture of finger extension. Each EMG activity lasted less than 50 msec. EMG discharges are relatively rhythmic. The ACC, therefore, demonstrates relatively sinusoidal wave corresponding to so-called "cortical tremor." From Terada K, Ikeda A, Mima T, et al. Familial cortical myoclonic tremor as a unique form of cortical reflex myoclonus. *Mov Disord.* 1997;12:370–377, with permission.

Epilepsia partialis continua is another example of the rhythmic, periodic, or arrhythmic recurrence of myoclonus. The cortical site of origin of the spike discharges and the site of origin of the associated focal myoclonic seizures do not necessarily coincide.[22]

Pathophysiology

The term epileptic myoclonus implies a central nervous system origin, presumably accompanied by neuronal depolarization shifts with subsequent hyperpolarizing potentials. To clarify the underlying pathophysiologic mechanisms of myoclonus, electrophysiologic studies are useful (i.e., electromyogram [EMG], somatosensory evoked potential [SEP], C-reflex, and jerk-locked back averaging [JLA]). Hallett et al.[54,57] divided epileptic myoclonus into three categories: cortical reflex myoclonus, primary generalized epileptic myoclonus, and reticular reflex myoclonus. Guerrini et al.[48] also divided this disorder into cortical, thalamocortical, and reticular form.

From an EMG point of view, myoclonus appears as short bursts of synchronized activity, which may involve agonist and antagonist muscles at the same time. The duration of EMG burst during epileptic myoclonus ranges between 10 and 100 msec, usually less than 50 msec (Fig. 1), and that of the EMG silent period of epileptic negative myoclonus from 50 to 400 msec (Fig. 2).[44] By recording the EMG, the nature of myoclonus can be described (i.e., positive or negative myoclonus, duration of EMG burst, rhythmicity and periodicity, synchrony of agonist and antagonist muscles, distribution of myoclonus, spreading pattern of myoclonus, and so on).

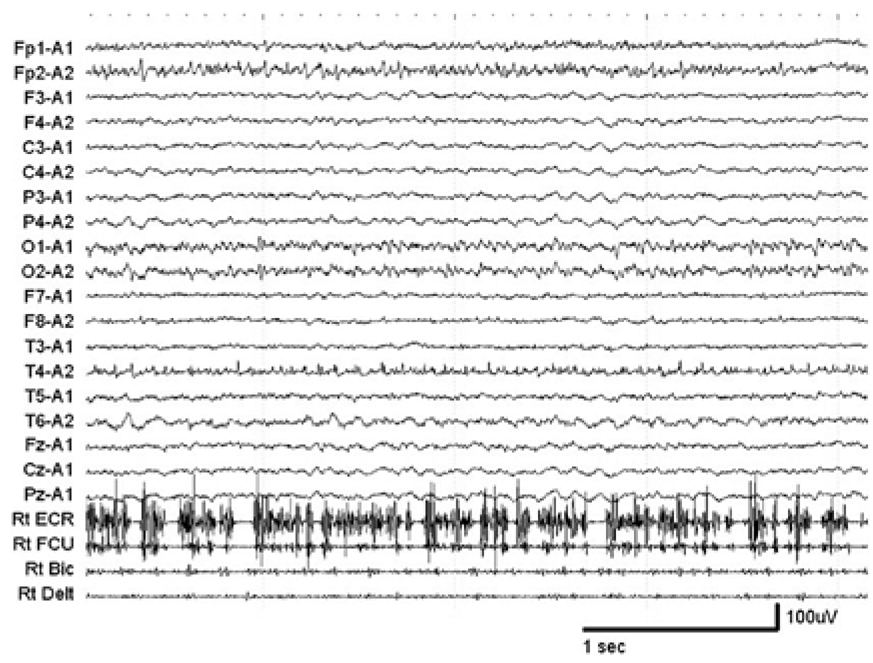

FIGURE 2. Polygraphic EEG/EMG records in a patient with ENM. The record was obtained while the patient maintained an extended posture of right wrist. SPs are seen in the right wrist extensor (ECR) and flexor (FCU) muscles synchronously. They are sometimes preceded by positive myoclonus. EEG shows no clear spikes in association with the jerks in this polygraphic recording.

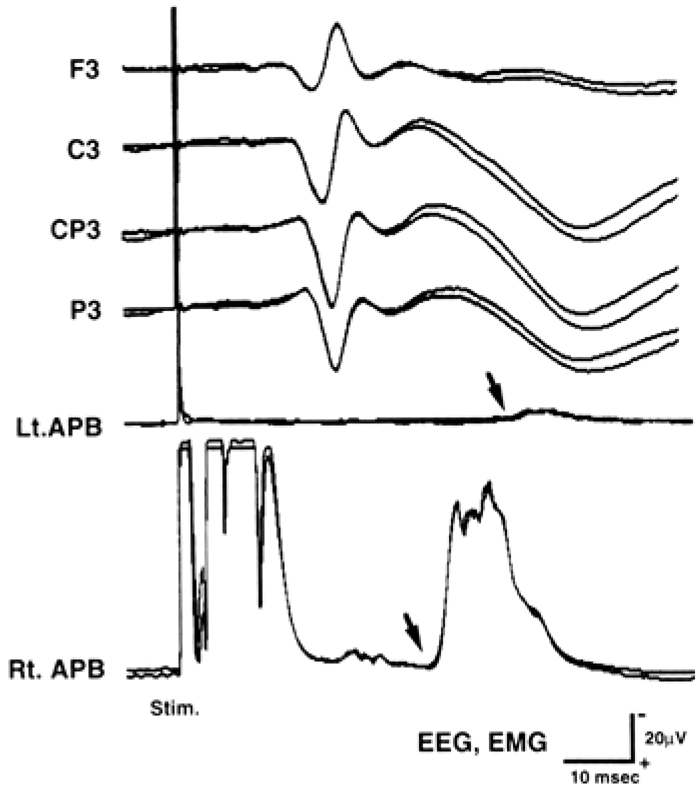

FIGURE 3. SEP and C-reflex following electric stimulation of the right median nerve in a patient with cortical myoclonus. The amplitudes of all SEP components except for N20 are abnormally large. Enhanced C-reflex is seen not only on the stimulated but also on the contralateral side. The arrows indicate the onset of C-reflex in abductor pollicis brevis (APB) muscles on each side. FromTerada K, Ikeda A, Mima T, et al. Familial cortical myoclonic tremor as a unique form of cortical reflex myoclonus. *Mov Disord.* 1997;12:370–377, with permission.

Cortical Myoclonus

Cortical myoclonus reflects impulses that originate in the sensorimotor cortex and travel down the brainstem. Cortical myoclonus is typically seen in progressive myoclonus epilepsy. Muscles involved tend to be distal more than proximal and flexor more than extensor, and to involve more the face and upper extremities than the rest of the body. Cortical myoclonus is more commonly encountered in a multifocal form, presenting with multifocal spike discharges. If myoclonus is triggered by stimuli, the term *cortical reflex myoclonus* is used. If myoclonus occurs periodically, the term *epilepsia partialis continua* is used. The neurons in the sensorimotor cortex may be primarily hyperexcitable, or may be driven by abnormal inputs from the neurons of other brain parts. Therefore, cortical myoclonus occasionally is called *fragmented epileptic convulsion*.

In patients with cortical reflex myoclonus, the cortical components of median-nerve SEP showed abnormally large amplitude (Fig. 3). Usually, the initial peaks (N20/P22) are not large, and the following components become higher. This giant SEP is thought to indicate hyperexcitability of the sensorimotor cortex. Abnormally large evoked potentials were also reported by photic stimulation.[104]

When the peripheral nerve is stimulated, the stimulus goes up the spino-thalamo-cortical tract and, after excitation of the pyramidal neuron, it goes down the cortico-spinal tract, resulting in muscle contraction (long-loop reflex). In normal subjects, long-loop reflex can be recorded only when subjects maintain muscle contractions. In patients with cortical reflex myoclonus, however, this reflex can be recorded even while resting (C-reflex) (see Fig. 3). The latency of C-reflex for median nerve stimulation is about 40 to 45 msec, which is almost double of the latency of N20 to the median nerve stimulation. When the C-reflex is recorded from the contralateral limbs to the stimuli, the latency delay is about 10 msec to the ipsilateral limbs, which corresponds to the traveling time of the transcallosal pathway. This stimulation-locked muscle contraction is believed to share the same underlying mechanism with cortical reflex myoclonus.

Some EEG correlates are time-locked to cortical myoclonus. However, because of the relatively smaller amplitude of the EEG spikes in comparison with the background activities, the physiologic correlates of myoclonus can only be detected by using jerk-locked (EEG or magnetoencephalograhic [MEG]) averaging (JLA of jerk-locked magentic field [JLF]) (Fig. 4) or coherence analysis method.[46,102] In JLA, EEGs are averaged with respect to the EMG onset, to reduce the non–time locked background EEG activities. Positive peak of the EEG spikes is 15 to 20 msec prior to the myoclonus for the upper limbs, and 25 to 40 msec for the lower limbs. Spikes are located around the contralateral primary motor cortex.

As such, cortical reflex myoclonus is caused by hyperexcitability of the primary sensorimotor cortex. However, because giant SEPs are not always present in patients with cortical reflex myoclonus (as in dentatorubral-pallidoluysian atrophy [DRPLA]), some other pathophysiologic mechanisms may exist.

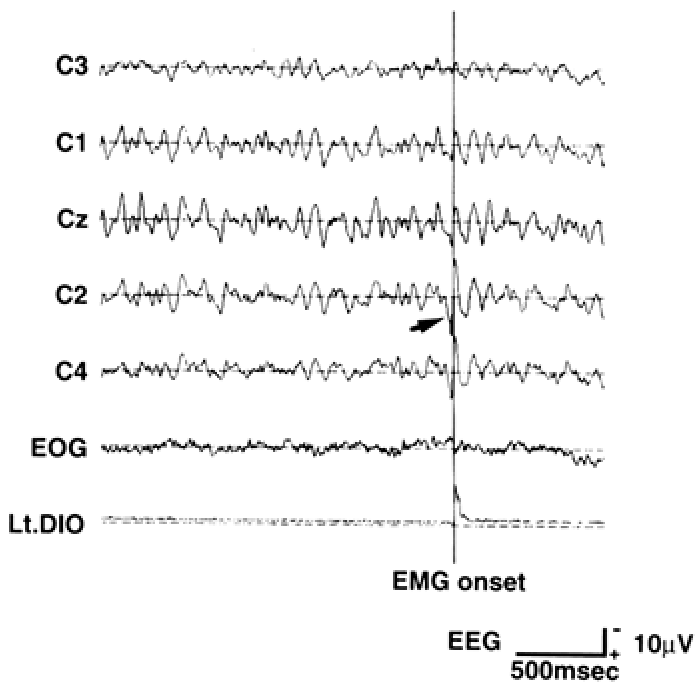

FIGURE 4. Waveforms of cortical discharge demonstrated by jerk-locked back averaging time-locked to the involuntary EMG activity of the left dorsal interosseus muscle (DIO) in a patient with cortical myoclonus. The positive/negative biphasic spike (*arrow*) is maximal at the right central area (C2), which precedes the EMG onset by about 30 msec. From Terada K, Ikeda A, Mima T, et al. Familial cortical myoclonic tremor as a unique form of cortical reflex myoclonus. *Mov Disord.* 1997;12: 370–377, with permission.

In Lennox-Gastaut syndrome (LGS), myoclonus is rare and disclosed only in those cases with a cortical lesion affecting the rolandic area;[12] thus, myoclonus appears to be produced by a secondary generalization of focal cortical myoclonus. They also present with arrhythmic, distal small focal jerks, leading to the individual tiny finger movements unaccompanied by premyoclonic potentials on JLA that Wilkins et al.[119]

P.588

proposed to call *minipolymyoclonus*. Brown et al.[14] indicated that the major role of facilitation of inter- and intrahemis-pheric spread of cortical myoclonic activity is through trans-callosal or intrahemispheric corticocortical pathways in producing generalized or bilateral myoclonus. Therefore, bilateral jerks may not be synchronous in patients with cortical myoclonus.

Thalamocortical Myoclonus

Thalamocortical myoclonus or idiopathic generalized epileptic myoclonus represents the common type of myoclonus in various epileptic syndromes. Myoclonia are often spontaneous, predominantly arrhythmic and axial with varying severity, and associated chronologically with an EEG pattern of diffuse polyspikes or (poly) spike-and-wave discharges. A hyperexcitable cortex is thought to be driven diffusely and synchronously by ascending subcortical inputs that trigger the paroxysmal events. As a consequence, muscles from both sides are activated, and muscles innervated by the cranial nerves are involved through a rostrocaudal manner.

Electrophysiologically, SEP usually does not show giant SEP, and C-reflex may be recorded at rest. A negative peak of the generalized spike (30–100 msec duration) precedes the jerk (<100 msec duration) by 20 to 75 msec. The latency of the spike is relatively longer, and the temporal relationship is looser than in that of cortical myoclonus. The underlying mechanism of the thalamocortical myoclonus is still uncertain. The myoclonus of benign myoclonic epilepsy of infancy, myoclonic-astatic epilepsy, and JME belongs to this category.[46]

Myoclonus observed in patients with Dravet syndrome is not straightforward: Patients may exhibit massive myoclonus combined with a generalized spike-wave (rarely in infancy, mostly in childhood),[32] and erratic myoclonus, particularly during episodes of myoclonic status, in which the patient is drowsy with diffuse slow wave activity and few spikes. The generator remains unidentified.

Reticular Reflex Myoclonus

Reticular reflex myoclonus originates in a hyperexcitable caudal brainstem reticular formation, giving rise to a widespread pattern of muscle activation with proximal and flexor predominance, spontaneous or induced by various stimuli. The impulses may travel up the brainstem. Reticular reflex myoclonus may be present simultaneously with cortical myoclonus.

Reticular reflex myoclonus is not time-locked to EEG discharges, and the sensory evoked potentials are not enhanced. Myoclonus is triggered by stimuli, but the temporal relationship is variable between the stimuli and the myoclonus, whereas it is constant in patients with cortical reflex myoclonus. The EMG discharges start in the areas of lower cranial nerves (sternocleidomastoid muscle, trapezius muscle). They go up to the facial muscles, down to the upper limbs, then to lower limbs. Therefore, it was speculated that the stimuli excited the reticular formation and that abnormal electrical activity then spread from it to the upper brainstem and the spinal cord.[56]

Other Myoclonus

Epilepsy generally does not occur with these other conditions. In spinal myoclonus, the jerks are generated in the spinal cord. Propriospinal myoclonus, nocturnal myoclonus, and periodic leg movements may be involved in this category.

Psychogenic myoclonus is also considered when other organic disorders are ruled out.[81] In patients with psychogenic myoclonus, readiness potentials are present preceding the myoclonus, indicating underlying mechanisms similar to voluntary movements.[112]

Clinical and Electrographic Features of Myoclonic Seizures

Patients may refer to their myoclonus as a jerk, shock, jump, start, involuntary movement, or even stiffness and numbness. Patients may describe being thrown down, as though pushed by someone. Usually, patients do not notice any warnings, but sometimes smaller seizures serve as precursors to more severe ones. Myoclonus may be predominant in axial muscle groups or in the distal ones. Injury caused by falls or by striking a nearby object with a hand or limb may occur during an attack. Myoclonus occurs spontaneously, sometimes predominantly on awakening, and may be precipitated by various internal or external, simple or complex stimuli. Myoclonus may occur in isolation or in patients experiencing generalized tonic–clonic seizures (GTCs) or other forms of epileptic attacks.

In the following section, we describe the clinical and electrographic features of myoclonus in generalized forms. Because the clinical characteristics and EEG expressions of myoclonus are distinct in accordance with the epileptic syndromes, the descriptions accompany the syndromic classification. Detailed descriptions of the individual syndromes can be found elsewhere.[92]

Myoclonic Epilepsies of Infancy and Early Childhood

Harper[58] called attention to the fact that myoclonic seizures occur in childhood, just as in adolescence or adulthood; he described true myoclonic epilepsy in childhood in the age group of 3 to 7 years. Aicardi[3,4] further argued that approximately two thirds of the myoclonic epilepsies occur during the first 5 years of life, and that the true myoclonic epilepsies of childhood—which should be delineated from epilepsies with other types of brief axial motor seizures, such as epileptic spasms and tonic seizures of the LGS—might be subdivided into several forms. International classification of epilepsies and epileptic syndromes[21] covers several distinctive syndromes occurring in infancy and early childhood in which myoclonus is a main seizure type.

Early Myoclonic Encephalopathy

Clinical Features

Massive or axial bilateral myoclonus is the myoclonic feature of early myoclonic encephalopathy, a rare syndrome with several causes occurring during the first 28 days of life (see Chapter 224). In addition, erratic myoclonus frequently repeats as the earliest and main clinical events, with a tendency to shift incessantly from one part of the body to another in an anarchic and asynchronous way.[5,7] Events may be restricted to a very small territory, such as a finger or eyebrow, but sometimes may involve a whole limb. Focal motor seizures and, in the later stage, epileptic spasms or tonic seizures also may appear. Affected infants have severe neurologic abnormalities along with therapy-resistant seizures, and more than half of them die by the age of 1 year.

Electrophysiologic Features

The EEG activity consists of complex bursts of asynchronous spikes and irregular, arrhythmic sharp waves and slow waves lasting 1 to 5 seconds and alternating with flat periods of 3 to 10 seconds (suppression-burst pattern). Normal background activity is absent. The paroxysmal bursts are sometimes synchronous with bursts of bilateral myoclonus. The EEG may later evolve toward atypical hypsarrhythmia.

Myoclonic Status in Nonprogressive Encephalopathies

Clinical Features

This condition is characterized essentially by the recurrence of atypical status combined with an impairment of contact and continuous jerks in infants suffering from a nonprogressive severe encephalopathy with profound cognitive deficit and hypotonia.[23] The myoclonus is more or less rhythmic, asynchronous, and multifocal, affecting periorbital, perioral, and distal muscles. It may be followed by a brief silent period but, in some patients, a negative myoclonus may be predominant. This electroclinical picture is usually observed in children with Angelman syndrome and with 4p-syndrome, allowing an early diagnosis of these disorders.

Other seizure types are focal motor seizures, myoclonic absences, and rare generalized or unilateral clonic seizures. The recognition of this condition is important to exclude the assumption of progressive disease and to allow an adequate treatment against the worsening of the cognitive impairment.

Electrophysiologic Features

The EEG shows bursts of more or less diffuse, more or less synchronous, rhythmic or arrhythmic discharges of diffuse slow spike-waves, often fluctuating, during wakefulness and sleep. Between these bursts are inserted periods of variable duration without obvious paroxysmal discharges but with θ-wave activity of variable amplitude involving both central regions subcontinuously.[23] Bilateral jerk may be time locked with a cortical spike.

Benign Myoclonic Epilepsy in Infancy

Clinical Features

Myoclonus in this rare syndrome occurs during the first or second years of life in normal children who often have a family history of seizures or epilepsy. The seizures are characterized by frequent, brief, mostly symmetrical myoclonus isolated or grouped in clusters and involving the axis of the body and limbs. These seizures provoke a head drop and an upward-outward movement of the upper limbs, with flexion of the lower limbs and sometimes a rolling of the eyeballs.[30,31] They may repeat pseudorhythmically. They occur at any time of day but may be enhanced by drowsiness. In some patients, myoclonus can be triggered by photic stimulation, or by a sudden noise or contact. The myoclonus represents the only seizure type, except for occasional febrile convulsions and GTCs, that occasionally develops later during adolescence. Seizures do not occur in series, and flexion of the entire body, tonic seizures, or absence seizures are never observed. Myoclonus is easily controlled by appropriate medical treatment but psychomotor development may be delayed; hence, the term "benign" is disputed.

Electrophysiologic Features

On EEG, myoclonus is accompanied by a discharge of bilateral spike-wave or polyspike-wave (Fig. 5) that sometimes occurs in rapid succession at more than 3 Hz. The background activity is normal for the child's age, and drowsiness and the early stage of sleep may activate bilateral spike-waves. Myoclonus of about 100 msec duration consists of symmetric, rostocaudal muscle activation, and a premyoclonus negative spike precedes a jerk by about 30 msec.

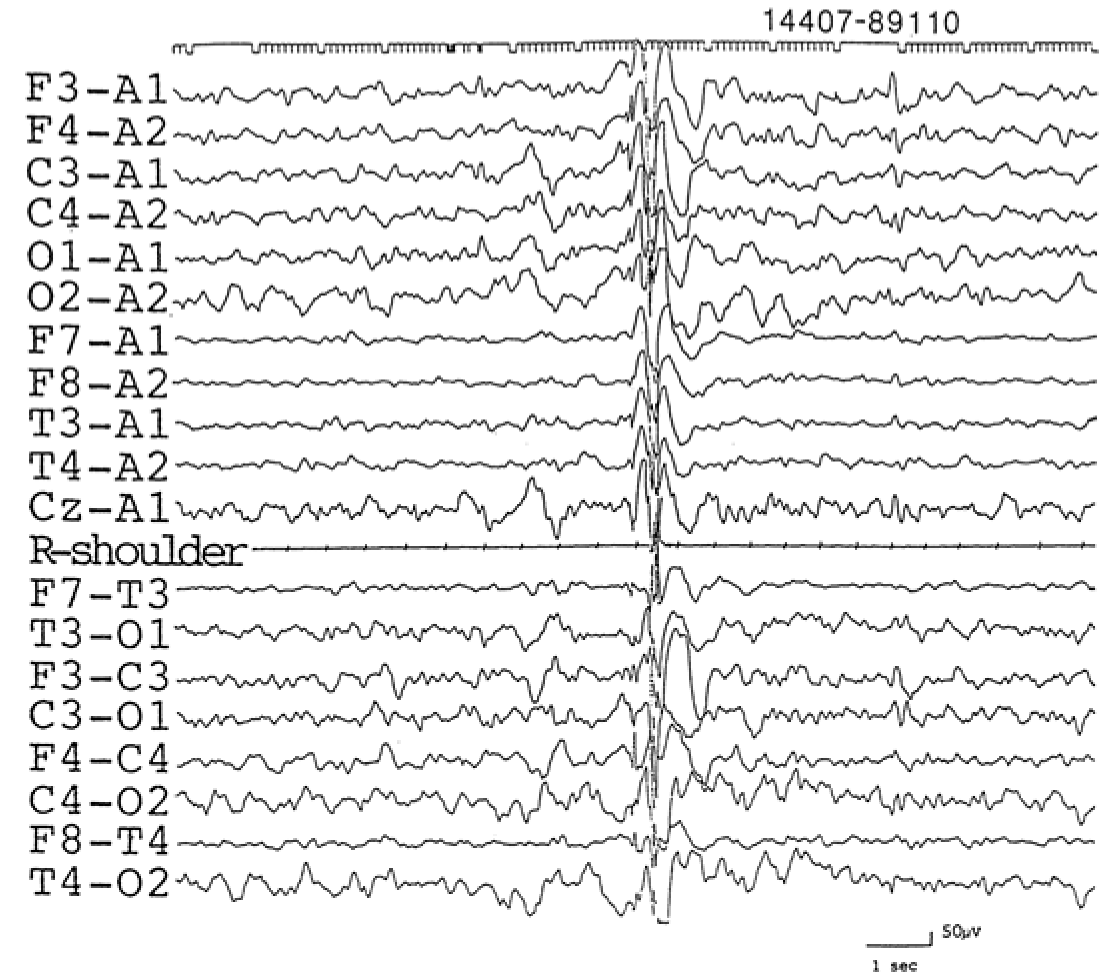

FIGURE 5. An EEG correlate of a myoclonus recorded in a boy, aged 2 years and 11 months, of benign myoclonic epilepsy in infancy. A brief burst of bisynchronous and symmetrical high-amplitude slow waves, maximal in the anterior head part and notched with small spikes, preceded the occurrence of

muscle potentials of the right shoulder. The boy experienced daily axial myoclonus accompanied with abduction of the upper extremities starting at age 2 years and 8 months.

Severe Myoclonic Epilepsy in Infancy (Dravet Syndrome)

Clinical Features

Dravet syndrome (see Chapter 230) is characterized by isolated or grouped axial-dominant bilateral myoclonus, which may lead to throwing of objects the child is holding and to falling. It is one of the typical features of severe myoclonic epilepsy in infancy. Symptoms appear between the ages of 2 and 5 years and occur very frequently, especially on awakening or in the hours preceding a major seizure. In the course of the disease, frequent, distally predominant and perioral erratic myoclonus that exists at rest but increases with movement may be seen, combined with drowsiness and drooling, in the context of nonconvulsive status epilepticus.

As a rule, this syndrome begins with a generalized or unilateral, often prolonged, febrile convulsive seizure before 1 year of age in normal infants.[33,34] The seizures consist of myoclonic, clonic, or clonic–tonic–clonic seizures, atypical absences—often with clonic components—and complex

partial seizures. The seizures are extremely difficult to control, but myoclonus decreases and may disappear in the long-term course. Psychomotor development is retarded from the second year of life onward. This is accompanied by neurologic signs such as ataxia and slight pyramidal signs.

Myoclonus may be induced by variations in illumination, closure of the eyes, and fixation on patterns that can produce an autostimulation phenomenon.

Electrophysiologic Features

Myoclonus is accompanied by a burst of bisynchronous spike-waves or multiple spike-waves (Fig. 6), and appears to originate from spread of cortical myoclonus, whereas distal erratic myoclonus is often without EEG correlates, even on JLA.[4,46] Photosensitivity, including pattern sensitivity, is rather common, and a photoconvulsive response may appear during the first 2 years of life—even as early as 4 or 5 months of age. The EEG background activity fluctuates, depending on the number and duration of the clinical seizure events. Paroxysmally, rhythmic θ-activity at 4 to 5 Hz appears in the centroparietal areas, as do fast bilateral spike-waves, which may be associated later with variable focal or multifocal abnormalities. This syndrome represents an epileptic encephalopathy with diffuse hyperexcitability of the brain, as revealed by sodium channel dysfunction.

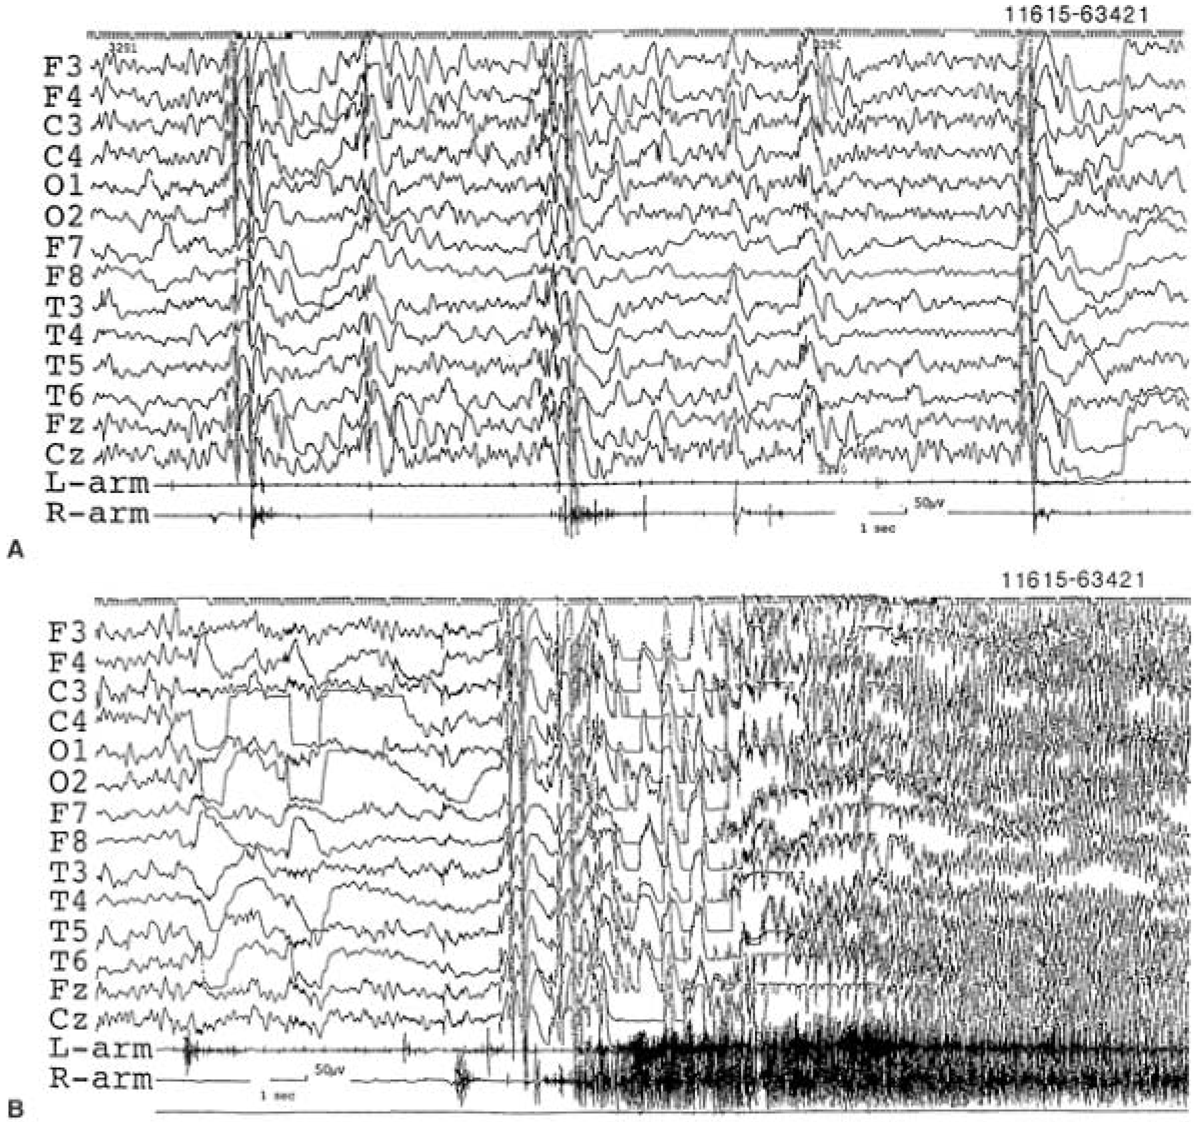

FIGURE 6. A: Frequent myoclonia shown as muscle potentials of arms concurrently occurring with bisynchronous and almost symmetrical polyspike-waves in EEG recorded in a 3-year-old boy. **B:** The myoclonus eventually cumulated into a generalized clonic–tonic–clonic seizure. He suffered from severe myoclonic epilepsy in infancy from 5 months of age on. Myoclonus became prominent from the age of 1 year and 2 months.

Lennox-Gastaut Syndrome

Clinical Features

This syndrome is discussed more completely in Chapter 241. The myoclonic jerks of LGS are generally bilateral and symmetrical (massive), commonly occur upon falling asleep and awakening, and lead preferentially to a flexion of the trunk and abduction of the arms. Bilateral myoclonus followed by an atonic state may lead to abrupt falling and injury, although injuries occur less frequently than in tonic falling.[62] In LGS, myoclonus is never the predominant symptom. Gastaut et al.[43] originally described the rarity of massive myoclonus. Rather, atypical absences and axial tonic seizures occur frequently and sometimes, in series, predominate. Aicardi[6] found that myoclonus was present in 11% to 28% of the patients with this syndrome. Those cases in which myoclonus is observed, called a myoclonic variant of LGS by some authors,[4,43] cannot be distinguished from myoclonic-astatic epilepsy (MAE);[68] (an unfavorable course in which the patients develop myoclonic status lasting several months and are left with tonic seizures in sleep). Indeed, the concept of myoclonic variant of LGS was developed before the nosology of MAE was clarified. The presence of myoclonus in LGS indicates some lesion in the rolandic cortex.[12]

This syndrome generally starts before the age of 8 years, with a peak between 3 and 5 years of age, in children with or

P.591

without neurologic antecedent. It is frequently followed by a disturbance of psychomotor development.

Electrophysiologic Features

The ictal EEG of the myoclonus consists of bilateral and symmetrical spikes or sharp waves of brief duration followed by one or several slow waves (Fig. 7). Bonanni et al.[12] reported that the epileptic myoclonus in LGS originates from a stable generator in the frontal cortex, with spread to contralateral and ipsilateral cortical areas. The background EEG is often slow and poorly structured, with bursts of diffuse slow spike-wave patterns of 2 to 2.5 Hz and runs of widespread rhythmic spike discharges at around 10 Hz during sleep. Multifocal spikes and spike-waves may also be recorded.

