Introduction

Valproic acid was first synthesized in 1882 as an organic solvent in research laboratories.[59] Its anticonvulsant effects were discovered serendipitously in 1962, when it was used as a lipophilic vehicle for dissolving water-insoluble khellin derivatives. A significant anticonvulsant effect against pentylenetetrazol-induced seizures was observed in the vehicle control.[94] The first clinical trials of valproic acid were reported in 1964.[24] It was initially marketed in France in 1967, and later approved by the U.S. Food and Drug Administration (FDA) as a treatment for epilepsy in 1978. Since then, valproic acid has established itself as one of the major antiepileptic drugs (AEDs) with efficacy against multiple seizure types.

Chemical Structure and Formulations

Valproic acid is a simple, branched-chain carboxylic acid with a structure unlike other AEDs[77] (Fig. 1). It is a colorless liquid with a pKa value of 4.56 and a molecular weight of 144.21.[76] Because it is highly ionized at a pH of 7.4, valproic acid is less lipophilic than the standard AEDs.[78] This results in a low volume of distribution, because only the nonionized, lipid-soluble part of a drug distributes from blood to tissues via passive diffusion. Therefore, the rapid penetration of valproic acid into the brain cannot result from its chemical properties and is thought to be mediated by active transport mechanisms across the blood–brain barrier.[77]

Valproate (VPA) is available in multiple forms. Sodium valproate is the sodium salt and dissociates rapidly in the body to valproic acid. Divalproex sodium is a stable coordination compound, comprised of sodium valproate and valproic acid in a 1:1 molar relationship, which dissociates in the gastrointestinal tract into valproic acid.

The extended release divalproex (Divalproex ER) is a newer formulation (Fig. 2) consisting of a hydrophilic polymer matrix, controlled-release tablet system, which allows for the slow release of the drug in the stomach, small intestine, and large intestine over an 18- to 24-hour period.[2] This extended-release product is intended for once-a-day oral administration.

Pharmacology

Activity in Experimental Models and Mechanisms of Action

Experimentally, VPA has an anticonvulsant effect on almost all animal models of seizures including different types of generalized and partial seizures.[77] The cellular mechanisms of action of VPA include primarily potentiation of γ-aminobutyric acid (GABA)ergic mechanisms and, less importantly, blockades of voltage-dependent sodium (Na) channels and glutamatergic mechanisms.[77]

VPA increases cerebrospinal fluid (CSF)[79] and whole-brain GABA levels.[52,100] This increase in GABA level may be due to an inhibitory effect on GABA degradation or an enhancement of GABA synthesis.[77] Another potentially important mechanism is direct potentiation of the neuronal responses to GABA.[82,105] VPA suppresses glutamate responses and *N*-methyl-D-aspartate (NMDA)-evoked transient depolarization in rat neocortex.[148] This attenuation of NMDA receptor–mediated excitation may be an essential mode of action for the anticonvulsant effect of VPA. VPA was also shown to diminish the high-frequency repetitive firing of action potentials of cultured central neurons.[77] It was suggested that the most likely explanation for this effect is through use-dependent reduction of the inward Na current.[91] Although this mechanism is somewhat similar to that of carbamazepine and phenytoin, the reduction in sustained repetitive firing in the case of VPA might be due to enhancement of potassium (K) channels involved in action potential repolarization.[46,95]

VPA was shown to block low-threshold T-type calcium (Ca) channels in peripheral ganglion neurons but not in thalamic neurons.[32,71]

VPA also appears to affect basal ganglia circuits, which are important in cortical hyperexcitability and seizure spread. For example, VPA increases the excitatory threshold for the caudate-thalamocortical systems[97] possibly through increased activity in the substantia nigra pars reticulata.[65]

Clinical Pharmacokinetics

Absorption, Protein Binding, and Distribution

Valproic acid bioavailability after oral administration ranges from 70% to 100% in humans.[77] The bioavailability of divalproex ER is approximately 8% to 20% less than divalproex. Proportional dosing with 8% to 20% higher daily doses of divalproex ER compared with divalproex was shown to produce equivalent serum VPA levels in healthy volunteers and patients with epilepsy.[41,129]

Following oral administration, peak plasma VPA concentrations (C_{max}) are achieved within 2 hours (T_{max}) for valproic acid and sodium VPA, and within 3 to 8 hours for divalproex and divalproex ER.[70]

Valproic acid is highly protein bound (~90%), and this binding is saturable at therapeutic levels. For example, when the total VPA serum level increases from 50 to 150 μg/mL, the serum level of the free fraction of VPA increases from 3.5 to 45 μg/mL.[33] The apparent volume of distribution of VPA is 0.13 to 0.19 L/kg, with the central nervous system (CNS) concentration averaging 20% of the serum concentration.[77]

Metabolism and Elimination

VPA is primarily metabolized by three primary pathways in the liver to a number of metabolites, some of which are

biologically active.[70] Less than 5% of the parent compound is excreted unchanged in the urine. The primary pathway is through mitochondrial β-oxidation to three metabolites: 2–en-VPA, 3–OH-VPA, and 3–oxo-VPA. The 2–en-VPA is biologically active, with a long half-life.[140] The second pathway is via the cytochrome P450 system to toxic intermediary metabolites known as 4–en-VPA and 2,4–en-VPA. The concomitant use of hepatic enzyme inducers activates this pathway and increases the toxic metabolites of VPA. The third pathway consists of glucuronidation of VPA to a number of inactive compounds.

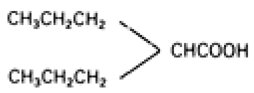

FIGURE 1. Chemical formula of valproate.

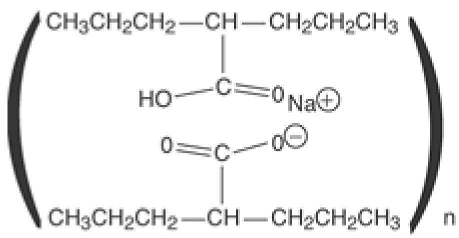

FIGURE 2. Chemical formula of extended-release divalproex.

When administered as monotherapy to adults, the elimination half-life of VPA averages 13 to 16 hours.[55,108] In the presence of hepatic enzyme inducers, its half-life is decreased to 9 hours.[109] Children metabolize VPA faster, which results in an average half-life of 11 to 12 hours.[28]

Efficacy

Absence Seizures

Typical absence seizures can occur in a number of epilepsy syndromes, including childhood absence (pyknolepsy), juvenile absence, juvenile myoclonic, and myoclonic absence epilepsies. VPA is considered to be a first-line agent for the treatment of absence seizures despite a paucity of data derived from well-designed clinical trials. Three small studies compared the efficacy of VPA and ethosuximide for children and adolescents with absence seizures.[23,87,123] Two were open-label, parallel group trials that randomized patients with newly,[23] or recently diagnosed[87] simple absence seizures to VPA or ethosuximide monotherapy. The third was a randomized double-blind conditional cross-over study that randomized 45 children and adolescents with newly diagnosed or refractory absence seizures to monotherapy or add-on treatment with VPA or ethosuximide.[123] All trials found a comparable efficacy between the two AEDs, with seizure-free rates ranging between 40% and 86%.[111] However, none of those trials was powered to detect equivalence. The most common side effects reported in those studies consisted of nausea, vomiting, drowsiness, thrombocytopenia, and leukopenia.

A more recent open-label trial compared VPA with lamotrigine in 38 children newly diagnosed with childhood or juvenile absence seizures.[30] The dose of VPA was initiated at 10 mg/kg per day and, if needed, increased by 5 mg/kg per day every 3 days up to a maximum dose of 30 mg/kg per day. Lamotrigine was started at 0.5 mg/kg per day for 2 weeks, titrated to 1 mg/kg per day for 2 weeks with increments, if needed, of 1 mg/kg per day every 5 days up to a maximum dose of 12 mg/kg per day. The percent of seizure-free patients at 1 month were 52.6% and 5.3% in the VPA and lamotrigine groups, respectively ($p = 0.004$). At 3 months, those percentages were 63.1% and 36.8%, respectively, a difference that did not reach statistical significance. After 12 months of treatment, the percentages of seizure-free patients were 68.4% and 52.6% in the VPA and lamotrigine groups, respectively. Adverse events occurred in 10.6% of children treated with VPA and 31.8% of those treated with lamotrigine. This study showed that both VPA and lamotrigine can be efficacious against absence seizures, but that VPA's efficacy is much faster, partly due to its shorter titration schedule.[30] It is, however, important to note that this trial was not powered to detect equivalence, and that the lack of a significant difference in efficacy between the two drugs could be due to the small sample size.

Juvenile Myoclonic Epilepsy

VPA is often considered the drug of choice in juvenile myoclonic epilepsy, an epilepsy syndrome characterized by myoclonus, generalized tonic–clonic seizures, with or without absence seizures. This is mostly based on clinical experience, because the evidence derived from clinical trials is scant and anectodal.[35,54,107]

Partial-Onset Seizures and Generalized Tonic–Clonic Seizures

The fact that VPA possesses anticonvulsant properties as monotherapy and add-on therapy against partial-onset seizures was unequivocally demonstrated in double-blind, parallel group, multicenter superiority trials.[13,142] The monotherapy study was a concentration-dependent trial that randomized 143 patients with medically refractory partial-onset seizures to high (80–150 μg/mL) or low (25–50 μg/mL) plasma VPA groups. The efficacy results were significantly in favor of the high plasma VPA, with a 30% median reduction in complex partial seizure frequency compared to baseline, versus a 19% increase for patients randomized to the low plasma VPA group.[13] Adverse events that occurred significantly more frequently in the high plasma VPA group included tremors, thrombocytopenia, alopecia, asthenia, diarrhea, vomiting, and anorexia.[13]

The adjunctive trial randomized 144 patients experiencing at least eight complex partial seizures over an 8-week period while maintained on carbamazepine or phenytoin monotherapy to add-on treatment with VPA or placebo.[142] Add-on treatment with VPA resulted in a median reduction of 7.9 complex partial seizures per 8 weeks compared with 2.5 in the placebo group ($p = 0.001$). In addition, the 50% responder rates were 38% and 19%, in the add-on VPA group and placebo group, respectively ($p = 0.011$).

The comparative trials that evaluated the relative efficacy and effectiveness of VPA versus other standard or newer AEDs have yielded conflicting results, especially with regard to efficacy against partial seizures. A number of open-label, active-control trials compared the relative efficacy of VPA, carbamazepine, phenytoin, and phenobarbital in adults and children with newly diagnosed epilepsy.[22,36,58,80,115,117,133,136] Most trials only enrolled patients with newly diagnosed epilepsy, including those with partial-onset and generalized tonic–clonic seizures,[22,36,57,117,133,136] whereas one trial only enrolled patients with primarily generalized tonic–clonic seizures.[115] All trials reported similar efficacy between VPA and the other AEDs on the outcome variables that included time to first

seizure, percent of seizure-free patients, and time to seizure remission. Those results were similar when data from patients with partial-onset seizures and primarily generalized tonic–clonic seizures were separately analyzed.

The only double-blind comparative trial was an active-control study that compared VPA to carbamazepine in

480 patients with partial-onset seizures.[88] Patients were stratified into two groups, one consisting of those with predominantly secondarily generalized seizures and the other of those with predominantly complex partial seizures. For patients with predominantly secondarily generalized tonic–clonic seizures, no significant efficacy differences were noted between VPA and carbamazepine. On the other hand, the efficacy of carbamazepine was reported to be significantly better than VPA for patients with predominantly complex partial seizures, based on multiple outcome measures, including time to first seizure and a composite score of seizure severity.[88] However, the percentages of patients who remained seizure-free at 1 year were comparable between the two groups. A number of factors were suggested to explain the discrepancy of results between this trial and the open-label comparative trials, including that the majority of patients in the VA cooperative trial were males, and that only approximately 50% of the participants were newly diagnosed with epilepsy.[116] However, a meta-analysis of trials comparing carbamazepine and VPA found that, for partial-onset seizures, carbamazepine was significantly superior for time to 12 months of seizure remission and time to first seizure.[86] A separate meta-analysis failed to find significant difference in efficacy between VPA and phenytoin for partial seizures or primarily generalized tonic–clonic seizures.[132]

Two comparative trials evaluated VPA with one of the newer AEDs. In a double-blind, parallel-group trial, 249 patients with newly diagnosed epilepsy, aged 15 to 65 years and experiencing partial-onset seizures or generalized tonic–clonic seizures, were randomized to treatment with VPA or oxcarbazepine.[26] The study consisted of an 8-week titration followed by a 48-week maintenance period. The results showed no significant efficacy difference between the two groups, with 53.8% and 56.6% of patients randomized to VPA and oxcarbazepine, respectively, remaining seizure-free throughout the 48-week maintenance period. The numbers of premature discontinuations due to adverse events were also comparable between the two groups.[26]

A more recent active-control, double-blind trial compared the efficacy of topiramate with the investigator's choice of carbamazepine or VPA as initial treatment for patients with newly diagnosed epilepsy.[113] The investigators were asked to select carbamazepine (600 mg/day) or VPA (1,250 mg/day) based on the clinical presentation. Within each group, patients were randomized in a double-blind fashion to treatment with one of the two standard AEDs versus topiramate administered at 100 mg/day or 200 mg/day. Patients continued double-blind treatment until exiting the study or until 6 months after the last patient was randomized. Of the 78 patients randomized to VPA, 42% were considered to have partial-onset seizures, 63% primarily generalized tonic or clonic or tonic–clonic seizures, and 1% could not be classified. In that subgroup, 145 patients were randomized to topiramate (100 mg/day or 200 mg/day), with 41% considered to have partial-onset seizures, 65% primarily generalized tonic or clonic or tonic–clonic seizures, and 2% could not be classified. The results indicated no significant difference in time to exit, adverse events, or inadequate effect between the VPA and topiramate groups.[113]

Infantile Spasms

Two uncontrolled, open-label, prospective studies suggested the efficacy of VPA against infantile spasms[45,126] at daily doses ranging from 25 to 100 mg/kg per day. Cessation of spasms occurred in 72% to 73% of children within 2 weeks to 3 months after initiation of therapy, with a 23% relapse rate reported in one of the studies.[126] Consequent to the high doses used, approximately one-third of the children developed thrombocytopenia.[126] Long-term outcome of children with infantile spasms was evaluated in two retrospective studies, with conflicting results.[61,103] One study, which compared treatment with adrenocorticotropic hormone (ACTH), pyridoxine, and VPA reported that none of the VPA-treated patients had a normal IQ, but that all were seizure-free.[104] In the other study, which compared ACTH to VPA, only 26% of children were seizure-free, with no significant difference between the two groups.[61]

The data on VPA in infantile spasm are largely anecdotal and insufficient to recommend VPA as initial treatment of infantile spasms[83] but may be considered in patients with spasms that are refractory to ACTH and vigabatrin.

Febrile Seizures

A number of studies evaluated the efficacy of continuous treatment with VPA in the prevention of recurrent febrile seizures (FS).[73,84,101,138,141] In an open-label, randomized trial of 58 children who experienced their second simple febrile seizure, the recurrence rate did not differ between the VPA-treated group and the no-treatment group.[141] The other trials comparing the relative efficacy of VPA to that of phenobarbital and placebo or no treatment found that VPA was significantly better than no treatment or placebo in preventing further FS, and that its efficacy did not significantly differ from that of phenobarbital.[73,84,101,138] For example, 73 children with their first generalized febrile seizure were randomized in a single-blind, placebo-controlled clinical trial to treatment with VPA, phenobarbital, or placebo.[84] The recurrence rates were 4%, 19%, and 35% in the VPA, phenobarbital, and placebo groups, respectively. Similar results were reported in another, double-blind, placebo-controlled trial conducted in children enrolled after their first simple febrile seizure.[101]

Those data provide evidence that continuous treatment with VPA significantly reduces the likelihood of further FS and that its efficacy in that regard is overall at least comparable to that of phenobarbital. However, the Practice Parameter developed by the American Academy of Pediatrics does not recommend the use of daily anticonvulsant treatment, because it does not influence the long-term outcome in children with simple FS.[7] In addition, the risk of serious hepatotoxicity is greatest in the age group in which FS usually present, and studies of valproic acid in FS were insufficiently powered to detect a risk of serious hepatotoxicity.

Status Epilepticus

Following the availability of the intravenous formulation of VPA, there was an interest to evaluate its potential usefulness in the management of patients with status epilepticus (SE). Its theoretical safety advantages compared to phenytoin, the benzodiazepines, and the barbiturates is that it can be administered at a physiologic pH and has not been found to be associated with hypotension, sedation, or respiratory depression.[99,112]

Efficacy data in children and adults are mostly anecdotal and based on case reports or small open-label series.[25,60,134] In the great majority of cases, VPA was administered to patients with refractory convulsive or nonconvulsive SE who had failed previous treatment with benzodiazepines, phenytoin, and barbiturates. In children, the loading dose was 20 to 30 mg/kg over 1 hour, followed by maintenance doses of up to 60 mg/kg per day with an attempt to achieve plasma VPA

P.1676

concentrations between 60 and 100 μg/mL.[25,60] In the largest series to date, 41 children with refractory SE received a VPA loading dose of 20 to 40 mg/kg administered over 1 to 5 minutes, followed by a maintenance rate of 5 mg/kg per hour.[134] Using this protocol, SE was successfully aborted clinically and electroencephalographically in 78% of children. The majority of those recovered following the administration of the loading dose, which resulted in mean plasma VPA concentrations of 121 μg/mL. No adverse events were reported with the use of this protocol.[134]

The data in adults are overall similar and using more aggressive loading doses as clinical experience grew. For example, in the initial published study, a loading dose of 400 mg was administered followed by a maintenance dose of 100 to 300 mg/hour.[112] In later case series, the loading dose of VPA was increased up to 25 mg/kg and administered at 20 to 50 mg/minute.[99] As would be expected in patients with refractory status, some patients improved while others did not following the administration of intravenous VPA. One study is of particular importance,[51] because intravenous VPA was used as the initial treatment in 23 adult patients with SE (15 with nonconvulsive and eight with convulsive SE). The initial protocol, which consisted of a 12-mg/kg loading dose followed by a maintenance dose of 0.5 mg/kg per hour, was only used for the first four patients, because it resulted in a mean post-loading serum VPA level of only 52.5 μg/mL. The amended regimen, consisting of a loading dose of 15 mg/kg followed by a 1-mg/kg per hour maintenance dose was used in the remaining 19 patients and resulted in a mean post-loading serum VPA level of 68.5 μg/mL.[51] In that study, it was reported that the status was aborted clinically and electroencephalographically within 20 minutes of initiation of VPA treatment in 19 patients (83%), and that both patients with convulsive and nonconvulsive status responded equally well. No adverse events were reported using this treatment regimen.[51]

There is little data on the use of intravenous VPA for other types of SE. In a case report, a 15-year-old girl who presented in myoclonic SE reportedly recovered after receiving 500 mg of intravenous VPA administered over 30 minutes.[127] Her VPA plasma level was 28 µg/mL when she recovered clinically.

The data so far suggest that intravenous VPA is a promising option for the treatment of SE in children and adults. There is still insufficient data to recommend this drug as initial treatment, but it can certainly be considered in patients with refractory status who failed treatment with phenytoin (or fosphenytoin), benzodiazepines, and/or barbiturates. The optimum loading and maintenance doses have not yet been established, but a loading dose of 20 to 40 mg/kg administered over a few minutes, followed by a maintenance dose of 5 mg/kg per hour appears to be safe and efficacious in children. In adults, a loading dose of at least 15 mg/kg followed by a maintenance dose of at least 1 mg/kg per hour should be used.

Adverse Effects

Neurologic

A postural tremor can occur following treatment with VPA. This side effect is dose- and serum level-dependent and usually improves following a dose reduction or treatment with propranolol.[13,69] Sleepiness, lethargy, and confusion can occur with VPA treatment, but are rare and typically occur with serum VPA levels above 100 µg/mL.[19] VPA has also been associated with reversible parkinsonism, thought to be unrelated to dopaminergic neuronal loss.[11,43,122]

Another neurologic side effect related to VPA is a reversible encephalopathy characterized by acute mental status changes that can progress to coma. This condition is associated with generalized δ-wave slowing on electroencephalograph (EEG), is unrelated to hyperammonemia, and usually improves within 2 to 3 days of stopping VPA.[85,119] VPA-induced hyperammonemic encephalopathy is characterized by an acute deterioration of mental status with confusion and lethargy, focal findings on neurologic examination, and increased seizure frequency that can progress to stupor and coma.[137] EEG changes consist of generalized slowing associated with an increase in the frequency of epileptiform discharges. The ammonia level is elevated without concomitant evidence of liver failure. No association between VPA dose, elevation of ammonia level, and severity of the encephalopathy was found.[137] VPA-induced hyperammonemic encephalopathy quickly resolves following discontinuation of VPA.[137]

Gastrointestinal

VPA frequently causes nausea, vomiting, diarrhea, and anorexia.[13] These symptoms typically occur during the initiation of treatment and were found to be less frequent and less severe with the enteric-coated formulation.[19]

Elevated liver enzyme activity is common with the use of VPA, and it has been suggested that raised liver enzymes up to three times the upper limit of normal do not require a change in treatment in asymptomatic patients with no other abnormal liver function tests.[48] Benign elevation of liver enzymes should be differentiated from fulminant hepatotoxicity, a relatively rare and serious idiosyncratic adverse event characterized by decreased alertness, jaundice, vomiting, hemorrhage, increased seizures, anorexia, and edema as the most common presenting signs.[21,39,40] The major risk factors associated with this idiosyncratic reaction were young age, polytherapy, developmental delay, and coincident metabolic disorders.[21] Children under 2 years of age receiving VPA polytherapy had a 1:600 risk of liver failure. The risk was extremely low in adults and cognitively normal individuals. The much higher incidence of hepatotoxicity in children with metabolic disorders, particularly Alpers disease, other mitochondrial disorders, and urea cycle disorders, may reflect the fact that these diseases often manifest with both seizures and liver failure. Dreifuss reported that five pairs of siblings with inherited metabolic disorders died of hepatic failure and had histopathologic findings consistent with VPA hepatotoxicity but were discordant for VPA exposure.[21] Nonfatal and fatal pancreatitis can rarely occur in adults and children on VPA.[15,53]

Weight gain is a common side effect in patients receiving VPA.[31,38,42,44,66,102,130] In a recent randomized, double-blind comparative study of VPA versus lamotrigine, patients treated with VPA at 20 mg/kg per day experienced a mean weight increase of 12.8 ± 9.3 lb after 8 months of treatment.[16] In this study and previous studies,[102,130] there were no predictive factors for weight gain, such as age, gender, pretreatment body weight, or VPA dosage.