Epilepsy with Myoclonic-Astatic Seizures

Clinical Features

This recently identified condition is characterized by symmetrical brief jerking involving more proximal muscles, such as of the shoulders and arms; these are isolated or replicated in short series, often with nodding of the head, with or without a subsequent abrupt loss of muscle tone.[28,29] Violent jerks or jerks followed by atonia may lead to abrupt falling and subsequent injury. In severe cases, irregular twitching of the upper extremities and facial muscles, especially of the mouth and tongue, may occur. In rare cases, photostimuli precipitate the myoclonus. Myoclonus may appear in a status form with focal erratic jerks on distal and facial muscles. Other seizure types occurring in this syndrome are atonic seizures, short absences, and febrile and afebrile generalized tonic–clonic seizures.

This syndrome starts mostly between 2 and 5 years of age, in normal children with a high incidence of seizures and/or abnormal EEGs in relatives. For further information, see Chapter 232.

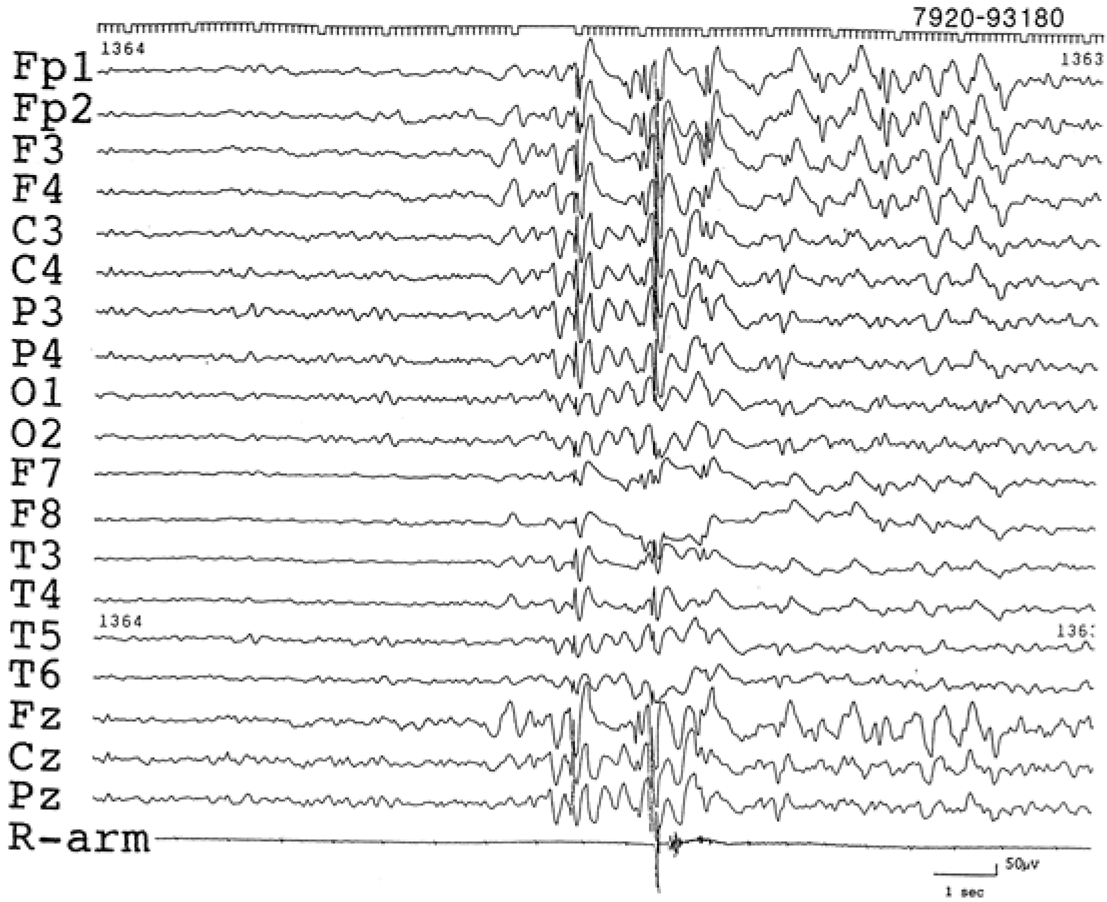

FIGURE 7. A 16-year-old patient suffering from Lennox-Gastaut syndrome. Seizures consisted of tonic seizures with or without falling, atypical absences, generalized tonic–clonic seizures, and myoclonus since the age of 4 years and 3 months. The EEG findings were recurrent bursts of bilateral diffuse spike-waves of 2.5 to 3 Hz, high-voltage waves of about 4 Hz, polyspike-waves, and diffuse fast spike rhythms. The figure represents an axial myoclonus occurring many times a day.

Electrophysiologic Features

The ictal EEG typically shows short paroxysms of bilateral synchronous spike-waves and polyspike-waves (Fig. 8) with an interside latency of 2 to 4 msec.[12] The myoclonus has a duration

P.592

of <100 msec, is synchronous on both sides of the body, and time-locked to the negative EEG potential, with a mean latency of around 30 msec. The erratic myoclonus during the status could be of cortical origin, according to JLA,[51] although it is difficult to conceive that the same patient starts with thalamo-cortical myoclonus, then develops cortical myoclonus. This contrast illustrates the difficulties in identifying the determinants of myoclonus based on neurophysiologic studies. The interictal EEG pattern may vary according to seizure type in that, in cases with mainly astatic seizures, irregular 2- to 3-Hz spike-waves predominate. The presence of the interictal θ-rhythm over the centroparietal areas is a feature of this syndrome.

Epilepsy with Myoclonic Absences

Clinical Features

The distinct feature of this syndrome is the rhythmic bilateral myoclonus mainly involving the muscles of shoulders, arms, and legs, associated with a mild axial tonic contraction that results in progressive elevation of the upper extremities (15 and Chapter 240). When the face is involved, myoclonus is more evident around the chin and mouth. Consciousness is cloudy, but not completely interrupted. Falling is uncommon, but a backward or forward oscillation is frequently seen. The duration of myoclonic absence ranges from 10 to 60 seconds, slightly longer than usual absence, and the seizure occurs many times daily. Other types of seizures are rare. The seizure onset is around 7 years of age.

Electrophysiologic Features

The ictal EEG consists of rhythmic, bilateral, synchronous, and symmetric spike-waves at 3 Hz. The onset and end of the discharges are usually abrupt. Myoclonus appears at the same frequency as the spike-waves, and later accompanies a tonic contraction that is maximal on the shoulder and deltoid muscles and responsible for the elevation of the arms. Each spike is followed by a myoclonus with a latency of 15 to 40 msec (proximal muscles).[15] Interictal EEG may show generalized or, rarely, focal spike-waves.

Myoclonic Epilepsies of Late Childhood and Adolescence

The best-known epileptic syndrome belonging to this age group is JME. Other forms of idiopathic generalized epilepsy, such as juvenile absence epilepsy and epilepsy with GTCs on awakening, may also display myoclonus, but far less often. Patients with myoclonus induced by photic stimulation in the environment or laboratory are also discussed in this section, although some of them have onsets in earlier childhood.

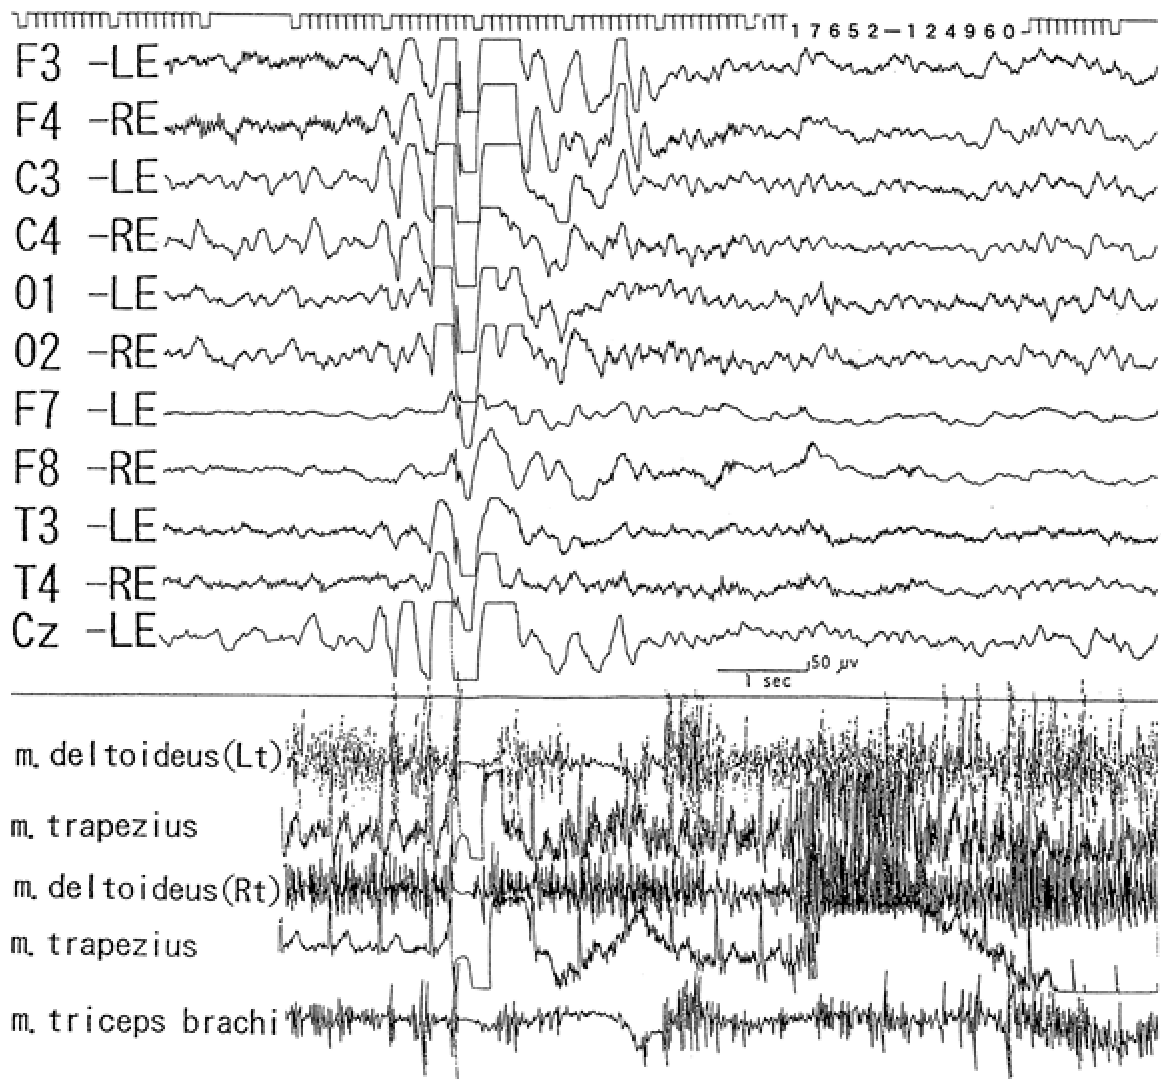

FIGURE 8. A myoclonus immediately followed by a brief atonia leading to a fall, recorded at the age of 2 years and 8 months in a boy with myoclonic-astatic seizures of Doose. Myoclonus precipitated by a high fever began at the age of 2 years. At age 2 years and 7 months, astatic seizures that consisted of either

myoclono-atonia or atonia started in addition to GTCs and absences. The interictal EEG showed an irregular slow background activity of 4 to 6 Hz and paroxysms of bisynchronous high-amplitude slow waves.

Juvenile Myoclonic Epilepsy (Janz Syndrome)

Clinical Features

A complete discussion of JME can be found in Chapter 244. The cardinal symptom of JME, the myoclonus, is characterized by very short, bilateral, symmetrical, and synchronous

P.593

jerks affecting mainly the shoulders and arms. The jerks may occur singly or in close succession in clusters at irregular intervals; they may vary in frequency and intensity. They are sometimes perceived only inwardly, as a mild electrical shock, but may also lead to such violent movements that the patient may throw down things he is holding. Because the jerks occur preferentially after waking, irrespective of whether the patient has risen or is still lying in bed, the objects thrown are usually those connected with the patient's morning toilet or breakfast. If the jerks are violent, the patient may drop to his knees or, in rare cases, may fall, but stand again immediately. In some cases, the jerks occur only in one arm and, in rare cases, the jerks are both monolateral and bilateral. Occasionally, especially if the patient continues activities and does not lie down immediately, the jerks may occur in a protracted series or may lead to a true myoclonic status. A status of this sort is reminiscent of a chorea, with more or less violent jerks at irregular intervals. The series and status usually end in a GTC. Unlike absences, the jerks occur while the patient is fully conscious. Only a sharp knock may cause the patient to appear momentarily "in a fog" or briefly "miles away."

Myoclonus produces contractions of synergistic groups of muscles, with the effect of moving entire limbs. Janz and Christian[67] opted for the purely descriptive name of *impulsive petit mal* for these jerks, harking back historically to Herpin.[59]

The seizures are precipitated by sleep withdrawal and most commonly occur shortly after awakening. According to Touchon,[114] half the patients he observed had manifestation peaks after awakening in the morning, and one third at nocturnal awakening. Some peaks were in the evening relaxation period and during sleep. Some patients report seizure precipitation by intermittent light stimuli. Occasionally, the jerks can be reflectively induced by mental activities connected with manual movements, psychic tension, and decision-making (praxis induction). Even the ideation of action can induce the jerks.[64] Frequent seizure occurrence while using a toothbrush or handling a table knife or a fork might indicate a seizure induction by such actions that could be in line with the praxis. Matsuoka et al.[77] pointed out the usefulness of "neuropsychological EEG activation." Mayer et al.[78] reported perioral (mostly single, lightning-like oro-linguo-facial) myoclonus induced by talking, which is often underestimated in patients with JME.

Additional generalized tonic–clonic seizures often occur, less often absences, usually of infrequent repetition. Onset of the seizures is pre- to postpuberty. The response to appropriate

P.594

antiepileptic drugs (AEDs) is good, but relapse after discontinuation of therapy is high.[65]

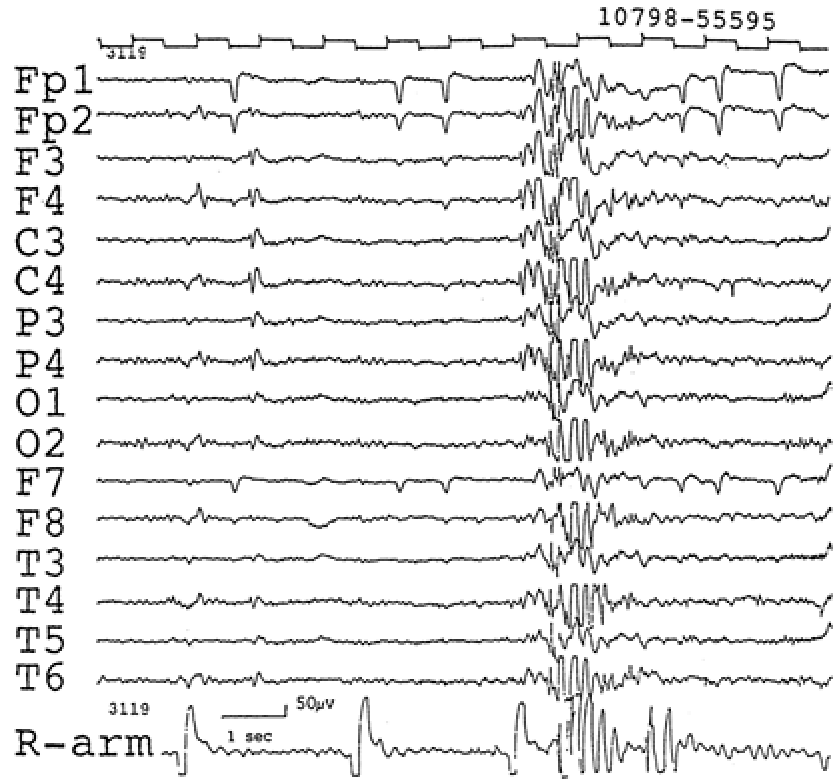

FIGURE 9. Myoclonus of a 47-year-old patient with JME. The seizures occurred predominantly on awakening, but were also provoked when practicing tasks requiring complex mental and manual activities.

Electrophysiologic Features

The characteristic EEG of jerks in JME is bilaterally symmetrical, frontocentrally accentuated polyspike-waves, with the number of spikes ranging from 5 to 20 (Fig. 9). A burst of spikes suddenly occurs with the jerks and is followed by slow waves of varying frequency of 10 to 16 Hz. Interictal polyspike-wave patterns usually display fewer spikes and are often restricted to the frontal leads. Usui et al.[117] found focal clinical or EEG features or both in a substantial number of patients with JME. In 14% of patients with JME, giant SEP were observed.[96] Panzica et al.[89] investigated the myoclonus of JME with JLA, and concluded that the ultimate mechanism responsible for myoclonus is largely similar to the cortical myoclonus in PME.

Myoclonic Epilepsies of Non–Age-Related and Special Conditions

The progressive myoclonus epilepsies (PME) and benign adult familial myoclonic epilepsy (BAFME) are included within this group. In Creutzfeldt-Jakob disease and subacute sclerosing panencephalitis, the duration of the jerks is clearly over 100 msec, and they do not therefore correspond to myoclonus *stricto sensu.* Metabolic diseases (e.g., hepatic encephalopathy, uremia, Hashimoto encephalopathy, drug-induced encephalopathy, toxic encephalopathy, and so on) and cortico-basal degeneration sometimes show jerks, the characteristics of which are often not determined precisely; generalized tonic–clonic seizure is not a typical feature.

Progressive Myoclonus Epilepsy

Clinical Features

PME is commonly hereditary and characterized by myoclonus and generalized convulsions. Patients with PME frequently demonstrate cerebellar ataxia, mental deterioration, pyramidal signs, and rigidity. These symptoms start in late childhood or adolescence, progress slowly, and are fatal in many instances. This category comprises different forms such as Unverricht-Lundborg disease, Lafora disease, myoclonic epilepsy with ragged red fibers, neuronal ceroidlipofuscinosis, sialidosis, and dentatorubral-pallidoluysian atrophy. The clinical picture involves a combination of parcellar or segmental, arrhythmic, asynchronous, asymmetric myoclonus, and massive myoclonus. The myoclonus is often precipitated by action, posturing, or various sensory stimuli. A long build-up of myoclonus may culminate in a tonic–clonic seizure.

Other seizure types, including tonic–clonic, clonic, absence, and focal seizures, as well as their intensity, vary depending on the etiology.

Electrophysiologic Features

The EEG shows generalized polyspikes and spike-waves, frequently induced by photic stimulation. The background EEG activity becomes progressively slower. Giant SEP, C-reflex at rest, and premyoclonus spike are often observed, indicating the underlying mechanisms of cortical reflex myoclonus. However, because the findings may differ among various types of PME, the other mechanisms could overlay it.

Benign Adult Familial Myoclonic Epilepsy

Clinical Features

In patients with familial cortical reflex myoclonus, some demonstrate rare epileptic seizures, but do not present with the ataxia, mental deterioration, or progression seen in PME. Clinical symptoms start between 18 and 64 years. Family history indicates autosomal dominant traits. Magnetic resonance imaging (MRI) results are usually normal. Many reports come from Japan, and the terms *cortical tremor,*[60] *familial essential myoclonus and epilepsy*,[63] *familial benign myoclonus epilepsy of adult onset*,[86] *familial cortical myoclonic tremor*,[111] and *familial cortical myoclonic tremor with*

epilepsy[118] were used in addition to the term benign adult familial myoclonic epilepsy.[120] A similar disease was reported from Europe as *autosomal dominant cortical myoclonus and epilepsy* (ADCME).[47] However, patients with ADCME have mental retardation and partial seizures, which are not typically seen in patients with BAFME. Linkage analysis demonstrated a map on chromosome 8q23.3–q24.1 in Japanese (BAFME) and on 2p11.1–2q12.2 in European pedigrees (ADCME). Negative linkage analyses also were reported in BAFME;[26,37,71] this syndrome therefore may be hetero- geneous.

Electrophysiologic Features

The background EEG is normal. Generalized polyspikes and spike-waves may be demonstrated, frequently induced by photic stimulation. Giant SEP, C-reflex at rest, and premyoclonus spike are often observed.

Delineation from Other Seizure Types

The delineation of myoclonus from other types of seizures is sometimes difficult. Tonic seizures characterized by more or less sustained increased muscle tone and atonic seizures characterized by sudden loss of axial (or appendicular) muscle tone can be easily confused with myoclonus, especially when the seizures are short and abrupt. However, the EEG pattern is entirely different: In tonic seizures, commonly a synchronous recruiting activity occurs before any spike-and-wave activity develops. Polygraphic recording helps to sort out the differences. Myoclonus is manifested as biphasic or polyphasic EMG potentials of 20- to 100-msec duration, whereas tonic seizure indicates an inferential muscle discharge of longer duration that may be of crescendo pattern at onset, similar to that in voluntary contraction. During atonic seizures, EMG shows suppression of normal tonic activity in the involved muscles. Myoclonus may be followed by sustained residual tonic contractions or by a brief period of inhibition of muscle tone that may be sufficient to produce head nodding or even a fall. Episodes of myoclonus may be preceded by a tonic seizure.

Confusion of myoclonus with epileptic spasms is possible on clinical grounds, and the distinction may require video-EEG recording. Particularly in early infancy, the distinction between early epileptic encephalopathy and neonatal myoclonic encephalopathy may be a challenge that has etiologic and therapeutic implications.

Etiologic and neurobehavioral correlates, and their responses to AEDs, are also of importance for differentiation.

Subcortical negative myoclonus is usually characterized by rhythmic, EMG silent periods occurring at a rate of 6 to 11 Hz, without any detectable EEG correlate, even by using the technique of silent period-locked averaging. Early cortical components of SEPs are not enhanced.[100] The subcortical NM may appear as a bilateral, although not perfectly synchronous, phenomenon, affecting both hands. NM in toxic-metabolic encephalopathies—that is, "asterixis" —displays the characteristics of subcortical NM, although, in some cases, the demonstration of a cortical correlate by means of averaging the EMG–EEG signal[2,8,115] and the evidence of giant SEPs and a C-reflex[113] support a cortical origin. Finally, subcortical NM has been obtained through electrical stimulation of the human internal capsule.[87]

Negative Myoclonus

The first description of sudden, irregular lapses interrupting a tonic contraction dates back to 1949, when Adams and Foley[1] used the term "asterixis" to describe the brief, involuntary jerky movements on the maintenance of posture that occurred in patients suffering from hepatic encephalopathy. In 1963, Lance and Adams[72] reported lapses of postural control in the postanoxic intention myoclonus syndrome as a result of a muscular silent period (SP), whether preceded by myoclonus or not, in relation to a spike-and-slow-wave complex. Periods of muscular inhibition, strictly and only related to a diffuse or focal spike, without preceding myoclonia, were defined as "spike-related epileptic silent periods."[105,107] The term "*negative myoclonus*" was introduced by Shahani and Young in 1976;[99] they analyzed the clinical and EMG characteristics of posthypoxic intention myoclonus and asterixis, and concluded that "because these synchronous brief pauses, which occur at irregular intervals in the ongoing voluntary EMG activity, produce movements that appear clinically to be myoclonic, one may characterize this as *'negative myoclonus.'"* Indeed, at present, NM encompasses all the above-mentioned phenomena, and is extended to define any brief, jerky interruption of tonic muscular activity that causes a sudden postural lapse.

NM is a nonspecific motor disorder that can be observed in a variety of physiologic as well as pathologic conditions. NM of epileptic nature, such as *epileptic negative myoclonus* (ENM)[49,106,108] identifies an interruption of tonic muscular activity, time-locked to a spike on the EEG, without evidence of an antecedent myoclonus. Recently, the Task Force of the International League Against Epilepsy on Classification and Terminology has recognized NM as a seizure type,[38] defining it as an "interruption of tonic muscular activity for < 500 msec without evidence of preceding myoclonia."[11]

Clinical Manifestations

NM appears as a shock-like involuntary jerky movement caused by a sudden brief interruption of muscular activity. As proposed by Young and Shahani,[121] "asterixis" is a type of NM that occurs typically in toxic-metabolic encephalopathies, often associated with reduced alertness; it can also be observed during the recovery phase following general anesthesia with sedative drugs. Obeso et al.[83] considered as a separate form of NM the *postural lapses* that can be observed in posthypoxic action myoclonus, characterized by interruptions of the tonic muscular activity of postural muscles (neck, trunk, proximal leg muscles) lasting 200 to 500 msec, and usually following a myoclonic potential.[72] A similar phenomenon can be observed also in other diseases such as progressive myoclonus epilepsies (Lafora disease, Unverricht-Lundborg syndrome), torsion dystonia, cerebellar ataxia, and Huntington disease. In these conditions, a combination of positive myoclonus and NM can often be observed; however, NM seems to be the most disabling disturbance, significantly affecting the ability to stand or walk.

In epileptic patients, ENM can be either unilateral or bilateral.[108] In some instances, this disorder can be a clinically very mild or almost undetectable motor event, giving rise to an "instability." More often, ENM can cause dropping of objects from the hands, "tremulousness" of a limb with difficulties in writing and feeding, head nodding or, at times, gait instability and falls.[20,24] Despite the relatively short duration, ENM can be so frequent as to lead to a severe motor disturbance resembling motor neglect of the affected arm. Capovilla et al.[17] reported two children suffering from partial benign epilepsy and presenting with sudden falls and episodes of fecal incontinence related to ENM in one lower limb and the pelvic floor muscles.

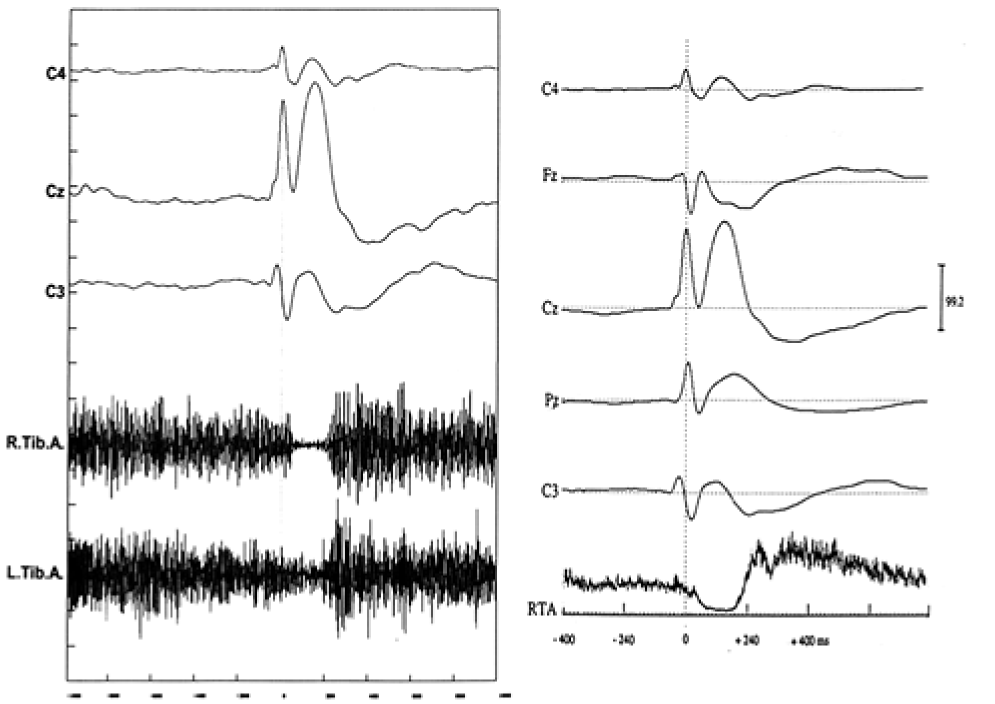

FIGURE 10. Epileptic negative myoclonus (ENM) in a child with idiopathic partial epilepsy. *Left panel*: A spike-and-wave complex on Cz is associated with a brief interruption in a tonic contraction in the right tibialis anterior. *Right panel*: Average of 20 spike-complexes, triggered from the peak of the spike, showing that the muscular suppression of ENM is not preceded by a positive myoclonia; moreover, the onset of the EMG SP precedes the onset of the slow wave in Cz.

Syndromes and Diseases in Which ENM Occurs

ENM is a nonspecific motor disorder that can be observed in a wide variety of epileptic conditions. It is classified according to etiologic criteria as idiopathic, symptomatic, or cryptogenic.[108] In the idiopathic form, it is usually detected in children suffering from partial epilepsy of childhood (including benign epilepsy with rolandic spikes).[16,17,24,69,84,85,108] ENM as an isolated

clinical manifestation has never been reported; seizures associated with ENM can be partial motor (often of the rolandic type), absences, or atonic. The evolution of both ENM and epilepsy in this group of patients is usually benign. In the pediatric group, ENM can be observed in the *epileptic encephalopathy with electrical status epilepticus during sleep* or ESES syndrome. In this condition, ENM is associated with various seizure types and impairment of higher functions, such as language regression, behavioral disturbances, and ataxia.[110] The mechanism of drop attacks may be challenging, especially if masked by benzodiazepines.[9] Gambardella et al.[41] described a patient with photic-induced negative myoclonus suffering from a form of idiopathic generalized epilepsy.

ENM can occur in pediatric as well as adult patients in symptomatic epileptic conditions such as mitochondrial diseases, birth anoxia, vascular malformations, progressive myoclonus epilepsies, epileptic encephalopathies, and neuronal migration disorders. Seizure types associated with ENM in these epileptic conditions can vary from simple to complex partial seizures, tonic seizures, spasms, and generalized tonic–clonic seizures. Occurrence of ENM in a newborn with Ohtahara syndrome and hemimegalencephaly has been recently reported.[52]

Finally, NM is not infrequently induced as the side effect of various anticonvulsive drugs.

Pathophysiology

Classifications based on the possible site of the generator have distinguished *subcortical* and *cortical*

NM.[83,100,109] Focal NM has been observed in patients presenting with focal brain lesions involving subcortical structures such as thalamus, internal capsule, midbrain, and pons, and cortical structures such as the parietal lobe and medial frontal cortex.[13,25,70,88,91,121]

In cortical NM, EMG SPs are usually longer in duration (100–400 msec) as compared to subcortical myoclonus; the resulting falls are “progressive” and rarely responsible for any injury. Cortical NM of epileptic nature (i.e., ENM) is associated with an EEG event such as an epileptic spike[49,105,108] or a low-amplitude EEG transient.[108] Tassinari et al.[105,107] showed that the onset of the EMG SP was related to a negative component of the spike on the EEG, occurring before the slow-wave (Fig. 10). The fact that NM can be evoked by intracranial cortical stimulation using single electric pulses lends support to the hypothesis of a NM related only to a spike event.[95] The involvement of cortical mechanisms has been clearly demonstrated in cortical reflex negative myoclonus, described by Shibasaki et al.[103] in progressive myoclonus epilepsies. In these patients, electrical stimulation of the median nerve during sustained tonic contraction caused a postural lapse at the wrists, with an EMG SP ranging from 100 to 400 msec. A C-reflex could precede this stimulus-induced NM. The occurrence of an induced EMG SP and giant SEPs were significantly correlated. Furthermore, recovery of function of the N33 component was slow and similar to the duration of the induced EMG SP. Summarizing this evidence, the authors concluded that this form of stimulus-induced NM occurred via a transcortical reflex mechanism, hence the definition of “cortical reflex negative myoclonus.” Shibasaki[101] hypothesized that the generation of ENM requires an enhanced inhibitory activity in the primary motor cortex. Excessive inputs into the motor cortex, as may occur following spontaneous epileptic activity in the premotor or postcentral areas, or due to enhanced excitability of the sensory cortex, can activate the already hyperactive inhibitory motor system, thus suppressing the cortico-spinal volley to the spinal motoneurons and producing the EMG SP that results in clinical NM. The hypothesis of cortical inhibitory mechanisms mediating ENM was further supported by the inability of transcranial magnetic stimulation to elicit a motor evoked potential when magnetic stimuli were delivered during the EMG SP of ENM.[108] Preserved spinal excitability in ENM was demonstrated by recording normal F waves during the period of muscular inhibition.[108]

It is also possible that some NM might be caused by excessive excitation of a group of cortical neurons that activate inhibitory interneurons at the spinal level.

Rubboli et al.[95] described a frontal EEG potential encompassed in spikes and associated with ENM preceding the onset of the interruption of the tonic muscular activity. Baumgartner et al.,[10] by combined use of EEG and single photon emission computed tomography (SPECT)-MRI coregistration, and Meletti et al.[80] provided further evidence supporting a role for frontal cortical regions in the generation of ENM. These findings may be supported by intracerebral

electrical stimulation results in epileptic patients demonstrating the existence, in the lateral and mesial aspects of the frontal lobes, of cortical areas whose activation can produce motor inhibition.[74,75] The involvement of postcentral parietal areas has been suggested by Noachtar et al.,[82] who showed the association of epileptic spikes in the postcentral cortex, recorded by subdural grids, with ENM in the contralateral upper limb.

The role of premotor cortex, primary motor and somatosensory cortex, and supplementary motor area in the generation of NM was investigated by means of single-pulse intracerebral electrical stimulation.[61,93] In particular, Rubboli et al.[93] observed that NM could be obtained by stimulating all these cortical areas; however, its occurrence by activation of premotor, primary motor, and primary somatosensory cortex depended on the intensity of stimulation—NM could be observed mainly at low stimulus intensity, whereas higher stimulation evoked a motor evoked potential followed by a SP. On the contrary, supplementary motor area stimulation induced only NM regardless of stimulus intensity.

Hypotheses suggesting that positive myoclonus and NM are two distinct motor events (with positive myoclonus requiring the involvement of the primary motor cortex and NM depending on the activation of cortical inhibitory areas), or two aspects of the same phenomenon (both resulting from an altered sensory-motor cortex output producing different degrees of positive or negative effects on the motor system) have been proposed.[113] It might be that both phenomena are associated more often than expected: Indeed, for NM to become apparent, a tonic contraction is required that could masquerade a preceding or following muscular burst; on the other hand, a myoclonic jerk at rest can be easily appreciated, whereas an associated SP would not be observable due to the lack of muscular tone.

This concept of a cortical inhibitory area is unlikely to apply to all types of NM. Indeed, in idiopathic focal epilepsy that never undergoes intracranial recordings, video-polygraphic recordings show the strict correspondence of the myoclonus and the slow wave of the spike-wave complex.[39] The corresponding clinical condition often comprises continuous spike waves in slow sleep (CSWS). It is remarkable that, in symptomatic conditions with CSWS, a series has highlighted the frequency of thalamic lesions,[53] a remarkable feature related to the frequent effect of ethosuximide.

Diagnosis

The incidence and prevalence of ENM are underestimated because this sometimes mild and transitory disorder often is overlooked. Polygraphic recording is the essential neurophysiologic tool used to define ENM. Only simultaneous EEG-EMG monitoring, recording activity from the agonist and antagonist muscles of the body segment affected by ENM, can allow the diagnosis of this motor disturbance by showing a brief interruption of a tonic EMG activity not preceded by a positive myoclonus.

The clinical features of NM—a sudden involuntary jerk—may make it difficult to distinguish from positive myoclonus. In addition, in certain conditions, both disorders are commonly observed in the same patient. It must be pointed out that to unveil NM, a tonic contraction of the affected muscle is necessary; the diagnosis of NM requires the exclusion of a positive myoclonus preceding the onset of the EMG SP.

NM can occur in a continuous fashion, rhythmic or arrhythmic, as soon as the patient maintains a posture: In this case, the affected limbs look "tremulous." Depending on the frequency of this "tremulousness," it may be difficult to differentiate it from true tremor. In NM, polygraphic recording demonstrates the simultaneous interruption of EMG activity in agonist and antagonist muscles, whereas in tremor, the muscular contractions in the two muscular groups tend to occur in an alternate fashion.

In epileptic patients, sudden postural lapses leading to a fall may be caused by ENM involving axial and leg muscu- lature.[17,94,101]

Responses to Medical Treatment

The drugs used to treat conditions with myoclonus include valproic acid (VPA), benzodiazepines, piracetam, levetiracetam (LEV), phenobarbital or primidone, acetazolamide, ethosuximide (ESM), topiramate (TPM), and zonisamide (ZNS).

VPA is the drug of choice in many conditions with myoclonus. In patients with epilepsy with myoclonic-astatic seizures and with a syndrome of myoclonic absences, ESM or benzodiazepines may be added to VPA. Stiripentol or TPM may be used in combination with VPA and clobazam in Dravet syndrome, although bromide or a ketogenic diet may also be instituted.[97] LEV, benzodiazepines, TPM, or ZNS can be used in JME instead of, or in addition to, VPA, although benzodiazepines may not reduce GTCs.[79] ENM may be successfully treated by ESM.[16,85] In progressive myoclonus epilepsy, in addition to medical treatment using conventional or newer antiepileptic agents such as VPA, benzodiazepines, piracetam, phenobarbital, LEV, or ZNS, various other treatments may be applied according to the etiology.

Some drugs may aggravate myoclonus, such as carbamazepine, oxcarbazepine, phenytoin, gabapentin, vigabatrin, and tiagabin.[98] Lamotrigine should be used with caution because, in high doses, it may initiate myoclonus or even myoclonic status, particularly in Dravet syndrome.[50] The inhibition of carnitine uptake when using VPA should be taken into account in the treatment of progressive myoclonus epilepsy with ragged red fibers.

Summary and Conclusions

Myoclonus is characterized by coordinated or synergic movements of the limbs or the trunk. It is an involuntary, quick, and often arrhythmic positive or negative movement. It typically presents spike- or polyspike-wave patterns in EEG and short bursts or interruptions of synchronized activity involving both agonist and antagonist muscles in EMG.

Differentiation of myoclonus from other seizure types such as brief tonic seizures and atonic seizures and from brisk non- epileptic movements associated with physiologic or pathologic conditions requires a knowledge of clinical, etiologic, and electrophysiological contexts.

Chapter 51

Atonic and Myoclonic–Atonic Seizures

Carlo Alberto Tassinari

Roberto Michelucci

Hideo Shigematsu

Masakazu Seino

Introduction

Atonic and myoclonic–atonic seizures represent specific seizure types whose definition implies a characteristic physiopathologic mechanism and a well-defined electro-clinical pattern that may be demonstrated only by polygraphic and video-polygraphic recording. Therefore, these seizures cannot be diagnosed only on the basis of the clinical history, which may usually reveal recurrent "falling" seizures, associated or not with minor motor events. Falling seizures, otherwise termed *epileptic drop-attacks* or *astatic seizures,*[5] are a heterogeneous group of epileptic seizures in which the fall represents the main or only clinical feature, with no major motor phenomena (e.g., convulsions) occurring.[58,82] Falling seizures may represent a variety of seizure types (either generalized or focal) and mechanisms, including widespread myoclonic jerks, tonic contraction, pure atonic events, or the combinations of motor phenomena, as in the case of myoclonic–astatic seizures. These observations may explain the controversies in the terminology of epileptic falls and the high number of terms used in the past (akinetic, atonic, astatic, static, drop, apoplectic, inhibitory).

Atonic and myoclonic–atonic seizures are usually classified among generalized seizure types.[24] However ictal atonic events may be also recognized in focal seizures, such as drop-attacks of frontoparietal origin,[75] focal inhibitory seizures,[39] and negative myoclonus.[84,85]

History

Seizures characterized by a sudden fall have been known for a long time. Apart from early clinical notes by Tissot and Newman dating back to the 18th and 19th centuries, respectively, the first detailed description of atonic seizures was given by Hunt in 1922, who called the condition "static epilepsy"—that is, a "form of epilepsy characterized by sudden losses of postural control."[40] In 1945, Lennox proposed the term *akinetic seizures* for attacks of this type, which he rebaptized *astatic* in 1951.[47,48] These seizures were considered to belong to the electro-clinical group of petit mal absences: Lennox suggested the term *petit mal triad* to include absences, myoclonic jerks, and akinetic attacks.[49] In 1966, Gastaut et al.[29] described the *Lennox-Gastaut syndrome*, in which falling seizures were a characteristic seizure type, and also reported a few cases of polygraphically studied atonic seizures.[30] In the same years, there was the first polygraphic demonstration of a specific seizure type with a combination of myoclonus preceding atonia, which was termed *myoclonic–astatic* seizure by Kruse.[42] In 1981, the Commission on Terminology and Classification of the International League Against Epilepsy (ILAE) established the term *atonic seizure* for falling attacks with loss of tone.[11] Last, in 2001, the Task Force on classification and terminology of the ILAE included atonic seizures and myoclonic–atonic seizures within an accepted list of generalized seizures.[24]

Definitions

Atonic seizures are currently defined as epileptic attacks characterized by a sudden loss or diminution of muscle tone, which may be confined to a segment (limb, jaw, head), or involve all postural muscles, leading to a slumping to the ground.[5,11,28] In atonic seizures, the loss or diminution of muscle tone is "pure," without apparent preceding myoclonic or tonic events.[5]

Myoclonic–atonic seizures may be defined as epileptic attacks in which the atonia is preceded by a myoclonic jerk (i.e., a sudden and brief—<100 msec—involuntary contraction of muscle groups of variable topography).[5]

In the recent glossary of descriptive terminology for ictal semiology,[5] it has been also stated that "falling seizures" are better termed *astatic*, this term implying "loss of erect posture that results from atonic, myoclonic or tonic mechanism"; drop attack would be a synonym.

Epidemiology

Because of controversies in terminology and the need of a polygraphic recording to perform a reliable diagnosis, exact figures for the incidence of these seizure types are not available. Atonic seizures have been quoted to occur in at least 50% of cases of Lennox-Gastaut syndrome and probably in 2% to 3% of an epileptic population.[60] However the introduction of video-polygraphic systems in the analysis of "astatic" seizures has clarified that seizures characterized by pure diminution or loss of tone (atonic seizures) are distinctly rare, accounting for only a minority of epileptic drop attacks. Gastaut et al.[30] found atonic seizures only in 3 out of 2,000 epileptic patients followed at the Centre St. Paul in Marseille. Myoclonic astatic seizures are likely to reflect the prevalence of myoclonic–astatic epilepsy, accounting for 1% to 2% of all childhood epilepsies.[17]

Anatomic pathways and pathophysiology

Because of the variety of seizures featuring atonia as the main clinical and polygraphic event, it is likely that different mechanisms are implicated, involving cortical and subcortical structures.

Gastaut and Broughton[27] considered "epileptic drop attacks" to be related to very brief but intense inhibitory mechanisms, suggesting the importance of motor cortex participation. Data from electrical stimulation of human cerebral cortex reveal the existence of frontal regions whose activation produces inhibition of voluntary movement.[52,53,54] These regions, defined as "negative motor areas", have been localized in the superior bank of the sylvian fissure near the

P.602

rolandic representation of the face ("primary negative motor area")[52,70] and in the rostral portion of the supplementary motor area (SMA), in a region immediately anterior to the primary motor cortex ("supplementary negative motor area").[50] The importance of these cortical inhibitory areas is well established in the genesis of focal atonic seizures and negative myoclonus[72,76,84] but is only presumed in the origin of atonic falling seizures.[75] An alternative explanation is that epileptic discharges in the primary sensorimotor cortex can produce negative motor phenomena via direct inhibition of the spinal motoneuron pool, as suggested in humans by means of direct cortical stimulation through subdural electrodes[36] or ictal electrocorticogram.[55]

Gloor[32] stressed the importance of recurrent cortical inhibition (mediated via the thalamocortical volleys) leading to interference with cortical function during the spike-and-wave discharges (SWDs) of absence seizures. Oguni et al.[64] suggested that atonic seizures associated with generalized SWDs may have a neurophysiologic mechanism in common with absence seizures, with the atonic phenomenon being only the expression of a stronger disruption of cortical activity.

The good results of callosotomy in the treatment of epileptic drop attacks in the context of partial epilepsies suggest that bilateral synchronization of the epileptic discharge via the corpus callosum is a crucial mechanism.[65] Whether this may lead to a bilateral activation of inhibitory cortical areas or of cortical regions projecting downward to brainstem structures is not known.

The brainstem has also been considered to play a role in the origin of atonic seizures, both generalized and partial.[10,23,41,89] In the brainstem, the direct or indirect (via the corticoreticular efferents) activation of the pontomedullary reticular formation, which is responsible for atonia or inability to move in rapid eye movement (REM) sleep and in cataplexy, could produce a motor inhibition and underlie atonic seizures.[44]

Electroclinical features

Atonic and myoclonic–atonic seizures have been mostly documented in large clinical series of generalized epilepsies of infancy, such as Lennox-Gastaut syndrome or myoclonic astatic epilepsy.

Gastaut et al.[30] studied the electroclinical features of 300 "*effondrements epileptique*" by using video-polygraphic methods in three young patients with Lennox-Gastaut syndrome. Egli et al.[23] recorded 239 "drop seizures" both by radiotelemetered electroencephalographic (EEG) split-screen videotaping and polygraphically in 45 patients suffering from "secondary generalized epilepsy."

Similarly, Ikeno et al.[37] recorded 48 epileptic falls in 15 children, captured by a self-tracking video monitoring system. Oguni et al.[62] studied 36 drop seizures in five patients with myoclonic–astatic epilepsy of early childhood with simultaneous split-screen video recording and polygraph. By using the same technique, Yaqub[90] also recorded falling seizures in 21 patients with Lennox-Gastaut syndrome.

Dravet et al.[20] reported the various types of epileptic drop attacks in eight children whose seizures were recorded by polygraphy and simultaneous video.

Oguni et al.[63] described the video-EEG (V-EEG) and video-polygraphic findings of myoclonic, atonic, and myoclonic–atonic seizures in 30 children with myoclonic–astatic epilepsy.

The analysis of these studies has clarified some of the complexities of the falling or astatic seizures, which have been found to encompass four different seizure types: pure atonic seizures, myoclonic–atonic seizures, myoclonic seizures, and tonic seizures (including axial spasms).[77,82].

Moreover atonic seizures may have a generalized or focal origin.

Generalized Atonic Seizures

Clinical Features

Only a few polygraphically documented atonic seizures are available in the literature: atonic seizures were present in one of 15 children studied by Ikeno et al.,[37] in nine of 45 patients observed by Egli et al. with epileptic falls,[23] in 10 of 30 patients studied by Oguni et al.,[63] and in three children described by Gastaut et al.[30]

From clinical observation, two forms of atonic seizures have been recognized[30]

- *Brief atonic seizures* (also called *effondrements epileptiques*), in which loss of tone may be restricted to the head (head drop) or involve all postural muscles, leading to a slumping to the ground. If consciousness is lost, this loss is extremely brief. The patients are able to stand up immediately after the fall.
- *Prolonged atonic seizures* (also called *akinetic seizures*), in which the loss of consciousness and the generalized atonia last for 1 to several minutes. The patient falls to the ground and remains mute and motionless.

Gastaut et al.[30] studied the clinical features of the brief atonic seizures by video recording and found that the patients fall to the ground in less than 1 second, with a typical sequence of events being (a) head drop (lasting for 250 msec) and (b) trunk and legs drop (from 250 to 800 msec) (Fig. 1).

After an intermediate period of about 1 second, patients recover a normal standing position in about 2 seconds. Oguni et al.,[62] by examining the video-polygraphic features of 69 "atonic epileptic drop attacks" recorded in two patients with myoclonic–astatic epilepsy, observed that the clinical manifestations ranged from collapsing and landing on the buttocks to head nodding only. Detailed video analysis of the drop attacks with the patient in standing position demonstrated the first manifestations to be flexion at the waist and knees, followed by further knee flexion, leading to falling straight down and landing on the buttocks. More recently, the same authors recorded atonic seizures in 11 children while they were either in a sitting or standing position.[63] When in a standing posture, patients fell straight downward, landed on their buttocks, and recovered immediately. When sitting, the patients fell forward or backward depending on the position of their center of gravity. The polygraphs, corresponding to the atonic seizures, showed sudden interruptions of ongoing electromyographic (EMG) potentials confined to the upper trunk when seizures were mild, and extending to the lower antigravity muscles when they were intense. The duration of EMG silence extended to 400 msec, which indicated rapid recovery, either immediately after or possibly during the fall.

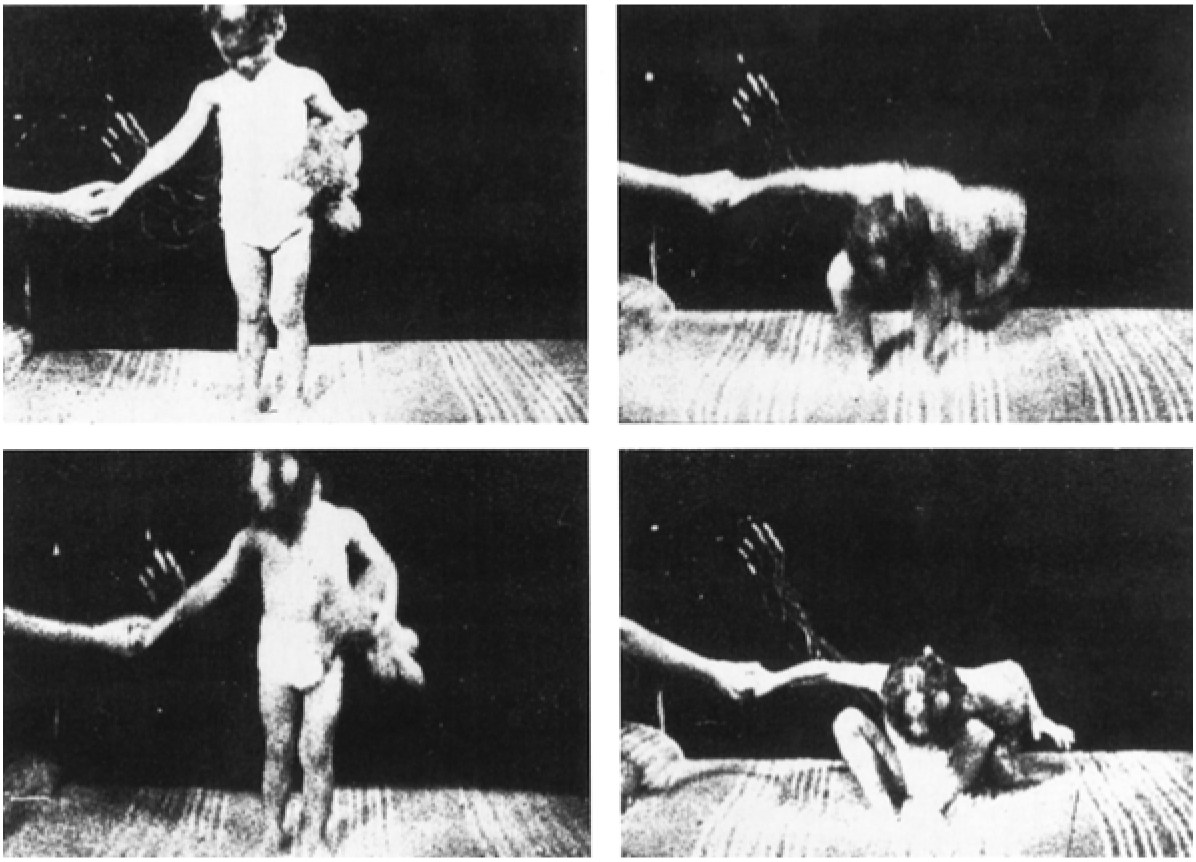

FIGURE 1. Brief atonic seizures ("effondrement atonique epileptique"). Video recording of a very brief atonic seizure, showing a typical sequence of events: initial head drop (*left*) and subsequent trunk and leg drop (*right*). It is interesting to note that the fall occurs exactly on the body axis, and the arms are not involved by tonic or myoclonic phenomena. These features may help in identifying an epileptic atonic fall on direct clinical observation. From Gastaut H, Tassinari CA, Bureau-Paillas M. Etude polygraphique et clinique des "effondrements atoniques epileptiques." *Rev Neurol.* 1966;36:5–21, with permission.

Electroencephalographic Findings

Interictal EEG findings are not specific and consist of bursts of slow spike-and-wave activity or polyspike-and-wave (PSW) complexes.

The ictal EEG of atonic seizures discloses a generalized PSW discharge, with loss of tone usually being associated with the slow wave component of the spike-and-wave complexes (Figs. 2A, 3, and 4). Other ictal patterns include low- or high-voltage fast activity, flattening, or a burst of polyspikes followed by generalized spike-and-wave activity. Polygraphic recording may reveal additional subtle clinical signs, such as bradycardia or brief arrest of respiration.

P.603

Generalized Myoclonic–Atonic Seizures

Clinical Features

Myoclonic–atonic seizures represent the main seizure type in myoclonic–astatic epilepsy of early childhood of

Doose,[16,18,21] and are probably more frequent than previously believed (see Chapter 232). These seizures have been documented in nine of 45 patients studied by Egli et al.,[23] in three of 15 children reported by Ikeno et al.,[37] and in four of 21 patients described by Yaqub.[90] They have also been reported in detail by Gastaut and Broughton[27] and Dravet et al.[20]

Surprisingly, in a video polygraphic study performed in myoclonic–astatic epilepsy of early childhood, Oguni et al.[62] recorded 36 drop seizures in five children, and found that most patients had pure atonic attacks without a myoclonic component. However, in these patients, the clinical impression was noted of minimal myoclonic contraction of facial muscles or extremities preceding the falls. More recently, the same authors reported a larger group of 30 children with myoclonic–astatic epilepsy studied by means of video-polygraphy and found myoclonic seizures in 16 cases, atonic seizures with or without preceding minor myoclonus in 11 cases, and myoclonic–atonic seizures in three.[63]

From the clinical point of view, myoclonic–atonic seizures are characterized by a sudden fall preceded by some degree of jerky movement (of the face, trunk, or arms).

Electroencephalographic Findings

Interictal EEG findings are not specific and show generalized slow spike-and-wave complexes.

The ictal EEG shows generalized slow spike-and-wave or PSW discharges (at 2–3 Hz), with the spike usually being associated with myoclonia and the slow wave with the ensuing atonia (Fig. 2B).

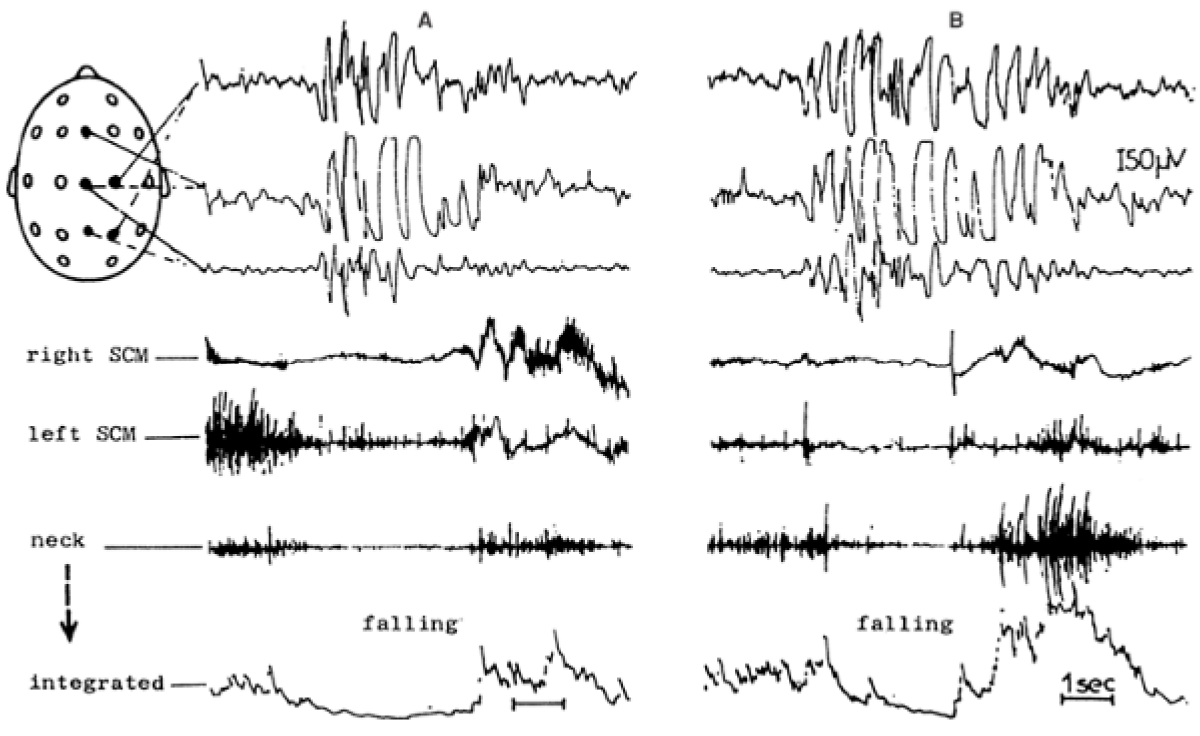

FIGURE 2. Falling seizures (atonic and myoclonic–atonic seizures). In the first drop attack (**A**), a rather irregular multiple SWD is associated with abrupt and complete loss of postural tone, which is very quickly regained at the end of the discharge; the patient returns immediately to an erect position. In the second episode (**B**), the drop is preceded by a brief myoclonic jerk, and postural tone returns before the end of the discharge. SCM, sternomastoideus muscle. In:Vinken PJ, Bruyn GW, eds. *The Epilepsies-Handbook of Cinical Neurology, Vol 15.* Amsterdam: North-Holland Publishing; 1974:130–134, with permission.

Focal Atonic Seizures

At least three types of ictal atonic phenomena may be seen in focal seizures[76]: drop attacks, focal inhibitory seizures, and negative myoclonus.

Epileptic drop-attacks or falling seizures may occur in the context of focal epilepsies, being usually due to symmetric or asymmetric tonic stiffening caused by discharges involving the frontal lobe or SMAs.[82,88] More rarely, falling seizures of focal origin are considered to result from atonic mechanisms, and video-polygraphic demonstration is available only in few cases

of the literature.[75,77] These seizures are also called drop attacks to emphasize their short duration and semiology—"like a bolt from the blue without any preceding sign."[51] Satow et al.,[75] however, provided polygraphic evidence that the epileptic falls were slow (2–5 sec in duration) in two patients with frontal and parietal lobe epilepsy exhibiting atonic seizures. Paroxysmal diminution of muscle tone mainly involved the axial muscles in both patients. Ictal EEG records showed low-voltage fast activity in the fronto-central area, followed by repetitive spikes at the midline in the patient with frontal lobe epilepsy and rhythmic spikes in the left central area in the patient with parietal lobe epilepsy. Interictal FDG-positron emission tomography (PET) disclosed hypometabolic regions consistent with the clinical and EEG findings.

Landolt[45] and Caffi[7] coined the term *temporal lobe syncope* to define individuals who have psychomotor seizures and drop attacks. This term, however, is unsatisfactory in that patients may not necessarily have a temporal lobe origin for their seizures, nor have they obviously fainted. Delgado Escueta et al.[14,15] considered drop attacks of this type to be an ictal behavioral manifestation of so-called type III complex partial seizures and suggested that these may be the product of bitemporal or extratemporal foci. Clinically, they are characterized by a rapid and abrupt fall, without preceding or accompanying sign, and followed by a complete recovery within a few seconds or minutes.[38,69] Gambardella et al.[26] reported the stereo-EEG recording of a drop attack in a patient with temporal lobe epilepsy, showing initial involvement of the left amygdaloid and hippocampal regions, with rapid spread to the right hippocampal and both orbitofrontal regions. Unfortunately, the EMG recording was not available.

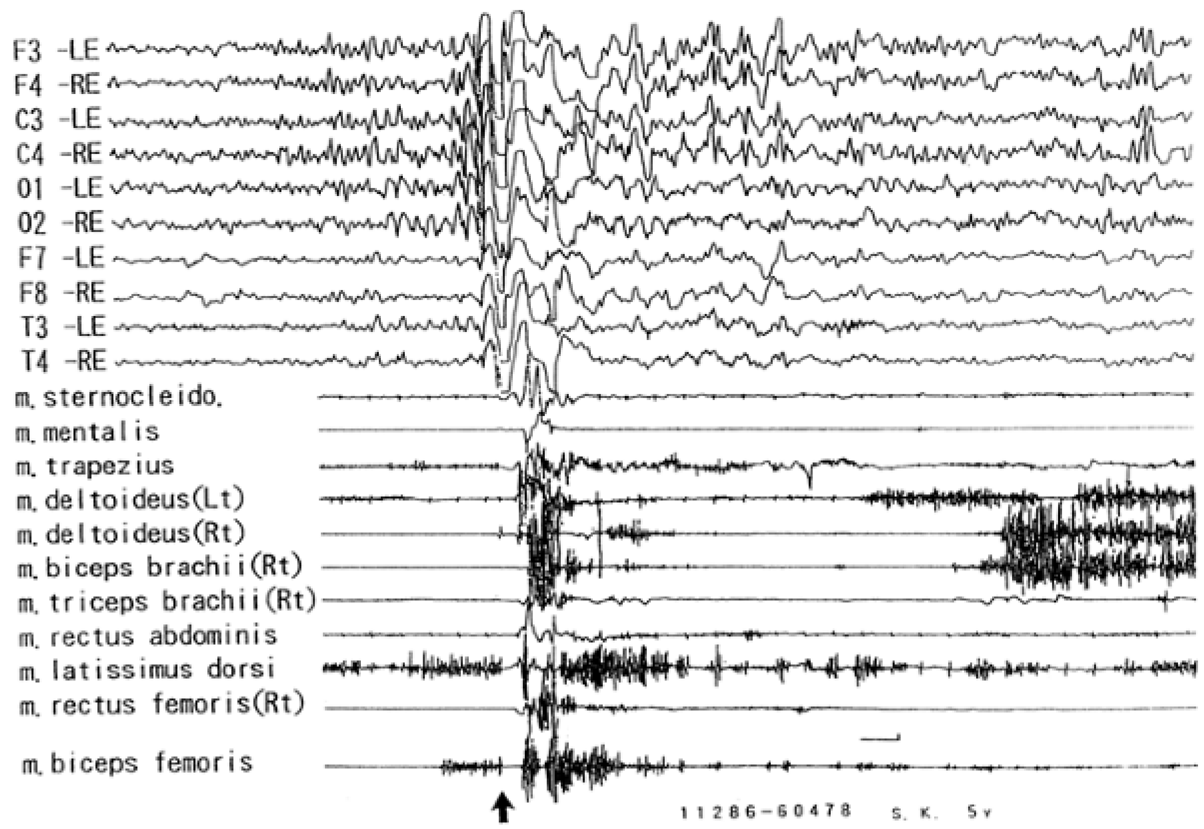

FIGURE 3. Atonic epileptic fall (epilepsy with myoclonic–astatic seizures). This 5-year-old child, who was the younger brother of monozygotic twins, had a history of febrile and afebrile convulsions. Since the age of 4

years, myoclonic seizures, drop attacks, and atypical absences appeared. He had mental retardation, and brain computed tomographic (CT) scan showed mild cortical atrophy. His co-twin was normal. Interictal EEGs demonstrated diffuse bilateral spike-and-wave, polyspike-and-wave, and monorhythmic θ activity over parieto-occipital areas. The figure shows the ictal polygraphic EEG recording of an atonic seizure: The disappearance of the myographic potentials (*arrow*) coincides with the wave component of the generalized SWD. (H. Shigematsu and M. Seino, personal observation.)

More recently, particular attention is being paid to apparently “atonic” seizures occurring in focal epilepsies in which the falls are the result of true syncopes caused by asystole triggered by the epileptic discharge.[73]

Focal inhibitory seizures are partial seizures with ictal paresis or paralysis of one or more parts of the body, which must be distinguished from the more common postictal Todd paralysis. Several reports in the literature, using V-EEG documentation of these seizures, are available.[39,46,57,87] Clinically, the ictal paralysis (usually hemiparesis) may be preceded or accompanied by a somatosensory aura affecting the same side of the body that subsequently develops focal atonia. Focal atonic seizures may have a long duration (>30 min) and therefore may present as status epilepticus (SE).[6] Ictal EEG was recorded in 30 patients and showed spike-and-wave or slow-wave discharges (53%) or rhythmic ictal activity (47%) in frontal or centroparietal areas (63%), the temporal lobe (20%), or distributed over a wide scalp region (17%) contralateral to the paralyzed limb.[35] In the only two patients with ictal electrocorticogram did the seizure discharges involve the mesial frontal or the primary sensorimotor cortices.[55,61] Isolated focal atonic seizures, particularly when of new onset, cannot be reliably distinguished from focal cerebral ischemia without EEG proof that an accompanying ictal discharge is present.