Reproductive

In 1993, a possible association between the use of VPA and occurrence of reproductive endocrine disturbances in women with epilepsy was reported.[67] This was followed by other studies from the same group reporting a high frequency of polycystic ovaries, hyperandrogenism, high serum insulin levels, and menstrual irregularities related to treatment with VPA, raising the possibility of an association between VPA and polycystic ovaries syndrome.[66,68] More recently, the effect of epilepsy syndrome (localization-related epilepsy vs. idiopathic generalized epilepsy) and type of AED (carbamazepine, phenytoin,

phenobarbital, VPA, lamotrigine, or gabapentin) on ovulatory function was evaluated in 94 women with epilepsy and 23 controls.[96] No significant associations were found between the type of AED used and anovulatory cycles, nor between the type of AED and presence of polycystic ovaries. However, it was reported that women with idiopathic generalized epilepsy who were taking or who had taken VPA within the previous 3 years were at the highest risk for anovulatory cycles. Of importance is that none of the women in this study satisfied the National Institutes of Health criteria for the polycystic ovaries syndrome.[96] Other studies failed to detect an association between reproductive abnormalities and the intake of VPA. For example, a prospective study on 93 women with chronic focal epilepsy failed to detect an association between VPA and polycystic ovaries syndrome.[12] In contrast to other studies, menstrual disorders were found to be more common among women taking AEDs (33%) other than VPA (24%).[12] Similar results were reported in two other studies.[14,81]

The issue of a possible association between VPA and reproductive abnormalities, polycystic ovaries, or polycystic ovaries syndrome was recently reviewed critically.[93] It was concluded that women with epilepsy are at risk for developing reproductive endocrine disorders, but that there is not yet definite evidence that polycystic ovaries syndrome is more frequent in these patients nor that VPA may be the cause of endocrine problems. It is likely that both the epileptic disorder and the antiepileptic treatment play different roles in the development of such disturbances.[95] (For further discussion, see Chapters 196 and 198.)

Hematologic

VPA can lead to various hematologic adverse events including dysfunction of the coagulation system, thrombocytopenia, abnormal platelet function, hypofibrinogenemia, von Willebrand disease, and, rarely, a decrease of vitamin K–dependent factors.[3,49,110,131] Occasional fatal bone marrow failure, myelodysplasia, and a clinical picture resembling acute promyelocytic leukemia have been reported with VPA use.[3] A significant relationship was found between platelet counts and impaired platelet function on the one hand and VPA dose and VPA plasma concentrations on the other.[13,49] These hematologic dysfunctions usually occur with serum VPA levels greater than 100 μg/mL and may improve with dosage reduction.[3]

Other Side Effects

VPA was found to cause osteopenia and osteoporosis by direct bone resorption, a mechanism different from that of enzyme inducers, such as phenytoin, carbamazepine, and the barbiturates, which cause hypovitaminosis D and secondary bone loss.[18,124]

Teratogenicity

Maternal exposure to VPA has been associated with a variety of major malformations, including neural tube defect (NTD), and with developmental delay (see Chapter 108). A fetal AED syndrome has been associated with several drugs, particularly phenytoin and VPA. Characteristic features of the VPA syndrome consist of arched eyebrows, short nose, thin upper lip, and broad nasal bridge.[37] Other traits include cleft lip and palate, radial ray defects, congenital heart defects, and genitourinary problems. In addition, prenatal VPA exposure has been associated with bilateral congenital blepharoptosis and optic chiasm hypoplasia.[50,92] A prospective study in North America reported that the prevalence of major malformations was 10.7% in infants born to mothers receiving VPA compared with 2.9% in infants born to mothers receiving other AEDs, and 1.62% in infants born to nonepileptic mothers not receiving any AEDs.[145] Thus, the relative risk of having a major malformation after exposure to VPA when compared with mothers not exposed to AEDs was 7.3. Similarly, a prospective study in Australia reported that the prevalence of major malformations was 16% in infants born to mothers receiving VPA in the first trimester compared with 2.4% in infants born to mothers receiving other AEDs in the first trimester and 3.1% in infants born to epileptic mothers not receiving any AEDs.[135] This study emphasized the effect of higher dosages on teratogenicity. The prevalence of malformations was 30.2% with VPA doses of greater than 1,100 mg and 3.2% with doses of less than 1,100 mg/day.

The association between VPA and NTDs was first reported in 1982.[118] Since then, a number of risk factors for the development of NTD were identified. They include a previous pregnancy with a NTD, ethnic and geographic predisposition, excessive exposure to vitamin A, a higher prepregnancy weight, and deficiencies of glutathione, folate, vitamin C, riboflavin, zinc, cyanocobalamin, and selenium.[139] It is even suggested that VPA may be a necessary but not sufficient risk factor for the development of NTDs.[146]

An analysis of five prospective studies found that VPA was associated with spina bifida in 3.8% of at-risk pregnancies.[121] This association was dose-dependent, so that spina bifida did not occur with VPA doses of less than a 1,000 mg/day (0 out of 54 pregnancies), whereas it occurred in 6.7% of exposed women on daily VPA doses of 1 to 1.5 g (2 out of 30 pregnancies). This percentage increased to 37.5% when the dose of VPA exceeded 1.5 g/day (three out of eight pregnancies). A similar dose-related increase in major congenital defects was reported in another study.[89]

In addition to the teratogenic risk, recent evidence suggests that children exposed to VPA in utero are at an increased risk of developmental delay.[4,104] (For further discussion, see Chapter 109.) For example, a recent study found a significantly decreased verbal IQ in children exposed to polytherapy with VPA, but no effect from exposure to carbamazepine.[47] Another study showed that children exposed to VPA monotherapy in utero had significantly lower verbal IQ (VIQ) scores compared with children exposed to carbamazepine or phenytoin monotherapy, with suggestions of a dose-related effect. Risk factors for drop in VIQ were the occurrence of five or more tonic–clonic seizures during pregnancy and low maternal IQ.[5] However, a recent review identified a number of methodologic shortcomings with those studies and concluded that the currently available data are insufficient to draw any definite conclusions.[6]

Drug Interactions

Effects of Valproate on Other Drugs

The hepatic metabolism of drugs occurs via the cytochrome P450 (C450) and uridine diphosphate glucuronosyltransferase (UGT) enzymes. C450 is a family of multiple enzymes that include three major families (CYP1, CYP2, CYP3). The seven isoenzymes primarily involved in the hepatic metabolism of most drugs are CYP1A2, CYP2A6, CYP2C8/9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. The last is the most abundant isoenzyme, has the broadest substrate specificity, and is involved in the metabolism of more than 50% of all drugs.[144]

VPA is a broad-spectrum inhibitor of hepatic metabolism, including inhibition of CYP2C9, uridine glucuronyl transferase (UGT), and epoxide hydrolase.[8,64] VPA primarily inhibits drugs metabolized by the CYP2C9 subfamily

(phenobarbital and phenytoin).[125] VPA significantly increases lamotrigine plasma concentrations, presumably by competitively inhibiting the glucuronidation of lamotrigine.[147] It also inhibits the epoxide hydrolase enzyme, which catalyzes the metabolism of carbamazepine 10,11-epoxide.[90,114] Therefore, when VPA and carbamazepine are concomitantly administered, the serum concentrations of the carbamazepine 10,11-epoxide increases with or without an increase in the total carbamazepine concentration, which could result in side effects.

VPA is highly protein-bound to albumin, and can displace other highly protein-bound drugs (phenytoin, carbamazepine, diazepam) from their binding sites, increasing the free plasma levels of those drugs.[125] For example, the effect of VPA on phenytoin is a combination of displacement from protein-binding sites and enzyme inhibition. These interactions can result in a disruption of the relationship between free and total plasma phenytoin concentrations. Total phenytoin concentrations can increase, decrease, or not change when VPA is added. However, the free phenytoin fraction will usually increase. Ideally, free phenytoin concentrations should be monitored in a patient receiving both VPA and phenytoin.[56,72,75]

Concerning medications other than antiepileptics, VPA does not affect the cyclosporine level[57] nor does it interact with the metabolism of oral contraceptives.[34] However, it increases the plasma level of lorazepam[9] and zidovudine,[74] by inhibiting the glucuronide conjugation of these drugs. In addition, VPA increases concentrations of amitriptyline and its major metabolite, nortriptyline, by approximately 20%.[143]

Effects of Other Drugs on Valproate

VPA is metabolized through the liver, predominantly by UGT-catalyzed glucuronide conjugation and ß-oxidation (VPA is a substrate for CYP2C9 and CYP2C19).[8] The concentration of VPA is decreased in the presence of CYP2- and UGT-inducing drugs such as phenytoin, carbamazepine, and phenobarbital.[8] Felbamate significantly inhibits VPA metabolism by inhibiting the ß-oxidation pathway.[62] Lamotrigine is a weak inducer of UGT and causes a decrease in VPA plasma concentrations.[10] Topiramate causes a modest decrease in VPA plasma concentrations by inducing its ß-oxidation.[8] Ethosuximide was found to reduce VPA concentrations by approximately one-third,[120] whereas tiagabine resulted in a slight reduction in VPA plasma concentrations.[20]

Acetylsalicylic acid displaces VPA from albumin, leading to higher unbound levels,[106] and inhibits the beta-oxidation of VPA, resulting in increased microsomal metabolism and 4-en-VPA.[1] Carbapenems inhibit the hydrolysis of VPA-glucuronide to VPA; this causes a decrease in plasma concentration of VPA and results in seizure exacerbation in patients treated with VPA and carbapenems.[27,29,98]

Role in Epilepsy Treatment

VPA is considered to be a broad-spectrum AED, effective against all seizure types. It is generally considered a first-line agent (or drug of choice) for absence, myoclonic, and primarily generalized tonic–clonic seizures. In addition, it is often used as monotherapy or part of a polytherapy regimen for patients with symptomatic generalized epilepsies. For patients with newly diagnosed, localization-related epilepsy, clinicians do not usually consider VPA to be the drug of choice. It is, however, frequently used as an alternative monotherapy agent or as part of a polytherapy regimen for patients with refractory seizures of partial onset.

VPA is available in oral formulations of various strengths and as a parenteral formulation. To minimize adverse events, it is best to start the drug at a low daily dose with a gradual titration to efficacy. For adults, and especially the elderly, a starting dose of 250 mg twice daily is usually better tolerated than the 10 to 15 mg/kg starting dose recommended in the package insert. The dose can subsequently be increased by increments of 250 mg/day on a weekly basis. For patients with newly diagnosed epilepsy, the usual effective daily dose is between 750 and 1,500 mg. Patients with localization related epilepsies will usually require higher daily doses and higher trough serum levels to achieve seizure control, compared with those with idiopathic generalized epilepsies. For children, a starting dose of 15 mg/kg per day is recommended, with weekly increases of 5 to 10 mg/kg per day. The usual maintenance dose ranges between 15 and 30 mg/kg per day. Patients experiencing adverse events on the delayed release formulation,[2] or those wishing to be treated with a once-daily regimen, can be switched to the extended-release formulation.[2] This is based on a few studies that suggested that divalproex ER is better tolerated by some patients compared with the delayed-release formulation.[128] If such a switch is conducted, the total daily dose of divalproex ER should be 10% to 20% higher that that of divalproex DR to ensure similar steady-state serum levels. The intravenous formulation of VPA is useful for patients unable to take medications orally or for initiation of therapy before discharge from the epilepsy monitoring unit.[17] As previously mentioned, the role of intravenous VPA for the treatment of SE is promising, but more studies are needed to better delineate its potential role in this condition.

The most common early side effects of VPA involve the gastrointestinal tract. Dose-related side effects include tremor and thrombocytopenia. Although the tremor usually responds to treatment with ß-blockers,[69] it is best to try to reduce the dose if the tremor is bothering the patient. Hair loss sometimes responds to treatment with zinc and selenium supplementation.[63] Some patients develop substantial weight gain on VPA, which can be treatment limiting.

Patients treated with VPA, especially at high doses, should have their platelet counts monitored. Liver function tests should be monitored in very young children, especially those who are mentally retarded and with symptomatic generalized epilepsy. Amylase and ammonia levels should be checked based on the clinical picture. Because patients on long-term treatment with VPA are at risk to develop osteopenia or osteoporosis,[124] it would be useful to have a baseline bone densitometry performed with follow-up studies every few years. Treatment with calcium and vitamin D supplementation should be considered in all patients, whereas bisphosphonates should be reserved for patients who develop osteopenia/osteoporosis.

There are some concerns about the use of VPA in women of childbearing age, because of its potential association with polycystic ovary syndrome and risk of teratogenicity. Although alternative agents can easily be considered for the localization-related epilepsies, VPA can be the most efficacious AED in the generalized epilepsies and the only AED associated with seizure control. For those patients, VPA should be considered the drug of choice, and the minimal effective dose of VPA with folate supplementation (0.4–5 mg/day) should be used. Pregnant women on VPA should undergo a serum α-fetoprotein level and a level II ultrasound at 14 to 18 weeks of gestation to evaluate for the possibility of NTDs.

Summary and Conclusions

VPA possesses multiple mechanisms of action, has a broad spectrum against all seizure types, and an adverse event profile that differs from other AEDs. It is available in oral formulations of various strengths and as a parenteral formulation. VPA is an

inhibitor of hepatic metabolism and therefore can increase the serum level of other drugs, including some AEDs, notably lamotrigine. Although the use of VPA in pregnancy is associated with NTDs, it still may be the best option for treating some specific epilepsy syndromes.

Chapter 161
Vigabatrin

Elinor Ben-Menachem

Olivier Dulac

Catherine Chiron

Introduction

Vigabatrin is a novel antiepileptic drug (AED). It differs from most other agents in that it was designed to have a specific effect on brain chemistry and was subsequently proved to produce that effect. Thus, it is still one of the few AEDs whose mechanism of action is presumably completely known. The mechanism consists of irreversible inhibition of γ-aminobutyric acid (GABA)-transaminase, the enzyme that degrades the inhibitory neurotransmitter GABA in the central nervous system (CNS). A great deal of information has been obtained about this unique compound from clinical trials and also from the large number of patients receiving vigabatrin as a registered drug in nearly 50 countries worldwide. It is not, however, available in the United States because of its tendency to cause irreversible visual field defects (VFDs). The possibility exists, nevertheless, that vigabatrin will one day be available in the United States for use in children with infantile spasms. This chapter reviews the current preclinical data, efficacy, safety, and clinical use of vigabatrin.

Chemical Characteristics, Formulations, and Methods for Determination in Body Fluids

Chemical Characteristics

Vigabatrin (4-amino-5-hexenoic acid, γ-vinyl GABA, GVG) is a structural analog of GABA with a vinyl appendage (Fig. 1). It is a rationally designed, enzyme-activated, irreversible selective inhibitor of GABA-transaminase.[38,76] Vigabatrin is highly water-soluble, only slightly soluble in ethanol and methanol, and insoluble in hexane and toluene. It is a white to off-white crystalline solid with a melting point of 171° to 177°C. The molecular weight is 129.16, and the conversion factor (CF) is 7.75 (mg/L × CF = μmol/L).

Vigabatrin is a racemic mixture of *R*-(-) and *S*-(+)-enantiomers in equal proportions and exhibits no optical activity. The pharmacologic activity and toxic effects of vigabatrin are associated only with the *S*-(+)-enantiomer; the *R*-(-)-enantiomer is entirely inactive.[40,87] The duration of effect is determined by the half-life of the enzyme rather than by that of *S*-(+)-vigabatrin because GABA-transaminase has a much longer half-life than *S*-(+)-vigabatrin itself.[8,50]

Formulations

The only available forms of vigabatrin are oral formulations (500-mg tablets and 500-mg sachets). Sachet contents may be placed in a beverage (e.g., water, fruit juice, or milk) immediately before oral administration.

Methods of Determination in Body Fluids

Vigabatrin is a highly water-soluble amino acid and can be measured using standard automatic amino acid analysis, high-performance liquid chromatography (HPLC), or gas chromatography-mass spectrometry.

HPLC is the most commonly used method of analysis for vigabatrin in body fluids. A reversed-phase HPLC assay was developed by Smithers et al.[101] Tsanaclis et al.[111] described a single-step protein precipitation with subsequent precolumn derivatization with *o*-phthaldialdehyde and direct injection into a Microsorb C18 column. The isocratic HPLC method developed subsequently by Chollet et al.[20] is more rapid than previous methods. Since only the *S*-(+)-enantiomer is pharmacologically active, it is generally preferable to utilize assays that differentiate between enantiomers, such as that described by Vermeij and Edelbroek.[113]

Pharmacology

Activity in Experimental Models of Seizures/Epilepsy

Vigabatrin has been tested in numerous seizure models and has been shown to be effective in some, but not all. It is inactive in models such as maximal electroshock (MES), bicuculline (GABA antagonist), and pentylenetetrazol unless injected directly into the midbrain of rats.[31] However, after an intravenous injection of vigabatrin, seizure protection was observed against bicuculline-induced myoclonic activity,[54] strychnine-induced tonic seizures,[98] isoniazid-induced generalized seizures,[98] audiogenic seizures in the mouse,[96] light-induced seizures in the baboon,[71] and amygdala-kindled seizures in the rat.[76,103]

Stereotaxic injections of small amounts of vigabatrin into certain areas of rat brain gave seizure protection in relation to the locally increased GABA levels.[31] Seizure protection in the MES model was most prominent with local GABA increases in the midbrain tegmentum, including the substantia nigra and the midbrain reticular formation. Injections of vigabatrin into the thalamus, hippocampus, and cortex did not protect against seizures in this model. The duration of seizure protection was as long as 72 hours after a single injection to the substantia nigra. Only by the fifth day did the rats respond normally to MES. This finding supports the observation that the rate of recovery of GABA-transaminase is 5 days,[50] and suggests that the anticonvulsant effect is a consequence of the local increase in GABA levels rather than of a direct effect of vigabatrin itself.

Mechanisms of action

Studies in Animals

The pharmacokinetics in the CNS and effects on GABA, GABA-transaminase, glutamate decarboxylase, and other neurotransmitters and amino acids in animals demonstrate the specific effects of vigabatrin in the brain. In one of the first experiments studying the effects of vigabatrin, 1,500 mg/kg of the compound were injected intraperitoneally in mice. The brain content of GABA, GABA-transaminase, and glutamate decarboxylase was measured over time. By 4 hours, a fivefold increase of whole-brain GABA was noted.[50] At the same time, a sharp decline occurred in GABA-transaminase activity, with a recovery to 60% of baseline after 5 days. Glutamate decarboxylase was also affected, with a 30% reduction of activity. However, this decrease was seen only at very high doses (1,500 mg/kg), and the probable cause is considered to be feedback following the rise in GABA concentration.

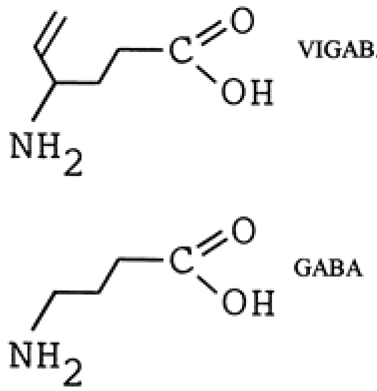

FIGURE 1. Chemical structure of vigabatrin.

In addition to GABA, vigabatrin also influences other amino acids and transmitters, at least at high doses.[82] An increase in brain ß-alanine (an alternative substrate for GABA-transaminase), as well as homocarnosine and hypotaurine, was demonstrated, whereas glutamine and threonine levels decreased.

Studies in Humans

Observing effects on GABA and other neurotransmitters in the cerebrospinal fluid (CSF) has been an important method to study the effects of vigabatrin on GABA and other neurotransmitters and amino acids in the human brain. The first study to investigate the relationship between vigabatrin and GABA in the CSF was carried out by Grove et al.[38] Patients with various neurologic conditions were given 0.5, 1, 2, or 6 g daily for 3 days. Free and total GABA, ß-alanine, homocarnosine, and vigabatrin increased in a dose-responsive manner, except at a dose of 0.5 g/day, with which no changes in the parameters studied were recorded. Schechter et al.[96] studied ten patients given 0.5 g vigabatrin twice daily for 2 weeks followed by 1 g twice daily for 2 weeks and then placebo for 2 weeks. When parameters were measured at the end of the treatment period, there were no changes from baseline in homovanillic acid (HVA; the metabolite of dopamine) and 5-hydroxyindolacetic acid (5-HIAA; the metabolite of serotonin), but dose-related increases were seen in free and total GABA, and in homocarnosine. At the end of the placebo period, the levels of GABA and homocarnosine had declined to baseline levels.

No changes in CSF levels of acetylcholine, somatostatin, ß-endorphins, prolactin, cyclic adenosine monophosphate, or cyclic guanosine monophosphate were observed during long-term treatment.[84,99] No consistent changes have been found in amino acids, HVA, or 5-HIAA with long-term treatment of vigabatrin at 50 mg/kg up to 3.5 years either in tissue or CSF.[7,99] In a single-dose study, however, HVA and 5-HIAA concentrations increased initially up to 100%, but they returned to the baseline level or slightly below baseline level after 1 month of treatment.[8]

At a dose of 50 mg/kg, vigabatrin causes a 200% to 300% increase in GABA in the CSF and brain tissues.[6] A reduction of vigabatrin dose from 3 g/day to 1.5 g/day caused a proportional reduction of GABA concentrations in the CSF.[99] Dose and percentage increase in CSF GABA concentrations show a good linear relationship, but the relationship between dose and efficacy appears more complex and depends on the nature of the epilepsy. Nuclear magnetic resonance spectroscopy in patients treated with vigabatrin have confirmed the observations seen using CSF GABA analysis.[69]

The effects of vigabatrin are also seen in blood GABA and platelet GABA-transaminase levels. Administration of vigabatrin causes a marked reduction in platelet GABA-transaminase at therapeutic doses of 2 to 3 g/day. It appears that a dose of 2 g/day maximally inhibits platelet GABA-transaminase, with mean enzyme inhibition at approximately 70%.[89] The concentration of plasma vigabatrin is almost tenfold that seen in the CSF and, because platelets cannot regenerate GABA transaminase, the effect of vigabatrin on this test system is also influenced by platelet regeneration.

There is no clear-cut correlation between blood concentration of vigabatrin and efficacy.[57]

Clinical PHARMACOKINETICS

Absorption

The only available forms of vigabatrin are oral. There are no intravenous or rectal formulations, so the absolute bioavailability of the drug has not been determined in humans. Studies in animals, however, indicate that the areas under the plasma concentration versus time curves (AUCs) are similar when intravenous, intraperitoneal, subcutaneous, intramuscular, and oral doses are administered.[50,101]

All pharmacokinetic studies[39,40,92] in humans have demonstrated that absorption is rapid, with the peak concentration reached in the first 2 hours after doses of between 0.5 and 3 g. Absorption half-life ranges from 0.18 to 0.59 hours. In a single-dose kinetic study that used an enantioselective assay,[40] peak plasma concentrations for both enantiomers were reached between 0.5 and 2 hours after a 1,500-mg dose.

The bioavailability of vigabatrin in tablet form and in solution has been studied in healthy volunteers.[45] Although there was a slightly lower, delayed peak concentration for the tablet, the pharmacokinetic profiles were very similar. Thus, it can be concluded that the vigabatrin tablet is bioequivalent to the oral solution. Approximately 60% to 80% of the drug can be recovered unchanged in the 0- to 24-hour urine. This indicates that bioavailability is at least 60% to 80%.

The effect of food on the bioavailability of vigabatrin in tablet form has been studied.[30,45] The AUC for fasted and fed volunteers was not significantly different. This indicates that food does not have an effect on the extent of absorption. The half-life was 7.15 hours, and renal clearance was 95.0 mL/min for the fasted group, and 9.15 hours and 99.9 mL/min for the fed group. Therefore, the time of administration and what and

P.1685

when a person eats should not influence the clinical response to vigabatrin.

Plasma Protein Binding and Distribution

Plasma Protein Binding, Volume of Distribution, and Penetration into the Cerebrospinal Fluid

Vigabatrin does not bind at all to plasma proteins.[89] The distribution of vigabatrin in the body is very wide. This is not surprising, because vigabatrin is not protein-bound and is a highly water-soluble compound. The apparent volume of distribution is 0.8 L/kg (total body water is 0.6 L/kg) in volunteers, with the half-life of distribution at 1 to 2 hours.

Vigabatrin levels in CSF have been analyzed in patients with epilepsy. The concentration of vigabatrin in the CSF was approximately 10% of that in the blood.[8] In this study, patients taking concomitant AEDs were given 50 mg/kg as a single dose. CSF and blood samples were taken for up to 5 days after dosing. The highest concentrations of vigabatrin were found in CSF after the first sample. By 24 hours, only a trace was detectable in the CSF, and no vigabatrin was found at 72 hours or thereafter. The peak concentration in the blood was reached by 1 hour and decreased thereafter, with only trace amounts detectable at 72 hours. After a 3-year follow-up at doses of 50 mg/kg per day, the levels of vigabatrin in CSF were not significantly increased when compared with the 6-month levels.[7]

Distribution in Placenta

Passage of *S*-(+)-vigabatrin and *R*-(−)-vigabatrin across the human placenta in vitro was studied by Challier et al.[16] The transfer from maternal to fetal blood across the placenta was low and comparable with that of other acidic α-amino acids. Clearance for both of the enantiomers was about 27% that of phenazone.

Distribution in Special Populations

To determine whether vigabatrin has a different distribution profile in the elderly, 1.5 g vigabatrin was given as an oral dose to healthy volunteers between the ages of 60 and 75. Steady-state volume of distribution was not markedly different from that in the younger volunteers.[39] However, in volunteers between the ages of 76 and 97 years, a decrease of the apparent volume of distribution occurred.

In renally impaired patients, the volume of distribution was about one-half to one-third that in healthy volunteers.[39] Because most of the renally impaired volunteers were elderly (mean age, 86.4 years), the reduced muscle mass probably contributed to the reduced volume of distribution.

Metabolism

Vigabatrin is not significantly metabolized in humans. Up to 82% of the oral dose is excreted unchanged in the urine (data on file, Sanofi-Aventis, Paris, France).

Elimination

Half-Life and Clearance

The elimination half-life is 5 to 8 hours, and the total clearance is about 1.7 to 1.9 mL/min per kilogram, with renal clearance accounting for 70% of the total apparent oral clearance. Elimination is not influenced by dose or duration of treatment.[37] Again, it should be stressed that the biologic half-life—that is, the half-life for inhibition of GABA-transaminase—is measured in the order of days, not hours.

Elimination parameters have also been assessed separately for the two vigabatrin enantiomers. The pharmacokinetics of the *S*-(+)-enantiomer is independent of that of the *R*-(–)-enantiomer. After dosing with pure *S*-(+)-vigabatrin, the mean terminal half-life was 386 minutes. The half-life for the *R*-(–)-enantiomer was 485 minutes, and 447 minutes for the *S*-(+)-enantiomer in the racemate.[40] The AUC was 39.2 μmol/mL per minute for the *R*-(–)-enantiomer and 30.1 μmol/mL per minute for the *S*-(+)-enantiomer. The AUC for the pure *S*-(+)-vigabatrin was 30.6 μmol/mL per minute. An explanation to account for the lower AUC value for the *S*-(+)-enantiomer is that some of the *S*-(+)-enantiomer is bound irreversibly to the enzyme GABA-transaminase and is unavailable for analytical measurement. The *R*-(–)-enantiomer is inactive and therefore does not bind to the enzyme. No chiral inversion exists in humans.

Elimination in Children

In a preliminary study, children and, particularly, infants showed a lower AUC than historical adult controls, but renal clearance was comparable.[87] This might indicate that infants and children may have a lower bioavailability (which could explain why infants may need higher doses of vigabatrin to achieve seizure control), although more studies are required to characterize differences in vigabatrin pharmacokinetics between adults and children.

Elimination in the Elderly and the Renally Impaired

In elderly patients, both renal and total body clearance are slower. Terminal half-life showed an inverse relationship to renal function.[39] The elimination of vigabatrin is slower in elderly patients because of their reduced renal function. A direct correlation exists between renal clearance of vigabatrin and creatinine clearance. Renally impaired patients have higher plasma concentrations of vigabatrin, and the half-life is longer. The half-life in renally impaired patients with reduced creatinine clearance is approximately twice that of normal healthy volunteers. Analysis of AUC-to-body weight ratio versus creatinine clearance shows a nonlinear increase in the ratio of AUC to body weight as creatinine clearance falls below 60 mL/min.[39]

Efficacy

Adjunctive Therapy in Adults

Partial Seizures

The largest number of controlled clinical trials of vigabatrin have been performed in adults with previously intractable seizures taking the drug as add-on therapy. Table 1 outlines the designs of the six single-center, double-blinded European trials. Although most of the trials enrolled patients with other seizure types, the majority of patients had partial seizures. All trials demonstrated a statistically significant superiority of vigabatrin over placebo. In all but one, an overall mean or median seizure reduction of 40% or greater was obtained when patients were on vigabatrin in comparison with placebo. In a somewhat different type of trial design,[88] 33 patients were placed on open-label vigabatrin. Only those achieving a seizure reduction greater than 50% were studied further in a double-blinded phase and randomized to placebo or continued vigabatrin. Patients randomized to vigabatrin maintained a mean 54.7% seizure reduction, whereas patients randomized to placebo had a relatively rapid return of seizures.

P.1686

Table 1 Summary of the double-blind placebo-controlled add-on trials of vigabatrin for refractory (mainly partial onset) seizures

Authors and date (Ref.)	Trial design	Length of trial	Number of patients	Completers	Seizure type	Responder rate (50% seizure reduction)
Rimmer and Richens 1984[90]	Crossover	9 weeks	24	21	Mainly partial seizures	Not given. Mean of 6.2 seizures/week for placebo vs. 3.5 seizures/week for vigabatrin (3 g)
Gram et al. 1985[34]	Crossover	12 weeks each arm	21	18	Complex partial seizures	Eight patients (vigabatrin dose: 3 g)
Loiseau et al. 1986[59]	Crossover	10 weeks each arm	23	19	17 partial seizures; two primary generalized seizures	11 patients (vigabatrin dose: 3 g)
Remy et al. 1986[86]	Crossover	12 weeks	23	17	Partial, primary generalized, and secondarily generalized	Mean 37% decrease in seizure frequency (vigabatrin dose: 3 g)

					tonic-clonic seizures	
Tartara et al. 1986[106]	Crossover	7 weeks each arm	23	20	17 partial seizures; six mixed seizure types	12 patients (vigabatrin dose: 2 or 3 g depending on body weight)
Tassinari et al. 1987[108]	Crossover	12 weeks each arm	31	30	15 complex partial seizures; 15 mixed seizure types	10 patients (vigabatrin dose: 2 or 3 g depending on body weight)
French et al. 1996[28]	Parallel-group	12 weeks	182	170	Complex partial seizures	19% placebo 43% vigabatrin 3 g
Dean et al. 1999[23]	Parallel-group	12 weeks	174	149	Complex partial seizures	7% placebo 24% at 1 g 51% at 3g 54% at 6 g
Bruni et al. 2000[12]	Parallel-group	36 weeks	111	90	Complex partial and/or partial secondarily generalized seizures	26% placebo 48% vigabatrin (vigabatrin dose: 2–4 g)

The European trials were performed primarily on patients with partial seizures, but patients with other seizure types were also included. A meta-analysis was performed to examine results among the 98 patients with partial epilepsy. In 46%, seizure reduction was greater than 50% after vigabatrin treatment in comparison with placebo, whereas in 11%, seizures worsened.[34,59,86,90,106,108]

Unlike the European trials, the two U.S. double-blind trials were of parallel rather than crossover design, and both were multicenter trials.[10,23,28] They enrolled exclusively patients with complex partial seizures, with or without secondary generalization. Details of these trials are outlined in Table 1. Both trials demonstrated a statistically significant reduction in seizures when vigabatrin was compared to placebo.

In the Canadian double-blind trial,[12] 111 patients with refractory partial seizures were given either placebo or vigabatrin at doses of 2 to 4 g per day. Magnetic resonance imaging (MRI) and evoked potentials and neuropsychological testing were done at regular intervals for a 36-week period. In the vigabatrin group, 48% of patients achieved a 50% or more seizure reduction compared with 26% on placebo. However, seizure-free rates were not presented, only seizure-free days. Vigabatrin was well tolerated, and no changes were noted in the MRI or visual evoked potential (VEP) in this short-term study.

The response to vigabatrin in partial epilepsy may depend on patient characteristics. Patients with localization-related epilepsy, one seizure type, and a low seizure frequency appear to have a greater chance of improvement.[108] All the European and U.S. trials enrolled patients with secondarily generalized tonic–clonic seizures. Many of these trials were able to demonstrate a trend of improvement in the secondarily generalized seizures but, in most, the percentage of patients with this seizure type was too small for improvement to reach statistical significance.[11,28]

Long-Term Efficacy

Several AEDs, most notably the benzodiazepines, may be highly effective initially, but effectiveness may wane. Theoretically, increased GABA levels in the CNS for a prolonged period could bring homeostatic mechanisms into play to reduce GABA levels, or postsynaptic receptors could become desensitized as excess GABA floods the synapse. Because of the unique mechanism of action of vigabatrin, it is very important to assess long-term efficacy. Studies have demonstrated that GABA levels in spinal fluid remain elevated during years of long-term use of vigabatrin.[6,7] Several studies of long-term efficacy have been performed. One way of evaluating long-term efficacy is by assessing how many patients remain on treatment through time. Presumably, patients for whom the treatment loses efficacy will abandon treatment to search for other drugs. In several long-term studies, 39% to 72% of patients remained on vigabatrin for more than 3 years. Among the patients electing to continue treatment, the majority had maintained their initial positive response and, in this particular subset, there was no evidence of loss of efficacy.[11,21,73,85,100,107]

Monotherapy in Adults

In a Finnish trial, 100 patients with new-onset epilepsy of all types were randomly assigned to receive carbamazepine or vigabatrin.[51] Treatment was more likely to fail because of lack of efficacy in the vigabatrin group and because of adverse events in the carbamazepine group. Thirty-two percent of the vigabatrin patients were seizure-free, in comparison with 52% of the carbamazepine patients. None of the vigabatrin patients and 24% of the carbamazepine patients discontinued treatment because of adverse events. Rash was the most common reason for carbamazepine discontinuation. The lower seizure-free rate seen with vigabatrin may in part have been a consequence of the heterogeneous patient population enrolled, which included many patients with generalized epilepsy.

The definitive study on the efficacy of vigabatrin in new-onset seizures is from the United Kingdom.[15] A total of 459 patients were enrolled in this study and randomized to either carbamazepine or vigabatrin for new-onset seizures. The patients were followed for 1 year. The results demonstrated that, although vigabatrin was better tolerated, patients on vigabatrin had more psychiatric symptoms than those on carbamazepine (25% vs. 15%), and weight gain was also more common on vigabatrin than on carbamazepine (11% vs. 5%). The carbamazepine group had more rashes (10% vs. 3%). As for efficacy, carbamazepine was more effective at time to first seizure but not at 6 months, at which point the number of remissions did not differ statistically between the groups. This study concluded that "vigabatrin seems less effective but better tolerated than carbamazepine, which is the first-choice drug for the treatment of partial epilepsies. Vigabatrin cannot therefore be recommended as a first-line drug for monotherapy in this group of patients."

Children

Partial Seizures

Children with partial seizures have a response to vigabatrin similar to that of adults, with up to 50% reduction in seizure frequency in adjunctive therapy studies.[2,18,35,62,78]

An attempt to compare vigabatrin to carbamazepine in newly diagnosed partial seizures in children led to the conclusion that the two drugs had comparable efficacy and similar proportion of side effects.[102] However, this study only included 28 children per group, was open-label, and apparently not randomized, and therefore no firm conclusions can be drawn about the comparative effectiveness of vigabatrin and carbamazepine monotherapy in children.

Other Seizure Types (Excluding Spasms)

Fewer data are available about seizure types other than complex partial. In an analysis of published adjunctive-therapy trials, the majority (71%) of patients with generalized epilepsy syndromes did not respond to vigabatrin.[72] There have been varied reports of worsening after vigabatrin administration in patients with Lennox-Gastaut syndrome and myoclonic epilepsy,[40,50] whereas others report significant improvement.[27,44] Rarely, myoclonic jerks or absence seizures may develop when none have been seen previously.[22,119]

Infantile Spasms

Several trials have assessed vigabatrin for the treatment of infantile spasms, and all have shown an impressive response.[2,17] Overall, the majority of children with infantile spasms improve substantially with the addition of 100 to 150 mg/kg of vigabatrin daily, even when spasms have been previously resistant to drug therapy. Based on these results, vigabatrin has been proposed as an alternative first-line therapy to adrenocorticotropic hormone (ACTH) or steroids, the reference therapy in infantile spasms.[3]

Table 2 Incidence of the most frequent (>5%) adverse events (AE) reported in a randomized double-blind monotherapy trial of vigabatrin versus carbamazepine in adults with newly diagnosed partial epilepsy

Adverse event (AE)	Carbamazepine group (*n* = 229,195 with at least one AE; %)	Vigabatrin group (*n* = 228,191 with at least one AE; %)
Central nervous system	63	62
Amnesia	7	7
Drowsiness	28	21
Fatigue	22	20
Headache	21	21
Psychiatry	15	25
Agitation	6	7
Depression	3	7

Insomnia	2	7
Skin	23	14
Rash	10	3

Other events		
Asthenia	7	2
Weight increase	5	11
Dizziness	13	13

(From Chadwick D. Safety and efficacy of vigabatrin and carbamazepine in newly diagnosed epilepsy: A multicenter randomized double-blind study. Vigabatrin European Monotherapy Study Group. *Lancet*. 1999;354(9172):13–91, with permission.) The study was conducted before the discovery of visual field defects.

Vigabatrin has been shown to be effective in the treatment of spasms in double-blind trials that compared it to placebo[4]

P.1688

or compared low (less than 40 mg/kg per day) to high (100 to 150 mg/kg per day) doses.[26] Efficacy is greater in patients starting before the age of 3 months (>90%) than in those starting later.[1] Overall, more than a third of children can be expected to have complete resolution of spasms, and more than 50% to have a reduction greater than 50%.[17] The response is favorable in symptomatic as well as cryptogenic etiologies, but the actual rate of total suppression of spasms depends on etiology. It is reached in 90% of infants with tuberous sclerosis[19] and focal cortical dysplasia,[61] whereas patients with spasms due to perinatal hypoxic–ischemic injury better respond to hormonal treatment (ACTH) than to vigabatrin.[114] Only 54% in patients with a variety of other conditions than tuberous sclerosis completely cease to have spasms with vigabatrin, a proportion significantly inferior to that observed with hormonal treatment at 14 days of randomized therapy.[64] However, the absence of spasms later on, at 12 to 14 months of age, is similar on vigabatrin and hormonal treatment,[64] and the rate of relapses is higher with ACTH.[114] In cryptogenic cases, the success rate may reach 100% when adding ACTH in patients not responding to vigabatrin monotherapy.[36,53] There seems to be a particular group of patients with psychomotor delay prior to the first spasms and no MRI abnormalities who also require the combination of vigabatrin and hormonal treatment to come under control and a duration of treatment of more than 3 months to prevent relapse.[115]

Long-term outcome is favorable in terms of maintaining spasm reduction, but less favorable in terms of overall development. The children who become spasm-free tend to remain so in long-term follow-up (up to 3 years). This is particularly true of patients with tuberous sclerosis. However, other seizure types, such as partial seizures, may emerge, and progressive cerebral deterioration may continue despite control of spasms.[67]

Treatment strategy in infantile spasms mainly depends on drug availability in different countries. In most countries, vigabatrin is considered the drug of choice as first-line monotherapy, although evidence is still insufficient for consensus,[65] the major remaining question being for how long treatment should be continued. In Down syndrome, 6-month control of spasms using vigabatrin was followed by no relapse after the cessation of treatment.[77] However, in tuberous sclerosis and cortical dysplasia, the risk is definitely high until the age of 5 years (personal data), and spasms following relapse tend to be highly pharmacoresistant.[14]

Adverse Effects

Dose-Related, Nonidiosyncratic Reactions

Most Common Adverse Effects Observed in Early Clinical Trials

Most data on the adverse effects of vigabatrin are based on add-on studies in patients with previously uncontrolled seizures taking between one to four other AEDs concomitantly. Table 2 shows the most significant side effects (except for VFDs) from the U.K. monotherapy trial comparing carbamazepine and vigabatrin.[15] Sedation and fatigue were the most commonly reported side effects. Weight gain can also be a not-uncommon troublesome effect, particularly during long-term use.