Negative myoclonus is an interruption of tonic muscular activity for <500 msec without evidence of antecedent myoclonia[5,24,84] (Fig. 5). Clinically, the negative myoclonus

may be unilateral or bilateral, and it is manifest by brief lapses in tone that interfere with motor coordination.[9,33,81] At times, it may be a very mild or almost undetected motor event, giving rise to an “instability”; more often, it causes dropping of objects from the hands, head nodding, or falls.[81,84] Negative myoclonus can occur in a variety of extremely different epileptic conditions, including idiopathic and symptomatic entities.[9,66,83,84] From a neurophysiologic viewpoint, the negative myoclonus consists of an EMG silent period of 50 to 400 msec duration, time-locked to an EEG sharp wave or spike in the contralateral centroparietal cortex that precedes the EMG silent period by 15 to 50 msec for the upper limbs.[84,85]

Diagnostic considerations

Because many seizure types and different mechanisms may be responsible for epileptic falling seizures, video-polygraphic monitoring is mandatory to achieve a correct diagnosis. Indeed, what may resemble an atonic fit on clinical observation may turn out to be a myoclonic–atonic seizure or a tonic spasm on polygraphic examination. By disclosing the basic mechanism of the fall, video-polygraphic monitoring is crucial for a correct semiology of falling seizures and is likely to improve and clarify the terminology and classification in this field of epileptology.[58,82]

Ancillary diagnostic tools may be considered for specific purposes. Magnetic resonance imaging (MRI) is needed in drop attacks of focal origin or in generalized atonic seizures to disclose specific etiologies, such as cortical malformations.[34] Stereo-EEG recording and ictal single positron emission computed tomography (SPECT) may be required in partial atonic seizures of symptomatic or probably symptomatic etiology when a surgical therapy is postulated.

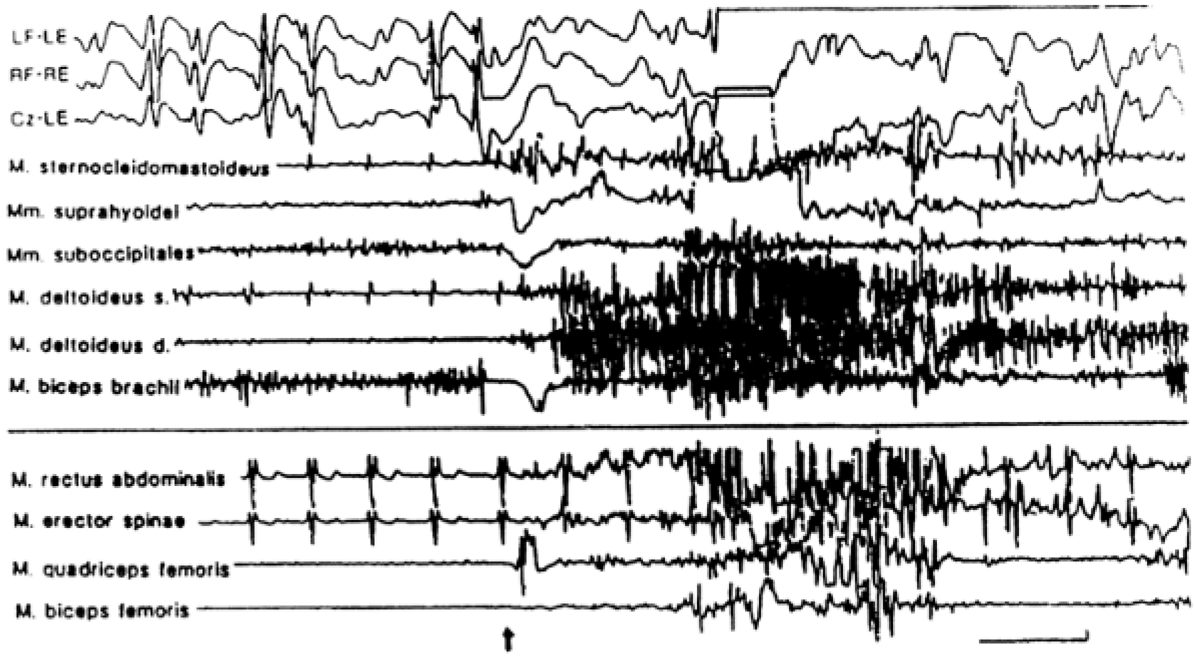

FIGURE 4. Atonic epileptic fall (Lennox-Gastaut syndrome). This 7-year-old boy with a family history of febrile convulsions had suffered from head nods since the age of 1 year. Tonic seizures, drop attacks, and atypical absences appeared at 5 years, 3 months. He had severe mental and motor retardation. Interictal EEGs showed diffuse spike-and-wave and polyspike-and-wave activity. The figure shows the ictal polygraphic EEG recording of an atonic seizure: Immediately before the appearance of the initial sign of the fall (*arrow*), bilateral double spikes were recorded in the frontal regions. EMG tracings support the presence of a very brief atonia, most clearly shown in the biceps muscle. From Ikeno T, Shigematsu H, Miyakashi M, et al. An analytic study of epileptic falls. *Epilepsia.* 1985;26:612–621, with permission.

Differential Diagnosis

Aside from pure atonic or myoclonic–atonic seizures, epileptic drops and falls may be caused by myoclonic seizures and, more frequently, tonic seizures (including axial spasms).

Myoclonic seizures causing sudden falls have been exceptionally documented by polygraphic studies. Dravet et al.[20] reported one such case in which head drops or true violent falls to the ground were associated with polygraphically proven axial myoclonic jerks. Oguni et al.[62] also described myoclonic drop attacks in one child with myoclonic–astatic epilepsy who had a propulsive flexion of the body at the waist and a forward thrust of the upper body due to myoclonic seizures or spasms. More recently, the same authors identified myoclonic seizures in 16 out of 30 patients with myoclonic–astatic epilepsy and found that six of them had a history of drop attacks.[63] Similarly Yaqub[90] described myoclonic seizures without loss of tone involving limbs, trunk, or neck and causing sudden falls.

From the EEG viewpoint, the jerks were associated with generalized SWDs at 3- to 3.5-Hz in these cases.

Tonic seizures represent the most common cause of sudden fall to the ground in children with Lennox-Gastaut syndrome.[20,23,37,78] From the clinical viewpoint, tonic seizures may be axial, axorhizomelic, or global. They are characterized by sudden flexion of the neck and body, rising of the arms in a semiflexed position, extension of the legs, contraction of facial muscles, rolling of the eyes, apnea, tachy- or bradycardia, dilated pupils, enuresis, and facial flushing. Tonic seizures may be either symmetric or asymmetric and diurnal or nocturnal.[78]

Two types of tonic seizures associated with falls ("tonic drop seizures") have been described, namely *short* tonic seizures and *prolonged* tonic seizures.

Short tonic seizures, or axial spasms, resemble those of infantile spasms and are characterized by an abrupt and widespread increase of tone, maximal in the neck and shoulder girdle. The ictal EEG shows either generalized slow waves or no changes, or occasionally a slight attenuation.[23,37]

Prolonged tonic seizures are characterized by an overt and sustained increase of tone over the axial and segmental muscles, over both agonist and antagonist muscles. The ictal EEG expression is either a run of low-voltage, fast activity, or a brief burst of generalized spike-and-wave or PSW activity.[20,78]

Tonic posturing and stiffening is also responsible for the vast majority of epileptic falls occurring in localization-related epilepsies.

Video-polygraphic monitoring may be needed also to exclude drop attacks of nonepileptic origin. Meissner et al.[56] analyzed the diagnosis in 108 consecutive patients with a history of drop attacks and found the following etiologies: unknown (64%), cardiac (12%), cerebrovascular insufficiency (8%), combined cardiac and cerebrovascular disease (7%), seizures (5%), vestibular (3%), and psychogenic (1%). Other conditions to be included in the differential diagnosis include cataplexy, syncopes, and breath-holding spells.

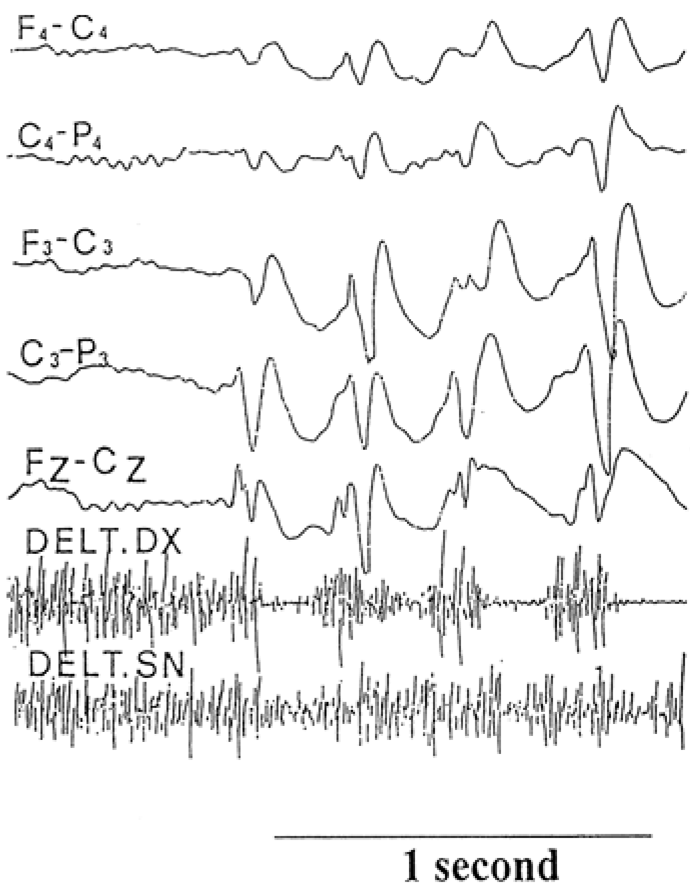

FIGURE 5. Negative myoclonus. An EEG polygraphic recording of a 4-year-old child suffering from benign partial epilepsy with centrotemporal spikes. The patient was holding arms outstretched. The appearance of triphasic spikes (*left central region*) is accompanied by a sudden interruption of the EMG activity on the right deltoid (*Delt. Dx*). Note that when the spikes become more diffuse and also involve the right central regions, brief decrements of EMG amplitude are also seen on the left deltoid (*Delt. Sn.*). From Tassinari CA, Rubboli G, Parmeggiani L, et al. Epileptic Negative Myoclonus. In: Fahn S, Hallett M, Lüders H, Marsden CD, eds. *Advances in Neurology*, Vol. 67. *Negative Motor Phenomena*. Philadelphia: Lippincott-Raven,1995;181–197, with permission.

Specific syndromes incorporating atonic and myoclonic–atonic seizures as an integral feature

Epileptic falls and head nodding of pure atonic or myoclonic–atonic origin have been mainly described in myoclonic–astatic epilepsy (also known as Doose syndrome; see Chapter 232) and Lennox-Gastaut syndrome (Chapter 241).[18,62,63] Myoclonic, atonic, and myoclonic–atonic attacks are usually responsible for falling in Doose syndrome, whereas tonic seizures or axial spasms are more frequently involved in the Lennox-Gastaut syndrome. At variance with what was defined in the present international classification,[12] myoclonic–astatic epilepsy is considered an idiopathic generalized epilepsy in the proposed diagnostic scheme,[24] because it includes only children with myoclonic–atonic seizures who are otherwise normal with no discernible causes other than a strong genetic background. Myoclonic–atonic seizures may be also observed, however, in epileptic encephalopathies of infancy such as Dravet syndrome,[19] Lennox-Gastaut syndrome,[2] and atypical benign epilepsy of childhood.[1]

In epilepsy with electrical SE during slow sleep, atypical absences with atonic components, epileptic falls, and negative myoclonus have been described in subgroups of patients,[13,79] formerly reported under the heading of atypical benign epilepsy of childhood.[1]

In severe myoclonic epilepsy of infants or Dravet syndrome, seizures begin during the first year of life in the form of generalized or unilateral febrile clonic seizures, with the secondary appearance of myoclonic jerks and often partial seizures; in these patients, falling seizures result from either vide supra, myoclonic jerks or partial seizures with atonic pheno- mena (see Chapter 230).[19]

"Epileptic drop-attacks" are also described in focal epilepsies, particularly of frontotemporal origin and with marked bilateral synchrony.[31,69,88] In these cases, however, the falls are usually associated with tonic stiffening, and polygraphic documentation is scanty. Satow et al.[75] reported pure atonic seizures in two patients with localization-related epilepsy (of frontal and parietal origin) studied by means of prolonged V-EEG monitoring. Epileptic "drop-attacks" have been found to be a very frequent seizure type in localization-related epilepsies caused by focal neuronal migration disorders, especially when they involve the central cortical regions[34,43,68] or in the context of the epileptic syndrome linked to hypothalamic hamartomas.[4]

Whatever the origin and mechanisms of falling seizures in localization-related epilepsy, their occurrence often represents an ominous sign because they are frequent, resistant to therapy, physically dangerous, and portend personality changes.

Response to treatment

Medical Treatment

The medical treatment of atonic and myoclonic–atonic seizures remains empirical. Valproic acid associated with lamotrigine and a benzodiazepine is usually considered the treatment of choice, either in generalized or focal epilepsies exhibiting epileptic drop attacks.[22,86] Ethosuximide, alone or in combination with the above drugs, has also been demonstrated to improve atonic seizures and negative myoclonus.[8,67] Some of the new antiepileptics, particularly lamotrigine, felbamate, and topiramate have shown some promise for the treatment of the Lennox-Gastaut syndrome, with atypical absences and "astatic" seizures being particularly improved.[25,59,74] However, these results await confirmation in large multicenter studies.

Some compounds, on the other hand, should be given with extreme caution because they may contribute to worsen atonic, myoclonic–atonic, and negative myoclonus, particularly in generalized syndromes of infancy. These dangerous drugs include carbamazepine, oxcarbazepine, phenytoin, vigabatrin, and phenobarbital.[71] Instances of tonic SE precipitated by intravenous administration of benzodiazepines have been documented in children with Lennox-Gastaut syndrome.[80]

Surgical Treatment

Callosotomy is widely considered the surgical treatment of choice in patients with falling seizures who are not candidates for classical resective surgery.

From the review of the literature, it appears that patients with tonic or atonic falls had a reduction of about 80% in seizure frequency after callosotomy, although in most cases complete or permanent control of other seizure patterns did not occur.[3] The aim of callosotomy is to limit the spread of convulsive discharges from one hemisphere to the other, and therefore, patients with mainly lateralized foci with secondary generalization should benefit most. Indeed, in the Montreal experience,[65] patients with lateralized EEG abnormalities tended to have a better result than did those without lateralization, but patients with synchronous and symmetric SWDs also benefited. Partial seizures, often inconspicuous before surgery, may emerge after callosotomy in some patients.

Summary and conclusions

Atonic and myoclonic atonic seizures are specific seizure types whose identification rests on an accurate video-polygraphic analysis of the ictal events. Atonic seizures are characterized by sudden and pure loss of tone, whereas myoclonic–atonic seizures show an initial myoclonic potential, sometimes in sequence, followed by muscle silence. Both seizure types are accompanied by generalized/diffuse spike-and-wave and PSW complexes, with the slow-wave component usually being associated with atonia in atonic seizures and the spike with myoclonia in myoclonic–atonic seizures. Both seizure types are a common cause of epileptic falls or drops in childhood epileptic encephalopathies, such as Lennox-Gastaut syndrome, Dravet syndrome, and atypical idiopathic localization-related epilepsy of childhood,[2] as well as in idiopathic generalized syndromes—namely, myoclonic-astatic epilepsy of Doose. Moreover, these seizures must be distinguished from tonic and myoclonic seizures, which also account for falling in epileptic encephalopathies of childhood. Tonic seizures of very brief duration (axial spasms) are responsible for most epileptic falls in Lennox-Gastaut syndrome, whereas

P.608

myoclonic–atonic seizures are more frequently encountered in Doose syndrome. Atonic seizures may also have (vide supra) a focal origin, and may be classified into three main focal seizure types:

- Epileptic drop attacks, usually in the context of frontal or frontotemporal or parietal epilepsies, sometimes with outstanding secondary bilateral synchrony on the EEG.
- Focal inhibitory seizures, with ictal paresis or paralysis of one or more parts of the body, sometimes accompanied by a somatosensory aura. These seizures may have a long duration and are associated by a discharge usually involving the centroparietal areas.
- Negative myoclonus, defined by an interruption of tonic muscular activity for <500 msec without evidence of antecedent myoclonia, causing unilateral or bilateral drops, head nodding, falls, or brief lapses in tone that interfere with motor coordination.

The pathophysiology of atonic seizures or the atonic components of seizures is largely unknown, but subcortical and cortical mechanisms have been proposed to explain the ictal loss of tone. Medical treatment is often unsatisfactory, but some of the newer antiepileptic drugs such as lamotrigine, felbamate, and topiramate have shown encouraging results. Callosotomy may be helpful in selected cases of falling seizures of tonic or atonic origin, with the best results being obtained in patients with lateralized EEG discharges.

Chapter 52

Generalized Tonic Seizures

Introduction

Generalized tonic seizures are convulsive events in which the tonic component is predominant and not followed by clonic jerks. Actually, the majority of convulsive generalized seizures have both tonic and clonic components, especially in generalized epilepsies. Also, in partial epilepsy a secondary generalized seizure usually manifests a clonic phase.[53] On the basis of experimental animal models of epilepsy, there is evidence that different circuits are responsible for tonic and clonic seizures and indicate that the anatomic substrate for tonic seizures could be in the brainstem.[58] Possibly due to their intrinsic pathophysiology, which heavily involves the brainstem, tonic seizures are a common manifestation in pediatric age and especially in symptomatic/lesional epilepsies, in which a forebrain/brainstem dysfunction could be more easily hypothesized. In the neonatal period tonic seizures are recorded in early infantile epileptic encephalopathy (EIEE), in early myoclonic encephalopathy (EME) (see Chapters 224 and 225), and in severe symptomatic neonatal seizures, especially those due to hypoxic-ischemic perinatal injury, which account for 50% of such seizures.[2] During infancy, tonic seizures are observed in refractory infantile spasms, especially after the first year of life and are sometimes associated with epileptic spasms (tonic-spasm epileptic seizure).[14] Tonic seizures are the main seizure type in symptomatic generalized epilepsy associated with an inverted duplication of chromosome 15[49] and in Lennox-Gastaut syndrome.[3] Among the partial epilepsies, tonic events are the main type of seizures recorded in startle-induced epilepsy, in which the tonic seizure is often generalized, despite the focality of the underlying lesion. Although rare, there are also reports of tonic seizures belonging to idiopathic generalized epilepsies[32] and in this case they follow the same course as generalized tonic–clonic seizures.

Definitions

Tonic seizures are classified among the generalized seizures and described as follows: "a rigid, violent muscular contraction, fixing the limbs in some strained position, with usually deviation of the eyes and of the head toward one side." Thus, we consider a seizure as purely tonic when the hypertonia, mainly involving the axial muscles, is not followed by clonic jerks. This is independent of the symmetry or the extention nature of the contraction.

The glossary of descriptive terminology for ictal semeiology describes, among the generalized events, the tonic seizure as "a sustained increase in muscle contraction lasting a few seconds to minutes."[10]

On the basis of a single case, Jackson and Barnes[28] and Jackson and Singer[29] accurately described tonic seizures as "the axial type," which were considered immature grand mal seizures. Lennox[35] described tonic seizures as convulsive variants, involving brief muscle rigidity without subsequent clonus. Detailed clinicoelectroencephalographic studies of tonic seizures were later conducted by Ouachi et al.[43] and Gastaut et al.,[22] mainly on the tonic seizures of Lennox-Gastaut syndrome. A clear distinction between tonic and tonic–clonic seizures was made. Following these studies, tonic seizures were classified as a separate type of generalized epileptic attack.[7,18] However, the tonic seizure may also be a clinical manifestation of localization-related epilepsies, especially of those originating from frontal lobe areas.[11]

From a clinical point of view, and especially where only historical information is available, it is not always easy to distinguish clearly between pure tonic and tonic–clonic seizures. Unfortunately, the distinction between the two types of seizure are not always clear in the literature as well.

Epidemiology

Epidemiologic data about tonic seizures are difficult to identify outside the context of the epileptic syndrome in which they occur. However, in recent years more attention has been given to the epidemiology of each epileptic syndrome, and some data about the prevalence of Lennox-Gastaut syndrome, refractory infantile spasms, EIEE, and focal epilepsies are now available.[32,34,54] In the population-based study conducted using a multiple-source surveillance system for epilepsy and developmental disability by Trevathan et al.,[54] the prevalence among Atlanta children of Lennox-Gastaut syndrome was 4% of all children with epilepsy. In the study reported by Kramer et al.,[32] the relative frequency and age of onset of the different seizure types were analyzed in a 20-year cohort of a pediatric neurology outpatient clinic in Tel Aviv. Lennox-Gastaut syndrome accounted for 1.5%, EIEE for 0.2%, and generalized tonic seizures not otherwise specified for 6.6%. In a subsequent study by Kwong et al.[34] performed in a cohort of 309 Chinese children, Lennox-Gastaut syndrome prevalence was 3%, but the prevalence of tonic seizures was not specified separately.

Previously, data regarding only Lennox-Gastaut syndrome showed that tonic seizures, as reported in papers by Gastaut et al.[20] and other authors,[6,39] were experienced in 55% to 60% of cases. Gastaut et al.[23] reported that such a percentage probably underestimates the real incidence of tonic seizures in Lennox-Gastaut syndrome, as the incidence of tonic seizures rises to 92% at the Centre Saint-Paul, a specialized institution in which the patients are under constant observation and are usually recorded during sleep.

More difficult to estimate is the prevalence of reflex tonic seizures in startle-induced epilepsy. The papers on tonic reflex seizures come mainly from laboratories specializing in the surgical treatment of medically resistant lesional startle-induced epilepsies, which, therefore, have limited epidemiologic value. Kramer et al.[32] reported that startle-induced epilepsy in their cohort accounted for 0.2% of cases.

P.612

Anatomic Pathways and Pathophysiology

There is relative agreement on the brainstem involvement or origin of tonic seizures, both in Lennox-Gastaut syndrome and in EIEE or EME, whereas a cortical circuit is presumed to be involved in tonic seizures of startle-induced epilepsy. In animal models, the tonic extensor convulsion is the characteristic motor pattern of seizures evoked by maximal electroshock and high doses of chemoconvulsants.[16] As demonstrated by Tanaka and Mishima[50] and later by Browning and Nelson,[5] in animal models a tonic convulsion requires the integrity of the brainstem but not the forebrain. However, the anatomic substrates within the brainstem responsible for generating tonic seizures have not fully been characterized. The reticular formation of the lower midbrain and pons are surely involved, as stimulation of these regions triggers tonic convulsions, and a lesion can attenuate them.[17] As a result of these experiments and the similarity between clinical tonic seizures and those induced in animals, a role for the brainstem in the initiation of convulsive seizures has long been suspected. However, as pointed out by Velasco and Velasco,[56] the literature on the role of the brainstem in the initiation and propagation of seizure activity is very contradictory. Velasco et al.[57] recorded ictal discharges of various types of generalized seizures within the centromedian thalamic nucleus (CM) and the cerebral cortex in children with intractable generalized seizures related to Lennox-Gastaut syndrome. Ictal CM discharges were consistently correlated with widespread surface cortical electroencephalographic (EEG) activities and symptoms in all patients and all types of generalized seizures. Fast spike discharges in the CM correlated with onset of tonic and tonic–clonic generalized seizures. Ictal EEG activity occurred simultaneously in the right and left CM and the surface at the onset of all seizure types of a generalized nature, with the exception of myoclonic seizure. Velasco et al.[57] maintain that simultaneous thalamic and cortical activation depends on epileptic discharges arising from cerebral structures outside the thalamocortical system. They postulate that the presence of abnormalities in the brainstem close to the red nucleus noted in MRI scans of all children with Lennox-Gastaut syndrome imply that epileptic discharges may arise from the brainstem.[55] The fact that tonic seizures occur more frequently during slow-wave sleep than during rapid eye movement (REM) sleep, modify sleep organization,[27,45,62] and raise the level of vigilance[36] also support the hypothesis that tonic seizures originate in the brainstem. Recently Veliskova et al.[58] provided evidence from animal studies that the anatomic substrate for tonic seizure could be in the brainstem, suggesting that different circuits are responsible for tonic and clonic seizures. In a previous animal study, excitation of the brainstem reticular formation produced convulsive seizures in decerebrated rats and cats, demonstrating that reticular neuronal circuits are independent of cortical networks in seizure generation.[33] Rodin et al.[47] used Metrazol and Megimide to produce seizures. He hypothesized that different functional states of the animal were a significant variable in the distribution of seizure activity. In paralyzed and unanesthetized animals, epileptic discharges were evident in the thalamus and cortex, whereas they were mainly in the brainstem reticular formation in freely moving animal.

A cortical origin for tonic reflex seizures seems to be likely, based on neuroimaging and neurophysiologic studies performed in surgery centers. Such data support involvement of the supplementary motor area in generation of this seizure type.[38,40] Gates et al.[25,26] and Courtney et al.[8] described the effectiveness of corpus callosotomy in patients with refractory tonic seizures. Disappearance of reflex tonic seizures after callosal section (which prevents the spread from one unilateral focus to the contralateral homotopic motor center) is not completely unexpected. More difficult to explain is how seizures believed to originate from brainstem structures are improved by a callosal section. Though there is both, speculation[26] and controversy[24] concerning the efficacy of corpus callosotomy in controlling generalized tonic seizures, clinical and experimental evidence currently available indicates that seizure activity can spread and generalize in humans and experimental animals via both the corpus callosum and the reticular formation.[12]

Clinical Manifestations

In newborns with EIEE or EME, tonic seizures are a predominant feature. In EIEE the prevailing initial seizure type is tonic seizures, whereas in EME tonic seizures develop in the course of the disease. Interestingly, Djukic et al.[9] pointed out that the two conditions represent a continuum of progressive pathology and dysfunction and that the presence versus absence of tonic seizures indicates the severity of the brainstem pathology or dysfunction at the time the syndrome presents. If the EEG shows a burst-suppression pattern, tonic seizures usually correlates with the burst (Fig. 1). In such cases prognosis remains poor. Clinically tonic seizures involve axial and limb muscles are of brief duration, and may present with abrupt onset resembling an epileptic spasm or epileptic myoclonus. However contractions persist and last longer than either spasms or myoclonus. Focal signs consisting of asymmetric contraction or unilateral head or eye deviation may be present, depending on the presence of an underlying structural lesion.

Although spasms and tonic seizures are two clearly distinct types of epileptic events, they may appear closely associated in the so-called tonic-spasm seizure, a particular form of generalized tonic seizure (Fig. 2). The beginning of this type of seizure is marked by a real "spasm," with flexor contraction of trunk and limbs lasting about 1 second. Immediately afterward, there is a tonic contraction lasting a few seconds that makes the patient maintain the position assumed during the spasm. This type of seizure has two characteristics in common with spasms: They appear in series that can last several minutes, and a tendency to occur mostly upon awakening. Tonic-spasms seizures are mainly observed in children with drug-resistant infantile spasms of unknown cause, who then develop an epileptic encephalopathy with cognitive impairment and multifocal EEG abnormalities.

In Lennox-Gastaut syndrome, tonic seizures manifest mainly during phases 1 or 2 of non-REM sleep. At times they are associated with minimal clinical signs, such as opening the eyes and apnea, and at times with a more violent behavior with sustained diffuse contractions, usually of brief duration. The seizures tend to persist until the sleep phase changes into slow-wave sleep. They present again in the same phase of each cycle over the course of the night. The characteristics of tonic seizures are the following: Rapid, mostly flexor contraction of muscles extending from the body axis to the upper or lower extremities; when awake the patient, may fall if standing and lose consciousness. If muscle tone is tested during the seizures, it is impossible to move the body parts involved. Tonic contractions may be symmetric or asymmetric. Seizure duration varies from several seconds to a minute (most last for 5 to 20 seconds). Seizure frequency varies from patient to patient, ranging from once a month to several dozen times a day. Occasionally, seizures are so frequent that status epilepticus occurs. Regarding the topography of the contractions, Gastaut et al.[19,23] divided tonic seizures into three types: Tonic “axial” seizures, tonic “axorhizomelic” seizures, and tonic “global” seizures. Tonic “axial” seizures are characterized by tonic contraction of the neck muscles, causing either fixation of the head in an erect position or slight displacement of the head, depending on the relative predominance of flexor or extensor muscle groups. Contraction of the superior

facial muscles and the frontal muscles causes the elevation of the eyebrows and eyelids (Fig. 3). Respiration often accelerates or ceases (apnea). Tonic “axorhizomelic” seizures begin like tonic axial seizures but are accompanied by involvement of the proximal musculature of the upper limbs. Thus, contraction of the trapezius and deltoid muscles follows contraction of the neck muscles, resulting in elevation of the shoulder (Fig. 4). During tonic “global” seizures, the contraction spreads from axial muscles axis to all muscles of the upper and lower limbs (Fig. 5). The upper limbs are in abducted and semiflexed; the lower limbs are flexed or, more infrequently, in extension, also with trunk extension. The different contraction patterns of muscles of the lower limbs and trunk can cause the patient to fall forward or backward. Contraction of the respiratory muscles causes apnea.

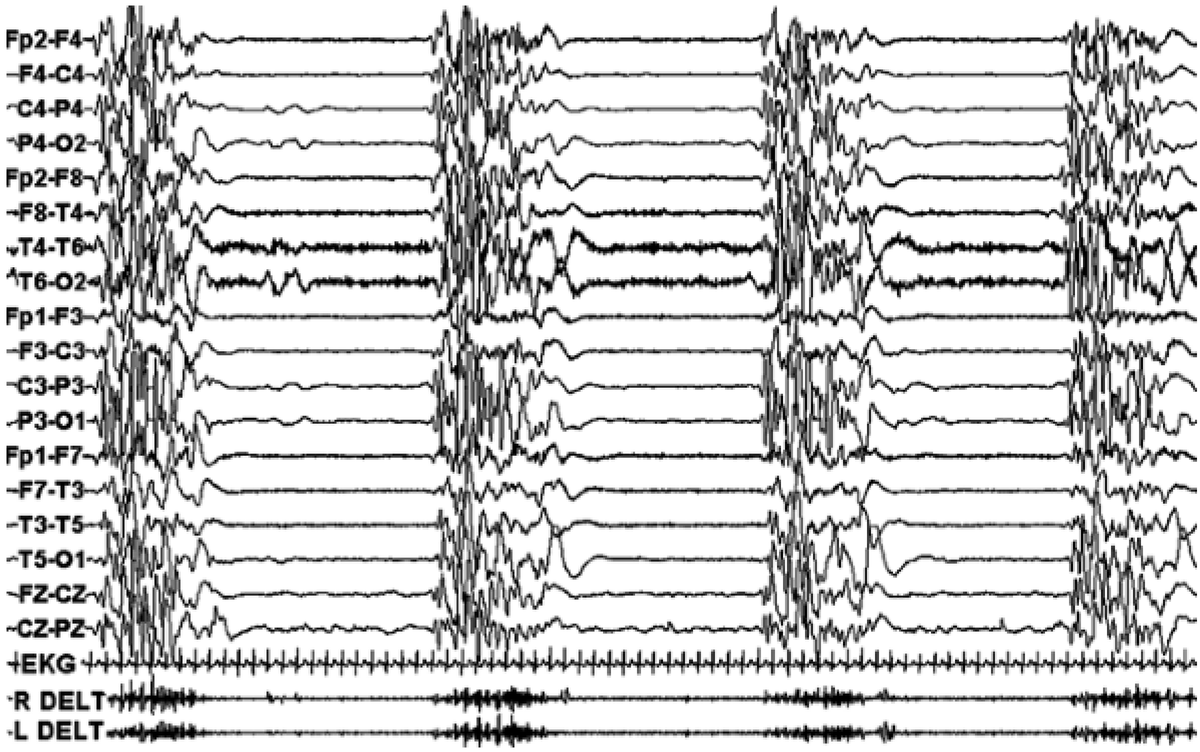

FIGURE 1. Burst-suppression pattern in a 1-month-old boy: The burst is strictly correlated with the appearance of brief tonic seizures recorded over both the deltoids.