Visual Field Defects

Vigabatrin was deemed a drug with few side effects and rather safe. Microvacuoles, which were evident in animal models using rats and dogs, have not been detected in humans despite repeated MRI studies and pathologic analyses of brains retrieved during autopsy or epilepsy surgery.[14,47] Animals had also shown retinal changes, and so patients in clinical trials were investigated using VEPs, visual evaluation according to Donders, and funduscopy. No investigator or treating physician looked specifically at visual field problems associated with vigabatrin (or with any other drug for that matter). In 1997, Eke et al.[25] published the first paper indicating that some patients had VFDs that adversely affected their daily living activities. This was an important finding, and all patients on vigabatrin were encouraged to have their visual fields tested more rigorously. The particular VFD induced by VGB is recognized as a defect involving peripheral vision, with a pattern of typically bilateral, concentric (most often profound nasally) constriction of the visual field, the severity of which varies from mild to severe, although it remains asymptomatic in the large majority of cases.[117]

The prevalence of VFDs attributable to vigabatrin discloses a huge disparity (from 14%–92%) mainly arising from the sampling bias of relatively small cohorts and from the diversity of the perimetric techniques used to assess the visual fields. Static perimetry (Humphrey) should be preferred to kinetic perimetry (Goldman) when available. The validity of visual electrophysiologic techniques (such as electroretinography, electro-oculography, or VEPs, which do not require patient collaboration, contrary to perimetry) to diagnose vigabatrin-induced VFDs is not yet fully established.[43] Because of difficulties in assessing the visual field by perimetry below a developmental age of 9 years, a specific method based on visual-evoked potentials is under development in children 3 years of age and older.[42]

From published studies, it would seem that at least 30% of adult patients who have taken vigabatrin have VFDs.[52] The prevalence of VFDs may be lower in children,[112] and no child treated for infantile spasms in infancy has as yet been shown to develop symptomatic VFDs. Three risk factors for vigabatrin-induced VFDs have emerged: male gender, increased duration of treatment, and cumulative dose of vigabatrin given.[66,112] Data gathered so far suggest that the cumulative incidence increases rapidly during the first 2 years of treatment and within the first 2 kg of vigabatrin intake, and stabilizes at 3 years and after a total vigabatrin dose of 3 kg.[52] Patients with VFDs who are withdrawn from vigabatrin do not show improvement in the visual defects but do not progress either.[79] Based on this identified toxicity, recommendations are now given to monitor the visual field before treatment and every 4 to 6 months on vigabatrin and to reconsider the benefit–risk ratio if any VFD attributable to vigabatrin is discovered.

The etiology for the VFDs is not known. One study in rats[24] showed that damage affected initially the cone inner and outer segments, possibly because vigabatrin causes a high concentration of GABA in the retinal area. However, a study by Izumi et al.[46] in rats showed that an increase in GABA did not cause retinotoxicity with damage to the cones. Vigabatrin caused retinotoxicity, but only when the animals were exposed to light and not to darkness. This suggests that retinal toxicity is related to vigabatrin itself and not to GABA.

Vigabatrin, because of this serious irreversible side effect, should not be used as a first-line drug, except in catastrophic epilepsies of childhood such as infantile spasms. If used, then the time on treatment should be limited and the dose given be as low as possible.

Psychiatric Adverse Effects

In clinical trials, about 2.2% to 7.3% of patients withdrew because of psychiatric side effects. Depression, confusion, and other behavioral abnormalities accounted for about 5% of the reported adverse events. In children, hyperkinesia and agitation were reported in some patients, most often in those treated with high doses.[2] Most side effects were dose-related and could be reversed when the drug was stopped or the dose reduced.

Depression seems to be an established adverse effect of vigabatrin, and the same applies to psychosis. The question of whether vigabatrin can elicit psychosis was first raised by Sander et al.,[93,94] who reported that 14 of 210 patients experienced severe psychiatric reactions in connection with vigabatrin treatment. Subsequently, other case reports have been published in the literature with warnings that vigabatrin can cause psychosis. The two U.S. multicenter, placebo-controlled double-blinded studies[23,28] included a careful analysis of psychiatric side effects. The studies did not, however, include patients with severe brain damage or severe psychiatric disorders because it was assumed that development of clinically important psychiatric adverse events would result in patient drop-out. From the combined results of the two studies, 0.7% of patients in the placebo group (n = 135), 2.2% in the 1-g treatment group (n = 45), 6.6% in the 3-g treatment group (n = 135), and 7.3% in the 6-g treatment group (n = 41) dropped out because of a psychiatric adverse event. These and similar results from other studies support the contention that severe psychiatric adverse events do appear in about 5% of patients treated with vigabatrin. A large postmarketing surveillance study of vigabatrin from the Drug Safety Research Unit at the University of Southampton that included more than 6,000 patients, however, reported only 88 cases (0.64%) that could be associated with psychotic reactions, such as hallucinations, paranoia, or delusions (data on file at Sanofi-Aventis, Paris, France). This is not greater than the number of severe psychiatric adverse events seen during treatment with other AEDs,[68,118] which is not surprising, because psychiatric problems are common in patients with intractable epilepsy, especially those with partial seizures.[105]

To minimize the problem of psychiatric adverse events, patients who have a history of severe psychiatric disturbances, who have very severe brain damage, or who respond to vigabatrin with a dramatic reduction in seizures should be watched carefully. Patients with a dramatic reduction of seizures can experience “forced normalization,” which has been described to cause psychosis.[55] Vigabatrin should be titrated upward slowly, except in small children, and should never be withdrawn rapidly, because rapid withdrawal can elicit an increase of seizures and lead to postictal psychosis.

Intramyelinic Edema

During toxicology studies, vigabatrin doses as low as 30 mg/kg were found to cause intramyelinic vacuolation or edema in specific areas of rodent and dog brains, primarily the hippocampus, cerebellum, visual pathways, and columns of the fornix.[33] These microvacuoles were reversible when the drug was stopped. Monkeys treated with 300 mg/kg daily for 16 months did not have more microvacuoles at autopsy than did controls.[32] Delayed conduction times using somatosensory and VEPs were found to correlate with the onset of vacuolation in dogs as detected by MRI.[104,116]

Because the microvacuoles could be detected with MRI investigations, and their existence monitored by testing for increased conduction times using evoked potentials, it has been considered important to follow with both MRI and studies of evoked potentials those patients who participated in the initial studies and who have been treated for long periods. According to Sanofi-Aventis, MRI and evoked potentials have been

used to follow more than 500 patients, with no indication that microvacuolation occurs in humans. Some of the patients have been followed for more than 8 years without changes in evoked potentials being detected.[10,41,56,107,110]

Neuropathologic studies have been carried out on patients who died or had epilepsy surgery during vigabatrin treatment. Sixty case reports have been published comprising 10 postmortem and 50 surgical samples. Treatment periods were up to 108 months. These cases were reviewed in a blinded fashion, with other samples from patients not treated with vigabatrin used as a basis for comparison. None of the material examined has shown evidence to suggest that vacuolation occurs in humans.[14]

Idiosyncratic Reactions

Immune-mediated hypersensitivity reactions such as skin rashes or other allergic reactions are observed rarely with vigabatrin.

Second-Generation Effects

In animals, no teratogenic effects have been reported, except for an increased incidence of cleft palate in rabbits receiving high doses (data on file at Sanofi-Aventis, Paris, France). Because vigabatrin has been primarily used as add-on therapy in patients taking other AEDs with known teratogenic effects, it is very hard to determine the relationship of vigabatrin alone to any malformations that may appear. As with all AEDs, there is a class warning against the use of vigabatrin in pregnancy because of inadequate evidence regarding teratogenic effects. The same caution should therefore be taken as with the older AEDs. Published information about pregnancy and vigabatrin comprises 48 pregnancies. All patients were taking at least one other AED. Twenty-three continued to use vigabatrin throughout pregnancy, and the offspring were normal. Twelve patients used vigabatrin during the first trimester only and had normal offspring. Five spontaneous abortions occurred between 7 and 14 weeks, as well as four reports of major abnormalities: an absent diaphragm, a death because of intracerebral hemorrhage, a case of Siamese twins in which an abortion was carried out at 17 weeks, and a case of spina bifida. Four minor abnormalities were reported: one undescended testicle, one hip dysplasia, one hypospadia, and a possible club foot.[75] These 48 pregnancies may not represent a random sample of all the pregnant patients taking vigabatrin, because pregnancies resulting in adverse outcomes are more likely to be reported. Now, since vigabatrin use is restricted, very few pregnancies are reported with vigabatrin.

Drug Interactions

Vigabatrin does not appear to interact significantly with most other AEDs or other compounds. However, in two early placebo-controlled clinical trials to determine the efficacy and safety of vigabatrin in patients with partial epilepsy taking other AEDs simultaneously, phenytoin concentrations fell by about 20%.[10,90] Phenobarbitone and primidone were also significantly lower in the first study. The reason for this is not apparent, although several studies attempted to elucidate the nature of the reduction of phenytoin.[91] No changes have been found in protein binding or in the absorption, metabolism, or clearance of phenytoin.[89] No evidence suggests that any loss of efficacy occurs because of the lowered concentrations of phenytoin in occasional patients. Jedrzejczak et al.[49] reported an increase in serum carbamazepine levels of at least 10% in 70% of patients started on adjunctive therapy with vigabatrin. This observation contrasts with results of clinical trials, which did not detect any major changes in serum carbamazepine concentrations during vigabatrin treatment.

Role in EPILEPSY TREATMENT

Indications

Vigabatrin can be used as a first-line treatment for infantile spasms. It may also be used for patients with partial onset seizures who have been refractory to several other AEDs. Before starting treatment, the patient or his parents or guardians must be made aware of the risk of irreversible VFDs and about the need to monitor the visual fields at regular intervals to detect if any damage has occurred.

Dosing Recommendations

Optimal Maintenance Dosage

The most commonly used effective dose range in adults is between 2 and 4 g/day. This dose range was established from the results of several dose-titration studies[10,11,95] in which many patients experienced increasing benefit as doses were titrated upward. When, in a clinical trial, vigabatrin doses were reduced from 3 to 1.5 g/day in a blinded fashion, the majority of patients experienced deterioration in seizure control, although seizure frequency did not return to baseline.[99] Some evidence suggests that the optimal vigabatrin dose varies with the individual. Some patients may deteriorate when the dose is raised from 2 to 3 g, whereas others may improve.[70,76] In the large U.S. multicenter studies,[23,28] efficacy at 1, 3, and 6 g of vigabatrin was compared. Statistically significant seizure reduction could not be demonstrated with 1 g. Efficacy was equivalent and statistically significant with 3 and 6 g, but side effects increased substantially at the higher doses.

In infants with infantile spasms—the primary indication—optimal dosages range from 100 to 150 mg/kg daily. Due to the risk of retinal toxicity, the optimal regimen should be the minimal dose and the minimal duration necessary to obtain therapeutic benefit. Doses of at least 100 mg/kg per day have proved to produce the best response in most patients;[26] in fact, Asian patients constantly relapsed at doses under 60 mg/kg per day,[109] and there was a need to increase dose from 50 to 100 mg/kg per day in 59% of European patients.[1] How long to treat remains a major question, considering the risk of relapse of spasms and subsequent development of intractable seizures.[13] In Down syndrome, a short vigabatrin course proved sufficient.[17] In cryptogenic cases, 6 months seems to be reasonable. For tuberous sclerosis, the risk of a severe and intractable relapse seems to persist until the age of 5 years.

Dosing Interval

Dosing once or twice daily is recommended. Theoretically, the ability of vigabatrin to inhibit GABA-transaminase irreversibly should produce an effective CNS half-life of several days. Yet seizure control seems to deteriorate when vigabatrin is administered at intervals of greater than 24 hours.[9]

Dose Titration

Although there is no pharmacokinetic reason to titrate vigabatrin slowly, there is concern that rapid dose titration may

P.1691

increase the likelihood of side effects, especially sedation, depression, confusion, and, rarely, psychosis. At present, the recommendation in adults is to initiate therapy with 0.5 to 1 g and titrate upward by similar amounts every 1 to 2 weeks depending on clinical urgency. In the treatment of infantile spasms, rapid titration to 100 mg/kg per day (in less than 5 days) proved to be well tolerated[4] and efficacy was obtained in less than 2 weeks,[19,26] two important advantages if one considers the rapid deterioration of psychomotor status associated with infantile spasms.

The tablet dissolves completely in water and is tasteless. Therefore, in infants and other patients who cannot swallow tablets, these (or the contents of the sachet) can be quickly dissolved in almost any fluid.

Withdrawal

Crossover efficacy studies, in which half of the patients were switched from active drug to placebo, provide information about the effect of abrupt withdrawal of vigabatrin. In four such studies,[18,59,90,108] possible withdrawal seizures were seen. Tassinari et al.[108] reported 4 of 16 patients with nearly continuous seizures after withdrawal. Therefore, vigabatrin treatment should not be interrupted abruptly.

Precautions and Contraindications

Careful consideration of the risk to benefit ratio is needed in view of the risk of VFDs, and monitoring of visual fields (or alternative electrophysiologic measures, as discussed earlier) is required before and during vigabatrin treatment.

Patients with a history of depression, psychosis, or behavioral disturbances may be at greater risk to develop psychiatric effects. If vigabatrin is considered necessary in these patients, slower dose titration and careful monitoring of response is required.

Elderly patients have been found to develop adverse CNS effects at lower dosages compared with younger adults. If vigabatrin is used in elderly persons, the initial doses should be lower and titrated more slowly. Similar precautions apply to patients with impaired renal function.

Vigabatrin may induce aggravation of seizures, particularly absence and myoclonic seizures in patients with generalized epilepsies.[60]

Summary and Conclusions

Vigabatrin is a selective, irreversible inhibitor of GABA-transaminase, the enzyme that degrades the inhibitory neurotransmitter GABA. It thereby increases GABA levels in the CNS in a dose-related manner. Vigabatrin is an amino acid that is not metabolized, nor is it protein-bound. It is excreted unchanged in the urine. Efficacy for refractory partial seizures and infantile spasms has been confirmed from a large number of clinical trials, but the discovery of irreversible toxicity on the retina has deeply modified the indications and limited the use of this very effective drug. Infantile spasms, a highly refractory and deleterious epileptic encephalopathy, is now the primary indication of vigabatrin, whereas its use in refractory partial epilepsy is limited to adjunctive therapy, when all other appropriate drug combinations have proved inadequate or have not been tolerated, and with mandatory visual field testing before the start of treatment and at regular intervals during treatment.

Chapter 162
Zonisamide

Masakazu Seino

Ilo E. Leppik

Introduction

After a long hiatus in the development of novel drugs for treating epilepsy, the early 1990s saw several new antiepileptic drugs (AEDs) developed and approved for use in patients with epilepsy. This progress in the treatment of epilepsy may have occurred because we understand more about the mechanisms of action of existing AEDs as well as the underlying pathophysiology of epileptic seizures. However, despite the advances made, a large number of patients with various types of seizures still remain refractory to treatment using existing AEDs.

One of the new drugs to join the global therapy list of AEDs during the 1990s is zonisamide (ZNS) (Fig. 1), a broad-spectrum AED that was developed in Japan by Dainippon Pharmaceutical Co. Ltd. Zonisamide was originally synthesized in 1972 by Uno et al.[58,59] as one of a series of 1,2-benzisoxazole derivatives. In the course of routine tests with these derivatives, some of the sulfonamide analogs, most notably ZNS, showed anticonvulsant activity in maximal electroshock (MES) experiments. In animal models, ZNS also demonstrated strong anticonvulsant activity and, based on its structure–activity relationship, was selected as a candidate for development.[55]

Structure and Chemistry

Zonisamide (1,2-benzisoxazole-3-methanesulfonamide) (Fig. 1) is chemically similar to indole. Zonisamide is synthesized from 1,2-benzisoxazole-3-acetic acid, which is prepared by the Posner reaction between 4-hydroxycoumarin and hydroxylamine.[58,59] The intermediate compound, 1,2-benzisoxazole-3-methanesulfonic acid sodium, was synthesized by a chlorosulfonic acid–dioxane complex method. The molecular formula of ZNS is $C_8H_8N_2O_3S$, its molecular weight is 212.23, and its melting point is 164°C to 168°C. Zonisamide consists of nonhygroscopic white to pale yellow crystals or crystalline powder, and it has a slightly bitter taste. It is freely soluble in acetone, sparingly soluble in methanol, and slightly soluble in 95% ethanol. Solubility in water depends on pH and increases sharply at a pH of 8. The infrared spectrum shows absorption bands indicating an amino group at 3,320 and 3,160 cm^{-1} and a sulfonyl group at 1,330 and 1,145 cm^{-1}. The nuclear magnetic resonance spectrum shows signals corresponding to methylene protons, amino protons, and aromatic protons.[59] The ultraviolet spectrum in a methanol solution shows absorption maxima at 239, 245, and 284 nm. The N-O bond of ZNS was cleaved by hydrogenation to give 1-(2-hydroxybenzoyl) methanesulfonamide and its imide, the former being identical to one of the metabolites. At present, plasma and urine concentrations of ZNS can be measured using high-performance liquid chromatography (HPLC),[20,35] gas chromatography,[35] and enzyme immunoassay[21] without disturbance of the other AEDs and their metabolites.

Basic Mechanisms of Action

ZNS was tested in many animal models to investigate its antiepileptic properties. When administered orally, ZNS protected mice, rats, rabbits, and dogs from induced maximal seizures.[30] The plasma concentrations that suppressed the tonic extensor components of MES were approximately 10 mg/L in all of the animals examined[30,31] and caused neurologic side effects at concentrations over 70 mg/L, demonstrating a wider therapeutic range than phenytoin (PHT) or carbamazepine (CBZ).[31] In contrast to the latter two drugs, the anti-MES effect of ZNS remained unchanged after repeated oral administration in rats, indicating no development of metabolic or pharmacodynamic tolerance to its anti-MES effect.[32] On the other hand, ZNS had no effect on minimal seizures induced by subcutaneous administration of pentylenetetrazol in mice.[30] In spontaneously epileptic rats, ZNS inhibited tonic seizures without affecting absence-like seizures.[38] These results suggest that ZNS, like PHT and CBZ, exerts anticonvulsant effects by inhibiting the spread of seizures and has a wider therapeutic plasma concentration range than the latter two drugs.

The antiepileptic action of ZNS was found to result from inhibition of seizure propagation in behavioral studies, and this was confirmed in electroencephalographic (EEG) studies on animal models of epilepsy.[18,60] Specifically, ZNS restricted the spread of focal seizures evoked by electrical stimulation of the visual cortex in cats and prevented the propagation of seizures from the cortex to subcortical structures evoked by cortical freezing in cats and by electrical stimulation in visual cortex–kindled cats. One paper reported that ZNS prevented spreading from the amygdala to the hippocampus and cortex of seizures induced by intra-amygdaloid application of kainic acid in rats.[54] Other EEG studies confirmed that ZNS has another mode of antiepileptic action, that is, suppression of the epileptogenic focus activity. ZNS, like sodium valproate (VPA), decreased the amplitude and frequency of spikes induced by cortical freezing in cats and abolished interictal spikes induced by cortical application of tungstic acid gel in rats, whereas PHT, CBZ, and phenobarbital did not,[13,18,19] suggesting that ZNS suppresses epileptogenic focus activity.

In kindled models, ZNS suppressed clinical convulsions and afterdischarges in cortex- and hippocampus-kindled rats[23] and amygdala-kindled rats[10] and cats.[22] Zonisamide also suppressed photically evoked myoclonus in lateral geniculate–kindled cats.[61] In addition to its effectiveness in kindled animal models, ZNS has demonstrated its antiepileptic effects in other animal models of epilepsy.[1,17]

The mechanism of action of ZNS has been clarified in several cell lines. One of the first reports showed that ZNS selectively increased the time constant for recovery from steady-state slow sodium (Na^+) inactivation in voltage-clamped *Myxicola* giant axon.[47] In another report by Rock et al.,[46] ZNS, like PHT, blocked the sustained repetitive firing of the intracellular action potential without affecting the initial firing of cultured mouse embryo spinal cord neurons, suggesting an

P.1696

effect of ZNS on Na^+ current inactivation kinetics. Furthermore, Suzuki et al.[53] reported that ZNS dose-dependently reduced voltage-dependent transient inward currents (T-type calcium [Ca^{2+}] currents) in cultured neurons of the rat embryo cerebral cortex. This reduction by ZNS of T-type Ca^{2+} currents was confirmed in cultured human neuroblastoma cells.[25] These results suggest that ZNS suppresses neuronal hypersynchronization through the blockage of Na^+ and Ca^{2+} channels.

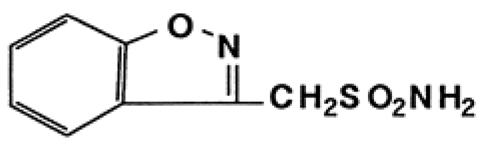

FIGURE 1. Chemical structure of zonisamide.

Pharmacologic Fundamentals

In animals and humans, ZNS was rapidly and virtually completely absorbed, evenly distributed in the whole tissues including the brain, and rather slowly eliminated. The metabolism of ZNS was extensive, and its excretion route was through urine.

Absorption and Routes of Administration

When [^{14}C]ZNS was administered orally in rats, dogs, and monkeys, radioactivity in plasma reached maximum levels within 3 hours.[35] In healthy volunteers administered single oral doses of 200, 400, and 800 mg ZNS, mean plasma concentrations reached peaks of 2.3 to 3, 5.2 to 5.5, and 12.5 mg/L, respectively, within 2 to 5 hours.[20,35] The linear pharmacokinetic properties of ZNS were observed in rats and in adult and pediatric patients. When ZNS was administered once a day for 2 days in volunteers, mean peak plasma concentration was 5.1 mg/L after 200 mg daily and 13 mg/L after 400 mg daily. Extrapolation of pharmacokinetic data obtained from single-dose administration indicates that plasma concentration of ZNS reaches steady state after 10 days of daily administration of a 200-mg dose.[20]

ZNS was markedly concentrated in erythrocytes, as are other sulfonamides. In healthy volunteers administered a 200-mg oral dose, the mean concentration of ZNS in erythrocytes was approximately four to nine times higher and maintained longer than in plasma.[20,35] However, uptake of ZNS by erythrocytes was both linear and saturated[20]—ZNS bound to erythrocytes rapidly at low concentrations, and therapeutic concentrations of ZNS in erythrocytes and whole blood exerted a nonlinear relationship with the dose administered.[41] Thus, it is recommended that the plasma or serum concentration of ZNS be measured for therapeutic monitoring. Erythrocytes contain a large amount of carbonic anhydrase. Thus, it is possible that ZNS, like acetazolamide, inhibits the enzyme. However, the inhibition by ZNS of human carbonic anhydrase II, an essential enzyme involved in the antiepileptic effect of acetazolamide, was 180 times less potent than that by acetazolamide.[29]

Distribution and Protein Binding

Distribution of [^{14}C]ZNS was rather uniform. The levels of radioactivity in most tissues, including brain, were similar to plasma levels, with slightly higher levels in the liver and kidney, and decreased in parallel with the plasma levels in rats.[34,35] In pregnant rats, levels of radioactivity in the fetus and placenta were similar to maternal plasma levels.[6] Tissue levels in sucklings were virtually the same as in young adult rats.[33] When [^{14}C]ZNS was administered intravenously, high uptake was observed in the rat cortex and midbrain.[37] In a single-oral-dose study in epileptic patients, the apparent volume of distribution decreased from 1.8 L/kg after a 200-mg dose to 1.2 L/kg after an 800-mg dose, reflecting the nonlinear binding characteristics of ZNS in erythrocytes.[20]

Protein binding of ZNS was 30% to >50% in rat plasma and serum[24,35] and >50% to 60% in human sera.[35,41] In human serum, approximately >50% of ZNS bound to protein in vitro at 21.3 mg/L; binding was not significantly affected by the presence of therapeutic levels of PHT, phenobarbital, and sulthiame.[35]

Metabolism

The metabolism of ZNS was rather extensive, measured by evaluating metabolites in animal urine.[36,52,66] Direct acetyl or glucuronyl conjugation occurred. Hydroxylation occurred and was followed by oxidation of the methylene carbon of the sulfamoylmethyl group, finally resulting in loss of the sulfamoyl group. N–O bond cleavage of the isoxazole ring produced two ring-cleft metabolites. Hydroxylation also occurred in the benzene ring. The latter three pathways were followed by conjugation with sulfuric acid or glucuronic acid. Analysis of urine samples in healthy volunteers revealed that ZNS was metabolized by acetylation, and cleavage of the isoxazole ring was followed by conjugation with glucuronic acid.[20,35] The P450 CYP3A species is the major isoenzyme involved in its metabolism to the primary metabolite.[39] Metabolites of ZNS, with the exception of acetyl-ZNS, were pharmacologically ineffective.

Elimination

Plasma elimination half-lives of orally administered ZNS were 8, 15, and 23 hours in rats, dogs, and monkeys, respectively,[35] and 50 to 68 hours in healthy volunteers administered single oral doses of 200 to 800 mg.[20] In healthy volunteers administered 200 mg and 400 mg, the excretion rates of ZNS and glucuronyl conjugate in urine were 29% to 48% and 12% to 19%.[35] The total combined excretion recovered in ß-glucuronidase-treated urine was 48% to 60%, suggesting that urine is the major route of excretion in humans.[20] When [^{14}C]ZNS was administered orally to rats and dogs, radioactivity rates in urine were 87% and 97%, supporting the results obtained in humans. Within 48 hours after oral administration of [^{14}C]ZNS in biliary fistula–implanted rats, biliary excretion of radioactivity was 22%.[35]

Adverse Effects

Dose-Related Effects

The incidence rates of adverse events in U.S. and European placebo-controlled studies were 92% and 59% in the ZNS group and 58% and 28% in the placebo group (Table 1).[48,62] Adverse events in both the U.S. and European studies were somnolence, ataxia, anorexia, confusion, and abnormal thinking, and the incidence rate was significantly higher in the ZNS group than in the placebo group. Discontinuation rates because of adverse events in the U.S. studies were 14% in the ZNS group and 1% in the placebo group. In the European studies, the discontinuation rate because of adverse events was

P.1697

3% in the ZNS group; there were no discontinued cases in the placebo group.

Table 1 Incidence rate of adverse events with zonisamide in multicenter clinical trials

		Incidence of adverse events	
Study (Ref.)	**Number of patients**	**ZNS (%)**	**Control (%)**
Placebo-controlled (U.S.) (56)	152 adults	92	58 (placebo)
Placebo-controlled (Europe) (42)	139 adults	59	28 (placebo)
Active-controlled (Japan) (51)	123 adults	52	57 (CBZ)
Open-labeled (U.S.) (26)	169 adults	81	
Open-labeled (Japan) (45)	538 adults	58	

Open-labeled (Japan) (45)	257 children	44

The incidence rate of adverse events in the active-control study on ZNS and CBZ in Japan was 52% in the ZNS group and 57% in the CBZ group (Table 1),[51] with no statistical significance between the two groups. The incidence rates of somnolence, slowing of mental activity, decreased spontaneity, and skin rash or itching were almost the same in the two groups, whereas anorexia was observed more frequently in the ZNS group (12% vs. 0%, $p = 0.02$), and ataxia was observed more frequently in the CBZ group (35% vs. 9%, $p < 0.01$). The rates of discontinuation for adverse events were 12% in the ZNS group and 16% in the CBZ group. The overall safety ratings of ZNS and CBZ evaluated according to adverse events and laboratory test deviations were 83% and 66% (cumulative of "safe" and "almost safe"), suggesting that ZNS is safer than CBZ ($p = 0.08$).

The incidence rate of adverse events in the open-labeled, multicenter studies in the United States was 81% (Table 1),[26] and the withdrawal rate because of adverse events was 13%. On the other hand, the incidence rates in Japanese studies were 58% in adults and 44% in children.[45] Of 1,008 patients in Phase II and Phase III open trials in Japan, the overall incidence rate of adverse events was 51%, and the dropout rate for adverse events was 18%.[49] The most frequent adverse events in these patients in order of frequency were drowsiness (24%), ataxia (13%), loss of appetite (11%), gastrointestinal symptoms (7%), loss of or decrease in spontaneity (6%), and slowing of mental activity (5%). In 55 patients on ZNS monotherapy, drowsiness (9%), loss of appetite (7%), gastrointestinal symptoms (7%), loss of or decrease in spontaneity (6%), headache (6%), skin rash or itching (6%), and loss of weight (6%) were observed.

In postmarketing surveillance in Japan, anhidrosis accompanied by increased body temperature was reported in pediatric patients in the summertime, especially during extremely hot periods.[7,14] In the United States, a postmarketing study has reported an estimated incidence of one case per 5,490 patient-years, with most cases occurring in children.[28]

In two U.S. studies and one European study, 13 (11 in the United States and two in Europe) of 505 patients developed nephrolithiasis. Ten of these 13 patients had positive histories of renal calculi, urinary tract surgery, and similar disorders.[50] On the other hand, only two cases out of 1,008 patients in Japanese Phase II and III open studies developed kidney stones; both patients had family histories of renal calculi, and the stones passed spontaneously. Furthermore, in postmarketing surveys conducted over 6 years following launch in Japan, only three cases with renal calculi were reported out of 5,418 patients surveyed. In six cases out of the 13 patients mentioned above[50] in whom ZNS administration was ongoing or temporarily discontinued, 24-hour urine collections were obtained; these revealed a decrease in urine citrate concentration, which can be an inhibitory factor for the formation of calcium stones, and a marginal increase in urine pH.[67] Similarly, the 24-hour urine collections of ten epileptic patients in Japan taken 1 month before and after the start of ZNS administration showed no change in urinary calcium levels, and only a decrease in urinary citrate concentration was observed.[50] In short, although differences were observed in the number of incidences of renal stones in the United States and Europe versus Japan, decreases in urinary citrate concentration were consistent, as was the composition of the stones (calcium oxalate, calcium phosphate).[5]

The only adverse event differing significantly from placebo was weight loss, although somnolence, anorexia, and ataxia were slightly more common with zonisamide treatment.[3] The odds ratio (OR) for treatment withdrawal was 1.74 (95%; confidence interval [CI], 1.03 to 2.95). Side effects found to be significant with OR ratios associated with zonisamide were ataxia 3.94 (1.23 to 12.57); somnolence 2.11 (1.11 to 3.98); agitation 3.52 (1.26 to 9.68); agitation and irritability 2.43 (1.04 to 5.66); and anorexia 2.98 (1.38 to 6.42).

Not all side effects are negative. Weight loss has been observed in studies of zonisamide.[5] To more fully evaluate the efficacy of zonisamide for weight loss in obese adults, a 16-week randomized, double-blind, placebo-controlled trial was conducted. Fifty-five (92%) women and five (8%) men (mean [SE] body mass index, 36.3 [0.5]; mean age, 37.0 [1.0] years) were randomly assigned to receive zonisamide or placebo. Zonisamide therapy was started at 100 mg/d orally, with gradual increase to 400 mg/d and further increase to 600 mg/d for some patients. The zonisamide group lost more body weight than the placebo group (mean [SE], 5.9 [0.8] kg [6.0% loss] vs. 0.9 [0.4] kg [1.0% loss]; $t = 5.5$; P <. 001) during the 16-week period.[8]

Idiosyncratic

Hypersensitivity reactions such as eruptions were observed in 6% of cases in Japanese clinical trials.[49] Postmarketing studies in Japan reported the following adverse events: Stevens-Johnson syndrome, Lyell syndrome, agranulocytosis, and acute renal failure.[16]

Teratogenicity

In monkeys, spontaneous abortion was observed at the maximal human daily dose (10 mg/kg), and in mice, rats, and dogs, teratogenic effects were observed at 50, 20, and 3 times the human maximal daily dose.[56,57]

To date, the following events have also been reported: imminent abortion in one patient treated concurrently with

P.1698

phenobarbital (PB), abortion (abnormal development of cranium and abnormal cerebral and cerebellar growth) in one patient treated concurrently with PHT, and atrial septal defect in one patient treated concurrently with PHT and VPA.[16] Therefore, treatment is recommended for women who are pregnant or suspected to be pregnant only if the therapeutic benefits outweigh the potential risks.

Drug Interactions

Protein binding of ZNS is unaffected by PHT, PB, or CBZ, and the converse is also true. Zonisamide did not affect the extent of protein binding of VPA or PHT in patients.[50] The elimination half-life of ZNS is decreased to 36 hours with CBZ and to 27 hours with PHT.[43] The mean ratio of plasma levels to daily dose (L/D ratio) was 3.8 in 65 epileptic patients with monotherapy and slightly lower at 3.0 in 781 patients with at least one concomitant AED.[15] A significant decrease in ZNS plasma concentration was observed in concurrent therapy with CBZ or VPA.[64] One exceptional case of PHT toxicity caused by add-on therapy with ZNS was reported.[40] Therefore, concurrent treatment with PHT, CBZ, and VPA may decrease plasma concentration of ZNS, just as reduced or discontinued dosage of these concomitant AEDs may cause blood levels of ZNS to be elevated.

Clinical Indications

Indications

The efficacy of ZNS was evaluated in two placebo-controlled double-blind studies in the United States and Europe.[48,62] In these studies, 152 American and 139 European adult patients with complex partial seizures refractory to other conventional AEDs were enrolled and placed on add-on therapy for 12 weeks with ZNS or placebo while being treated with other AEDs. The results of these two studies were very similar. The median percentage change in seizure frequency in the ZNS group was a decrease of 28% to 30% in both U.S. and European studies, which was significantly different from the placebo group in both studies ($p < 0.01$). Furthermore, the percentage of patients with >50% or more reduction in seizure frequency in the ZNS group was 29% to 30% in the U.S. and European studies and again significantly different from the placebo group in both studies ($p < 0.05$). The percentage of patients in the ZNS group who were judged “improved” by physicians was 62% in the two studies (placebo versus ZNS, $p < 0.01$).

In addition, two randomized controlled studies were performed in Japan to evaluate and compare the efficacy of ZNS using CBZ and VPA as active control drugs.[42,51] In the study using CBZ, 123 adult patients with complex partial seizures refractory to up to three other conventional AEDs were enrolled and randomly treated with ZNS or CBZ for 16 weeks. Although the safety rating in the ZNS group was superior to that in the CBZ group, there was no statistical significance to the efficacy of either drug. The average seizure frequency, expressed as number of simple or complex partial seizures every 4 weeks, decreased from 13 to four in the CBZ group and from 15 to three in the ZNS group, and that of secondarily generalized tonic–clonic seizures decreased from two to 0.7 and from two to 0.6. The percentages of patients with >50% or more reduction in seizure frequency were 71% in the CBZ group and 82% in the ZNS group, and the overall improvement rates were 65%

and 66% in those groups.

In the study using VPA, 32 pediatric patients (>15 years old) with convulsive or nonconvulsive generalized seizures (more than four seizures/month), who were refractory to up to three other conventional AEDs, were enrolled and treated with either VPA or ZNS for 8 weeks. The median percentage changes in seizure frequency of generalized tonic–clonic seizures were decreases of 67% and 81% from baseline, the percentages of patients with >50% seizure reduction were 53% and 77%, and the overall improvement rate was 44% and >50% in the VPA and ZNS groups.

In Phase II and III open studies in Japan, a total of 55 patients (23 children and 32 adults) were treated with ZNS monotherapy.[63] The percentage of patients with >50% reduction in seizure frequency was 75% (41 patients) for partial seizures and 25% (14 patients) for generalized seizures.

A search of the Cochrane Epilepsy Group trial register reviewed three trials (499 participants). The overall OR (95%; CI) for >50% or more reduction in seizure frequency compared to placebo was 2.72 (95%; CI, 1.74 to 4.25) for the full treatment period of 12 weeks including varied rates of titration to 400 mg/day.[3] The OR for treatment withdrawal was 1.74 (95%; CI, 1.03 to 2.95). Side effects found to be significant with OR ratios associated with zonisamide were: ataxia 3.94 (1.23 to 12.57); somnolence 2.11 (1.11 to 3.98); agitation 3.52 (1.26 to 9.68); agitation and irritability 2.43 (1.04 to 5.66); and anorexia 2.98 (1.38 to 6.42).

Since the Cochrane report, two other major studies have been published. A randomized, double-blind, placebo-controlled trial enrolling 203 patients conducted at 20 U.S. sites to assess ZNS efficacy found 400 mg/day ZNS reduced the median frequency of all seizures by 40.5% from baseline, compared with a 9% reduction ($p = 0.0009$) with placebo treatment. A >50% or greater seizure reduction was observed in 42% of patients. A dosage of 100 mg/day produced a 20.5% reduction in median seizure frequency ($p = 0.038$ compared with placebo), and a dosage of 200 mg/day produced a 24.7% reduction in median seizure frequency ($p = 0.004$ compared with placebo), indicating a dose-response relationship.[5] The only adverse event differing significantly from placebo was weight loss, although somnolence, anorexia, and ataxia were slightly more common with ZNS treatment.

A study specifically designed to identify a dose-response relationship was conducted as a double-blind, placebo-controlled study of adjunctive ZNS in 351 patients with refractory partial seizures receiving a stable regimen of one to three AEDs. Patients were randomized to placebo or ZNS, 100 mg, 300 mg, or 500 mg/day (2:1:1:2) after a 12-week baseline. Dose titration was undertaken over a 6-week titration phase, which was followed by an 18-week fixed-dose assessment phase. Compared with placebo, a dose of ZNS 500 mg/day resulted in a significantly greater decrease in CP seizure frequency from baseline (51.2% vs. 16.3%; $p < 0.0001$) and a significantly higher proportion of CP responders (52.3% vs. 21.3%; $p < 0.001$). Both ZNS 500 mg/day and 300 mg/day were statistically superior to placebo. For all seizures, a significant dose-response relation was observed ($p < 0.0001$).[2]

Twenty-five previously untreated patients with cryptogenic localization-related epilepsy were treated with ZNS at 8 mg/kg per day once daily for more than 12 months in an open-labeled long-term study, in which 68% of patients showed complete seizure control. In three patients who experienced seizure recurrence, trough plasma ZNS levels were 15 μg/mL, and in three patients who complained of continuous drowsiness and whose peak levels were 40 μg/mL, dosage was reduced.[6]

In a ZNS open monotherapy (2–10 mg/kg/day) study in which 32 patients with partial epilepsy (21 cryptogenic and 11 symptomatic) and 15 patients with generalized epilepsy (11 idiopathic, one cryptogenic, and three symptomatic) were enrolled, seizures in 66% of these patients disappeared, and the percentage of patients with >50% or more reduction in seizure frequency was 17%.[11]

P.1699

In another ZNS open monotherapy (6 mg/kg per day) study in which 65 pediatric patients with partial and generalized seizures refractory to other AEDs were enrolled, the percentage of patients with >50% reduction in seizure frequency was 91% in both cryptogenic and symptomatic localization-related and generalized epilepsies (localization-related, 42 patients; generalized, 11), suggesting that ZNS monotherapy is just as effective on partial seizures as on generalized seizures.[64]

Seizure frequency was remarkably reduced by ZNS in two patients with the Unverricht-Lundborg (Baltic) type of progressive myoclonus epilepsy, and the seizures were well controlled.[12] Seizures in a patient with progressive myoclonus epilepsy ragged-red fibers (MERRF) disappeared with ZNS monotherapy (200 mg/day), and seizure frequencies in two patients with progressive myoclonus epilepsy in infancy were remarkably reduced.[63]

In four patients with severe myoclonic epilepsy in infancy (Dravet type) and ten patients with Lennox-Gastaut syndrome, add-on therapy with ZNS reduced seizure frequency by >50%, and seizures disappeared in three of the ten patients with Lennox-Gastaut syndrome.[65]

Recently, there have been remarkable cases of improvement in patients on ZNS monotherapy or add-on therapy. Seizures were significantly reduced or disappeared in five patients with infantile spasms (West syndrome), four patients with Lennox-Gastaut syndrome, and 14 patients with other symptomatic generalized epilepsies. Atypical absence seizures disappeared in a patient with Landau-Kleffner syndrome with ZNS add-on therapy.[64]

In Japan and South Korea, ZNS monotherapy or add-on therapy is approved in adults and children with the following types of seizures:

- Partial seizures: simple partial seizures, complex partial seizures, and partial seizures evolving into secondarily generalized tonic–clonic seizures.
- Generalized seizures: tonic–clonic seizures, tonic seizures, and atypical absence seizures.
- Mixed seizures: compound/combination of the above seizures.

Contraindications

ZNS is contraindicated in patients who are known to be hypersensitive to sulfonamides or ZNS.

How to Use the Drug

Dosage Formulations and Strengths

In Japan, ZNS is available in tablet and powder form. One tablet contains 100 mg ZNS, and 1 g of ZNS powder contains 200 mg of ZNS (20%). In the United States and Europe, ZNS is available in 25-, 50-, and 100-mg two-piece hard gelatin capsules.

Starting Doses

In adults, the recommended initial dose is 100 to 200 mg daily, in one or two divided doses.

In children older than 1 year, ZNS is administered at the initial daily dose of 2 to 4 mg/kg in one, two, or three divided doses. Dosage and safety have not been established in infants younger than 1 year of age.

Although 328 elderly patients over 65 years of age were observed in postmarketing surveys in Japan,[16] no systematic studies have been performed in elderly patients. In general, treatment should be started in these patients at the lowest dose of the therapeutic dose range. Reduced hepatic, renal, and cardiac functions as well as concurrent drugs should be taken into consideration in selecting the initial dose.

Maintenance Doses, Dosing Frequency, and Maximum Dose

Because the elimination half-life is as long as 60 hours, and 7 to 10 days is required to reach a steady-state plasma concentration, doses should be titrated gradually at 1- to 2-week intervals while efficacy and tolerability are carefully monitored. Abrupt dose increases may cause psychological symptoms and gastrointestinal symptoms such as anorexia.

Maintenance doses of ZNS in adults and children are 200 to 400 mg/day and 4 to 8 mg/kg per day, respectively.

The small difference between peak and trough of plasma concentration during treatment makes once-daily administration of ZNS possible.