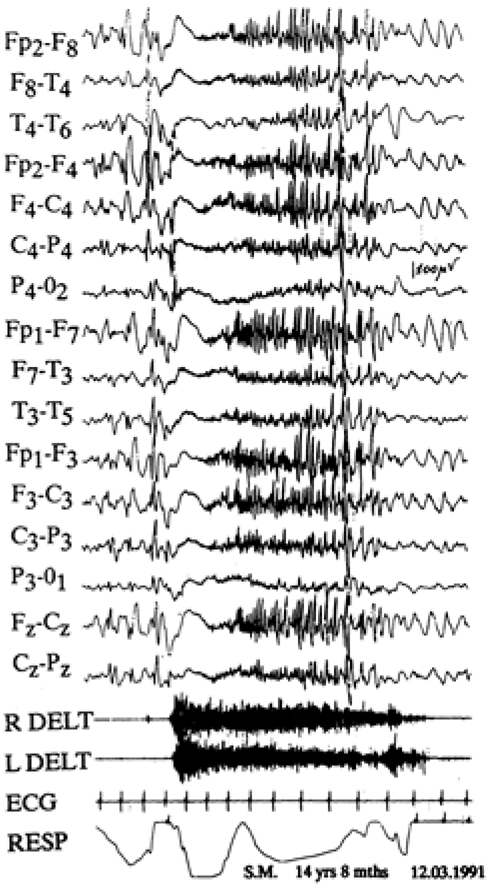

FIGURE 2. Tonic-spasm seizures in a 14-year-old boy who began having infantile spasms resistant to treatment in the first year of life. The spasms progressively transformed into tonic-spasm seizures. The ictal electroencephalogram is characterized by a diffuse high-amplitude slow wave, followed by a fast rhythm of increasing amplitude. Recording from the deltoid muscles shows first a contraction similar to a spasm, then a prolonged tonic contraction.

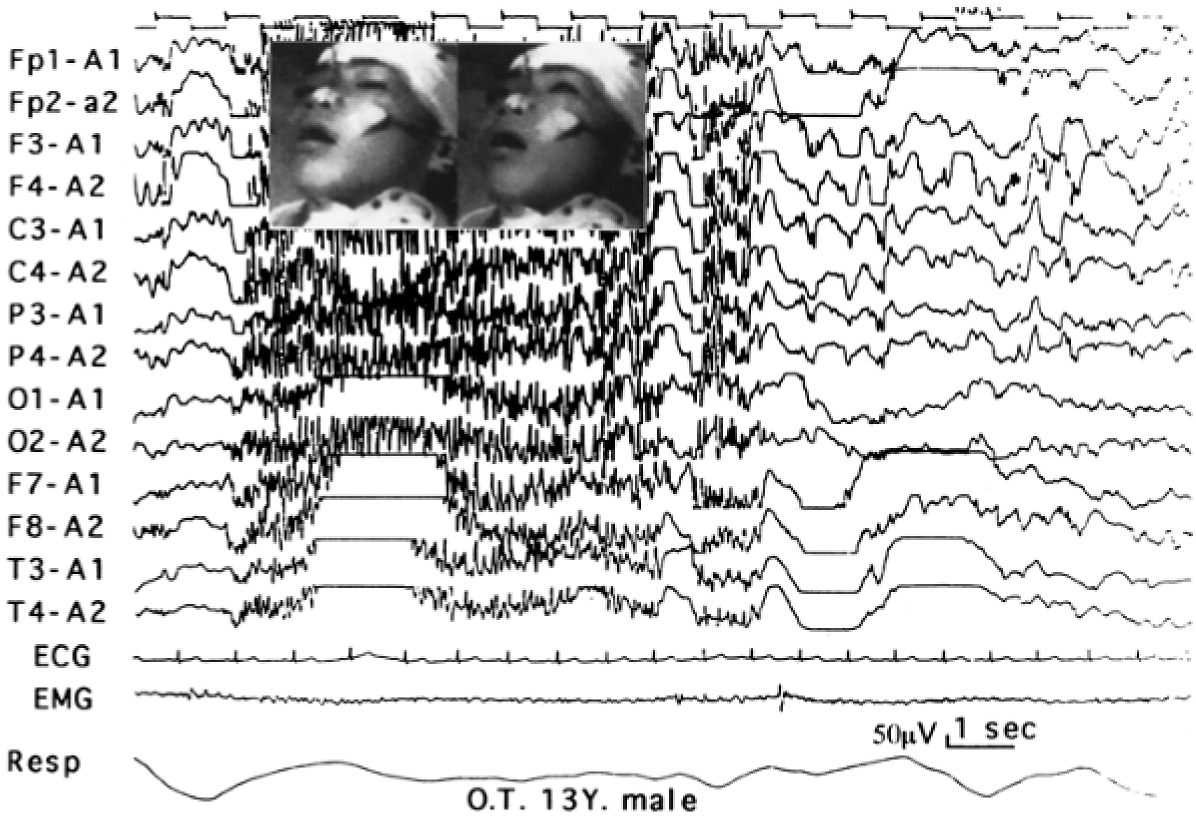

FIGURE 3. An axial tonic seizure in a 13-year-old boy with Lennox-Gastaut syndrome. The clinical manifestations are eye opening due to the elevation of both eyelids, suppression of respiration, and slight acceleration of heart rate. The electroencephalogram shows high-voltage fast discharges at about 14 Hz.

Tonic seizures are commonly accompanied by autonomic symptoms, including alteration of depth or frequency of respiration, tachycardia or bradycardia, pupillary dilation, and facial flushing. Seizure intensity varies greatly from patient to patient or from one seizure to another in the same patient. Seizures vary from rapid, massive contraction of trunk and limb muscles with apnea and cyanosis to ones limited to raising the eyebrows, mild contraction of the shoulder muscles, and minimal variation in respiratory rhythm. These latter seizures are observed especially during sleep. Postictal symptomatology is related to seizure intensity: The more violent seizures are followed by drowsiness and sleep, whereas the less intense ones may have no postictal symptom.

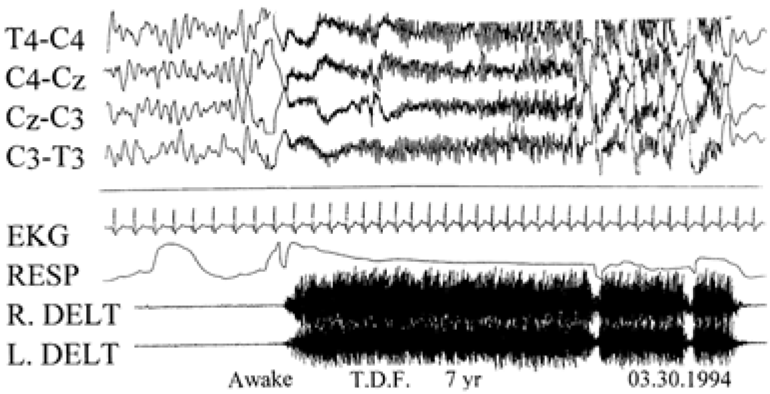

FIGURE 4. An axorhizomelic tonic seizure while awake in a 7-year-old boy with Lennox-Gastaut

syndrome. The tonic seizure involves deltoid muscles. During the seizure, the heart rate accelerates and respiration is suppressed. The electroencephalogram shows fast discharges at about 20 Hz of increasing amplitude.

In startle-induced epilepsy, the tonic seizures are generally a kind of global seizure, but the contraction involves mostly the postural muscles, to the extent that the patient assumes particular postures. The seizure is provoked by acoustic or sometimes proprioceptive stimuli and is observed in severely motor-impaired children. At times the tonic seizures may show focal signs, such as an asymmetry in tonic contraction, depending on the unilaterality of lesion. In fact, startle-induced tonic seizures are usually observed in the context of perinatal or infantile brain damage and contralateral hemiplegia,[40] and have

been attributed to a focus arising in the frontal lobe (Fig. 6). Although startle-induced epilepsy with motor seizures could be observed even in children without motor area lesions (mostly due to the unilateral or bilateral forebrain lesion, although the extent of brainstem involvement is unclear), subdural grids studies have repetitively shown that such a seizure derives from the supplementary motor area of one hemisphere and therefore should be considered a kind of partial event.[42,48] From a clinical point of view, startle-induced tonic seizure quickly arises after the stimulus and rapidly involves the axial and limb muscles, with impairment of consciousness that is often difficult to evaluate. Whatever the underlying pathophysiology, and especially in severely mentally retarded patients, startle-induced tonic seizures represent a kind of generalized motor seizure, which is often an emergent problem, as it is drug refractory and there is frequently self-injury.

Electroencephalographic Manifestations and Clinical Correlations

The ictal EEG of tonic seizures usually consists of rhythmic spiking.[30] The frequency and amplitude of the spikes vary widely. Frequency ranges between 10 and 25 Hz, and amplitude ranges from a very low-amplitude, desynchronized rhythm to more than 100 μV (Fig. 5). An initial brief flattening may precede fast activity, especially in startle-induced tonic seizures. Moreover, Gastaut et al.[23] described an ictal EEG of diffuse slow-wave discharges at theta and delta frequencies in subjects whose background EEG activity is very slow, and only during status epilepticus of tonic seizures in Lennox-Gastaut syndrome. Polygraphic recordings[61,62] have demonstrated how in tonic seizures there is a muscle contraction of increasing intensity that within 1 to 2 seconds can reach a level that then remains constant for the rest of the seizure. The muscle contraction occurs more slowly than in myoclonus or spasms.[13]

In EIEE and in EME, tonic seizures are a counterpart of the burst of burst-suppression pattern, especially in the neonatal and infantile period. The burst-suppression pattern tends to disappear by 6 months of age and is replaced by a hypsarrhythmic pattern in about 75% of cases.[41] Tonic seizures

have been then replaced by epileptic spasms or focal seizures. Although clinically a sleep–wake cycling is observed, neurophysiologically no differentiation between the wake state and sleep is recorded. In fact, the burst-suppression pattern is unchanged. As tonic seizures are strictly associated with the burst period, they are as frequent as the burst is (Fig. 1). However, although the burst-suppression pattern continues during sleep, tonic seizure does not, suggesting a forebrain involvement in the genesis of the phenomenon.

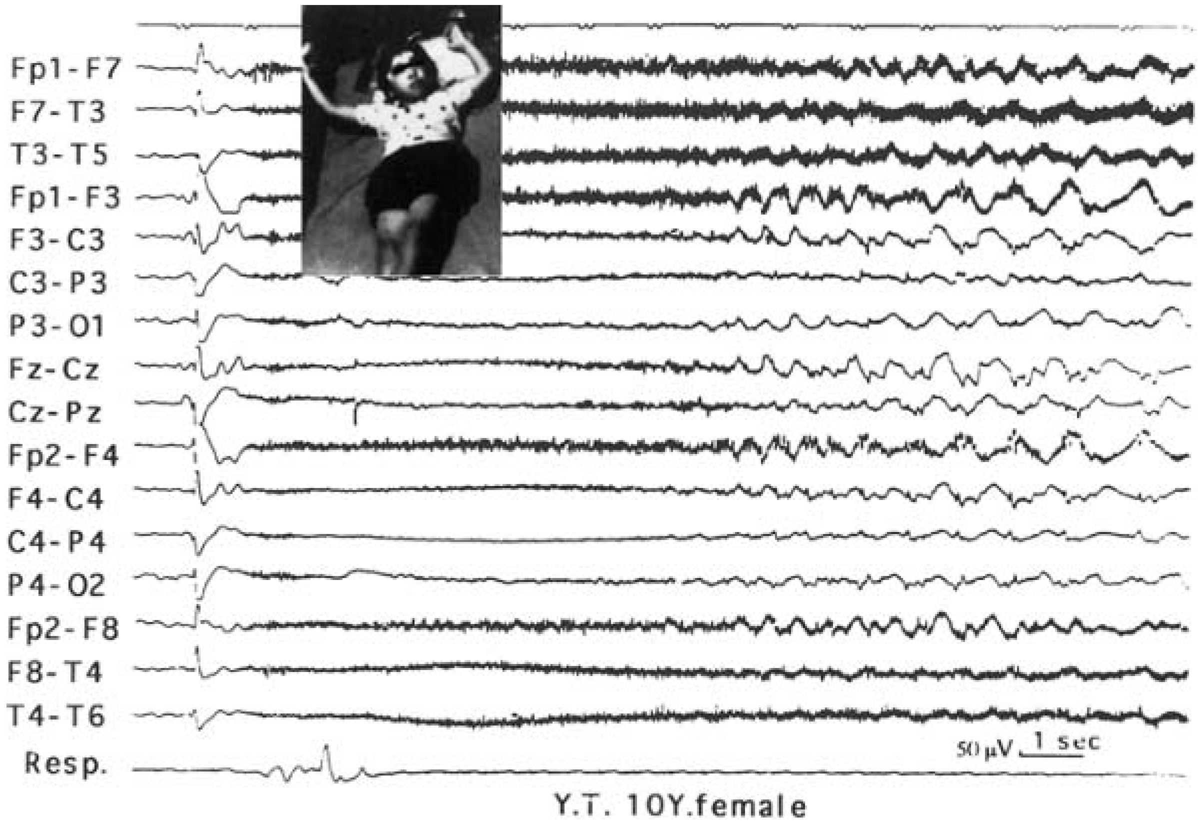

FIGURE 5. A global tonic seizure in a 10-year-old girl with Lennox-Gastaut syndrome. The manifestations are abrupt elevation of both arms, followed by a tonic state in both sides of the upper and lower extremities and trunk. The electroencephalogram shows high-voltage sharp waves and flattening upon jerking both upper extremities, then low-voltage fast discharges upon entering the generalized tonic state.

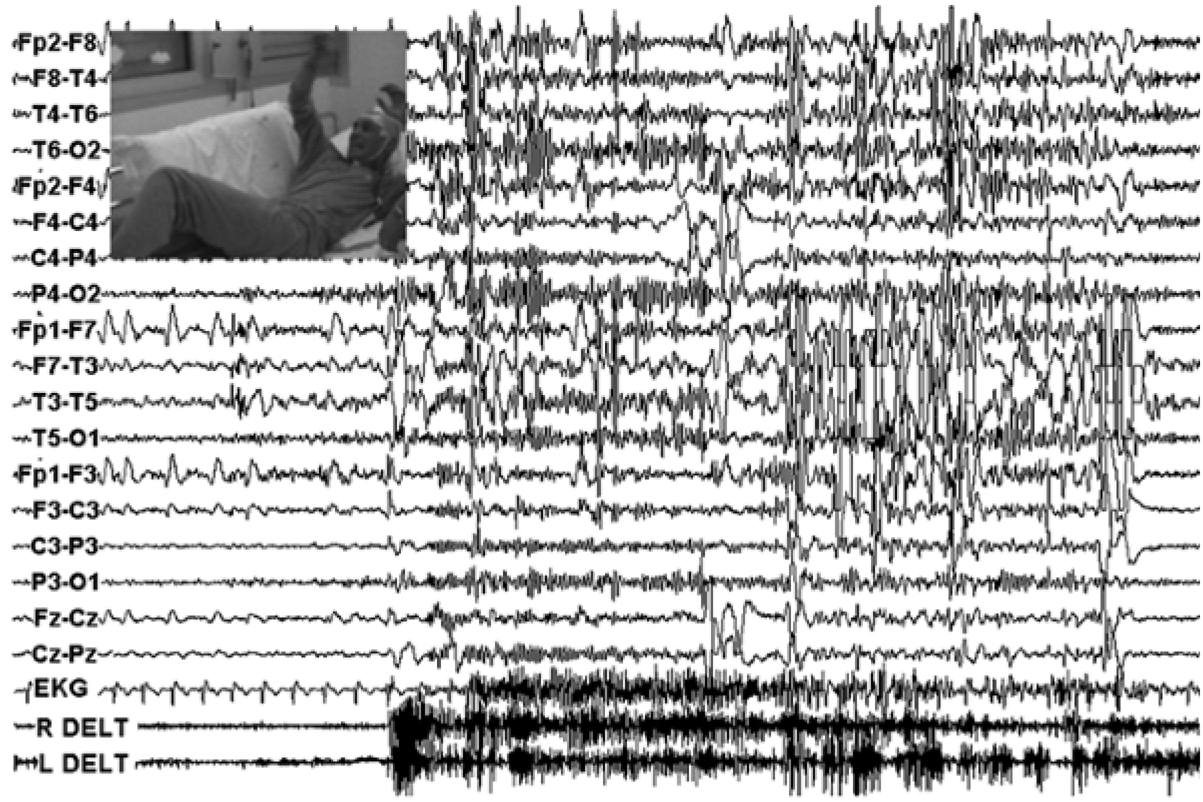

FIGURE 6. Startle epilepsy in a 15-year-old boy with a left porencephaly. This boy experiences many tonic startle seizures per day. The electroencephalogram pattern is characterized by the presence of a flattening of the cerebral activity over the frontocentral areas of the left hemisphere, which is then substituted by the recurrence of rhythmic spikes sometimes obscured by muscular artefacts.

The polygraphic pattern of tonic-spasm seizures is particularly characteristic (Fig. 2). On EEG, the seizure begins with a diffuse slow wave of high amplitude, positive over the vertex central regions, lasting 0.5 to 1 second. This is followed by a rapid rhythm of 10 to 15 Hz, with increasing amplitude lasting from 5 to 10 seconds. The polygraphic recording is characterized by a rhomboid pattern, as observed in spasms, that coincides with the wide slow wave. Immediately afterward there is a muscle contraction of increasing intensity that coincides with the rapid rhythm. This ictal pattern tends to occur in series lasting several minutes, with seizures every 20 to 30 seconds; the duration of the tonic phase can vary from one seizure to another in the same series.

The interictal EEG characteristics are strictly related to the epileptic syndrome in which the seizures occur.

Diagnostic Considerations

Based only on an anamnestic account, it is sometimes difficult to understand precisely whether the convulsive seizure of a patient is a real tonic seizure. From a semeiotic point of view, detailed questioning of eye witnesses to the seizures about the clinical manifestations can help to distinguish a real tonic seizure from other convulsive seizures. The presence of jerks at the beginning or end of the seizure permits the differentiation from clonic or tonic–clonic seizures. The presence of clear focal elements at the beginning of the seizures, such as focal hypertonia, focal clonus, or marked eye or head deviation, as well as jerks at the end of the seizure, permits the differentiation from partial seizures with prompt generalization. As an indirect element of diagnosis, it should be remembered that Lennox-Gastaut tonic seizures occur more often during sleep, whether in the afternoon or at night. The Lennox-Gastaut tonic seizures appear prevalently during the first sleep cycle, in the non-REM stage; they can also occur in quick succession, with intervals of only a few minutes, and be of varying intensity. From an etiologic point of view, the underlying epileptic syndrome should be assessed as precisely as possible. In Lennox-Gastaut syndrome, cerebral MRI scan should exclude or support a symptomatic etiology. Because Lennox-Gastaut syndrome appears after West syndrome in about half of the cases, it is necessary to remember that the etiologies associated with West syndrome are also the same as half of the cases of Lennox-Gastaut syndrome (see Chapter 241).

Differential Diagnosis

Differential diagnosis is made in relation to other epileptic seizures and to nonepileptic events.

Epileptic Seizures

Tonic–Clonic Seizures

Tonic seizures must be differentiated from generalized tonic–clonic seizures (GTCSs). Gastaut et al.[22] described GTCSs as follows: (a) their duration is usually longer than 1 minute; (b) their tonic phase is more intense and more generalized than the contraction of tonic seizures and rapidly ends with a general contraction and extension; (c) they have a clonic phase of gradually decreasing frequency that lasts twice as long as the initial tonic phase; (d) they are always followed by a stertorous phase, by residual muscular contractions, and by deep sleep; and (e) their EEG manifestations never consist of flattening of the tracings or of low-amplitude rapid synchronization during the tonic phase, but rather consist from the start of an epileptic recruiting rhythm at 10 Hz that quickly becomes associated with slow waves of inhibition during the clonic phase and always shows electrographic silence (cortical extinction) after the seizure.

Infantile Spasms

Infantile spasm is a particular type of seizure characterized by a complex flexor-extension movement of the trunk and limbs, and lasting about 1 second. As seen in the chapter dedicated to spasms, the EEG and polygraphic picture of the spasm differs substantially from that of the tonic seizure.[13] The ictal EEG of the spasm is characterized by a diffuse, slow wide wave or by a brief rapid rhythm, but never by a recruiting rhythm or by a prolonged fast activity of 20 Hz. The spasm is characterized polygraphically by a muscle contraction that lasts about 1 second and reaches a peak more rapidly than does a tonic seizure; it then decreases quickly and appears as a kind of "rhombus." The tonic seizure, instead, shows a prolonged muscle contraction of growing intensity.

Focal Seizure of Frontal Lobe Origin

The tonic postural seizures originating from the mesial frontal lobe and heavily involving the supplementary motor area manifest with tonic contraction of axial and limb muscles as in generalized tonic seizures.[60] The main differential pattern regards the consciousness that is lost in generalized tonic seizures and preserved or slightly impaired in partial tonic seizures. In fact, although the partial seizures of the frontal lobe show a bilateral body involvement, as the supplementary motor area has a bilateral motor representation, the ictal discharges remain confined to the unilateral frontal lobe, usually preserving consciousness.

Nonepileptic Seizures

Tonic Seizures in Hyperekplexia

Hyperekplexia is a disease characterized by an accentuation of the "startle response." Most cases are of autosomal dominant inheritance, although cases have been reported as having acquired brainstem lesion.[31] Children with this disease have myoclonic jerks as a reflex to tactile or acoustic stimulation. Furthermore, mostly in the early months of life, they can have prolonged stiffness seizures evoked by the same stimuli.[1] The child suddenly has a diffuse muscle contraction with limb extension; consciousness is preserved; the seizure causes respiratory arrest and cyanosis; if it lasts more than 2 to 3 minutes, the seizure can produce cardiac arrhythmia or sometimes death. The EEG does not show an ictal discharge, but only muscular artifacts. Whereas this seizure cannot be stopped by intravenous administration of antiepileptic drugs, it can be stopped by abrupt flexing of head and limbs to the trunk.[59] This movement permits a correct diagnosis.

Dystonic Seizures

Children with brain damage or epilepsy sometimes have dystonic movements with sustained muscle contractions that can be mistaken for epileptic seizures. In these dystonic events, the patient has a slow contraction of the trunk in dorsal extension, with deviation of the head to one side; the limbs contract in extension; consciousness is preserved; and the child often cries.

P.617

Such paroxysms can last from 3 to 10 seconds. The EEG does not show any ictal sequence. Such events are more frequent when the child has fever or feels pain.

Repetitive Sleep Starts in Neurologically Impaired Patients

Repetitive sleep starts occurring in clusters at the onset of sleep in neurologically impaired children have been reported as non-epileptic tonic or myoclonic manifestations.[15] Children who present with repetitive sleep starts have tetraparesis, and pyramidal or extrapyramidal features. Often they previously had a diagnosis of epilepsy in the first year of life. The onset of repetitive sleep starts is in the second year of life. Video-EEG recordings of the events during sleep show the presence of clusters of massive tonic contractions, resembling prolonged sleep starts, in the transition phase between wakefulness and sleep stage I, with the EEG counterpart being unremarkable. The clusters last from a few to 15 minutes. The duration of each muscle contraction is from 500 msec to 5 seconds, depending on the type of the contraction, which can be more or less tonic. No epileptiform pattern is observed as a counterpart of the clinical event. Muscle contraction is usually massive, involving more trunk than limbs, and onset is sudden and usually spontaneous but can be induced by acoustic and tactile stimulation. Clinical characteristics are similar to a startle.

Benign Myoclonus of Infancy

In 1977, Lombroso and Fejerman[37] described benign nonepileptic myoclonic manifestations in healthy children 6 to 12 months of age. While awake, the child has a brief tonic contraction, called myoclonus by the authors. This is actually a tonic contraction lasting 1 to 2 seconds that resembles a shiver. This phenomenon can happen several times a day, especially when the child is excited or tired. Consciousness is preserved and there are no postictal phenomena. The EEG is normal during the episode.

Specific Syndromes Incorporating Tonic Seizures as an Integral Feature

Generalized tonic seizures constitute one of the principal features of EIEE with suppression burst and of Lennox-Gastaut syndrome. Tonic seizures, not always generalized, constitute the main seizure type of the startle-induced epilepsy. In other syndromes, tonic seizures could be one of the several seizures presented. Epileptic tonic-spasms have been observed mostly in generalized symptomatic epileptic encephalopathy, independently from the underlying etiology. Tonic seizures are also the seizure type reported in epilepsy associated to some chromosopathy,[49] although a unifying syndromic picture has not yet been defined in these congenital conditions.

Response to Treatment

Tonic seizures are generally resistant to the commonly used antiepileptic drugs. Medications that make patients sleepy or lower their level of vigilance worsen tonic seizures, especially in Lennox-Gastaut syndrome, as the seizures occur more frequently during sleep than while awake. Consequently, a general principle of treatment is to consider all antiepileptic drugs, the only precaution being to avoid lowering the patient's vigilance level.[44]

Phenytoin can be effective for the treatment of tonic seizures and tonic status epilepticus, though it has side effects, including gingival hypertrophy, hypertrichosis, leukopenia, and disturbance of liver function.

Phenobarbital, primidone, and carbamazepine are at times effective for tonic seizures. Carbamazepine is particularly effective in the treatment of tonic postural seizures.

Sodium valproate is currently regarded as the drug of first-choice in Lennox-Gastaut syndrome. However, its effectiveness for tonic seizures is limited. Lamotrigine is an alternative initial therapy: It seems particularly effective in reducing falls and improving cognition and quality of life. Benzodiazepines such as clonazepam, nitrazepam, and clobazam are often used to treat tonic seizures. When a benzodiazepine is not effective, it should be withdrawn slowly to avoid withdrawal seizures or tonic seizure status epilepticus. Clobazam is useful in the treatment of Lennox-Gastaut syndrome because its side effects are much less marked than those of other benzodiazepines.[21] However, the development of tolerance is a problem with clobazam, as well as with other benzodiazepines.

Some authors have reported that intravenous injection of diazepam can induce tonic status epilepticus in patients with Lennox-Gastaut syndrome.[46,51]

Felbamate is indicated as adjunctive therapy in the treatment of generalized seizures associated with Lennox-Gastaut syndrome in children.[52] However, indications for its use are restricted because of recent data suggesting increased risks of developing aplastic anemia or liver failure in patients taking felbamate. In Japan, zonisamide is regarded as an effective drug for tonic seizures.[63]

Topiramate has been effective in some open and controlled trials, and anecdotal experience with levetiracetam suggests that this drug could also be effective in the treatment of tonic seizures. Vigabatrin could be very useful in the treatment of the tonic-spasm seizure moreover when the etiology is demonstrated to be symptomatic, although the risk:benefit ratio should be carefully considered.

Callosotomy has not been proven to be effective in the treatment of tonic seizures but is performed as a palliative measure. More clearly defined case selection and longer follow-ups are needed to fully evaluate its effectiveness.[4]

Summary and Conclusions

Tonic seizures are defined as such on the basis of a clinical phenomenon that actually includes different etiologies and pathophysiologic mechanisms. These occur mostly in patients with symptomatic epilepsies, but also in patients with cryptogenic epilepsies and, more rarely, in idiopathic epilepsies. Although there is the common element of tonic muscle contraction, it is possible to recognize shades of difference in the semiology that separate the various types of tonic seizures. It is probable that different types of tonic seizures utilize different anatomic pathways. Subcortical structures are surely involved, as are some cortical regions, especially the frontal lobe.

An element common to all the tonic seizures is their particular relation to sleep: Sleep and sleepiness facilitate tonic seizures. Another element, unfortunately common to all tonic seizures, is frequent drug resistance. Studies proposing to increase the knowledge of the pathophysiologic mechanisms of tonic seizures would permit a better treatment, both pharmacologic and neurosurgical, of this type of seizure in the future.

Chapter 53

Gelastic Seizures

Jeremy L. Freeman

Orvar Eeg-Olofsson

Introduction

It has long been recognized that laughter may be an epileptic phenomenon. Authors have cited different examples of the first mention of epileptic laughter, including the patient described in 1581 by Erastus and cited by Chen and Forster,[15] the patient of Trousseau published in 1873 and cited by Loiseau et al.[48] and Gascon and Lombroso,[29] the observations of Gowers in 1881 cited by Daly and Mulder,[16] and the report of Féré in 1898 cited by Druckman and Chao.[24] Daly and Mulder coined the term "gelastic epilepsy," from the Greek word *gelôs* meaning joy or laugh, to describe seizures in which laughter was an integral part.[16]

Gelastic seizures have most often been described in association with hypothalamic hamartoma, and there is good evidence that the gelastic seizures in those patients originate within the hamartoma itself (see later discussion). Gelastic seizures, however, are also described in patients without hypothalamic hamartoma, in whom a proven or suspected seizure focus lies in the frontal or temporal lobes, or where the origin of the seizures remains undetermined.

Definitions

After an earlier attempt by Gumpert et al.,[32] Gascon and Lombroso[29] suggested the following criteria for the diagnosis of gelastic epilepsy: Stereotyped recurrence of pathologic laughter; absence of external precipitants; concomitance of other manifestations generally accepted as epileptic (such as tonic or clonic movements, loss of consciousness, automatisms); presence of interictal and, where it can be recorded, ictal electroencephalographic (EEG) epileptiform discharges; and absence of other neuropathology that could explain pathologic laughter. Loiseau et al.[48] insisted on the now-accepted distinction between a seizure symptom or type and an epilepsy syndrome, arguing that there was no basis for the concept of "gelastic epilepsy," an example, in their opinion, of the futility of classifications based on a single symptom.

Epidemiology

Gelastic seizures are rare. The childhood prevalence of hypothalamic hamartoma with gelastic seizures was estimated at 0.5 per 100,000,[11] and although there are no estimates of the prevalence of gelastic seizures in patients without hypothalamic hamartoma, the number of cases reported in the literature is considerably smaller.

Clinical Features

Ictal Features

Laughter is the principal clinical manifestation and defines the gelastic seizure type. Whether there are features of the laughter or other ictal manifestations that can distinguish between different gelastic seizure foci has been a matter of much discussion, and the issue remains controversial. Gascon and Lombroso[29] noted that patients with probable temporal lobe seizure origin had either a pleasurable aura or a mirthful quality to their laughter, and Loiseau et al.[48] agreed that the laughter in such cases was an expression of emotion. Exceptions have been noted, however, including patients with temporal lobe tumors whose ictal laughter either sounded forced or did not have an infectious quality.[4,64] Conversely, gelastic seizures of frontal lobe origin are said to present a more uniform picture, in which laughter sounds unnatural, appears forced, is devoid of emotional content, and is not associated with feelings of mirth.[8,71] The clouding of consciousness and impairment of memory that often accompany gelastic seizures of temporal and frontal lobe origin make separation of the affective and motor components of ictal laughter fraught with difficulty. Furthermore, previous reviews of gelastic seizures not associated with hypothalamic hamartoma have included many cases described before the use of magnetic resonance imaging (MRI) and in which localization of the ictal onset zone was based primarily on scalp EEG abnormalities.[71] As is discussed further in Chapter 250, localized interictal EEG abnormalities and even invasive ictal recordings can be misleading in patients with hypothalamic hamartoma.[13] In addition, the diagnosis can easily be missed with computed tomographic imaging.[1,34,49]

The laughter in gelastic seizures associated with hypothalamic hamartoma has been described variously as "unnatural,"[21,69] "mechanical,"[13,70] "mirthless,"[44] "bubbling,"[20] "pleasant,"[5,70] or "normal."[1] Delay in diagnosis of gelastic seizures in patients with hypothalamic hamartoma (see Chapter 250) attests to the fact that the laughter may sound real[11] and be indistinguishable from the person's normal laughter.[1,3,54] The best-known example of this is the patient reported by Berkovic et al.[5] who won a happy baby contest. As the patient grows older, however, the quality of the vocalization may become increasingly less like normal laughter.[5]

As to the question of mirth associated with gelastic seizures in hypothalamic hamartoma, reports are limited in number because of the typically young age of patients and the frequent presence of intellectual impairment. Striano et al.[67] observed that older patients do not feel amused during gelastic seizures but, rather, are so embarrassed that they try to conceal them (e.g., by feigning a sneeze). On the other hand, Sturm et al.[68] described three adult patients who experienced a strong desire or "pressure to laugh" either separately from or just prior to typical gelastic seizures; one described this as a pleasant and emotional feeling in the chest, and another said it was a pleasant, nonsexual feeling that made him happy and would allow himself to laugh when this was socially appropriate.

Gelastic seizures may be closely related to seizures with epileptic crying, termed "dacrystic"[56] or "quiritarian."[64] Ictal crying has been noted in many patients with gelastic- seizures, mostly in association with hypothalamic hamar-toma[12,31,41,47,60,65,67,72,73] and less often associated with other

P.620

localized pathology.[64] By contrast, dacrystic seizures have rarely been reported in the absence of gelastic seizures.[17,18]

Gelastic seizures in patients with hypothalamic hamartoma are typically brief, lasting <30 seconds and often are just a few seconds in duration. Consciousness is said to be preserved during these brief events.[71] This appears to be based on the rapid resumption of previous activity in infants and young children and from interviews with adult patients; ictal cognitive testing, however, has not been undertaken. By contrast, laughter is said to be longer lasting in patients with frontal and temporal gelastic seizures and is associated with impairment of consciousness in temporal gelastic seizures.[71] Very frequent gelastic seizures that occur in wakefulness and from sleep are typical of infants with hypothalamic hamartoma.[22,62,65] Occasional cases of gelastic status epilepticus or "status gelasticus" have been reported, both in patients with hypothalamic hamartoma[55,59,73] and in one without it.[30]

Associated with the ictal laughter are other motor manifestations that have not been well characterized. Facial contraction resembling a grimace or smile is reported,[47,61] as are clonic buccal, palpebral, and ocular movements, producing a grimacing appearance.[20] Autonomic features including facial flushing, lacrimation, and pupillary dilation are known to occur in patients with hypothalamic hamartoma,[5,68] but whether these are unique to patients with hypothalamic hamartoma is uncertain. Cerullo et al.[14] demonstrated a rise in systolic and diastolic blood pressure, increased heart rate, facial flushing without diaphoresis, flattening of the plethysmogram, and modification of respiratory activity during gelastic seizures of two patients with hypothalamic hamartoma.

Interictal Features

Interictal clinical features in patients with gelastic seizures depend on the underlying syndrome diagnosis. There is insufficient knowledge of such clinical features in patients with gelastic seizures due to temporal or frontal lobe epilepsy. The interictal clinical features associated with hypothalamic hamartoma are discussed in relation to diagnostic considerations later in this chapter and in Chapter 250.

Postictal Features

Postictal features of gelastic seizures have not been well characterized. In older patients with hypothalamic hamartoma, gelastic seizures may be associated with impaired consciousness. In addition, gelastic seizures in hypothalamic hamartoma may be followed by nongelastic seizures, and the postictal features of these other seizure types may dominate the clinical picture. Whether these nongelastic seizures represent seizure spread from the hypothalamic hamartoma[13] or are otherwise "triggered" by the gelastic seizure[41] is unresolved, but both situations are possible.

Electroencephalographic Findings

Interictal Findings

Interictal EEG findings in patients with gelastic seizures necessarily depend on the associated syndrome diagnosis and, in patients with hypothalamic hamartoma, the degree of epileptic progression. In patients with hypothalamic hamartoma and gelastic seizures alone, particularly during infancy and early childhood, the interictal scalp EEG may be normal,[5,27] and the subsequent appearance of scalp EEG abnormalities coincides with the development of other seizure types and clinical features (see Chapter 250 for more details). Stereotactic depth EEG studies in some patients with hypothalamic hamartoma have demonstrated interictal discharges produced within the hamartoma,[43,46] but these do not coincide with scalp EEG discharges.[41] Recently, in vitro studies with surgically resected hypothalamic hamartoma tissue slices and single cells have demonstrated intrinsic pacemaker-like properties of GABAergic hamartoma neurons.[74] It is speculated that attachment of the hamartoma to the mammillary bodies enables seizure propagation via connection with the mammillothalamic tracts to other limbic areas and may facilitate progression of the epileptic syndrome and the development of widespread interictal epileptiform discharges, including slow spike-wave discharges, in a process akin to secondary epileptogenesis.[26,27,54]

Ictal Findings

Ictal EEG findings of gelastic seizures depend on the location of the ictal onset zone and patterns of seizure propagation. It is now widely accepted that the gelastic seizures associated with hypothalamic hamartoma originate within the intrinsically epileptogenic hamartoma.[6] The most important contribution to our understanding of the role of the hamartoma in the genesis of seizures came from the stereotactic depth EEG studies of patients conducted by Munari, Kahane, and colleagues in Grenoble.[40,41,42,43,54] They demonstrated that gelastic seizures are associated with an ictal discharge within the hamartoma itself and that electrical stimulation of the hamartoma can reproduce the patients' clinical symptoms. Kuzniecky et al.[46] replicated these results and performed ictal single photon emission computed tomography (SPECT) studies that demonstrated hyperperfusion in the region of the hamartoma. Confirmation of the intrinsic epileptogenicity of the lesion then formed the basis for the various forms of surgical treatment now offered to patients with hypothalamic hamartoma and refractory epilepsy (see Chapter 250). Propagation of the ictal discharge to the cingulate gyrus was also demonstrated with depth EEG.[54]

Scalp ictal EEG patterns during gelastic seizures associated with hypothalamic hamartoma may be absent.[3,57,65,70] When an ictal EEG pattern is noted, the most consistent finding is diffuse EEG desynchronization, which may be followed by diffuse or lateralized low-voltage fast activity.[5] Desynchronization of the EEG and cessation of the interictal epileptiform discharges may also be produced by depth electrode stimulation of the hamartoma.[41]

Diagnostic Considerations

The association between hypothalamic hamartoma and gelastic seizures is so strong that almost all patients with the hypothalamic hamartoma syndrome have gelastic seizures at some point in the course of their epilepsy.

Therefore, hypothalamic hamartoma should be considered in any person with ictal laughter.

The mechanisms by which the clinical manifestations of gelastic seizures are produced are poorly understood, and it is uncertain whether ictal clinical features can distinguish between patients with and without hypothalamic hamartoma. Regarding the functional anatomy of mirth and laughter in humans, Arroyo et al.[2] presented a hypothesis drawing on their own observations, reports in the literature of conditions associated with pathologic laughter, and electrophysiologic aspects of laughter, including both stimulation experiments and ictal EEG recordings. They concluded that the cingulate and basal temporal cortex were important contributors to mirth and laughter, and suggested that the anterior cingulate was of primary importance in relation to motor aspects, whereas the basal temporal cortex was involved in processing emotional

aspects; the hypothalamus was presumed to subserve the autonomic nervous system response. Involvement of the hypothalamus in normal laughter has been implied by the association of various hypothalamic lesions with pathological laughter,[2,37] yet depth EEG studies in patients with hypothalamic hamartoma indicate that the hypothalamus proper is spared by the ictal discharge.[54]

Biraben et al.[8] suggested that ictal laughter might be produced by one of three mechanisms: (a) a simple reaction to a modified cognitive process, (b) an automatic behavior, or (c) a forced action. They argued that the latter two mechanisms are indistinguishable clinically but could have different anatomic and physiologic bases. Fried et al.[28] reported electrical stimulation of laughter in a girl who underwent subdural monitoring for epilepsy but did not have laughter as part of her ictal semiology. The area stimulated was in the left superior frontal gyrus, at the lateral limits of the supplementary motor area, and the resultant laughter was accompanied by a sensation of merriment or mirth. The patient offered a different explanation for it each time, attributing the laughter to whatever external stimulus was present. Fried et al. suggested a close link between the motor, affective, and cognitive components of laughter and that these components are represented in a neuronal network capable of parallel distributed processing, in which the entire network is activated as a whole by the stimulation of any of its constituent units.

Using $H_2{}^{15}O$ positron emission tomography (PET), Iwase et al.[38] investigated differences in brain activation between smiling produced voluntarily and that produced in response to comic stimulation in healthy subjects. They found that emotional smiling activated visual association areas, the left anterior temporal lobe, left uncus, left orbitofrontal cortex, and right medial prefrontal cortex, as opposed to voluntary smiling, which activated primary and supplementary motor cortex as well as bilateral parietal and insular cortex. According to Arroyo et al.,[2] the orbitofrontal cortex is a region responsible for inducing laughter associated with mirth.

Interictal clinical features and the circumstances surrounding the expression of gelastic seizures may be of greater use in distinguishing between patients with and without hypothalamic hamartoma. Gelastic seizures in patients with hypothalamic hamartoma usually begin in infancy or early childhood. Neonatal onset is common, and onset from the very first day of life is well known.[5,20,22,46,58,65] In patients with onset in early childhood, other seizure types characteristically appear in a delayed fashion along with worsening of the interictal EEG and cognitive deterioration.[5,27] In contrast, gelastic seizures in patients without hypothalamic hamartoma are said to have a later age of onset, and, if other seizure types occur, they do so concurrently or pre-date the gelastic seizures.[71] Onset of gelastic seizures in adult life, however, is known to occur in patients with hypothalamic hamartoma,[52] and other seizure types may present before gelastic seizures in both children and adults with hypothalamic hamartoma.[53] Central precocious puberty is associated with hypothalamic hamartoma and may be the presenting symptom in children[26]; it is not uncommon for the diagnosis of epilepsy to be made only after investigation for precocious puberty if gelastic seizures have been unrecognized. Hypothalamic hamartoma is usually an isolated and sporadic cerebral malformation, but gelastic seizures are reported in patients with Pallister-Hall syndrome,[45] an autosomal-dominant condition associated with hypothalamic hamartoma and insertional polydactyly.[7,10]

Continuous video-EEG monitoring is an essential investigation for characterization of gelastic seizures and the associated epilepsy syndrome. In patients with gelastic seizures not associated with hypothalamic hamartoma, useful information about the ictal onset zone may be obtained. In patients with hypothalamic hamartoma, characterization of gelastic seizures and other seizure types, along with evaluation of the interictal EEG in wakefulness and sleep, allows for assessment of the degree of epileptic progression, if any, on which treatment decisions may be predicated.

MRI examination of the brain with an appropriate high-resolution epilepsy imaging protocol is a mandatory investigation in patients with gelastic seizures but also when there is any component of laughter noted on history or video-EEG recording of seizures, including patients with a mirthful aura or a feeling of "pressure to laugh." In addition, attention should be drawn to the region of the hypothalamus by the referring physician in such cases. We have seen several patients in whom a small intrahypothalamic lesion was overlooked despite an adequate imaging study having been performed. In patients without hypothalamic hamartoma, MRI may disclose a tumor, focal cortical dysplasia, or other lesion. Although patients with hypothalamic hamartoma only rarely have associated potentially epileptogenic lesions elsewhere in the brain,[26] MRI studies should be of sufficient quality to detect such lesions in consideration of epilepsy surgery.

Other investigations, including functional brain imaging (SPECT, PET, or functional MRI), neuropsychological evaluation, and invasive EEG monitoring, may be indicated in patients with gelastic seizures in whom surgical management is entertained. In patients with hypothalamic hamartoma, however, functional imaging and invasive monitoring are now generally considered unnecessary for proving the origin of gelastic seizures.[35] Exceptions are rare cases with associated potentially epileptogenic lesions elsewhere in the brain.

Differential Diagnosis

The differential diagnosis of gelastic seizures includes pathologic laughter associated with other conditions of the nervous system, including progressive supranuclear palsy, multiple sclerosis, amyotrophic lateral sclerosis, and psychiatric illness, to name but a few.[9,37,50] The distinction between epileptic and nonepileptic pathologic laughter is generally made in accordance with the criteria of Gascon and Lombroso[29] and may be facilitated by the use of video-EEG monitoring. Narcolepsy-cataplexy has been mistaken for gelastic-atonic seizures in one case,[25,39] and this particular diagnosis may be challenging in cases of Niemann-Pick disease type C.[63]

The most difficulty, however, arises in distinguishing between normal laughter or crying and gelastic or dacrystic seizures in children with hypothalamic hamartoma, often resulting in late presentation and sometimes in diagnostic delay after medical attention is sought. There are several reasons for this. There is little appreciation among parents and doctors that laughter in the neonatal period is developmentally precocious and should be regarded as abnormal.[5,66] Unexplained crying in infancy is common and considered normal or attributed to other conditions such as infantile colic.[61] Gelastic seizures in infancy are not typically accompanied by "other manifestations generally accepted as epileptic," and interictal scalp EEG recordings of infants with hypothalamic hamartoma are usually without abnormality. Most importantly for the neurologist and epileptologist, ictal EEG patterns may be absent during gelastic seizures.[3,57,65,70] Therefore, a high index of suspicion in an infant with unexplained episodic laughter or crying in whom the episodes are unprovoked, brief, and stereotyped in appearance will lead to further investigation and correct diagnosis.

Specific Syndromes

Other symptomatic focal epilepsies are the next-most-common category of syndromes associated with gelastic seizures and may be further classified according to location

and etiology. The locations associated with gelastic seizures are the temporal lobe, with particular emphasis given to the basal temporal cortex[64] or the lateral convexity[48]; and the frontal lobe, with particular emphasis given to the cingulate gyrus[2,51] and the mesial forebrain.[48] The pathology reported in these cases has included tumors of various types and grades, including meningioma,[48] astrocytoma,[64] ependymoma,[16] oligodendroglioma,[4] and cavernous haemangioma[2]; focal cortical dysplasia[19,51]; and less specific findings including hemispheric atrophy or dilation of the lateral ventricular horns.[29] Probable symptomatic cases with normal MRI examinations and focal origin of seizures demonstrated with video-EEG monitoring and ictal SPECT are also reported.[8,67]

Gelastic seizures have been reported in association with other symptomatic (or probable symptomatic) epilepsy syndromes, including West syndrome,[11,23,24,27,53] tuberous sclerosis,[33,75] measles encephalopathy,[15] and Niemann-Pick disease type C[15,63] and in patients with widespread cerebral malformations such as lobar holoprosencephaly and lissencephaly.[36] By contrast, gelastic seizures have only rarely been described in patients with presumed idiopathic epilepsy syndromes.[36]

Response to Treatment

The prognosis for patients with gelastic seizures depends entirely on the associated epilepsy syndrome and the underlying etiology. Gelastic seizures associated with the hypothalamic hamartoma syndrome are typically refractory to medical treatment but may be amenable to surgical treatment (see Chapter 250). No particular prognostic significance is attached to the occurrence of gelastic seizures in other epilepsy syndromes or conditions associated with epilepsy. The management of patients with gelastic seizures also depends on the associated epilepsy syndrome and underlying etiology. Management of gelastic and other seizure types associated with the hypothalamic hamartoma syndrome is discussed in Chapter 250, and the management of symptomatic focal epilepsy syndromes, other epilepsy syndromes, and other causative conditions mentioned earlier are beyond the scope of this chapter and are discussed elsewhere.

Summary and Conclusions

Gelastic seizures are an uncommon seizure type in which ictal laughter is the principal manifestation and defining feature. The hypothalamic hamartoma syndrome is strongly associated with gelastic seizures and should be considered in all patients with ictal laughter, although there are frontal and temporal lobe epilepsy patients with various underlying pathologies and other, mostly symptomatic epilepsy syndromes in which gelastic seizures are reported. Interictal clinical features may be of more use than ictal clinical features in distinguishing between patients with and without hypothalamic hamartoma, whereas MRI is an indispensable diagnostic investigation.

Chapter 45

Neocortical Sensory Seizures

Paul C. Van Ness

Ronald P. Lesser

Michael S. Duchowny

Introduction

Simple sensory seizures represent challenging clinical phenomena. Neurologists readily accept that a patient's sensory symptoms prior to the appearance of motor symptoms or alteration of consciousness represent part of the patient's clinical seizure semiology and provide valuable localizing information. A challenge appears when a patient has only simple partial sensory seizures. Simple partial seizures are a relatively common seizure presentation among the childhood epilepsies, but motor seizures are predominant.[47] The paucity of psychic or sensory symptoms may reflect the child's inability to describe internal experiences in a way that is easily interpretable to adult observers. Since simple sensory seizures have no overt ictal behavior, the subjective description of the seizure symptomatology is the only clue that can lead to a proper clinical evaluation and treatment. Some patients react to sensory seizures in a stereotypic fashion. For example, a painful simple partial sensory seizure of the hand may result in hand rubbing or vocalization about the pain. Occasionally, physicians encounter patients who have simple partial seizures for many years prior to the appearance of more clinically apparent seizures. When patients with pure sensory seizures also have psychiatric complaints, the chances for misdiagnosis or delay of diagnosis are high.[121]

Simple sensory seizures were originally underrecognized as epilepsy.[35] While auras were known in ancient times as an event preceding seizures,[122] it was not until the early 19th century that partial seizures were clearly related to localized brain disease. Fritsch and Hitzig described localization of function in 1870, which led to modern concepts of cortical specification.[38]

Jackson also promoted the hypothesis that abnormal electrical activity in a localized region of cortex could cause symptoms such as those seen in epilepsy.[51,52] In the early 1900s, the work by Brodmann[18] and other neuroanatomists showed that the cerebral cortex had regional histologic variations often corresponding to different cerebral functions. Penfield, Jasper, and others made major contributions to mapping the localization of cerebral function and defining motor and sensory areas of the brain, as well as areas without obvious effect on sensory, motor, or speech activity.[83,85]

Definitions

Sensory seizures were defined by Penfield and Jasper separately from simple seizures with autonomic symptoms or psychic symptoms:[85]

â€œSensory seizures. Discharge in an area of sensory representation produces a sensation that may serve as a warning (aura) of a motor or psychical seizure. Actually, the sensation constitutes, in itself, a seizure. Under this heading we have taken up the sensory attacks that involve the trunk, head, and extremities (somatosensory), and the special senses (visual, auditory, vertiginous, gustatory, and olfactory).

1. Somatosensory seizures. Sensation of this type may be transient, or it may be continuous over a considerable period of time. The quality of sensation is tingling, numbness, sense of movement, desire to move, or, very occasionally, pain. A detailed march of sensation may occur from one somatic part to the

next in a manner similar to the Jacksonian motor march. The discharge, which produces this, usually occurs in the postcentral gyrus. There is a tendency for the sensory march to stop and to spread across the Rolandic fissure so as to produce movement in the same member. Spread in the reverse direction from motor to sensory representation, thus producing sensation after movement, is quite rare.

A somatosensory seizure may also be produced by discharge in the second sensory area on the upper bank of the fissure of Sylvius. Furthermore, peculiar body sensations may result from discharge in the supplementary motor area within midsagittal fissure.

2. Visual seizures result from discharge in one or the other occipital lobe. Lights, which may be colored, appear before the patient, or there may be dimming of vision and complete blindness even though the discharge originates in one occipital lobe. Complicated visual hallucinations and alterations in the interpretation of things seen are not included in this group, but are discussed under the heading of psychical seizures.
3. Auditory seizures are characterized by a simple sound, usually described as buzzing or drumming, and often referred by the patient to the opposite ear, or opposite side of the head. Like a visual seizure, there is nothing elaborate about it. Hallucinations of music, for example, are classified as dreamy states or psychical seizures and are discussed below.
4. Vertiginous seizures. What is called by the patient dizziness or unsteadiness is frequently reported, but there is rarely any recollection of direction of rotation as there is in the sudden dizziness of Meniere syndrome.
5. Olfactory seizures have been called uncinate fits because of the demonstration by Jackson of involvement of the uncinate gyrus in cases in which an aura of disagreeable odor constituted the initial feature. The localization of discharge is doubtless in or near the uncinate gyrus.â€

Penfield and Jasper's classification of simple partial sensory seizures has withstood the test of time since the international classification[26] of simple partial seizures with somatosensory or special sensory symptoms is nearly identical to the original description except for lack of description of gustatory seizures (Table 1). It is unlikely that another sensory modality will be discovered and change the classification further.

Table 1 Simple Partial Seizures with Somatosensory or Special Sensory Symptoms[a]

Somatosensory
Visual
Auditory
Olfactory
Gustatory
Vertiginous

[a]Simple hallucinations (e.g., tingling, light flashes, buzzing).

Penfield and Jasper recognized the difficulty of separating a simple sensation from a more complicated hallucination, for example, separating simple visual hallucinations from more complicated formed illusions. Occasionally one finds more complicated hallucinations with intraoperative stimulation, but more reliably localizing are the simple hallucinations of rather elementary sensory perceptions. A conscious patient may attach many complex descriptions to simple

P.530

hallucinations, and since we observers have nothing to observe other than the patient's subjective description, sometimes there may be a fine line between a classification of simple partial sensory seizure and a simple partial psychic seizure with prominent sensory complaints.

Epidemiology

Ideally, understanding the epidemiology of simple partial seizures would require evaluation of a large population in which patients with epilepsy are identified accurately and their seizures and epilepsies are classified based on a thorough clinical and laboratory investigation. Such studies are usually based on patients referred to specialized epilepsy centers. Focal epilepsy occurs in approximately 60% of patients with epilepsy, and 10% to 21% of these patients have simple partial seizures alone.[40] Detection of simple partial seizures can be difficult. Some patients with simple partial sensory seizures may be undiagnosed or unaware that their symptom represents epilepsy unless the seizure progresses into a more disabling seizure type. In patients with obvious epilepsy and more severe types of seizures, only a careful history will elicit remote sensory complaints that may no longer occur, as in several cases reported by Williamson et al.[123]

Isolated simple partial sensory seizures are uncommon in patients referred to major epilepsy centers. Among the focal epilepsies, temporal lobe and frontal lobe foci predominate in surgical series.[119] Parietal and occipital cases are rare because those epilepsies are either rare, rarely intractable, or rarely brought to surgery. For example, occipital epilepsy was identified in only 12 of 502 nontumoral epilepsy cases by Bidzinski et al.[12] Williamson et al. reviewed reports of occipital lobe epilepsy in the literature and found that <2% of focal epilepsy is occipital.[124] They found only sporadic reports when they reviewed parietal lobe epilepsy.[123]

These surgical data are typically grouped by lobe, not seizure type. It is likely that the epidemiology of simple partial sensory seizures differs from the lobar distribution of surgical cases. A review of the initial signs of seizure onset in data adapted from Penfield and Kristiansen showed that in 222 patients, 55 had somatosensory auras, 11 had visual auras, three had auditory auras, one had an olfactory aura, and two had gustatory auras.[62] Penfield and Perot noted visual hallucinations in 41 of 1,132 (3.6%) patients with focal epilepsy; 21 had only visual hallucinations.[87] Mauguiere and Courjon found somatosensory epilepsy in 127 of 8,938 (1.4%) patients with epilepsy when evaluated after age 3 years.[72] Young and Blume reported painful seizures in 24 of 858 (3%) epileptic patients[129] and Hausser-Hauw and Bancaud noted that 30 of 718 (4%) intractable epileptics had gustatory hallucinations.[43] West and Doty reviewed olfactory auras in epilepsy and concluded that prevalence is unknown but published estimates ranged from <1% to >30% depending on the epilepsy syndrome and pathology.[122]

The advent of magnetic resonance imaging (MRI) technology has further complicated matters. Patients with lesions identified in known sensory cortical regions may not volunteer information on sensory symptoms until thoroughly interrogated about an aura. At times, only with inpatient video-electroencephalography (V-EEG) and MRI can sensory symptoms be suspected and assessed. This is especially true in patients with sensory symptomatology at seizure onset that progresses to loss of consciousness and amnesia for the aura. These patients often have more intense seizures and EEG changes are usually bilateral.[103] Additionally, sensory symptoms may result from spread of a seizure from an unexpected location; for example, many patients with supplementary motor seizures complain of a somatosensory aura even when lesions are not near the sensory cortex.[106] Gustatory hallucinations may also represent seizure spread.[43] Visual hallucinations have been reported with frontal lesions,[102] as have jacksonian sensory seizures from a prefrontal lesion.[118] Thus, at this time, there is still need for adequate epidemiologic studies of localization-related epilepsies and partial sensory seizures using modern technology and appropriate clinical information.

Anatomic Pathways and Pathophysiology

Understanding neocortical anatomy and regional interconnections has led to a better understanding of seizure semiology and evolution. The neocortex is a repository for all primary sensory input for somatosensory, visual, auditory, and gustatory senses, while olfaction mostly utilizes portions of the limbic system and is the only special sense without thalamic relays.[21] Within the cerebral cortex, sensory functions are not so discreetly organized that there are sharp boundaries; for example, the sensory responses obtained by Penfield and Rasmussen[88] and Uematsu et al.[116,117] showed that sensory responses could be recorded from the precentral gyrus (see reference 85, p. 58, Fig III-12). Motor responses show similar dispersion. Penfield reported that removal of the precentral gyrus did not prevent motor responses from the postcentral gyrus, suggesting that activation of the postcentral gyrus alone could result in movements during seizures.

The sensory homunculus (see reference 85, p. 70, Fig III-15) must be considered as an artist's schematic diagram of data obtained by Penfield and Jasper on many patients; it is not entirely accurate for each patient. However, the homunculus does show significant organization of the cerebral cortex in an anatomically meaningful way (see reference 85, p. 71, Fig. III-17).

Some body parts (e.g., the tongue and hand) have large cortical sensory areas. Picard and Olivier have extensively reviewed the anatomy of the sensory tongue cortex in humans. The language-dominant hemisphere had a larger sensory cortical tongue representation and the tip of the tongue had more extensive representation than the middle or back portions of the tongue.[89] Most cortical representation was contralateral to somatic localization, but ipsilateral and bilateral responses to stimulation were reported, suggesting possible stimulation of the secondary sensory area, located at the base of the perirolandic cortex.

Penfield and Rasmussen[88] found a human second sensory area in the region of the termination of the motor strip in the frontoparietal operculum (see reference 85, p. 79, Fig III-21). When stimulated, the second sensory area on the superior bank of the frontoparietal sylvian fissure produces bilateral, contralateral, or ipsilateral sensations, often of the perioral regions (see reference 85, p. 79, Fig III-21). Ipsilateral inputs are less numerous as shown by Adrian in cats.[1] LÃ¼ders et al. recorded evoked potentials from the second sensory area that were of lower amplitude than primary sensory potentials.[67]

Other primary sensory cortices show highly organized anatomy; for example, the visual cortex deep within the calcarine fissure is organized so that the occipital pole is innervated polysynaptically by the macula and therefore is activated by the central visual field, whereas more rostral portions of the calcarine cortex contain representations of more peripheral visual fields.

The auditory cortex in the Heschl gyrus of the temporal lobe is tonotopically organized as shown by evoked potential mapping of longer-latency responses with magnetoencephal- ography.[82,115,119,120] Vestibular cortex is also in the superior temporal gyrus rostral to the auditory cortex, but stimulation does not produce anatomically specific symptoms, just mild vertigo.[85]

Taste is represented in the parietal operculum and possibly near the insula,[85] though Hausser-Hauw and Bancaud's detailed depth electrode studies point primarily to the parietal operculum.[43] Olfaction initially involves pathways from the olfactory epithelium through the cribriform plate to the olfactory bulbs, olfactory tracts, and lateral stria. These areas project to the anterior perforated space, prepiriform cortex, lateral olfactory gyrus, periamygdaloid cortex, entorhinal cortex, amygdala, septal nuclei, and hypothalamus.[122] Thus, most olfactory centers are located in the mesial temporal region and adjacent structures.

While a description of epileptogenesis is beyond the scope of this chapter, clearly any structural lesion, whether seen by MRI or not, involving a sensory cortex or adjacent area may provide the necessary and sufficient changes for chronic localization-related epilepsy to develop. The concept of the epileptogenic zone, as interpreted by Penfield and Jasper[85] and Ajmone-Marsan[4] and reviewed by LÃ¼ders and Awad,[65] implies that the locations in the cortex where symptoms are produced, where seizures are generated, where interictal spikes occur, and of any structural lesions all may contribute to epileptogenesis or to the symptom expression during seizures. It is certainly possible for sensory cortex to become activated late in a seizure and thus produce symptoms after the actual EEG onset in a silent cortical area. To experience somatosensory, visual, or auditory symptoms, white matter pathways, association cortices, and brain structures regulating attention and consciousness all play a role.

Epileptogenesis producing sensory seizures and focal epilepsy may occur without brain lesion or injury from peripheral nervous system injury. Spiller et al. reported three cases with soft tissue injuries to the hand where sensory seizures developed within months in the injured limb and all cases eventually had secondarily generalized tonicâ€“clonic seizures. The authors postulated that the injury resulted in cortical reorganization that was epileptogenic.[109]

Clinical Features

Simple sensory seizures show a wide variety of phenomenology and represent some of the most interesting seizures reported. Patients can have prolonged symptoms[70] and can relate elaborate descriptions of their seizure. Since sensory cortices are located in adjacent lobes, it is not surprising that multimodality sensory seizures are frequently reported in addition to sensory seizures from one modality.[72]

Seizures of the primary sensory cortex typically produce contralateral positive or negative symptomatology. Unilateral symptoms thought to originate in or near the contralateral postcentral gyrus include tingling, numbness, sense of movement, desire to move, somatic pain, heat or cold, electric shock sensations, agnosia for a body part, and phantom sensations.[60,72,85,99,123,129] The hand and fingers are most often involved initially.[72] Symptoms may be stationary or have a sensory march. Somatosensory seizures may be interpreted as motor activity by the patient, even when there is no visible movement seen. This can often lead to misinterpretation of seizure localization by a physician taking the history. Cephalic pain, occasionally migrainous in nature,[19] even if unilateral, may not have localizing value, while abdominal pain usually originates from the temporal lobe.[129] Genital pain probably originates at the mesial parietal termination of the sensory strip and is not necessarily associated with orgasmic seizures.[98,110,128] Attacks of limb agnosia (sudden loss of sensation for a body part) and phantom limb sensations (sense that the limb is in a position that is not the true position) probably originate in the posterior parietal region.[41,72,99] Ajmone-Marsan gives Foerster credit for pointing out that a postcentral-area seizure can be distinguished from the precentral seizure since motor symptoms stop earlier when the seizure originates in the postcentral gyrus and that the convulsing muscles are often more limited in distribution than when the primary motor cortex is seizing. Additionally, when a motor seizure occurs after activation of the sensory cortex, a tremor may be seen before true clonic spasms, if clonic spasms occur.[4] Russell and Whitty observed that somatosensory auras often spread quickly to involve at least the entire limb and that prolonged sensory seizures, comparable to the epilepsia partialis continua of motor seizures, were not observed in their 85 cases. Motor seizures rarely progress to a simple somatosensory seizure, while the reverse is common. Sensory seizures often end abruptly, unlike the gradual cessation typical of focal motor attacks.[99]

Seizures from the second sensory area may produce ipsilateral or bilateral symptoms that are identical in character to symptoms occurring in the primary sensory cortex (e.g., numbness and tingling). Affected body parts can be diffuse or axial but often symptoms localize to the fingertips, feet, lips, or tongue.[2,6,11,13,61,85,93,123] Second sensory-area seizures can arise from the frontoparietal operculum or the inferior parietal lobule.[126] It is also possible to have ipsilateral sensations with seizures originating near the supplementary motor area since there may be a corresponding supplementary sensory region adjacent to the primary sensory foot area.[85] Arseni and Maretsis' case 3 may have had ipsilateral seizures from this location.[6]

Somatosensory auras have been reported in temporal lobe epilepsy, usually with bilateral or unilateral tingling. Pain and numbness were also noted in Erickson et al.'s report and most symptoms were in the limbs but could involve the head or trunk.[36]

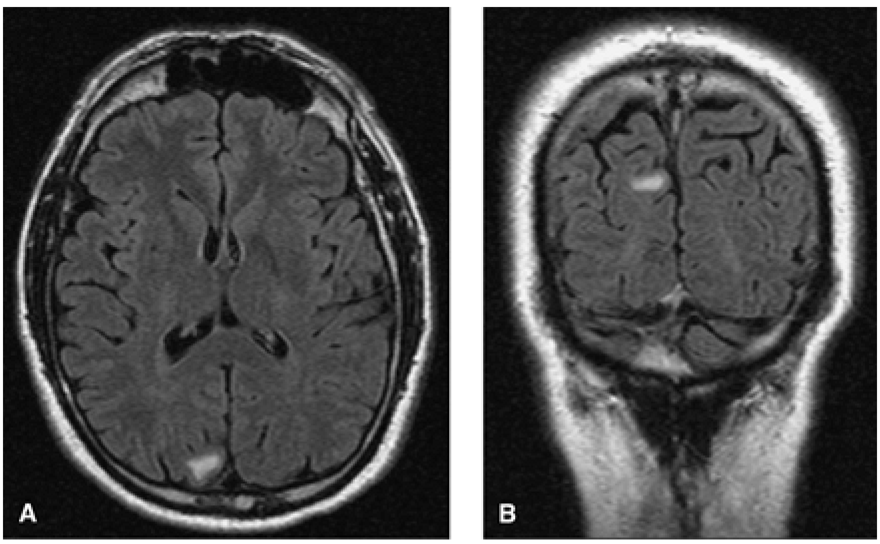

FIGURE 1. Poststroke occipital epilepsy. **A, B:** This is a magnetic resonance image of the brain in a 53-year-old male smoker and drinker with a right occipital infarct, mild left homonymous visual scotoma, and complex partial seizures with an aura of autonomic symptoms of epigastric sensation, facial flushing, and dizziness associated with â€œgraying outâ€ of his vision prior to loss of consciousness. Routine electroencephalography was normal and seizures are controlled by carbamazepine.