The maximum dose is 600 mg/day for adult patients and 12 mg/kg per day for pediatric patients.

Monitoring of blood levels of ZNS should be performed to control administration of the appropriate dosage. Therapeutic ranges of blood levels have been reported to be 20 to 30 mg/L or 10 to 50 mg/L; however, there are no established data.[64] Further studies are required to determine the optimal range of blood levels for ZNS.

Add-on therapy with other AEDs such as PHT, CBZ, and VPA, and reducing or discontinuing the dosage of concomitant AEDs, may cause blood levels of ZNS to become reduced or elevated, respectively. Careful monitoring of blood levels of ZNS in these patients is recommended.

Discontinuing the Drug

ZNS therapy should be discontinued immediately if clinical seizures are aggravated. Because Stevens-Johnson syndrome, Lyell syndrome, agranulocytosis, and acute renal failure may occur during ZNS treatment, administration should be discontinued if signs indicating these syndromes develop. Administration should also be discontinued if hypersensitivity reactions such as eruption or overt psychiatric disorders occur.

To minimize the possibility of increased seizure frequency, an abrupt discontinuation of dosage should be avoided. Dosage should be tapered off gradually and with caution.

Summary and Conclusions

ZNS has a broad antiepileptic spectrum and is effective against partial seizures (simple or complex partial seizures and secondarily generalized tonic–clonic seizures), generalized seizures (tonic–clonic, tonic, and atypical absence seizures), and compound and combination seizures in adults and children on monotherapy and add-on therapy. However, its efficacy against typical absence seizures and massive myoclonic seizures is still unclear. Against some types of progressive myoclonus epilepsies, ZNS has shown efficacy, but against juvenile myoclonic epilepsy, the effect of ZNS is unclear and further studies are needed.

Randomized controlled studies were conducted comparing ZNS with CBZ and valproate in Japan and with placebo in the United States, and results for ZNS were promising. However, to assess the benefits of ZNS thoroughly in relation to other AEDs, further randomized controlled studies comparing ZNS with PHT are necessary.

Adverse reactions related with ZNS are mainly drowsiness, loss of appetite, gastrointestinal symptoms, decreased

spontaneity, and loss of weight. Serious adverse events that may be life-threatening have not been reported.

Incidence rates of renal stone during ZNS treatment were 2.6% (13 of 505 cases) in U.S. and European studies and 0.2% (two of 1,008) and 0.1% (three of 5,418) in clinical trials in Japan and the 6-year postmarketing surveillance, respectively. Analysis of the renal stones revealed the same calcium oxalate and calcium phosphate composition in the United States, Europe, and Japan, as well as decreased concentrations of citrates, or inhibitory factors of calcium stone generation, in the urine of these patients. The difference in incidence rate of renal stones in the United States, Europe, and Japan may therefore be explained by the interaction of the decreased levels of the inhibitory factor with patient lifestyle and/or genetic factors.[4,9] Although a long-term study on the incidence of renal stones during ZNS treatment is needed, it is also worth investigating if oral administration of citrates to epileptic patients with decreased citrate concentrations in urine and a medical history of calcium renal stones could help prevent generation of renal stones.

The initial human experience with ZNS began with clinical trials almost 25 years ago. It was approved for use in Japan over 15 years ago, and in the United States more than 5 years ago. It has been recently approved in Europe. Clinical studies and postmarketing experience has shown it to be a useful addition to the list of drugs used for the treatment of epilepsy.[27]

Introduction

Trimethadione, paraldehyde, phenacemide, bromides, sulthiame, acetazolamide, and methsuximide are antiepileptic drugs (AEDs) that are rarely used today, because for most patients they are generally less effective or more toxic than alternative drugs. Each of these, however, may still occasionally be useful in carefully selected patients or special situations. Only paraldehyde and acetazolamide are available in the United States.

Trimethadione

Trimethadione is not marketed in the United States.

Structure and Chemistry

Trimethadione (3,5,5-trimethyl-2,4-oxazolidinedione; Tridione; TMO) is an oxazolidine-dione with a ring structure similar to that of other classes of antiepileptic drugs (Fig. 1). Several other oxazolidinediones also possess antiepileptic properties. Dimethadione (DMO) is of interest because it is the major, and perhaps the only, metabolite of TMO. Both TMO and DMO are white crystalline powders with molecular weights of 143.15 and 129.12, respectively. Trimethadione is readily soluble in aqueous and organic solvents.

Basic Mechanism of Action

A number of pharmacologic agents, including pentylenetetrazol, γ-hydroxybutyrate, and penicillin, induce seizures in rodents with clinical and EEG manifestations that are very similar to those of human absence seizures.[203] Such models are reproducible and easy to standardize, and they are useful in predicting the antiabsence activity of a drug in humans. Ethosuximide and DMO block the seizure manifestations of this group of agents.

T-type calcium channels (TCCs) are present in high densities in thalamic neurons and contribute importantly to the regenerative bursts that drive normal and pathologic thalamocortical rhythms.[45,46,47,48] Ethosuximide and DMO at therapeutic concentrations reduce TCCs when applied to thalamic neurons, whereas phenytoin and carbamazepine do not.[45,48] Reduction of TCCs is probably the mechanism of antiabsence activity for DMO.[15,45,175] Dimethadione may decrease the number of available TCCs or reduce individual TCC calcium conductance.[45]

Pharmacologic Fundamentals

Absorption and Routes of Administration

Trimethadione is rapidly absorbed by the oral route. Peak plasma TMO concentrations occur 30 to 60 minutes after oral administration.[246]

Distribution and Protein Binding

Neither TMO nor DMO binds to plasma proteins.[24,246] Trimethadione is distributed to the total body water in humans[24,246] and, in animals, has highest concentrations in brain, kidney, muscle, and liver.[247] Animal work indicates that DMO is rapidly distributed to, but not bound by, the various body tissues and has a volume of distribution somewhere between extracellular water and total body water volume.[247]

Metabolism, Including Active Metabolites, and Excretion

Trimethadione is quantitatively demethylated to DMO by he-patic cytochrome P450 enzymes (probably isoforms CYP3A4, CYP2C9, and CYP2E1).[34,76,166,216,249] Dimethadione is the only important metabolic product of TMO[247] and does not undergo further metabolic change. Of an administered dose of TMO, 96% to 99% is excreted in the urine as DMO (trimethadione and DMO have approximately equal antiepileptic properties).[24,75,245] Because TMO is rapidly metabolized to DMO, which is slowly excreted by the kidneys, DMO is the major antiepileptic drug present in the plasma of patients on chronic oral TMO therapy. The ratio of TMO to DMO in the plasma during chronic oral TMO therapy is approximately 1:20.[24,25]

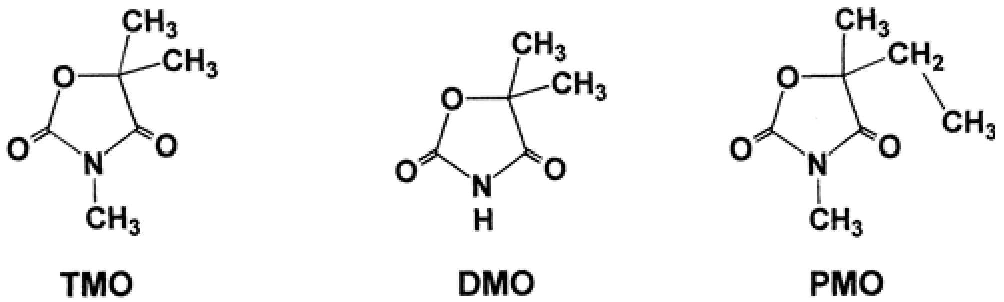

FIGURE 1. Structural formulas of trimethadione (TMO), dimethadione (DMO), and paramethadione (PMO).

Clinical Pharmacokinetics

The elimination half-life of TMO is approximately 12 to 16 hours in the young and 24 hours in the elderly.[24,25,76,215] The resulting DMO is excreted very slowly, with an elimination half-life of approximately 10 days or more.[25,35,76,115] The very slow elimination of DMO has three clinical consequences. First, the time for buildup to a steady-state DMO level is 30 days or more, and therefore, it takes many days before the full therapeutic (and toxic) effects of a given dose of TMO are realized.[38,89,246] Second, cessation of TMO therapy does not result in an immediate drop in DMO plasma concentration or in an immediate increase in seizure frequency.[89] Third, DMO

P.1704

plasma concentrations vary very little during the day, whereas plasma concentrations of TMO (which is more rapidly cleared) vary by 30% between peak and trough values on a three- or four-dose daily regimen.[25]

Several studies have indicated that 700 μg/mL is the lower limit of the therapeutic range for plasma DMO level.[23,25,38,115] The majority of patients with absence seizures who have DMO levels above 700 μg/mL have good control of seizures, whereas most patients with DMO levels below 700 μg/mL do not.[25]

Adverse Effects

Dose-related Effects

Hemeralopia (day blindness) is a phenomenon in which visual acuity is normal in low illumination but decreases when illumination is normal or brighter than normal. This is thought to be a retinal phenomenon in which the neuronal elements of cones (but not photochemical elements) are affected.[202] There are no external or ophthalmoscopic changes.[134] Detailed study reveals that TMO greatly prolongs the time of visual acuity adaptation when illumination changes from low to high or from high to low.[202] In most patients, visual acuity becomes normal after adaptation is complete.[202] Hemeralopia occurs in 30% of patients taking TMO[133,236] and disappears 1 to 10 weeks after TMO is discontinued.[78,133]

Drowsiness occurs in 3% to 6% of patients on TMO[133,236] but often subsides as tolerance to the drug develops.[78] Behavioral disturbances occur in 4% to 8% of patients on TMO.[133,236] Other central nervous system (CNS) side effects may include malaise, insomnia, vertigo, headache, paresthesias, and hiccups.[25,78,133,236] Increased frequency of tonic–clonic seizures has been reported by some workers[82] and denied by others.[54,177] Nausea, vomiting, abdominal pain, or gastric distress occurs in 7% to 8% of patients on TMO.[133,236]

Idiosyncratic Effects

Hematologic side effects are the most frequent and troublesome serious side effects of TMO.[78,236] Three classes of adverse hematologic responses to TMO have been identified: Modified normal response, controlled neutropenia, and pancytopenia.[78] More than 3,000 neutrophils per cubic millimeter constitutes a modified normal response, whereas less than this number is called a controlled neutropenia. The incidence of controlled neutropenia in association with TMO therapy is about 20%.[51,236] Unfortunately, the peripheral blood count is not an accurate reflection of changes in the bone marrow, and agranulocytosis may be established in the bone marrow well before the peripheral count is altered.[57] There have been at least 19 reported cases of pancytopenia in association with TMO therapy, and 13 ended fatally.[236] The earliest change in the peripheral blood is a decrease in megakaryocytes, followed by a reduction in the number of platelets; this in turn is followed by a prolonged clot retraction time.[57] Frequent examination of peripheral blood, including megakaryocytes and platelets, and measurements of clot retraction time are essential in patients taking TMO.

A possible relationship between TMO and lymphadenopathy or tumors of blood-forming organs has been discussed by Gallagher.[78] Firm proof of such a relationship has not been established.[78]

Dermatologic side effects include rash, erythema multiforme, and exfoliative dermatitis (including one fatal case)[79,236] and occur in 9% to 14% of patients taking TMO.[133,236] These disorders usually occur early in the course of TMO therapy and may be more frequent in children under the age of 10 years.[133] The more severe dermatologic reactions are rare and are generally nonfatal.[78]

At least nine cases of nephrotic syndrome (albuminuria, decreased plasma albumin, hypercholesterolemia) in association with TMO therapy have been reported.[78,236] Two of these cases ended fatally.[236]

Myasthenic syndrome, hepatitis, lupus erythematosus, hiccups, anorexia, hair loss, changes in blood pressure, photophobia, and diplopia have been reported to accompany TMO therapy.[26,61,78,119,173]

Teratogenicity

There are numerous reports of fetal malformations in association with TMO therapy.[26,86,164,216] A large collaborative study reported malformations in 18 of 61 children born to mothers who had taken TMO during the first trimester.[165] In some children, a characteristic set of findings has been termed the “fetal trimethadione syndrome.”[26,86] Malformed or low-set ears, cleft lip and palate, delayed mental development, speech impairment, urogenital malformations, V-shaped eyebrows, irregular teeth, skeletal malformations, and cardiac defects are the common features.[26,86] Less common features of the fetal trimethadione syndrome include intrauterine growth retardation, short stature, microcephaly, ocular anomalies, and simian creases.[86] In addition, the spontaneous abortion rate is high.[26] The mechanism of TMO teratogenicity may be oxidative macromolecular damage.[237] Although the mother was taking other drugs in most of these cases, the evidence suggesting TMO teratogenesis is so strong that TMO should be given during pregnancy only if the potential benefits are great enough to outweigh the considerable potential risks.

Drug Interactions

Although TMO and DMO have been in clinical use for many years, reports of interactions with other drugs are scarce.[248] The following animal data may have some clinical relevance: (a) TMO and methobarbital interfere with demethylation of each other by liver microsomes; (b) DMO inhibits demethylation of TMO and methobarbital; (c) drugs causing a distortion of acid–base balance (e.g., NH_4Cl, acetazolamide, and $NaHCO_3$) can affect the distribution and excretion of DMO (a weak acid); and (d) TMO does not induce liver enzymes.

P.1705

The Role of the Drug

Trimethadione is no longer manufactured in the United States. Chewable tablets (150 mg) are manufactured in Europe (Slovakofarma AS).

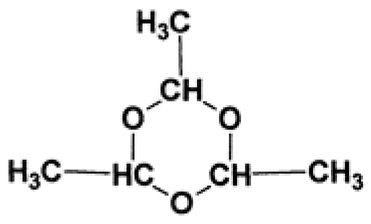

FIGURE 2. Structural formula of paraldhyde.

Trimethadione has been used to treat absence seizures that are refractory to less toxic drugs (i.e., ethosuximide, valproic acid, clonazepam, acetazolamide, and lamotrigine). Millichap and Aymat[159] reviewed 431 reported cases of absence seizures treated with TMO. Absence seizures were reduced in frequency by 75% or more in 56% of cases and were completely controlled in 18% of cases. Coatsworth's review[44] showed similar results. The drug thus possesses considerable antiabsence activity. A trial of TMO may be indicated when absence seizures are not controlled with less toxic drugs and when the potential benefits of TMO outweigh the potential risks (see above). Trimethadione is also sometimes effective for treating the refractory atypical absence, myoclonic, and atonic seizures of the Lennox-Gastaut syndrome.[52,56,134] TMO is also used as a cytochrome P450 2E1 probe for hepatic disease.[166,217]

How to Use the Drug

The usual starting daily dose is 0.9 g in adults and 0.3 g in children in three or four divided doses. Because of the long elimination half-life of DMO, adequate plasma concentrations should be maintained with doses given once daily, although such a regimen has not been systematically studied to determine the plasma concentrations and side effects of once-daily administration. The dosage of TMO may be increased at weekly intervals by 150 mg/day in children and 300 mg/day in adults. Maintenance dosage should be the smallest amount of drug required to maintain adequate seizure control. An oral solution form is available for children.

Paraldehyde

Structure and Chemistry

Paraldehyde (2,4,5-trimethyl-1,3,5-trioxane; PARALDEHYDE) is a cyclic polymer of acetaldehyde (Fig. 2). It is a colorless liquid with a strong aromatic odor and a burning, disagreeable taste. It is miscible with oils and has a molecular weight of 132.16.

Basic Mechanism of Action

The mechanism of action of paraldehyde is unknown.

Pharmacologic Fundamentals

Absorption and Routes of Administration

The times to peak plasma concentration of paraldehyde by various routes are as follows: IV route, immediately after infusion[79]; IM route, 20 to 60 minutes[1]; oral route (in water), 30 minutes[3]; oral route (in oil), 2 to 4 hours[79]; rectal route (in oil), 2 to 4 hours.[8,79] Clinical effects are usually evident long before maximum plasma concentration.[8,79,193,224]

Distribution

Paraldehyde is rapidly distributed to the brain. Following an IV injection, drowsiness ensues within 2 to 5 seconds, and anesthesia occurs within <2 minutes.[8,79,193] The steady-state volume of distribution of paraldehyde is 890 mL/kg.[8] Paraldehyde readily crosses the placental barrier and may cause delayed respirations in neonates.[79]

Metabolism and Excretion

Seventy to eighty percent of paraldehyde is metabolized by the liver, 20% to 30% is exhaled by the lungs, and a very small amount is excreted unchanged by the kidney.[14] In patients with liver disease, the rate of elimination of paraldehyde and the percentage of paraldehyde eliminated by the liver decrease, and the percentage of paraldehyde eliminated by the lungs increases.

Paraldehyde is depolymerized to acetaldehyde by the liver, and acetaldehyde is then oxidized to acetic acid, which is ultimately metabolized to carbon dioxide and water. Formation of acetaldehyde from paraldehyde has been demonstrated using mouse liver cytochrome P450 enzymes.[258,259]

Elimination Half-Life

The elimination half-life of paraldehyde in adults and children is 3.4 to 9.8 (mean 6.1 to 7.4) hours.[6,224] In two studies performed in neonates, the elimination half-life of paraldehyde was 10.2 ± 1.0 and 18.1 ± 5.5 hours.[79,83,90] The plasma disposition kinetics of paraldehyde fit an open two-compartment model after intravenous injection.[8] The elimination half-life of paraldehyde is prolonged in patients who have received phenobarbital before paraldehyde.[79]

Adverse Effects

Since paraldehyde was introduced in 1882, there have been at least 95 reports of death associated with its use.[14,103] These reports have led to widespread disrepute and infrequent use of paraldehyde. However, many (probably most) of these deaths were from one of the following factors: (a) suicidal overdosage, (b) use of decomposed drug, (c) use of doses larger than those currently recommended, and (d) use of improperly diluted paraldehyde. The incidence of death and serious side effects with U.S. Pharmacopeia (USP)-quality paraldehyde at recommended doses and following recommended administration procedures is unknown but probably is less than is generally supposed.

Overdosage

Overdosage with paraldehyde produces coma, right heart failure, and pulmonary edema and hemorrhages.[34,53]

Side Effects

By Any Route

Paraldehyde administered by any route may cause disagreeable breath odor (from exhaled paraldehyde), right heart failure, pulmonary edema and hemorrhage (especially if the drug is used in excessive dosage), rash, irritability, toxic hepatitis, or toxic nephritis.[14,34,201] Chronic use of paraldehyde may produce a metabolic acidosis.[103] Chronic paraldehyde use may

produce tolerance or physical dependence with a withdrawal syndrome similar to that seen with alcohol withdrawal.[107]

Intravenous Route

Three series[18,79,193] (totaling 181 patients) in which IV paraldehyde was used as an anesthetic agent report no serious complications, although many patients experienced coughing, choking, pharyngeal irritation, tachycardia, or pain at the site of infusion. On the other hand, there are case reports of IV paraldehyde suddenly producing apnea, coughing, cyanosis, hypotension, and clinical and radiographic signs of pulmonary edema.[201] All the above studies involved injection of undiluted or 10% solution of paraldehyde and thus failed to properly dilute paraldehyde so that it would remain soluble after IV injection (see below). Gessner[82] postulates that the above-cited pulmonary–cardiac complications were the result of pulmonary embolism of precipitated droplets of pure paraldehyde in the bloodstream as a result of improper dilution and cites two studies[8] in which properly diluted paraldehyde (4% to 8% solution) was administered IV without complications. Note that intra-arterial injection of paraldehyde may cause vascular injury[96,234] and that direct injection of undiluted paraldehyde into an umbilical artery catheter may cause vascular injury and injury to tissues by microembolization.[90,97]

Oral and Rectal Routes

Paraldehyde can cause irritation and corrosion of the mouth and stomach when given orally and of the rectum and large intestine when given rectally.[1] Rectal administration of decomposed paraldehyde has resulted in perforation of the large intestine.[1] The drug should be diluted properly before administration by these routes (see below).

Intramuscular Route

Permanent, severe sciatic nerve damage may result if paraldehyde is injected too close to the nerve.[70,103] Skin sloughing and sterile abscesses have also been caused by IM paraldehyde.[103]

Decomposed Paraldehyde

Decomposed paraldehyde may contain very high concentrations of acetic acid. Acetic acid is a highly toxic substance, and paraldehyde containing acetic acid appears to be considerably more toxic than USP-quality paraldehyde.[1,5,103]

Role of the Drug

Status Epilepticus

Evidence for the efficacy of paraldehyde in status epilepticus consists of uncontrolled trials[2,29,98,154,241,244] and testimo-nials.[29,55,238] One open-label study found that intramuscular paraldehyde controlled seizures lasting more than 5 minutes in children within 10 minutes of administration in 49% of patients.[2] These reports contain few details but suggest that paraldehyde can probably control status epilepticus in most adults and children; may control status epilepticus when other agents fail; and may be more effective for tonic–clonic status epilepticus than for partial status epilepticus. On the whole, paraldehyde is disappearing from hospital pharmacies as better and easier-to-store antiepileptic drugs have become widely available in the United States. However, paraldehyde is still used to treat status epilepticus in developing countries.[2] Comparison of the reported evidence leads to the conclusion that for almost all patients, IV lorazepam or diazepam is preferable to IV paraldehyde when immediate control of seizures is necessary, and that for most patients a loading dose of phenytoin or phenobarbital followed by maintenance doses is preferable to continued paraldehyde.[32,113] In patients with tonic–clonic status epilepticus refractory to first-line drugs (e.g., lorazepam, diazepam, phenytoin, and phenobarbital), anesthetic coma (if available) is probably more effective and safer than paraldehyde. There are three special situations in which paraldehyde may still find limited used for status epilepticus: (a) when the initial therapy must be given IM; (b) when the patient is allergic to safer agents; and (c) when phenytoin, phenobarbital, lorazepam, and diazepam fail, and anesthetic coma cannot be practically managed (no intensive care unit [ICU], no ventilator).