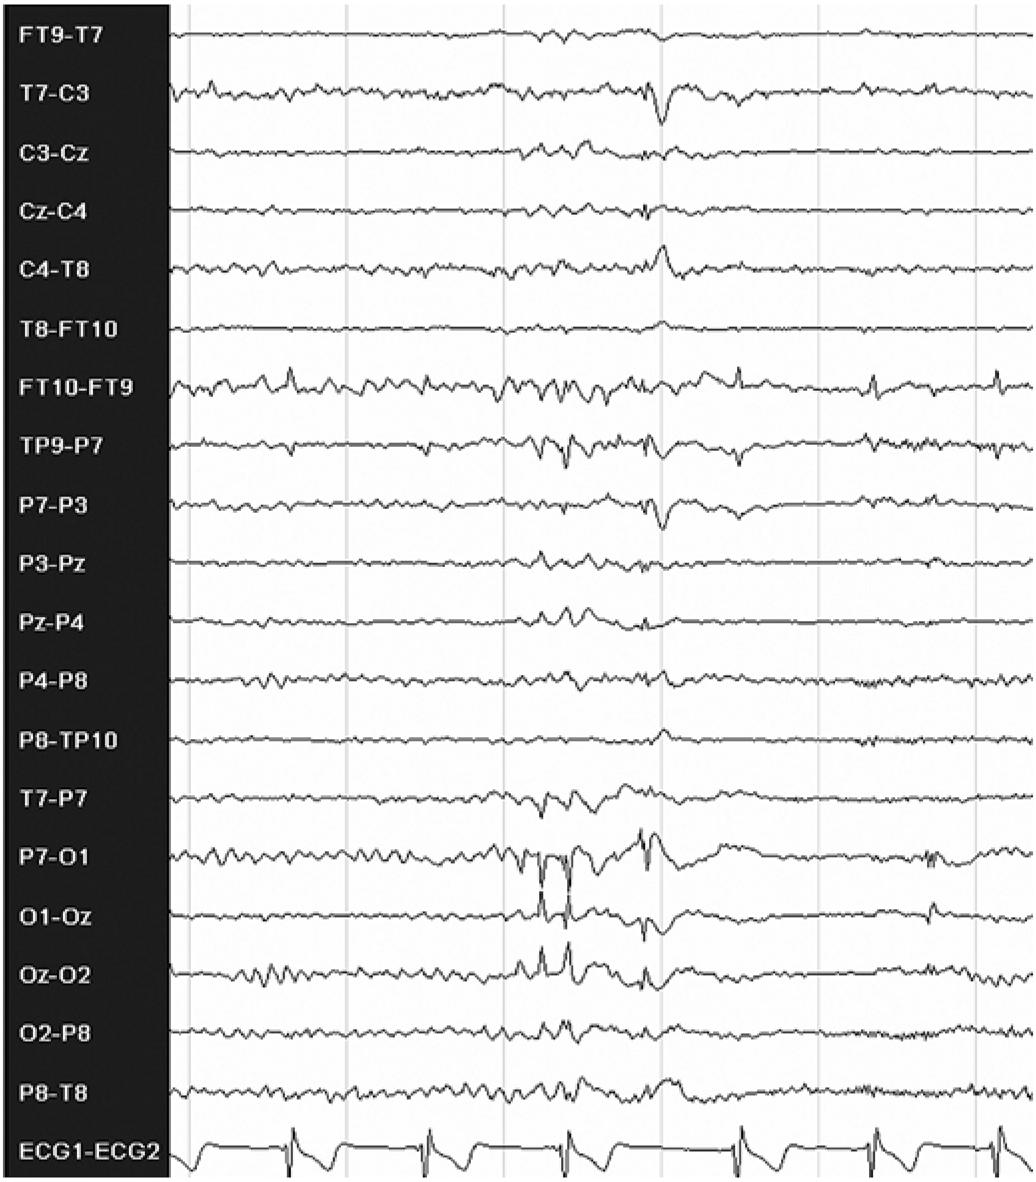

FIGURE 2. Interictal electroencephalogram showing left occipital spikes in an 18-year-old, right-handed male patient with a history of seizures since age 5, starting 3 months after a mild head trauma. He has an aura of right-sided flashing lights, then vertigo, followed by a subjective feeling of right arm twitching and then loss of consciousness. After that he turns his head to the right, raises his right arm, and progresses into a secondarily generalized tonicâ€“clonic seizure. Magnetic resonance imaging of the brain was normal. The patient became seizure free after adding levetiracetam to his monotherapy carbamazepine regimen.

FIGURE 3. A: Same patient as in FIGURE 2, 16 seconds after ictal onset showing the electroencephalographic onset of a left occipital seizure. Patient reported seeing flashing lights to his mother prior to this time. **B:** Left occipital seizure 28 seconds after clinical onset showing O1 spikes and later rhythmic fast activity. **C:** Same seizure, 40 seconds after clinical onset. Note the rhythmic sharp waves maximally over the left occipital region. The seizure subsequently spread and secondarily generalized, not ending until 88 seconds after clinical onset.

Simple sensory visual seizures' semiology includes positive symptoms and unilateral or bilateral negative symptoms.[49,101] Seizures of the calcarine cortex produce elementary visual hallucinations such as flashing or flickering lights, spots, colored lights, weaving patterns, zigzag lights, or visual field deficits such as scotoma or ictal amaurosis.[85,100,101,124] Other seizure symptoms attributed to the occipital lobe include eye movement sensations, sensations of object movement, ictal nystagmus, eye deviation, early forced blinking, and inversion of the visual field.[57,93,101,124] Some cases with autoscopic hallucinations where a person sees him- or herself without a mirror may be due to epilepsy.[63,100] Eye movements can complicate the clinical picture; for example, if a patient sees a bright light, he or she may look toward that light and yet the light continues to move away as his or her eyes deviate, giving a sensation of movement. Nystagmus may also occur and complicate the symptomatology. The patient may see colored lights. Negative symptoms can include loss of a visual field or quadrant; some patients complain of transient blindness. Ictal blindness probably results from seizure spread to the contralateral occipital lobe.[9] The visual symptoms often occur in areas of scotoma or other visual field defect.[58,100] While the simplest visual phenomena probably relate to involvement of the calcarine cortex,

adjacent areas may also participate, and occasionally patients with posterior temporal lesions or parietal lesions may report a visual aura with or without other disturbances. Formed or complex visual hallucinations, including remembered scenes[95] or distortions such as micropsia, macropsia, or changes in object shape, and blindness or hemianopia probably originate in the visual association cortex or adjacent parietal or temporal lobe[100] and are more often seen from the right or nondominant posterior temporal region.[87]

Auditory seizures were reported by Holmes as early as 1927.[46] Penfield and Kristiansen found only three patients, suggesting that this condition is rare.[86] The auditory symptoms can occur without dizziness. Certainly more complicated auditory hallucinations can occur, such as hearing words or music, but these seizures usually are classified as psychic, rather than just as sensory seizures, because of accompanying experiential phenomena. Simple sounds such as buzzing, drumming, or single tones, often contralateral, are typical of seizures from the auditory cortex.[85] One localizing sign noted occasionally with an auditory seizure consists of plugging an ear or placing the hand over the ear. This seems to correlate with an auditory aura that originates contralateral to the plugged ear in the auditory cortex.[25]

Simple partial olfactory sensory seizures (uncinate seizures) are relatively infrequent considering the large number of patients with temporal lobe epilepsy seen at most centers. These seizures may originate from the orbitofrontal cortex as well as the mesial temporal region. Howe and Gibson reported that there is not an increased incidence of tumors in patients with olfactory aura,[48] contrary to reports in other series (see reference 122 for review). Olfactory symptoms have also been reported in occipital- or central-area epilepsy by King and Ajmone-Marsan,[55] but seizure spread may explain at least some of the more unusual localizations. The odor is often but not exclusively unpleasant or disagreeable.[28,85,122] Daly described two types of olfactory phenomena. Hallucinations may be crude or elaborate with other sensory modalities involved, while illusions distort or alter the character of normal olfactory stimuli. Illusions were also noted interictally or postictally.[28]

Gustatory seizures are usually associated with temporal lobe epilepsy, often due to tumors. Daly reported that the sensations, though often unpleasant, can be acidic, bitter, salty, or sweet. Often a metallic taste is experienced.[28,29] The taste of bile or cigarette smoke has been reported.[43] Penfield and Jasper believed that gustatory symptoms result from seizures originating in or near the insula,[85] although Bornstein believed that the parietal operculum may also produce these seizures.[15] Rosetti et al. reported a case with dysgeusia and contralateral sensory symptoms from the insula in a case well documented with subdural ictal EEG recordings.[97] Hausser-Hauw and Bancaud reviewed their experience with gustatory hallucinations. Seizures originated in the parietal and temporal lobes in 20 of 30 patients with adequate ictal localization. Electrical stimulation of the parietal and/or rolandic operculum produced gustatory hallucinations and spontaneous seizures produced symptoms by spread to the opercular region.[43]

Seizures with vestibular symptoms, or vertigo, when isolated, are notoriously difficult to diagnose since these patients are often initially evaluated and treated for peripheral vestibular dysfunction. Symptoms include true vertigo, vague dizziness, or unsteadiness, with spinning most common.[56,85,86,105] Smith's study of 120 cases described rotation around the vertical or sagittal axis but not the coronal axis. Horizontal and vertical movements and also a sense of body or room tilting were described.[105] Lesions have been reported near the temporal parietal occipital junction as well as the superior temporal gyrus by Penfield and Kristiansen,[86] and Eviatar and Eviatar[37] have shown vertiginous symptoms in patients with frontal lobe epilepsy. Kogeorgos et al. found that 7 of 30 cases also had generalized tonicâ€“clonic seizures and 15 of 30 had absencelike episodes, while only two had auditory hallucinations with vertigo.[56]

Postictally, a variety of neurologic deficits can occur analogously to the classical Todd paralysis or postictal amaurosis or visual field deficits.[34,101] Patients with central-area epilepsy may have sensory deficits postictally that gradually improve, and these may only affect higher cortical sensory functions, such as graphesthesia or two-point discrimination. Olfactory sensitivity decreases postictally for several hours.[122] A severe seizure is not necessary to produce Todd paralysis and the process probably involves active inhibition of function rather than neuronal exhaustion.[34] Holmes found prominent postictal impairment infrequently in children with simple partial seizures.[47]

Electroencephalographic Findings and Clinical Correlations

Since sensory seizures can originate in a variety of brain regions, it is not surprising that a variety of interictal EEG abnormalities can be seen (Figs. 1, 2, and 3). Interictal changes could include changes in amplitude or frequency (e.g., focal slowing), particularly if there is a known structural lesion. Focal fast activity is less commonly seen with lesions. Interictal spikes may occur, but should be interpreted cautiously.

P.533

Blume et al. reported that 4 of 44 focal epilepsy cases that localized with ictal EEG had ictal onset clearly distant from the area of principal interictal spiking.[14] Temporal lobe spiking can occur in cingulate, frontal, parietal, and occipital lobe epilepsy.[107] Some authors report that ictal patterns are occasionally difficult to interpret in patients with seizures originating in the parietal or occipital region.[123,124] This is certainly true when seizures rapidly generalize and obscure the EEG record or muscle and movement artifact prevail. However, it is also recognized that some patients will have well-defined interictal spikes or ictal onsets from the occipital,[49,69] parietal, or central area[72] while clinical symptoms are recorded. Activation procedures can increase focal spiking and occipital spikes may be enhanced by eye closure or darkness.[69] Kogeorgos et al. found 28 of 30 patients with epileptic dizziness had abnormal interictal EEG, and localization was in the posterior temporal lobe unilaterally or bilaterally with sharp waves or focal slowing.[56]

Devinsky et al. studied the prevalence of scalp EEG changes in patients with simple partial seizures and found that when sensory symptoms alone predominate, only 15% of patients have EEG changes, whereas if motor symptoms are present, 33% will have EEG changes.[30] However, Bare et al. found that extra scalp electrodes improved the EEG yield in sensory seizures to 27%.[8] Sperling et al. reported that EEG changes may be absent in patients with simple partial seizures in presumed temporal lobe epilepsy when recording with bitemporal depth electrodes, and even in patients where postoperative seizure outcome was excellent.[108] The limited neocortical coverage with bitemporal depth electrodes may miss simple partial seizure ictal patterns from neocortex.

Kaibara and Blume studied postictal EEG changes.[53] Thirty-seven percent of cases had polymorphic delta, 29% had attenuation of background, 31% had immediate return to normal background, and 25% had spike activation. Some patients had more than one postictal pattern. All 51 patients in the study had focal seizures. The changes seen could be prolonged. When postictal EEG changes occur, one may appreciate postictal spiking or slowing that was not evident before the seizure occurred, and these findings may have some localizing value.

Diagnostic Considerations

As with any focal epilepsy, the history from the patient or reliable observer is very important for proper diagnosis. It may be helpful to ask the patient to watch for certain symptoms during subsequent seizures so that a more detailed description can be obtained later. Onset, evolution, postictal features, postictal deficits, patterns of occurrence, and precipitating factors should be thoroughly explored. The stereotypic nature of a seizure is also helpful in confirming a diagnosis of epilepsy.

P.534

P.535

MRI and routine EEG will often support a diagnosis of epilepsy, but negative initial MRI studies may require alternative MRI scanning protocols tailored for specific clinical situations such as cortical dysplasia or other neocortical lesions. Initially, nondiagnostic EEG studies should be repeated with prolonged recordings, or with sleep and other appropriate activation procedures. V-EEG monitoring may be quite helpful in patients when the diagnosis of epilepsy is uncertain or when seizures are medically intractable.[62] Other medical or neurologic disorders can result in epilepsy and should be considered during the evaluation process. Several genetic forms of focal epilepsy have been characterized, including autosomal dominant partial epilepsy with auditory features,[80] so it is likely that commercial testing for these syndromes will become available.

Differential Diagnosis

As alluded to earlier, pure sensory seizures can occasionally be confused with other nonepileptic conditions, such as cerebrovascular disease or psychiatric disorders.[61,121] Sensory symptoms due to ophthalmologic, otolaryngologic, or vestibulocochlear disease or to peripheral neuropathy need to be excluded. A thorough evaluation is warranted to avoid missing a more serious medical problem that is leading to the symptoms.

Specific Syndromes Incorporating the Seizure Type as an Integral Feature

In the 1989 proposed classification of the epilepsies,[27] one can identify a variety of epilepsy syndromes in which sensory seizures may occur; for example, in benign childhood epilepsy with centrotemporal spikes, sensory symptoms may be noted when partial seizures occur.[64] Seizures involving the central area may exhibit somatosensory symptomatology. Seizures of the temporal lobe can present with auditory or vertiginous sensations, as well as olfactory sensations.

The International Classification does not significantly address the issue of parietal lobe epilepsies. Seizures are clinically diverse and do not always include sensory auras.[123] Recently, Ho et al., using ictal single photon emission computed tomography (SPECT) and MRI, have described an anterior parietal syndrome with sensory symptomatology being quite prominent, whereas a more posterior parietal syndrome was characterized by psychoparetic complex partial seizures.[45]

Occipital lobe epilepsies can be divided into those with symptoms that are supracalcarine or infracalcarine, depending on the location of the visual hallucinations. Depth electrode studies have documented specific seizure spread patterns. Infracalcarine seizures, for example, more often manifest with a temporal lobe seizure spread pattern, whereas supracalcarine occipital lobe seizures may spread to the parietal and central area producing focal motor or even generalized seizure activity.[7,112] Not all occipital epilepsies produce appropriate visual auras.[68,124] Williamson et al. reported that 88% of their series of 25 occipital epilepsy patients had visual symptoms,[124] while only 73% of the Montreal series of 42 patients reported by Salanova et al. had a visual aura.[101] Childhood epilepsy with occipital paroxysms and the syndrome of migraine and seizures are often manifested by seizures that have visual symptomatology, simple or more complex.[27,39,78]

Some reflex epilepsies are associated with partial seizures rather than generalized seizures. Partial seizures of various

P.536

types are reportedly induced by startle, somatosensory input, proprioception, music, sounds, voices, hot water immersion, eating, reading, and other language functions.[94] Simple sensory seizures are infrequent manifestations of reflex epilepsy and usually develop after similar seizures develop spontaneously. Ritaccio believed that this represents postafferential facilitation of a preexisting condition.[94] Reading epilepsy can have seizures with a sensation of jaw movement, though often jaw clonic movements predominate.[94] Sutherling reported sensorimotor seizures triggered by music.[111] Caloric vestibular stimulation can produce temporal lobe seizures with auras of tinnitus and vertigo.[10,20] Ricci and Vigevano described stroboscopic provocation of occipital seizures with simple visual hallucinations in four cases and complex hallucinations in one patient;[92] however, most patients with photosensitive epilepsy have generalized seizures.[17,94] Brinciotti et al. found that pattern (checks or stripes)-sensitive seizures were more often associated with localization-related epilepsies.[17] Duncan et al. reported a case with gaze-evoked seizures in nonketotic hyperglycemia.[32] Reder and Wright described a 13-year-old boy whose seizures included ictal sensory loss in one arm provoked by using cutlery while eating. Accidental finger amputation resulted in seizure control.[91]

A wide variety of childhood epilepsy syndromes may exhibit simple sensory seizures, though motor seizures dominate the clinical picture. For example, cortical dysplasia can cause simple partial seizures with motor symptomatology that is extremely resistant to medical therapy.[81] Just as with motor seizures, status epileptics may present with sensory symptomatology. Chronic focal encephalitis typically presents with epilepsia partialis continua in association with unilateral progressive cortical atrophy.[5] Mitochondrial encephalopathy with lactic acidosis and strokelike episodes (MELAS)[74] has a similar, but more acute presentation. Epilepsia partialis continua is common in children with Alper disease[16] and focal cerebral vasculitis. In all these syndromes, sensory seizures, if present, are often relegated to a minor role in the complete clinical syndrome.

Responses to Treatment

A thorough discussion of medical and surgical management of epilepsy is beyond the scope of this chapter. However, if the epilepsy syndrome is focal, drugs used for partial seizures should be used first. These include carbamazepine, phenytoin, gabapentin, lamotrigine, topiramate, tiagabine, oxcarbazepine, levetiracetam, zonisamide, pregabalin, primidone, and phenobarbital. In suspected cases of pure sensory simple partial seizures without EEG changes, a blind trial of antiepileptic drugs may support the diagnosis;[127] however, a definitive treatment end-point is necessary to avoid prolonged unnecessary therapy.

The success of pharmacotherapy for simple sensory seizures is not well described in the literature, though some patients do respond well to medical therapy. At times, more severe seizure types will be eliminated by antiepileptic drugs but simple sensory seizures will persist as auras with minimal disability. Often patients will choose occasional auras over antiepileptic drug toxicity when higher doses are tried. Still, some patients claim severe disability from sensory seizures, resulting in medication changes and dose escalation until intolerable dose-related toxicity develops. These cases may benefit from counseling, treatment of comorbid underlying depression, and consideration for a surgical procedure.

The benign childhood epilepsy syndromes may resolve spontaneously, so lifelong therapy is unwarranted. When seizures persist in benign focal epilepsies, particularly benign rolandic epilepsy, one should consider alternative diagnoses.

If neuroimaging studies have shown specific lesions, such as tumor or vascular malformation, particularly when there is a risk of progression, specific surgical or nonsurgical therapy may help seizures, particularly in cases where the lesion is adjacent to important sensory cortex, rather than in the functional zone.

Surgery for patients with sensory seizures should proceed with caution to avoid significant postoperative deficits. Sufficient disability from seizures should exist. For example, careful thought should be given before suggesting surgery in an individual with sensory seizures alone, unless an underlying lesion was serious enough to require surgical intervention in any case. Careful mapping of ictal foci and cerebral function may be needed to plan a safe resection.[12,22,42,71,75,76,77,79,96,113,114,119,125] Functional MRI offers hope for noninvasive functional mapping.[50] Subdural electrodes[66] are preferred by most epilepsy centers because of potentially better localization and less risk of hemorrhage compared to depth electrodes[113,114] or epidural electrodes.[42] Still, selected cases with subcortical lesions, such as a cortical dysplasia case reported by Privitera et al., are better evaluated with intracerebral depth electrodes.[90] Subdural electrodes are more convenient for functional mapping by direct cortical stimulation or with evoked responses for various sensory modalities. Additionally, the use of subdural electrode recordings can help with decisions on the need for intraoperative electrocorticography and cortical mapping during awake craniotomies.

The role of magnetoencephalography is controversial, since the technique is better for interictal epileptiform discharge localization. Magnetoencephalography data should be considered complementary to scalp EEG. No randomized controlled studies exist to show superior surgical outcomes with the use of magnetoencephalography.

Subpial transection gained favor as more reports appeared in the literature demonstrating safety and efficacy.[31,76,77,104] Theoretically, subpial transection can spare sensory cortex and function, yet still help relieve seizures. However, deficits have been reported after this technique and a pathologic study suggested that subpial transection may produce small confluent lesions rather than disconnection.[54]

Lesionectomy can also decrease risks of sensory deficits and help seizures long term in about half of the cases.[23,24] Gamma Knife radiosurgery may be appropriate in selected patients.[44]

At times, resection of primary cortex is needed for seizure control and the sensory deficits may be acceptable to the patient. It is possible to remove portions of primary sensory or motor neocortex without producing a lasting neurologic deficit.[73] Lehman et al. reported that the disability was quite limited with resection of the sensorimotor face region in the lower central area.[59]

With reflex seizures, avoidance of the stimulus can play a role in management. In some patients, biofeedback or sensory input may also reduce seizures, as in Efron's remarkable case.[33] Aird reviewed alternative epilepsy therapies in 500 refractory patients with various forms of epilepsy and found that 43% benefited from lifestyle modification in areas such as hydration, central nervous system excitation, sleep habits, and anxiety.[3]

Safety concerns should also be considered if the seizures produce any disability. While most simple partial seizures with sensory symptomatology alone may not be very disabling, many have complex partial or secondarily generalized seizures also. Safety concerns are justified if a patient has a job where sudden, complete or partial loss of vision or disturbance of sensation could result in injury. Each case must be assessed individually for safety concerns.

Summary and Conclusions

Simple sensory seizures can occur in a variety of epileptic syndromes. Many patients have other seizure types that make

the diagnosis more obvious. Caution is recommended in those patients with subjective sensory symptoms alone, particularly without supportive EEG or neuroimaging findings. The chances for misdiagnosis are high, and these patients may require a more thorough investigation before nonepileptic, medical, or psychiatric conditions are diagnosed.

The epidemiology of simple partial seizures is incomplete. Evidently, these seizures are seen in a minority of patients with epilepsy. Identifying patients with simple sensory seizures can help localize structural lesions. Prolonged clinical manifestations are occasionally reported by patients. Postictal neurologic abnormalities should be sought in the history and examination. Scalp EEG, while not highly sensitive, can be diagnostic. Treatment is similar to treatment in other localization-related epilepsies.

The possibility of developing treatment strategies that could specifically inactivate seizures by altering sensory function transiently requires further exploration. Additionally, patients with well-defined sensory phenomena may be good candidates for studying treatment methods that rely on advance warning of an impending seizure. Since consciousness is maintained, at least during the patient's simple partial seizure, these patients would make ideal study subjects.

Seizure Semiology in Infants with Localization-Related Epilepsy

Douglas R. Nordli Jr.

Elaine Wyllie

Introduction

The clinical manifestations of seizures in infants differ from those in older children and adults.[11,16] These clinical differences relate, at least in part, to factors intrinsic to the immature brain that bestow unique electrophysiologic characteristics. These factors, which underlie normal brain development, include the topography of brain metabolism, the development of myelinated connections, and the properties of ion channels and their associated ion gradients. Differences probably also relate to the causes of seizures themselves, which in some sense could be viewed as extrinsic factors. The etiology of infantile seizures, when compared to that in older patient populations, is more likely to be due to disorders of cortical formation, intrauterine pathology, channelopathies, or inborn errors of metabolism. Some of these disorders may result in widespread or multifocal pathology that strongly influences the clinical and electrographic expression of seizures, but even when restricting the comparison to the relatively homogeneous category of localization-related epilepsies, key differences remain.

As the child matures, the intrinsic properties of brain physiology change and thereby alter the expression of seizures. Gradually, seizures take on characteristics seen in adults. These changes occur in an orderly fashion, so that an ontogeny of ictal semiology can be described, just as one can characterize and predict normal child development.[17] We believe that a general understanding of these key differences and some detailed knowledge of the electroclinical correlation of infantile seizures allow the examiner to ask better questions during the medical interview, aid the evaluation for epilepsy surgery, and increase the chances of making a correct epilepsy syndrome diagnosis.

Unique Features of Infantile Seizures

Several unique features of infantile focal seizures are seen as a result of the differences in the physiology and etiology of localization-related epilepsies. These can be summarized into several key points (Table 1).

Infantile Seizures Are Often Subtle

Many infantile seizures are subtle and lack declarative features seen in adults.[8] This is particularly true of those arising from the temporal lobe: The infant may pause ongoing behaviors, appear to suddenly stop movement, and exhibit simplistic automatisms such as mouthing movements.[23] These are sometimes referred to as behavioral arrest, behavioral change, or hypomotor seizures. Oxygen desaturation may accompany these events, and if the child is connected to an oxygen saturation monitor, the change in the tone of the monitor may be the first sign alerting observers to the presence of the seizure. Parents reliably and quickly detect the peculiar change in the infant's behavior, but others unfamiliar with the child's habitual behavior may have difficulty identifying the onset of the event. There are almost never other declarative features of mature temporal lobe seizures: The infant is unable to vocalize the presence of an aura, cannot be asked about his or her experiences during the event to determine consciousness, does not exhibit contralateral dystonic hand postures, and does not show ipsilateral fine hand automatisms. Well-developed secondary generalization with synchronized clonic activity of both sides of the body is rare, particularly in the symptomatic epilepsies.[14]

Duchowny studied 14 infants <2 years of age with focal seizures and lateralized ictal electroencephalographic (EEG) abnormalities.[9] Seizure semiology most frequently included behavioral arrest with forced head turning and tonic extension of the arms, sometimes accompanied by chewing, sucking, mouthing, or blinking. Yamamoto et al. compared focal seizures in 15 infants <2 years old with those in 23 children 3 to 13 years old.[25] They noted that the seizures in the infants were longer in duration and had simpler, predominantly oral automatisms.

Automatisms during partial seizures in infants and young children are usually subtle and predominantly oral, sometimes with simple gross motor movements of the proximal extremities.[3] These contrast with the more complex fine motor behaviors seen in older patients. Jayakar and Duchowny noted an age-dependent evolution, with complex fine motor automatisms first appearing in their preschool group (2–6 years old).[12] A similar ontogeny was reported by Nordli et al.[17] Karbowski et al. proposed the term *temporal pseudoabsences* to emphasize that decreased behavioral activity was more prominent than were automatisms in their infants with temporal lobe epilepsy.[13] All of these results suggest a continuum in development of automatisms during childhood from simple to complex.

Table 1 Semiology of Focal Seizures

Feature	Infants	Adults
Auras	Absent	Sometimes present
Behavioral arrest	Promiment, often isolated	Present, but often with other specific features
Clonus, limb	Present	Present
Cyanosis, perioral	Prominent, particularly with temporal lobe seizures	Sometimes present
Dystonic posture	Absent	May be present
Hand automatisms	Absent	May be present
Loss of consciousness	Difficult or impossible rigorously to determine	Often present, can be reliably determined
Myoclonus, diffuse	Sometimes seen at the start or end of a focal seizure	Rare
Secondary generalization	Rare	Common

Spasms	May be concurrent with focal seizures	Absent
Tonic postures, symmetric	Frequent	Unusual

The Terms "Simple" and "Complex" Are Difficult to Apply

It can be extraordinarily difficult reliably to determine alteration of consciousness in most infants. For these reasons, the terms "simple" and "complex" are difficult to apply with any degree of certainty to most infantile seizures. The

gold standard in adult monitoring units for assessing consciousness is to ask the patient to follow commands, repeat phrases, and recall test items. None of these can be performed in the preverbal child. Inattentiveness, such as not turning the head to alerting stimuli, is not the same as altered consciousness.

Dravet and colleagues studied children with partial epilepsy that began before 3 years of age and used the term *undetermined partial seizures* for three patients in whom they experienced difficulty with this assessment.[7] Duchowny accepted the term *complex partial* in this setting, under the assumption that some disturbance of consciousness must have occurred, based on unsuccessful attempts to influence attention by various maneuvers.[9] In a study at the Cleveland Clinic Foundation of videotaped seizures from infants <2 years old with localization-related epilepsy, the authors found it impossible to be as confident about level of consciousness, despite similar attempts.[1] Nordli et al.[16] reached the same conclusions, and Ohmori et al.[18] found it difficult to apply the labels "simple" or "complex" definitively.

Infantile Focal Seizures May Have "Generalized" Clinical Features

Apparently generalized features are relatively common and do not necessarily imply a diffuse or generalized epileptic diathesis. Two of the most important features in this category also are diffuse tonic postures and infantile spasms. Diffuse tonic postures, even symmetric ones, are common during infantile focal seizures. Brockhaus and Elger[3] studied age-related features of complex partial seizures in children and adolescents with temporal lobe epilepsy defined by EEG or magnetic resonance imaging (MRI). They compared 6 younger children (18 months to 6 years old) with 23 older children (8–16 years old) and found that the older children had seizure semiology similar to that of adults, including aura, arrest of activity, simple and complex automatisms, versive movements, and dystonic posturing. In contrast, the younger children lacked auras and complex automatisms, and instead often had symmetric motor phenomena. The authors concluded that some young children may be appropriate candidates for temporal lobe resections despite "atypical" seizure semiology.[3] Bilateral tonic stiffening or clonic or myoclonic movements may be seen during partial seizures in infants. Dravet et al. also observed that several children had "apparently generalized seizures" (flexor spasms, atonic or tonic seizures) with localized EEG ictal and interictal abnormalities.[7] These results illustrate that seizure semiology in infants may give limited clues to the localization-related nature of the epilepsy. In these infants, the ictal EEG findings are critical to clarifying the localized onset of the seizures. However, for some infants, interictal EEG features such as focal slowing, attenuation, or both can be even more illustrative.

Shields, Chugani, and associates at the University of California at Los Angeles emphasized the critical role of high-resolution MRI and positron emission tomography (PET) in identifying potentially resectable cortical lesions in children with infantile spasms and hypsarhythmia.[19] A similar experience was reported from the Cleveland Clinic.[24] The most commonly reported epileptogenic lesion in surgical series of children with infantile spasms is focal cortical dysplasia, especially in the temporal-parietal-occipital region, but frontal or temporal lobe tumors have also been noted.[2,22]

The observation that infantile spasms can result from a focal cortical lesion forces us to broaden our concept of localization-related epilepsy beyond that defined only by seizure semiology and ictal EEG. The 1989 classification of epilepsies and epileptic syndromes from the International League Against Epilepsy left room for this by defining localization-related (focal, local, or partial) epilepsies as those "in which seizure semiology or findings at investigation disclose a localized origin of the seizures."[6] For some infants, the critical diagnostic findings may be those of neuroimaging, either anatomic or functional, rather than ictal EEG. Recent observations from the Cleveland Clinic have further shown that this phenomenon (generalized EEG and nonlocalized seizure semiology) may also be seen in older children with surgically remediable focal epilepsy due to extensive focal or hemispheric brain lesions that are congenital or acquired early in life, especially malformations of cortical development or perinatal infarction.

Table 2 Common Manifestations of Infantile Focal Seizures

Spasms, asymmetric or combined with focal seizures
Behavioral arrest with version (hypomotor)
Focal clonic
Focal tonic
Others

Difficulty Lateralizing Based on Clinical Features

The ictal semiology provides fewer clues to the laterality of the seizure in infants when compared to older children or adults. This is largely due to the paucity of declarative features such as contralateral limb dystonia, ipsilateral hand automatisms, auras, and orderly secondary generalization. In addition, the presence of diffuse postures or spasms obscures some other features and makes it difficult to discern subtle asymmetries.

Types of Infantile Focal Seizures and their Electroclinical Correlations

Given the limitations of what one might deduce from the ictal semiology of an infantile seizure, it can be useful to record the event with simultaneous video-EEG recording to further characterizing the seizure. One study reviewed 2,112 patients and found 109 distinct seizures in 77 infants.[15] Overall, 13 seizure types were identified, of which 10 were seen in the localization-related epilepsies. The findings of this study can be combined with other observations to provide common descriptive elements of the most frequent infantile seizures.[1,7,8] Five of these account for the majority of focal seizures seen in infants (Table 2).