Paraldehyde may be the drug of choice for status epilepticus when drugs can be administered only by the IM route (e.g., no physician immediately available, suitable vein cannot be found, resuscitation equipment not available). Paraldehyde absorption by the IM route produces near-peak plasma concentrations in 15 to 20 minutes. Lorazepam, diazepam, phe-nytoin, and phenobarbital require significantly longer times for absorption by the IM route and do not produce therapeutic plasma concentrations within 15 to 20 minutes when given in the usual doses IM.[105,110,127,210,232,240]

Patients with no history of seizures except during alcohol withdrawal and patients with true seizure disorders and therapeutic plasma concentrations of antiepileptic drugs who have seizures only when withdrawing from alcohol are most often treated with benzodiazepines. Paraldehyde is an effective alternative to benzodiazepines, but paraldehyde probably has more side effects.[29,203] The preponderance of experimental and clinical evidence suggests that phenytoin is not effective for alcohol withdrawal seizures (see Chapter 268), and barbiturates are not generally used for treating alcohol withdrawal symptoms in the United States because of concern about habituation.

When status epilepticus continues after full loading doses of phenytoin and phenobarbital have been administered, paraldehyde is sometimes effective in stopping seizures.[29,238] However, the greater certainty of seizure control and greater safety of anesthetic coma makes it the treatment of choice, if available, for refractory status epilepticus.

Alcohol Withdrawal Syndrome and Delirium Tremens

There is abundant evidence that paraldehyde is effective as a primary therapy for alcohol withdrawal syndrome and for delirium tremens.[29,82,105,161] However, benzodiazepines are generally preferred because of greater safety and ease of use.

Other Indications

Paraldehyde has been reported to be effective for neonatal seizures,[126] including those due to hypoxic-ischemic encephalopathy.[10]

How to Use the Drug

Formulation

The water solubility of paraldehyde is greatest (12.8%) at 12°C and decreases as the temperature rises above, or falls below, this point. At 37°C, the water solubility of paraldehyde is 7.8%. Lack of awareness of these critical facts has led to the practice of injecting paraldehyde intravenously in its pure form or as a 10% solution. In either case, the solubility of paraldehyde at 37°C would be exceeded, and droplets of pure paraldehyde may form in the bloodstream, which can result in pulmonary emboli (see above).

P.1707

Paraldehyde has a slight tendency to depolymerize back to acetaldehyde. In the presence of air, acetaldehyde oxidizes to acetic acid, which then acts as a catalyst for further depolymerization of paraldehyde to acetaldehyde. Improper storage of paraldehyde has resulted in some samples containing 40% to 98% acetic acid,[103] and as little as 7 mL of such decomposed paraldehyde has proved fatal.[6] A survey of 42 paraldehyde samples collected from hospital wards in 1957 revealed that only 11% met USP standards.[103]

In 1965, USP specifications were altered to state that paraldehyde must be preserved "in well-fitted, tight, light-resistant containers not exceeding 30 ml and that the unused contents of any container that has been opened more than 24 hr be discarded." Such procedures should reduce (but may not completely eliminate) the hazards of decomposed paraldehyde.

Treatment of Status Epilepticus

The dosage of paraldehyde for treatment of status epilepticus is 0.1 to 0.15 mL/kg. This dose may be repeated every 2 to 4 hours if necessary. Before any paraldehyde is administered, it should be checked for purity and conformity with USP standards for storage.[29] The minimum therapeutic plasma concentration of paraldehyde for control of status epilepticus is approximately 300 ng/mL.[98]

The safety of paraldehyde by the IV route is controversial. When immediate control of seizures with an IV medication is indicated, one should probably use another drug (e.g., lorazepam or diazepam) whose safety by the IV route is much greater. If IV paraldehyde must be given, it needs to be diluted to a 4% solution and infused slowly.

Paraldehyde decomposes many plastics, including poly-styrene and styrene–acrylonitrile copolymer, and also rubber.[29,69,81,116,194,199,239] Glass syringes usually are recomm-ended.[118]

Absorption by way of the oral route is slower than by the IM route.[29] There is also a risk of aspiration of paraldehyde, which is highly noxious to the lungs. The oral route is best avoided in patients with status epilepticus.

The ease of administration of paraldehyde by way of the rectal route probably accounts for its frequent administration this way. However, rectal absorption is considerably slower than that by the IM or oral route, making the rectal route particularly undesirable for treating status epilepticus.[75] Furthermore, the slow rectal absorption of paraldehyde can result in administration of large doses to obtain a plasma concentration high enough to control seizures. When the large rectal reservoir of paraldehyde is eventually absorbed, toxic plasma concentrations of paraldehyde may result.[31] If rectal paraldehyde is administered, it should be diluted 2:1 in oil (olive or cottonseed) or diluted in 200 mL of 0.9% sodium chloride.

Phenacemide

Phenacemide is not marketed in the United States.

Structure and Chemistry

Phenacemide (phenylacetylurea, phenacetylcarbamide, Phe-nurone, PAC) is a straight-chain analog of 5-phenylhydantoin (Fig. 3).

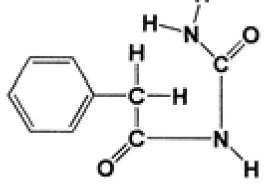

FIGURE 3. Structural formula of phenacemide.

Table 1 Toxicity of Phenacemide*

Side effect	Percentage of patients
Psychic changes	
All patients	15–20
Patients with pre-existing psychiatric problems	27
Patients without pre-existing psychiatric problems	5
Gastrointestinal symptoms	8–13
Rash	1–8
Headache	2–6
Drowsiness	4–5
Abnormal urinary findings	1–3
Hepatitis	0.6–2
Blood dyscrasia	0–2

*Based on data from Davidson DT, Lennox WG. Phenacetylurea (Phenurone) in epilepsy. *Dis Nerv Syst*. 1950;11:167–173; Gibbs FA, Evert GM, Richards RK. Phenurone in epilepsy. *Dis Nerv Syst*. 1949;10:47–49; Livingston S, Pauli LL. Phenacemide in the treatment of epilepsy: results of treatment of 411 patients and review of literature. *N Engl J Med*. 1957;256:588–591; and Tyler MW, King EQ. Phenacemide in the treatment of epilepsy. *JAMA*. 1951;147:17–21.

Basic Mechanism of Action

In experimental models of epilepsy, phenacemide elevates the seizure threshold for minimal electroshock, maximal electroshock, and pentylenetetrazol seizures.[158,212] In fact, phenacemide has higher protective indexes against minimal electroshock seizures (a model of complex partial seizures) and maximal electroshock seizures (a model of tonic–clonic seizures) than either phenytoin or phenobarbital.[212] The mechanism of action of phenacemide is probably similar to that of phenytoin because of the similar structural and three-dimensional conformation of phenacemide and phenytoin.[36,249]

Pharmacologic Fundamentals

Phenacemide is well absorbed from the intestine, with peak plasma concentrations occurring 3 to 5 hours after a single oral dose.[229] The extent of protein binding is unknown. Phenacemide is metabolized by means of hepatic microsomal enzymes by *para*-hydroxylation of the phenyl group followed by conjugation to a glucuronic acid.[193,229] Ring closure to form hydantoin does not occur.[31] The metabolite and its glucuronide are excreted through the kidneys, with little or no unchanged phenacemide found in the urine.[31] The elimination half-life of phenacemide is 5 to 12 hours.[31,192] The effective plasma concentration ranges from 16 to 75 μg/mL.[229]

Adverse Effects

The frequencies of the most common side effects of phenacemide are summarized in Table 1.

Dose-related Effects

Anorexia, nausea, vomiting, weight loss, and abdominal pain occur in 8% to 13% of patients on phenacemide.[89,140,227] In about 3% of such cases, the drug must be discontinued.[142] Headache or a feeling of "fullness in the head" occurs in 2% to 6% of patients on phenacemide.[49,89,140,227] The headache appears during the first few days of phenacemide therapy and is often severe. Drowsiness occurs in up to 5% of patients.[227]

Idiosyncratic Effects

Destructiveness, belligerence, marked irritability, restlessness, and depression are the most commonly observed behavioral changes.[89,140,227] Suicidal tendencies, paranoia, and acute psychotic states have also been reported.[227] Behavioral symptoms occur most commonly during the first 4 to 6 weeks of phenacemide treatment and disappear within a few weeks of stopping the drug.[134,227] Behavioral or psychiatric changes necessitate discontinuing phenacemide in about 10% of patients.[227] On the other hand, in some patients with pre-existing personality disorders, improvement has been noted after starting treatment with phenacemide.[49,140] In patients who have a history of psychiatric disorders, hospitalization during the first week of phenacemide therapy may be advisable. Patients and family should be alerted to report changes in behavior such as decreased interest in surroundings, depression, or aggressiveness.

Rashes of the maculopapular, scarlatiniform, or acneiform type may occur.[40,134,140] Rashes are most common during the first 3 weeks of phenacemide therapy and may be accompanied by fever.[49,134] The rashes are not dose related and disappear within a week of stopping the drug.[49]

Transient proteinuria without serious renal damage occurs in up to 3% of patients during the first week of paraldehyde treatment.[89] Acetonuria and glycosuria may also occur.[227] Nephritis and a fatal case of hepatorenal syndrome have also been reported.[227]

Hepatitis, which is often reversible, occurs in 0.6% to 2% of patients on phenacemide.[49,89,140,227] At least ten deaths from phenacemide-related hepatic toxicity have been reported.[97,140] The histologic picture in these cases was one of zonal (chiefly centrolobular) to submassive toxic necrosis.[97] If the patient survives, postnecrotic cirrhosis may develop.[97] Phenacemide should be avoided in patients with a history of hepatic disease. Liver function studies should be performed in all patients before and during phenacemide therapy.

Leukopenia, leukocytosis, thrombocytopenia, agranulocytosis, and aplastic anemia occur in 0% to 2% of patients on phenacemide,[49,89,140,227] and two fatal cases of aplastic anemia have been reported.[140] Complete blood counts should be obtained before starting phenacemide and at regular intervals during treatment.

Other side effects of phenacemide include insomnia, fatigue, fever, dizziness, paresthesias, muscle pain, palpitations, pruritus, and insensitivity to pain.[49,89,227]

Teratogenicity

The teratogenic potential of phenacemide in humans is unknown. However, because of its structural similarity to phenyt-oin and its high incidence of side effects, it is reasonable to suspect that phenacemide would likely produce teratogenic effects similar to those of phenytoin. Phenacemide should not be given during pregnancy unless the potential benefits outweigh the potential risks.

The Role of the Drug

Phenacemide is no longer manufactured in the United States. We could find no other international manufacturer.

Complex Partial Seizures

The major use for phenacemide has been in treatment of complex partial seizures (CPSs) that are refractory to less toxic drugs. Although phenacemide is moderately effective as a primary drug for CPSs,[140,227] it should never be used as the drug of first choice for any seizure type because of its high incidence of serious side effects (see above). Several studies have shown that phenacemide completely controls or markedly decreases CPSs in 30% to 60% of patients refractory to phenytoin and barbiturates.[49,89,140,227]

Phenacemide should not be administered to a patient with CPSs until it has been documented that maximum tolerated doses of first-line drugs (e.g., phenytoin, carbamazepine, oxcarbazepine, topiramate) and less toxic “backup” drugs (e.g., gabapentin, lamotrigine, levetiracetam) will not control seizures.

Tonic–Clonic and Simple Partial Seizures

Phenacemide has not proved particularly effective against either tonic–clonic or simple partial seizures, either as a primary or adjunctive agent.[44,140,227] However, a minority of patients with tonic–clonic seizures refractory to hydantoins and barbiturates have had a good response to phenacemide.[49,89,140,227]

Absence Seizures

Phenacemide is effective against absence seizures in only a minority of patients.[44,49,89,140,227] Given the abundance of less toxic antiabsence drugs that are available, there is no indication for phenacemide for this disorder.

How to Use the Drug

For adults, the usual starting dose of phenacemide is 1,500 mg/day in three divided doses. If seizures are not controlled, the daily dosage may be increased by 500 mg at weekly intervals. The usual daily maintenance dose in adults is 2,000 to 3,000 mg, although some patients have required as much as 5,000 mg/day. In children 5 to 10 years of age, the dosage of phenacemide is approximately one-half the adult dosage, administered in three divided doses. Because of its many side effects, maintenance dosage should be the smallest amount that provides adequate seizure control.

Phenacemide may be administered alone or in conjunction with other antiepileptic drugs. However, extreme caution must be exercised if the other antiepileptic drugs cause similar toxic effects. When phenacemide is to replace other antiepileptic drugs, the latter should be withdrawn gradually as the dosage of phenacemide is increased to maintain seizure control.

Bromides

Bromides are no longer marketed in the United States.

Bromides were the first effective antiepileptic drug treatment and thus a major turning point in the history of neurology. Potassium bromide was first prepared by Ballard in 1826 and first used for the treatment of scrofula by Pourché in 1828.[13] Potassium bromide was included in the London Pharmacopoeia in 1836 but subsequently excluded from the 1851 edition.[205] In the 1850s, its sedative properties were recognized, and the drug became used for psychiatric purposes.

In 1850, Huette called attention to the development of impotence and depression of the libido in a young man treated with bromide.[13] This effect quickly reversed after discontinuation of treatment. It was this observation that led Sir Charles Locock, an obstetrician to Queen Victoria, to use bromides in women with "hysterical" epilepsy. At the time, onanism and

P.1709

excessive sexual excitement were regarded as well-established causes of epilepsy, thus making bromides a logical choice for the treatment of seizures believed to be associated with such factors.[151] In 1857, Locock presented his experience with 14 or 15 women with "hysterical" epilepsy during the discussion of a paper presented by Edward Sieveking at the Royal Medical and Chirurgical Society of London.[143] Locock's patients had seizures mainly around the menstrual period, and they improved significantly when potassium bromide was administered. At the time, this was interpreted as a confirmation of the theories of onanism, nymphomania, and other forms of excessive sexual excitation in the genesis of epilepsy. Shortly after, C. Bland Radcliffe and Sir Samuel Wilks, based on Locock's observations, extended the use of bromides to other cases of epilepsy not necessarily related to "ovarian irritation."[77] In the ensuing years, use of bromides became massive, and by the mid-1870s, 2.5 tons of bromides were dispensed yearly at the National Hospital Queen Square.[221] Bromides continued to be the only effective medication for epilepsy until 1912, when phenobarbital was introduced.

Structure and Chemistry

Bromide is a simple inorganic anion that behaves in ways very similar to chloride. It is an essential micronutrient and can be found naturally in food, especially vegetables, or as a residue of certain chemicals such as pesticides. It is used by the thyroid gland in the biosynthesis of thyroxine and triiodothyronine. It is normally found in plasma in very small concentration, and a daily intake of 4 mg/kg is considered safe for humans.[231]

Mechanism of Action

It has been shown that both chloride and bromides cross the nerve cell membrane in response to inhibitory neurotransmitters.[63,65] Furthermore, the hydrated bromide ion has a smaller diameter than chloride and penetrates neuronal membranes more rapidly.[87] It is presumed that bromide enters neurons through the chloride channels. Intracellular accumulation of the negatively charged bromide ions hyperpolarizes the neuronal membrane, making it more difficult to generate action potentials. Bromide, like γ-aminobutyric acid (GABA), inhibits the basal and potassium-stimulated release of acetylcholine in the superior cervical ganglion, and this effect is additive with that of baclofen, a GABA receptor agonist.[151] In rat models, the addition of bromide resulted in an increased binding of [^{3}H]flunitrazepam to the benzodiazepine receptor.[173] It is likely that this effect on the GABA receptor complex is related to the action of bromide on the GABA ionophore (chloride channel). This conclusion is supported by the selective antagonism by bromide of picrotoxin- and pentylenetetrazol-induced seizures in animal models.[12] In this way, the action of GABA, which results in opening of the chloride channel and subsequent hyperpolarization of the neuronal membrane, is potentiated by the presence of bromide.[214] A more recent in vitro study confirmed the ability of bromine to increase GABAergic inhibition and suggested an effect of bromine on membrane excitability.[155]

Pharmacologic Fundamentals

Absorption and Distribution

All inorganic salts of bromide are highly water soluble and thus rapidly and completely absorbed from the intestinal tract. The bioavailability has been estimated at 96% ± 6% with a range of 75% to 118%.[230] Bromide is passively absorbed from the small intestine at a slightly faster rate than chloride.[204] The absorption of bromide is saturable, but only at very large doses.[230] The distribution of bromide is mostly into extracellular water space, similar to that of chloride. For this reason, oral bromide can be used in the calculation of the extracellular space.[230]

Bromide and chloride displace each other because body tissues do not distinguish between the two ions. With increasing bromide levels, the concentration of chloride is gradually decreased, because chloride is more rapidly eliminated by the kidney. When very large doses of bromide are given, as much as 40% to 45% of the total chloride in the body can be replaced.[59] Bromide is not bound to plasma proteins. The volume of distribution of bromide has been estimated at 408 ± 17 mL/kg (range 353 to 484 mL/kg).[230] Other studies have found slightly lower volumes of distribution.[255] Bromide is present in all extracellular fluids at concentrations similar to plasma with some exceptions: The concentration of bromide in saliva and gastric juice is higher than that of plasma by a ratio of 1.5.[255] The bromide secreted in saliva and gastric juice is completely reabsorbed at the small intestine, so that no bromides are usually found in feces. On the other hand, the concentration of bromide in the cerebrospinal fluid is lower than that in plasma.[249]

Bromides appear to be removed from the cerebrospinal fluid by bulk flow via the arachnoid villi and by active transport across the choroid plexus.[255] The latter process appears to be the most important and probably accounts for the lower concentrations of bromide in the cerebrospinal fluid.[255] Bromide freely crosses the placenta, with maternal plasma concentrations being slightly higher than fetal concentrations.[223]

Elimination and Pharmacokinetics

The half-life of bromides has been estimated at 11.9 ± 1.4 days.[230] Bromide is eliminated almost exclusively by the kidney as a result of glomerular filtration and tubular reabsorption. In a study of normal volunteers, the clearance rate of bromide was estimated to be 26 ± 1.7 mL/kg/day.[230] Chloride and bromide compete for tubular reabsorption. Thus, a high chloride load will increase bromide clearance and shorten its half-life.[130] A low concentration of chloride, as a result of a salt-deficient diet for example, may actually prolong the elimination of bromide. Given the very slow elimination rate of bromide, steady-state concentrations are not reached until about 40 to 50 days after starting chronic treatment.

Adverse Effects

Acute Intoxication

Acute bromide poisoning is rare today because of the shrinking use of bromides. Ingestion of a large dose usually results in gastric irritation and prominent vomiting, thus limiting its absorption.[136] At high doses, bromides are nephrotoxic and ototoxic.[136] Death can occur from acute renal failure.[24] Histologic examination shows acute tubular necrosis in the proximal convoluted tubules along with interstitial edema, followed by tubular dilation, cellular necrosis, and finally interstitial fibrosis and sclerosis.[92] The excretion of N-acetyl-*B*-glucosaminidase and *B*-galactosidase, lysosomal enzymes that are a sensitive and reliable method for detecting renal tubular dysfunction, was increased in patients with epilepsy taking a combination of valproate and potassium bromide.[168] Even though the significance of these changes is still unknown, patients receiving antiepileptic drugs show a slight increase in the amounts of these enzymes in the urine.[168] Patients taking a combination of valproate and bromides showed the highest urinary levels of N-acetyl-*B*-glucosaminidase.[168]

P.1710

Chronic Toxicity

Chronic toxicity from bromides has long been recognized in the medical literature and is known as bromism or bromide toxicosis. This condition is now rare but still occurs occasionally.[114] Clinical symptoms develop insidiously given the very prolonged half-life of bromides (about 12 days). Elderly persons are most susceptible, especially in the presence of decreased renal function, systemic illness, dehydration, or concomitant encephalopathy.[17,59] Early signs of bromism include drowsiness, asthenia, dizziness, headache, irritability, and emotional instability. Memory loss and lack of concentration are frequent and can be confused with Alzheimer disease or other dementias. More severe intoxication can result in dysarthria, hallucinations, disorientation, delirium, or even stupor.[17] Loss of papillary reflexes, hyperreflexia, or loss of deep tendon reflexes have been reported as well.[59,226] Skin rash occurs in 25% to 30% of cases and appears to be more common in younger patients.[226] It is usually an acneiform eruption that affects the face and trunk but may become generalized. More rarely, the rash may be nodular or bullous. When mild, bromide intoxication can be treated simply by eliminating the drug or reducing the dosage. Excretion of bromide can be accelerated by administration of chloride in the form of sodium chloride (saline injection) or ammonium chloride. Peritoneal or hemodialysis is an effective method for promoting clearance of bromide in cases of acute intoxication.[136] Neonatal bromism has been described in children born to mothers on bromide therapy, and it is characterized by hypotonia and depression of consciousness.[147,178] Significant concentrations of bromides are also found in human milk.[5] For this reason, use of bromides should be avoided during pregnancy or breastfeeding.