Spasms With Focal Features

Among the most common manifestations of infantile focal seizures are spasms. These can occur either as diffuse spasms accompanied by independent focal seizures or as spasms that with markedly asymmetric features, either clinical or electrographic. The focal seizures that accompany spasms may take a variety of forms and arise from nearly any region. Focal clonic and focal tonic manifestations are the most common.[15]

Behavioral Arrest With Version

Behavioral arrest seizures are characterized by a sudden cessation of ongoing behavior, often with associated staring. The infant abruptly stops his or her activity but does not demonstrate limb automatisms, dystonic posture, or clonus. In addition to the prominent behavioral arrest, these seizures also show pronounced version of the head, eyes, or both.[20] These seizures are associated with rhythmic ictal patterns often arising from the temporal, parietal, or occipital, but more diffuse hemispheric involvement at onset can also be seen. Capovilla et al. recorded seizures in infants with a benign form of localization-related epilepsy with similar clinical features but with prominent interictal vertex spikes.[4]

Focal Clonic Seizures

Focal clonic seizures are characterized by unilateral or bilateral asymmetric jerks of the limbs. The electrographic onset is always focal and most often involves the contralateral central region. Often, the EEG pattern of these seizures is distinctive, with a localized "crescendo" of rhythmic spikes or sharp waves in the central region followed by a "decrescendo" of ictal activity.

Focal Tonic Seizures

Focal tonic seizures are characterized by a predominant asymmetric tonic posture. The EEG ictal correlate of these seizures is diverse in terms of both pattern and focus.

Other Seizures

Rarely, seizures can be recorded in infants that arise in a focus and then secondarily spread into a more diffuse or generalized pattern. If the onset is not carefully observed, these seizures might be mistaken for generalized tonic–clonic seizures.[21] Other rare seizure types seen include those with prominent agitated behavior (hypermotor activity), focal tonic–clonic manifestations (involving just one side or part of the body), and migratory patterns in which the ictal discharge appears to wander from one cortical region to the other without any clear secondary generalization.

Further Comments on Infantile Seizure Classification

Even though there is a more limited repertoire of seizure semiology in infants than in adults, the immature nervous system still can produce a myriad of subtle variations in the particular clinical features of focal seizures. It is clearly an oversimplification to characterize seizures simply in broad categories as we have done, but at a minimum, this semiology-based classification allows for a quick means of communication and does correlate grossly with electrographic patterns. This should not, however, preclude more complete descriptions of seizures with detailed sequences of clinical events for surgical planning or other clinical circumstances.

Important Implications for Surgical Selection

The key elements indicating possibilities for epilepsy surgery include medically refractory epilepsy, the presence of a localized epileptogenic zone, and low risk for new postoperative neurologic deficits. In infants and children, definition of the epileptogenic zone is especially difficult and requires a different approach than that typically used to develop surgical strategy for adults. Challenges include the absence or paucity of localizing or lateralizing features in seizure semiology and often also on ictal and interictal EEG. Brain lesions that are congenital or acquired early in life—the typical etiologic substrate of catastrophic epilepsy in infants—may manifest with generalized EEG patterns and seizures that provide few or no

P.638

clues to the focal nature of the epileptogenic process. In infants, the manifestation is often epileptic spasms with hypsarrhythmia; in older children, the electroclinical phenotype may resemble other forms of symptomatic generalized epilepsy, including Lennox Gastaut syndrome.

It has become clear that generalized features on seizure semiology and EEG should not necessarily contraindicate epilepsy surgery in an infant or child with *a very clear and extensive* congenital or early-acquired epileptogenic lesion seen on MRI.[6,10] However, the italics are added to emphasize the critical importance of strong MRI findings to clarify a surgical strategy in the absence or paucity of localizing features on semiology and EEG. If MRI does not show a single clearly defined potentially resectable epileptogenic lesion such as a malformation of cortical development or encephalomalacia due to pre- or perinatal arterial infarction, *and* localizing or lateralizing clues are absent from seizure semiology and EEG, then any strategy for epilepsy would be weak. In cryptogenic cases with normal or equivocal MRI findings or in children with bilateral or multifocal MRI abnormalities, clearly localized findings on ictal and interictal EEG assume critical importance for surgical planning. Focal clonic activity ipsilateral to the lesion would be an important indicator of noncongruency. Whether the surgical plan is based on clearly localized EEG or MRI or both, however, the seizure semiology in infants with surgically remediable epilepsy may lack localizing features typically associated with focal epilepsy in adults. Referral of such children to specialized centers for pediatric epilepsy surgery is warranted, and systematic long-term follow-up is important to further clarify appropriate strategies for identification of pediatric candidates for epilepsy surgery. Severe medically refractory epilepsy and detailed parental informed consent are prerequisites for an ethical approach to epilepsy surgery in these difficult cases.

Summary and Conclusions

The semiology of infantile localation-related epilepsies, though different from seizures seen in adults and older children follows some predictable ontogenic patterns. In general, the repertoire is less complex in the immature, and there are fewer declarative features keeping with the limited connectivity of brain regions. Seizures in children less than one year of age seldom have recognizable distal automatisms, dystonic hand postures, orderly secondary generalization and ascertainable changes in consciousness. Instead, primitive oral automatisms, restless body movements, behavioral arrests, prominent autonomic features including oxygen desaturation and eye version are seen. Both symmetric and asymmetric tonic postures may be observed with infantile focal seizures. About one third or more of children with infantile spasms may have concurrent focal seizures.

In terms of electroclinical correlations some generalizations are possible. Focal clonic seizures lateralize well to the contralateral rolandic region and are usually characterized by runs of rhythmic spikes, sharp waves, or focal spike-wave complexes. Seizures with behavioral arrest may arise from any location, though ictal rhythmic “crescendo" patterns from the temporo-parietal-occipital region often present this way, manytimes combined with version. Symmetric infantile spasms and tonic postures can belie a true focal process and have unpredictable EEG correlates. Video-EEG recordings are useful in any infant with refractory epilepsy, but particularly in those with infantile spasms, tonic seizures or behavioral arrests. A detailed knowledge of the infantile seizure semiology should improve our ability to elicit a complete history, define the epilepsy syndrome, and screen for potential candidates for epilepsy surgery.

Chapter 56

Neonatal Seizures

Eli M. Mizrahi

Perrine Plouin

Robert R. Clancy

Introduction

Neonatal seizures may represent the first, and perhaps only, clinical sign of a central nervous system (CNS) disorder in the neonate. They prompt immediate concerns related to their etiologic diagnosis and management and future concerns relevant to the long-term outcomes of those who experience them. Our traditional understanding of neonatal seizures continues to evolve. It was recently believed that neonatal seizures, although easily provoked by acute injury in the immature brain, imparted little or no permanent anatomic or physiologic sequelae. Current research in both animal models and humans challenge this traditional view, and it is now believed that neonatal seizures may leave a permanent mark on the developing CNS.

Despite recent basic and clinical research of neonatal seizures there still remain considerable gaps in knowledge in areas that relate to diagnosis, pathophysiology, etiology, therapy, and prognosis. Although such work continues, the clinician is left with the task of developing strategies in diagnosis and management with limited scientifically confirmed data. The following discussion is based on both the best available data and, in their absence, clinical practice. This discussion has in part been presented elsewhere and is now updated and expanded.[31,113,114,119]

Controversies related to the characterization and classification of neonatal seizures have for the most part been definitively addressed. However, data relating to treatment and prognosis have not. While the debate continues in the basic neuroscience literature as to whether and how seizures cause significant brain injury in the developing brain, even less information is available concerning whether these findings are applicable to human newborns and whether the degree of injury, if present, is clinically significant. Resolution of these issues will ultimately guide antiepileptic drug (AED) therapy in neonates and more clearly define factors that predict long-term outcome.

The more practical approach is to consider the notion that the overriding determinant of outcome is seizure etiology. Seizure occurrence may indicate the presence of a potentially treatable etiology and should prompt an immediate search for this cause and institution of appropriate therapy. Seizures themselves may require emergent therapy because they may, directly or indirectly, disrupt the infant's homeostasis or contribute to additional brain injury. Seizure occurrence, and particularly the type of seizures, may have predictive value in determination of outcome.

The approach to the clinical management of an infant thought to have experienced a seizure is defined by the orderly consideration of issues that will improve long-term outcome: Accurate seizure characterization and classification, maintenance of infant homeostasis, urgent search for a treatable etiology, appropriate application of electroencephalography, institution of etiologic-specific treatment, thoughtful consideration of acute and then chronic AED treatment, and consideration of risk factors that predict outcome in order to plan for long-term care.

Definitions

The use of the term "seizure" to describe paroxysmal clinical events in the neonate represents a unique challenge. Early clinical investigations assumed that all such events were of epileptic origin; that is, such clinical events were generated by coincident electrographic seizures, composed of abnormal, excessive hypersynchronous discharges of networks of cortical neurons. Later studies suggested that, although most clinical seizures can be viewed in this way, some may be generated by nonepileptic mechanisms. Although it is appropriate to generically call all abnormal paroxysmal clinical events “seizures,” more detailed classification can relegate most of them to either epileptic or nonepileptic categories. These distinctions become most important clinically when considering AED therapy. However, the terms also become cumbersome in discussing neonatal “seizures” as a whole. Thus, in the discussions that follow, the term “neonatal seizures” will generally encompass those events of epileptic origin. There are, however, a few exceptions that will be specified.

The definition of an electrographic seizure also becomes important. This will be discussed in detail later. In brief, it is an abnormal electrical ictal event consisting of evolving, rhythmic activity of at least 10 seconds' duration—with or without accompaniment of a clinical seizure.

Definitions of the age of the infant are also relevant, since they provide a measure of the degree of brain maturation. The neonatal period is defined as the first 4 weeks (28 days) of life. Legal age (LA) refers to the number of weeks the baby has been alive since birth. Estimated gestational age (EGA) refers to the duration of pregnancy prior to birth. The gestational age plus the chronologic age defines the age since conception or conceptional age (CA). The CA is a useful metric that benchmarks brain maturation, regardless of whether the infant was born prematurely or at term. Thus, the electroencephalogram (EEG) of 1-week-old (LA), 39 weeks EGA infants (CA of 40 weeks) should match that of a premature baby of EGA 34 weeks who is now 6 weeks old (LA).

Epidemiology

The neonatal period is one of greatest periods of seizure hazard during the human life span. The incidence of seizure occurrence is greatest in childhood,[77,182] especially in the first month of life. Reported incidence rates of neonatal seizures range from 1.5 to 5.5 per 1,000 neonates[10,51,147,148,153,172] depending on the study methodologies and the populations investigated. Most neonatal seizures first appear within the first week of life.[87] It has also been suggested that seizure incidence varies with specific risk factors such as birthweight, degree of illness, and possible etiology. Lanska et al.[87] reported “seizure” occurrence, based solely on clinical recognition, to be greatest in preterm or low-birth-weight infants compared with term infants. They reported an incidence of clinically

suspected seizures in all neonates to be 3.5 per 1,000, but 57.5 per 1,000 in very–low-birth-weight (<1,500 g) infants, 4.4 per 1,000 in low-birth-weight (1,500–2,499 g) infants, and 2.8 per 1,000 in normal-birth-weight (2,500–3,999 g) infants. Scher et al.[158,159] reported that seizures occurred in 3.9% of neonates of less than 30 weeks' conceptional age and 1.5% in neonates older than 30 weeks. Similarly, Kohelet et al.[82] found an overall incidence of seizures in a cohort of very–low-birth-weight infants to be 5.6 per 1,000. However, the incidence of 57.5 per 1,000 in very–low-birth-weight infants reported by Lanska et al.[87] may be skewed by the inclusion of nonepileptic clinical events in the very premature population studied.

The International League Against Epilepsy (ILAE) has used the terms “acute reactive” or “symptomatic” to describe the trigger of most neonatal seizures. The ILAE has also designated *unprovoked* neonatal epileptic syndromes: Benign neonatal convulsions, benign familial neonatal convulsions, early myoclonic encephalopathy (EME), and early epileptic encephalopathy (EIEE).[32,33,114,182] Acute reactive or symptomatic seizures are very frequent, whereas, in contrast, the occurrence of specific neonatal epileptic syndromes, as defined by ILAE, are rare.

Clinical Features

Ictal Features

Seizures in the neonate have clinical features that are unique compared with those occurring in older infants and children. Such features include: Fragmentation, disorganization, unusual patterns of spread, and simultaneous, but asynchronous multiple regions of involvement. Some of these differences are based on mechanisms of epileptogenesis and the state of early development in the immature brain. Other differences are based on the relative importance of nonepileptic mechanism of "seizures" generation in this age group. Some similarities also are noted between neonatal seizures and those of older infants and children. These include the types of movements that characterize the events, such as clonic, tonic, and myoclonic seizures.

A number of methods have been used to classify neonatal seizures: According to clinical features, the relation between clinical seizures and electrical seizure activity on the EEG, seizure pathophysiology, and epileptic syndromes. Each classification has some clinical utility, and each provides some further insight into the clinical problems of diagnosis and management.

Clinical Classification

Efforts over the years to characterize and classify neonatal seizures[49,94,117,150,152,156,189,190,196] demonstrate an evolution of thought and also underscore the importance of the ground-breaking work of French investigators reported over 40 years ago.[49] Early classification schemes focused on the differences between neonatal seizures and those of older children: Neonatal seizures were reported to be clonic or tonic, not tonic–clonic, and, when the seizures were focal, they were characterized as unifocal or multifocal. Later classifications included myoclonus.[150]

Early investigators also identified clinical events that had less of a traditional organization of motor activity, considered an important distinction between seizures of the neonate and older children.[49,111,152] These seizures were initially characterized as "anarchic"[49] and later as "subtle"[189] or "minimal."[94] These descriptions included events of oral-buccal-lingual movements such as sucking and chewing; movements of progression, such as bicycling of the legs and swimming movements of the arms; and random eye movements. Although these events were initially considered to be epileptic in origin, others later suggested that they were exaggerated reflex behaviors and referred to them as "brainstem release phenomena" or "motor automatisms."[117] Table 1 lists the clinical characteristics of neonatal seizures according to a current classification scheme.[118] This scheme can be applied through clinical observation of the neonate. The basic classification includes seizures characterized as: Focal clonic, focal tonic, myoclonic, spasms, generalized tonic, and motor automatisms (also referred to as "subtle seizures").

Paroxysmal changes related to the autonomic nervous system have also been reported to be manifestations of seizures. These events include alterations in heart rate, respiration, and blood pressure as well as flushing, salivation, and pupillary dilation.[53,58,98,196,197] Any of these findings occurring as isolated epileptic events are rare. When they do occur, they do so most consistently in association with other clinical manifestations of seizures.[117]

Classification According to Temporal Relation to Electrical Seizure Activity

Although the classification scheme just described is based on the clinical characteristics of the seizures, other codification schemes consider the temporal relation of clinical events to the occurrence of electrical seizure activity on EEG. An "electroclinical" seizure occurs when the clinical event overlaps in time with electrographic seizure activity. A seizure is referred to as "clinical only" when it occurs in the absence of any EEG seizure activity. A seizure is referred to as electrographic "only" if the electrical seizure occurs without any coincident clinical seizure activity.

Table 1 Clinical characteristics, classification, and presumed pathophysiology of neonatal seizures

Classification	Characterization
Focal clonic	Repetitive, rhythmic contractions of muscle groups of the limbs, face, or trunk

	May be unifocal or multifocal May occur synchronously or asynchronously in muscle groups on one side of the body May occur simultaneously, but asynchronously on both sides Cannot be suppressed by restraint or repositioning Pathophysiology: Epileptic
Focal tonic	Sustained posturing of single limbs Sustained asymmetric posturing of the trunk Sustained eye deviation Cannot be provoked by stimulation or suppressed by restraint Pathophysiology: Epileptic
Generalized tonic	Sustained symmetric posturing of limbs, trunk, and neck May be flexor, extensor, or mixed flexor/extensor May be provoked or intensified by stimulation May be suppressed by restraint or repositioning Presumed pathophysiology: Nonepileptic
Myoclonic	Random, single, rapid contractions of muscle groups of the limbs, face, or trunk Typically not repetitive, or may recur at a slow rate May be generalized, focal, or fragmentary May be provoked by stimulation Presumed pathophysiology: May be epileptic or nonepileptic
Spasms	May be flexor, extensor, or mixed flexor/extensor May occur in clusters Cannot be provoked by stimulation or suppressed by restraint Pathophysiology: Epileptic
Motor automatisms Ocular signs	Random and roving eye movements or nystagmus (distinct from tonic eye deviation) May be provoked or intensified by tactile stimulation Presumed pathophysiology: Nonepileptic
Oral-buccal-lingual movements	Sucking, chewing, tongue protrusions May be provoked or intensified by stimulation Presumed pathophysiology: Nonepileptic
Progression movements	Rowing or swimming movements Pedaling or bicycling movements of the legs May be provoked or intensified by stimulation May be suppressed by restraint or repositioning Presumed pathophysiology: Nonepileptic
Complex purposeless	Sudden arousal with transient increased random activity of limbs

movements	May be provoked or intensified by stimulation Presumed pathophysiology: Nonepileptic

From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven; 1998:181, with permission.

Classification According to Pathophysiology

Seizures may also be classified according to their pathophysiology: Epileptic or nonepileptic in character (Table 2). This was suggested by Mizrahi and Kellaway,[117] who reported their findings of neonates experiencing seizures during video-EEG monitoring. These authors classified neonatal seizures based on clinical characteristics, the relation between EEG and clinical events, and also on presumed pathophysiology. They suggested that a group of behaviors, previously referred to as "subtle" seizures, had features more consistent with reflex phenomena rather than epileptic seizures. They demonstrated that the paroxysmal clinical events in some could be provoked by tactile stimulation of the infant; that the intensity of the response could be proportional to the intensity of the stimulus (both in terms of intensity at a single site of stimulation or consistent intensity with increasing sites of stimulation); that the response could spread to regions of the body distant from the site of stimulation; and that the clinical events could be suppressed by restraint of the infant. These were considered features of reflex behaviors.

When the concept of nonepileptic seizures is discussed in the literature, the absence of electrical seizure during clinical seizure activity is strongly emphasized by some.[191] These discussions speculate that electrical seizure discharges can be generated in "deeper" cortical or even subcortical regions and thus may not be visible by conventional EEG recorded at the scalp surface. Data from human adults and mature animal studies are provided to support this concept. Although this possibility cannot be discounted in human neonates, there is no supportive evidence of its occurrence. In addition, ictal single photon emission computed tomography (SPECT) performed in neonates with "nonepileptic" events (brainstem release phenomenon) have failed to demonstrate the characteristic hyperperfusion

P.641

hallmark of genuine epileptic seizures.[7] Finally, the lack of associated EEG seizure activity is not the only finding that suggests a nonepileptic pathophysiology; rather, the similarity of the events to the experimental models of reflex behaviors provides additional compelling data (Table 3).

Seizures of Epileptic Origin

Current research reveals that some clinical seizures can be confidently classified as epileptic in origin based solely on their clinical characteristics. Some seizures may be confidently classified as "epileptic" in nature just by their clinical appearance. The clinical events that are most clearly epileptic in origin are: Focal clonic, focal tonic, some types of myoclonic seizures, and spasms (Tables 1 and 2). These seizure types can be recognized and characterized at the bedside by the visible features of the spontaneous event. In addition, during the event, the clinician can attempt to suppress the motor behavior by holding the affected limb; a continuation of rhythmic muscle contractions indicates the epileptic basis of the event. These seizures occur in close association with EEG seizure activity, and the clinical event cannot be provoked by stimulation nor suppressed by

P.642

restraint of the infant. When EEG is utilized, seizures character- ized as electrical-only seizures are also considered, by definition, epileptic in origin. Specific features of the developing brain enhance acute seizure initiation, maintenance, and propagation. Similar factors promote a greater predisposition to epileptogenesis, the development of long-term, postnatal epilepsy in the wake of acute, reactive neonatal seizures. These properties include enhanced cellular excitation, enhanced synaptic excitation, and a tendency to promote propagation of an epileptic discharge.[62,68,121,144,161,179]

Table 2 Classification of neonatal seizures based on electroclinical findings

- Clinical seizures with a consistent electrocortical signature (pathophysiology: Epileptic)
  - Focal clonic
    - Unifocal
    - Multifocal
    - Hemiconvulsive
    - Axial
  - Focal tonic
    - Asymmetrical truncal posturing
    - Limb posturing
    - Sustained eye deviation
  - Myoclonic
    - Generalized
    - Focal
  - Spasms
    - Flexor
    - Extensor
    - Mixed extensor/flexor
- Clinical seizures without a consistent electrocortical signature (pathophysiology: Presumed nonepileptic)

Myoclonic

Generalized

Focal

Fragmentary

Generalized tonic

Flexor

Extensor

Mixed extensor/flexor

Motor automatisms

Oral-buccal-lingual movements

Ocular signs (aside from sustained eye deviation)

Progression movements

Complex purposeless movements

Electrical seizures without clinical seizure activity

From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven; 1998:181, with permission.[118]

Seizures of Nonepileptic Origin

Other seizures are best considered as nonepileptic in origin.[77,117] Clinical events classified as nonepileptic in origin include some types of myoclonic events, generalized tonic posturing, and motor automatisms such as oral-buccal-lingual movements, movements of progression, and some ocular signs (Tables 1 and 2). These events occur in the absence of electrical seizure activity, but more importantly, have clinical characteristics similar to reflex behaviors. These clinical events can be provoked by stimulation of the infant. Both the provoked and spontaneous events can be suppressed by restraint or by repositioning the infant during the event. In addition, the clinical events may increase in intensity with the increase in the repetition rate of stimulation (temporal summation) or the sites of simultaneous stimulation (spatial summation).

Table 3 Reflex physiology demonstrated in animal models compared with generalized tonic seizures and motor automatisms (so-called nonepileptic) seizures in human neonates

Animal models	Neonates
Decortication	Cortical depression, obtundation, or coma EEG background depressed and undifferentiated or electrocerebral silence
Reflex movements	Spontaneous or elicited movements
Progression	Motor automatisms
Posturing	Tonic posturing
Response to stimulation	Response to stimulation
Temporal summation	Temporal summation
Spatial summation	Spatial summation
Irradiation of the response	Irradiation of the response
Response to restraint	Response to restraint
Arrest of behavior	Arrest of behavior

Syndromic Classification

Most neonatal seizures are classified as acute reactive or symptomatic by the ILAE.[3,33,182] They occur as a consequence of a specific external trigger, such as hypoxic ischemic encephalopathy.[120] However, four specific neonatal epileptic syndromes also are identified by the ILAE. Two are relatively innocuous: Benign neonatal convulsions and benign familial neonatal convulsions; two others are associated with poor outcomes: Early myoclonic encephalopathy[5] and early epileptic encephalopathy.[128] The syndromes of neonatal seizures are discussed in detail in the following sections. A discussion also is included concerning other disorders that may have a consistent constellation of findings that may also suggest syndromic classification, including epilepsy in focal cortical dysplasia in infancy.[97]

Interictal Feature

Neonates who have experienced seizures have no typical clinical features, except for those with specific epileptic syndromes as defined by ILAE (these will be discussed in detail later).

However, clinical interictal findings in individual infants are significant. The interictal state of consciousness will vary depending on the etiology of the seizures, from alert to comatose. Often, these clinical findings may suggest cause and prognosis. The state of alertness usually correlates with the EEG background activity. In addition, focal neurologic signs may suggest focal brain lesions. Dysmorphic features may suggest genetic or developmental etiologies.

Postictal Features

Clinical and electroencephalographic postictal features are also not consistent. Usually, few, if any, postictal changes are present, particularly in neonates with more benign etiologies. They enjoy a rapid return to their baseline clinical and electrographic state. Prolonged focal paralysis is unusual and, if present, should suggest a structural brain lesion. In addition, a prolonged altered state of conscious is also unusual following individual neonatal seizures. Infants with severe acute encephalopathies often have abnormal levels of tone, activity, and awareness before seizures with little noticeable change in the postictal state.

FIGURE 1. Electrical seizure activity may be varied in frequency, morphology, voltage, and onset. **A:** Rhythmic sharp waves in the left central region, remaining confined to that region (2-week-old, 40-week gestational age). **B:** Rhythmic sharp and slow wave activity in the left occipital region (6-day-old, 40-week gestational age). **C:** High-voltage, repetitive, slow, sharp waves arising in the right frontal region, later appearing as faster and sharper activity spreading to the right central region (3-day-old, 40-week gestational age). **D**: Initial rhythmic, moderate-voltage, sharp-wave activity arising in the right central-temporal region, which remains unchanged as another seizure arises independently from the left temporal region with a complex morphology (2-day old, 39-week gestational age). From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven: 1998:181, with permission.[118]

Electroencephalographic Findings

The EEG is the most important laboratory examination to assist in the diagnosis of neonatal seizures. However, its application differs in the neonate when compared with older children and adults.

Interictal Findings

Interictal Focal Abnormalities

Focal sharp waves may be present interictally in the neonatal EEG, but are not considered epileptiform. Some focal sharp waves are normal, developmentally determined findings, such as frontal sharp transients (*encoches frontales*) and temporal sharp waves that occur randomly, that are low or moderate in voltage, and are present in transitional or light sleep.[116] Focal sharp waves that are persistent, excessively numerous, high amplitude, present in wakefulness and sleep, and have complex morphology suggest focal injury. Multifocal sharp waves may suggest diffuse dysfunction, such as might occur in meningitis or hypoglycemia. Focal spikes may suggest focal injury, such as localized stroke, or may have uncertain diagnostic significance.[73] In the neonate, interictal focal sharp waves and spikes are not considered direct evidence or confirmation that an individual has had or will have electrographic seizures. A similar conundrum arises in some older infants and children. A small percentage of nonepileptic infants have an incidental finding of interictal spikes or sharp waves. In others, unmistakable seizures can arise from an interictal background that lacks identifiable spikes or sharp waves.

Interictal Background EEG

The degree of abnormality of the interictal background activity may provide information concerning the extent and type of CNS dysfunction associated with seizures. The nature of the interictal background activity may also suggest the risk individual infants have in experiencing a seizure.[88] Infants with initial normal background activity are less likely to eventually experience electrographic seizures than are those with persistent diffuse background abnormalities. In addition, the extent, degree, evolution, and rate of resolution (if any) of background EEG abnormalities can suggest prognosis. An EEG with normal background activity recording within the first 24 hours of life may suggest a good outcome,[72] whereas EEG background activity with abnormal features that persist or resolve slowly suggests a poorer outcome.[73]

Ictal Findings

Although not clearly defined, it appears that electrical seizure activity in neonates is rare before 34 to 35 weeks. As previously noted,[87] suspected clinical seizures are reported with great frequency in very-low-birth-weight infants, but few of these have confirmed simultaneous EEG ictal patterns. When electrical seizure activity is recorded, its manifestations on EEG can vary widely.[116,135,156] Frequency, voltage, and morphology of the seizure discharges may change within an individual seizure, between seizures in an individual infant, or among infants (Fig. 1). The minimum duration has been designated to be 10 seconds,[28] but the duration of seizure discharges varies widely. The electrical events are predominantly focal and well circumscribed. They frequently arise from the central or centrotemporal region of one hemisphere and less commonly in the occipital, frontal, or midline central regions (Fig. 1). Although seizures may arise focally and remain confined to that region, they may also spread to other regions (Fig. 2): As a gradual widening of the focal area, by an abrupt change from a small regional focus to involvement of the entire hemisphere (a finding that characterizes a hemiconvulsive seizure), or by migration of the electrical seizure from one area of a hemisphere to another or from one hemisphere to another.[118]

Unique Neonatal Ictal Patterns

Two ictal patterns are relatively unique to the neonatal period; both are typically associated with severe encephalopathies and their associated abnormal background EEG. *Seizure discharges of the depressed brain* are typically low in voltage, long in duration, and highly localized (Fig. 3).[77] They may be unifocal or multifocal and show little tendency to spread or modulate. They are typically not associated with clinical seizures, even in the untreated infant. Seizure discharges of the depressed brain occur when the EEG background is depressed and undifferentiated, and their presence suggests a poor prognosis.

α-Seizure activity is characterized by a sudden appearance of paroxysmal, rhythmic activity of the α frequency (8–12 Hz), typically in the temporal or central region.[80,197,199] This pattern may evolve from the more typical seizure discharges or may appear de novo. As with seizure discharges of the depressed brain, clinical events usually do not occur with α-seizure discharges. The presence of an α-seizure discharge usually indicates the presence of a severe encephalopathy and poor prognosis (Fig. 4). Electrical seizure activity that is persistently focal may be consistent with a focal lesion in the corresponding region,[97] for example focal cortical dysplasia (Fig. 5).

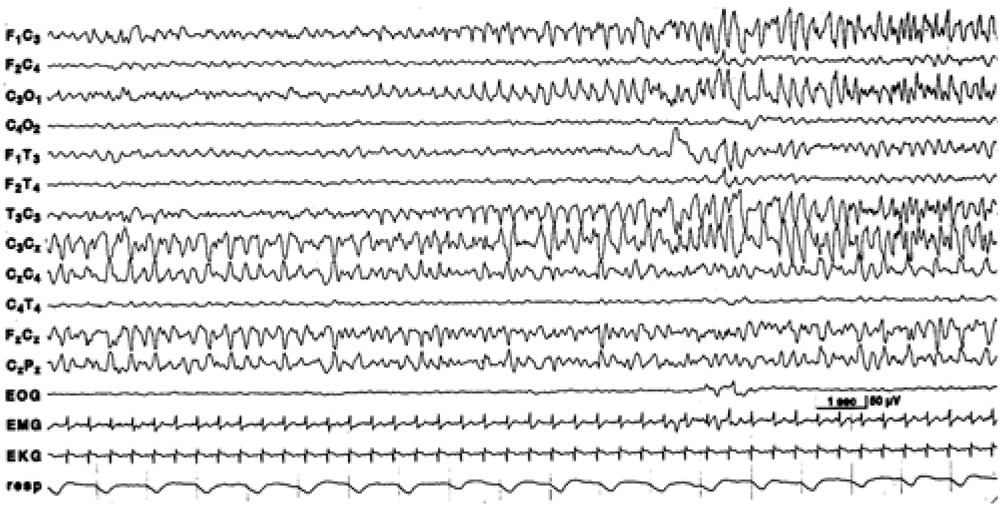

FIGURE 2. Migration of electrical seizure activity that begins in the midline region (CZ) and shifts to the left central region (C3) as the CZ region becomes less involved. This EEG was recorded from a 4-day-old, 40-week gestational age female infant with hypoxic–ischemic encephalopathy and suppression-burst EEG background. No clinical seizures were present during the electrical seizure activity. From Mizrahi EM, Kellaway P. *Diagnosis and Management of Neonatal Seizures*. Philadelphia: Lippincott-Raven: 1998:181, with permission.[118]

Video-EEG Monitoring

Video-EEG monitoring is a powerful tool in the diagnosis and management of neonatal seizures and initially had been the basis of clinical investigations that addressed seizure classification, therapy, and prognosis.[17,21,30,112,117] It is becoming increasingly more available at many centers for routine use, and is more widely employed in neonatal intensive care units.[27] However, its increasing popularity should not detract from the fact that attended EEG can provide important clinical information, when the recorded infant is observed by a trained

electroneurodiagnostic technologist (ENDT) who can carefully observe an infant's behavior and characterize the events.

Computer-Assisted EEG Analysis of Neonatal Seizures

Computer-assisted analysis of EEG to detect and quantify electrical seizure activity has been utilized reliably in long-term EEG monitoring of older children and adults in epilepsy monitoring units. EEG seizure detection in neonates is more challenging because of variability of the electrographic events. More recently, such programs have been developed and may provide reliable data, particularly if the recordings are attended by a trained ENDT.[59,122] There has also been renewed interest in the use of cerebral function monitors (CFMs), such as amplitude integrated EEG (aEEG), to detect neonatal seizures.[63,162,185] This technique is limited in terms of its ability to provide data from all brain regions and its reliance on nonexpert health care professionals. A recent study reports that, using CFMs, up to 50% of neonatal seizures were misclassified or unrecognized.[146] However, advocates suggest that the ability to monitor specific brain regions for long periods may, in some ways, balance the limited localization capability of the technique.[44] Another recent study examined 851 electrographic neonatal seizures detected in 125 conventional, full-array EEG recordings. A one-channel EEG (C3 → C4) was digitally created to simulate the contemporary use of single-channel EEGs for seizure detection by CFMs.[165] Although 78% of the seizures were visible in the single-EEG channel, the seizures were briefer and lower in amplitude, and less than half were diagnosed by aEEG based on the C3 → C4 channel.