Patients on bromide therapy show enhancement of cerebral blood vessels on computerized axial tomography as a result of the similar radiodensity of the bromide and the iodide halides.[172] Another common finding in patients receiving bromides is an apparent increase in chloride levels when automated electrolyte analyzers are used. This methodology does not distinguish between the chloride and bromide halides, leading to an artifactual or "pseudohyperchloremia."[164,191,257] Woody et al. have shown that there is a linear correlation between the increase in the values of "chloride" and the resulting calculated anion gap with the bromide serum concentrations.[257] In this way, an indirect determination of bromide levels can be obtained by using the widely available automated electrolyte analyzers. Steele and Woody have found enhanced neutrophil function in children on chronic bromide therapy.[207]

Drug Interactions

Bromide is not metabolized, has no liver-inducing properties, and does not bind to plasma proteins. As a result, no significant pharmacokinetic interactions with other antiepileptic drugs would be expected. Bromide has been shown not to interact with topiramate.[153] Bromides, however, appear to have a pharmacodynamic effect enhancing the action of other CNS depressant drugs, especially benzodiazepines.[255] Bromide levels are higher in patients receiving lithium salts.[39,238]

The Role of the Drug

Pharmaceutical preparations of bromide are no longer manufactured in the United States. However, pharmaceutical bromide preparations are available in several countries, including Japan.[120]

Following the introduction of phenobarbital in 1912 and phenytoin in 1938, the use of bromides dropped dramatically. Since then, the drug earned a reputation, unjustly according to several authors, of having a very narrow therapeutic index and being less effective than newer antiepileptic drugs.[117,141,256] Sporadic reports about the efficacy of bromides support the claim that this compound still has a limited but definite role in the management of epileptic seizures.[16,60,68,169,207,215,218,256] The majority of these studies, however, are mostly retrospective, unblinded, and uncontrolled.

Bromides seem to be most effective in treating generalized tonic–clonic seizures, somewhat effective in partial seizures, and generally ineffective in absence, myoclonic, and tonic seizures. Several authors have actually reported that bromides exacerbate tonic and myoclonic seizures.[22,68,198,203,218] Because bromides do not induce hepatic enzyme systems, they have been useful in the treatment of epilepsy associated with porphyria.[203]

Unlike most other antiepileptic drugs, bromide has a long elimination half-life in animals (e.g., 1.6 weeks in cats). Bromide is still used to treat epilepsy in cats and dogs.[27,180,225]

How to Use the Drug

Bromide is typically available as a potassium salt or as triple bromides, consisting of a combination of equal amounts of potassium, sodium, and ammonium bromide. It has been generally used as an elixir at concentrations of 1,200 mg of bromide salt per 5 mL, but tablets are also available. Recommended doses in children range from 30 to 80 mg/kg/day, with doses as high as 170 mg/kg having been used by some investigators without significant toxicity.[68,208] The starting dose is usually 10 mg/kg/day in two or three divided doses. Given its very prolonged half-life, monitoring plasma bromide concentration is of great importance in order to prevent toxicity. Under normal circumstances, steady state is reached in 40 to 50 days. The therapeutic concentration of bromide is approximately 75 to 125 mg/dL, with levels over 150 mg/dL being potentially toxic.[59] In a recent series, Steinhoff et al. reported mean bromide concentrations of 253 mg/dL (range 156 to 367 mg/dL) and proposed a therapeutic range of 200 to 300 mg/dL.[208] The authors noted that clinical toxicity was observed frequently with levels over 300 mg/dL.[207] In their series, however, the incidence of patients experiencing side effects was 53%, slightly higher than in other reports. Most other authors have recommended more conservative doses and a lower therapeutic range.[59,68,169,218] Certainly, with levels over 200 mg/dL, patients should be monitored very closely.

It should be noted that most of the preceding information comes from pediatric patients, who are have better tolerance to the neurotoxicity of bromides than adults and especially elderly patients. More conservative doses and closer monitoring are necessary in the elderly.

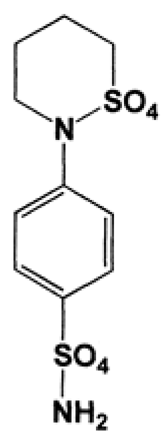

FIGURE 4. Structural formula of sulthiame.

Sulthiame

Structure and Chemistry

Sulthiame (tetrahydro-2-*p*-sulfamoylphenyl-2 H-1,2-thiazine-1,1-dioxide; Ospolot, Conadil, Elisal) is a sulfonamide derivative first synthesized in 1960 by Helferich and Kleb[104] (Fig. 4). It was introduced as an anticonvulsant in the early 1960s in Europe and Australia but never marketed in the United States because of lack of convincing evidence of its antiepileptic effect.[96] Sulthiame is chemically related to sulfanilamide and acetazol-amide. It is a carbonic anhydrase inhibitor but has no antibacterial activity and very weak diuretic properties.[243] Sulthiame is a white solid with a molecular weight of 290 and a melting point between 183°C and 187°C.[62] It is soluble in alkaline solutions but poorly soluble in water, ethanol, or acid solutions.

P.1711

Mechanism of Action

There is evidence for two mechanisms of action of sulthiame: Inhibition of carbonic anhydrase and blocking sodium channels. In animal models, sulthiame has shown efficacy against maximal electroshock and pentylenetetrazol seizures; it has no effect against strychnine-induced seizures.[243] There has been speculation that the mechanism of action may be similar to that of acetazolamide, given its similar but weaker inhibitory effect on carbonic anhydrase.[132,134,244] The inhibitory effect of sulthiame on the enzyme is about one-sixteenth the potency of acetazolamide.[244] The degree of anticonvulsant action of different carbonic anhydrase inhibitors parallels the degree of enzyme inhibition.[219] Tanimukai et al. found a differential effect of sulthiame on brain and erythrocytic carbonic anhydrase, with sulthiame being significantly more potent on the brain enzyme.[219] It has also been shown that sulthiame reduces voltage-gated sodium currents.[146]

Pharmacologic Fundamentals

Sulthiame is rapidly and completely absorbed from the gastrointestinal tract. In humans, over 90% of an oral dose is absorbed, with peak plasma concentrations observed within 1 to 5 hours.[58,99] The drug penetrates body tissues readily, and concentrations of sulthiame in brain and plasma have been similar in animal studies. However, in certain tissues such as red blood cells, sulthiame was slightly more concentrated. Although there is no direct evidence that sulthiame binds to plasma protein, Hooper et al. have found that sulthiame displaced phenytoin from plasma albumin to some extent.[107] A significant proportion of sulthiame, ranging from 17% to 69%, is eliminated unchanged in the urine.[58] An additional 25% to 50% of the dose undergoes hepatic metabolism and is eliminated as an inactive hydroxylated derivative.[58]

May et al. estimated the half-life of sulthiame in 11 patients with epilepsy after withdrawal of the drug.[152] The elimination of sulthiame was satisfactorily explained by a first-order or linear kinetics model.[152] The mean half-life was 8.65 ± 3.1 hours, with a range of 4.7 to 15.4 hours.[152] In this study, children under the age of 14 years showed shorter half-lives and higher daily fluctuations in plasma concentration, indicating a higher clearance of sulthiame. The relationship between sulthiame plasma concentrations and daily dosage has been ambiguous.[64,152] Feely et al. found a poor correlation (r = 0.54) in ten patients studied.[70] At doses between 4 and 12 mg/kg/day, levels usually ranged between 1.5 and 20 μg/mL, although extremes of 0 and 45 μg/mL were observed.[70] Other studies have found a better correlation.[64,152] In a study of 86 patients with epilepsy, sulthiame dose and plasma concentration were highly correlated (r = 0.82).[152] Children had lower sulthiame plasma concentrations compared to adults, although dose per body weight was comparable. In addition, patients comedicated with carbamazepine had lower sulthiame concentrations than those receiving valproate, an observation probably due to the liver enzyme–inducing properties of carbamazepine.[152]

The relationship between sulthiame plasma concentrations and seizure control remains poorly understood.[21,37,96,152] There are no studies that show a clear relationship between sulthiame plasma levels and efficacy.[152] Green et al.[96] commented that the lack of correlation between seizure frequency and plasma levels was disappointing. In this study, plasma concentration in most patients ranged from 10 to 50 μg/mL, but levels as high as 74 μg/mL were observed.[96] Callaghan et al., in a smaller series, also failed to show any significant correlation.[37] Egli et al. proposed a therapeutic range between 6 and 10 μg/mL but pointed out that good responses were also observed in individual patients with considerably lower levels.[64] Doose, who studied a series of patients with rolandic epilepsy, suggested a therapeutic range between 1.5 and 2.5 μg/mL.

Adverse Effects

Side effects are common with sulthiame. Hyperpnea is present to some extent in almost every patient.[142] The hyperpnea in itself is usually well tolerated, but it frequently may present as an exertional dyspnea with a decrease in respiratory reserve. When severe, it can be frightening to the patient and often a reason to discontinue the drug. Sulthiame stimulates pulmonary ventilation and leads to a compensated respiratory alkalosis.[244] At doses between 1,600 and 3,000 mg, sulthiame is associated with a decrease in plasma bicarbonate, along with a decrease in the PCO_2 and a corresponding increase in the PO_2; blood pH remains unchanged.[244] The hyperpnea often improves with reduction of the dose.[62] Paresthesias, often persistent, are another common complaint in patients taking sulthiame and are similar to those observed with acetazolamide.[62] They frequently affect the distal extremities or have a perioral distribution. The paresthesias appear to be dose related and often improve with a reduction in dose.[62] Gastrointestinal complaints are common including anorexia, nausea, or weight loss.[131,138]

Other reported side effects include headache, asthenia, somnolence, ataxia, hypersalivation, and dizziness. Occasionally, mental changes such as hallucinations, psychosis, and catatonia have been observed.[4,80,93,96,137,163,179] In some early studies, status epilepticus was reported as a relatively frequent complication, but more recent series have not supported this finding.[96] There is one report of acute renal failure associated with the use of sulthiame.[11] Deposits of calcium phosphate crystals in the renal papillae have been found at autopsy in one third of dogs on chronic sulthiame intake.[142] A single case of Stevens-Johnson syndrome associated with the use of sulthiame in combination with phenobarbital has been reported.[213] Rare cases of peripheral neuropathy developing during sulthiame therapy have been observed.[71] Acute overdose with sulthiame has usually been followed by a rapid recovery, but at least one fatal case has been reported.[3,209] There is virtually no information concerning the sulthiame's teratogenicity.

Drug Interactions

Sulthiame is a potent inhibitor of phenytoin metabolism, resulting in a consistent and often considerable elevation of phe-nytoin concentrations.[101] Sulthiame appears to inhibit the hydroxylation of phenytoin, leading to prolonged elimination half-life and a decrease in the 24-hour urinary excretion of 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (HPPH).[101,109] For

P.1712

reasons not well understood, this interaction may sometimes be delayed for 10 to 20 days.[101,177] Morselli et al.[162] found that when sulthiame was given to rats already receiving phe-nytoin, the brain concentrations of phenytoin were significantly higher in relation to the plasma concentrations (the phenyt-oin plasma/brain ratio fell from 1.6 to 0.9). Houghton and Richens[108] noted that 40% of patients admitted to their center receiving phenytoin in combination with sulthiame showed toxic levels of phenytoin. This important drug interaction may be partly responsible for the high incidence of side effects noted in the early studies, when sulthiame was frequently used in combination with phenytoin. Sulthiame may also elevate the plasma levels of phenobarbital and primidone, but this interaction appears to be of much less clinical significance.[171,177] It is possible that the effect in the inhibition of phenobarbital metabolism may be partially compensated by an increase in its urinary excretion because sulthiame increases 24-hour diuresis and the alkalinity of the urine.[171] Antiepileptic drugs with liver enzyme–inducing properties decrease the elimination half-life of sulthiame and result in lower plasma concentrations at a given dose.[152] Sulthiame does not lower topiramate plasma concentration.[153] Little is known about the interactions of other drugs with sulthiame.

The Role of the Drug

Early studies of sulthiame focused on partial seizures, especially complex partial seizures. Studies from the 1960s, when the drug was more widely used, showed that sulthiame was often effective as an adjunct for treating complex partial, generalized tonic–clonic, and myoclonic seizures.[28,111,123,125,131,142,148,160] Almost all of these early studies used sulthiame in combination with other antiepileptic drugs and seldom measured plasma concentrations. The study designs were generally inadequate to provide definitive evidence of efficacy by our current standards. When the interaction of sulthiame with phenytoin, and possibly other antiepileptic drugs, was recognized in 1968, results from the early studies were regarded with skepticism, and the efficacy of sulthiame as a primary antiepileptic drug was severely questioned.

In 1974, Green et al. published the results of a controlled clinical trial comparing sulthiame and phenytoin as monotherapy in 67 patients with partial seizures.[96] Patients were randomized to two consecutive 6-month treatment periods with sulthiame or phenytoin in a double-blind fashion. Doses of sulthiame ranged from 400 to 3,600 mg/day (mean 1,993 ± 648 mg/day), and plasma concentrations from 10 to 74 μg/mL (mean 28.9 ± 14.9 μg/mL). Only 21 patients completed the study. Of these, ten had fewer seizures on sulthiame, nine had fewer seizures on phenytoin, and two were seizure free with either drug. However, six of the ten patients on sulthiame and both seizure-free patients elected to continue treatment with phenytoin, mostly because of side effects. As a result, of 67 patients entering the study, only four preferred sulthiame. Analysis of patients who were dropped from the study showed that 21 left while taking phenytoin and 25 while taking sulthiame. However, in the phenytoin group, only seven left because of increased seizure frequency versus 17 in the sulthiame group, a statistically significant difference ($p < 0.05$). Toxicity was also significantly higher in patients receiving sulthiame. The authors' conclusion was that sulthiame had very little value as a primary antiepileptic drug. After this study was published, use of sulthiame dropped dramatically, and the drug was never marketed in the United States.

Several more recent studies of sulthiame have focused on its use in benign epilepsy with centrotemporal spikes (BECTS). The Sulthiame Study Group performed a randomized, double-blind, 6-month study of sulthiame monotherapy versus placebo for treatment of BECTS.[200] The primary outcome variable was treatment failure events (TFE) per group. TFEs consisted of first seizure after a 7-day run-in period, intolerable adverse events, development of another epileptic syndrome, or termination of trial by parents or patient. Twenty-five of 31 sulthiame-treated patients (81%) and 10 of 35 placebo-treated patients (29%) completed the trial without any TFEs ($p = 0.00002$). A number of uncontrolled studies also report favorable efficacy and tolerability of sulthiame for BECTS.[19,128]

The Sulthiame Study Group also found that the electroencephalogram (EEG) normalized in 21 of 31 patients on sulthiame and 5 of 35 patients on placebo ($p < 0.0001$).[13] Uncontrolled studies of the effects of sulthiame on the EEG in patients with BECTS have reported similar results.[19,66,128]

Debus et al.[54] performed a randomized, double-blind study of 37 infants with newly diagnosed infantile spasms (all on pyridoxine) who were randomly assigned to sulthiame or placebo. Complete cessation of infantile spasms and resolution of hypsarrhythmia on EEG were the criteria for being classified as a responder. Thirty percent of patients on sulthiame were responders, while none of the patients on placebo were responders ($p < 0.025$).

Uncontrolled trials of sulthiame for infantile spasms have also reported favorable results.[53] Limited evidence suggests that sulthiame may have efficacy against juvenile myoclonic epilepsy[135] but not absence seizures.[96]

Sulthiame is not approved by the Food and Drug Administration (FDA) in the United States, but it is available in Europe. It has only a limited role in the management of epilepsy. However, randomized, double-blind, placebo-controlled studies have demonstrated efficacy of sulthiame for BECTS and infantile spasms.

How to Use the Drug

Sulthiame is generally available in 50- and 200-mg tablets. Treatment should be initiated slowly and at low doses in order to minimize side effects. Maintenance doses of 5 to 10 mg/kg/day appear reasonable in children, whereas in adults recommended doses usually fall between 400 and 2,000 mg/day. Much higher doses have been used with relatively good tolerance.[96] Because of its short half-life and the marked daily fluctuation of its plasma concentrations, the drug should be administered at least twice, preferably three times, a day.[152] The clinical value of monitoring sulthiame plasma concentrations appears at present to be very limited.[177] A therapeutic range of 6 to 10 μg/mL has been proposed, but good results have been observed at concentrations ranging from 1.5 to 50 μg/mL.[96,110]

Acetazolamide

Structure and Chemistry

Acetazolamide (5-acetamido-1,3,4,-thiadiazole-2yl-sulfona-mide, Diamox) is an unsubstituted sulfonamide that was synthesized in 1950 by Roblin and Clapp.[194] Its use in the treatment of epilepsy was first reported by Bergstron et al. in 1952,[20] and its efficacy in the treatment of different seizure types was studied by Ansell and Clarke,[7] Forsythe et al.,[73] Golla and Sessions,[88] Lombroso et al.,[144] Millichap,[156] and Rating.[184] Acetazolamide has a molecular weight of 222 g. Its chemical structure is shown in FIGURE 5.

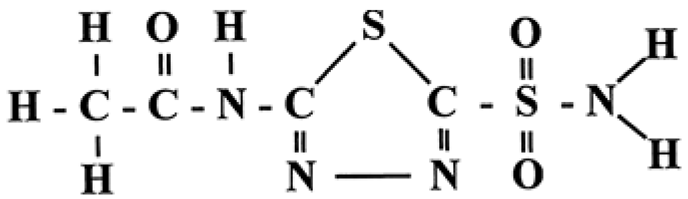

FIGURE 5. Structural formula of acetazolamide.

Basic Mechanism of Action

The enzyme carbonic anhydrase catalyzes the conversion of carbon dioxide and water to bicarbonate, which is important in maintaining acid–base balance. Inhibition of the enzyme

P.1713

is the only known and documented mechanism of action for acetazolamide and is believed to mediate the activity of the drug.[9,94,95,157,187] More than 99% of the brain carbonic anhydrase activity can be inhibited by acetazolamide, which results in the accumulation of CO_2.[250,251] The anticonvulsant effect of CO_2 can be potentiated by acetazolamide,[252,253] and aceta-zolamide probably acts by causing an accumulation of CO_2 in the brain.

Pharmacologic Fundamentals

Absorption and Routes

Acetazolamide is a weak acid (pKa of 7.4) and remains in the nonionized form in acidic pH of the stomach (pH ~2.0). The nonionized form has little water solubility, and only small amounts are absorbed in the stomach. The increasingly higher pH and larger absorptive surface area in the duodenum and upper jejunum make it the preferential site of absorption of acetazolamide. Peak plasma levels occur 2 to 4 hours after oral administration. Whereas oral doses of 500 to 750 mg (5 to 10 mg/kg) are completely absorbed,[149] absorption of higher doses is less predictable, which results in variable plasma levels.[150] The time-release formulation yields peak plasma levels at 3.5 hours and is maintained for 10 hours.

Distribution and Protein Binding

Acetazolamide is 85% to 95% protein bound,[149,150,254] and the affinity for the protein carrier is concentration dependent. The free fraction increases as the plasma level rises. The highest tissue concentration of acetazolamide is found in erythrocytes, kidney, and stomach, which contains high levels of carbonic anhydrase. The high volume of distribution of 1.8 L/kg is consistent with high tissue binding even in the early distribution phase.

Metabolism

The compound is not metabolized; it is eliminated unchanged in the urine, 20% through glomerular filtration and 80% through tubular secretion.[149,150] The renal elimination of acetazolamide is pH dependent and can be enhanced by alkalinizing the urine. A small quantity of acetazolamide is also excreted in bile and reabsorbed from the small bowel.

Clinical Pharmacokinetics

At physiologic pH, approximately 50% of the acetazolamide free in the serum is present in the un-ionized state, which diffuses into different body compartments. After a single dose, the plasma level time plot reveals two phases. The first phase lasts about 100 minutes and represents the rapid movement of the unbound drug into tissue compartments. Once in a tissue compartment, the drug binds to carbonic anhydrase enzyme and forms a stable inactive complex. The second, slower phase of the plasma decay curve represents the slow dissociation of drug–enzyme complex and subsequent renal excretion. The plasma half-life of the second phase is 2 to 4 days, with steady state achieved after 1 week or more of dosing. Effective blood levels may be maintained for 4 to 5 days after stopping the drug. The pharmacodynamic effect may exceed the pharmacokinetic profile, because upon entry into tissues acetazolamide forms a stable complex with carbonic anhydrase, which blocks the action of the enzyme. In elderly patients, elimination is altered by reduced glomerular filtration and by reduced protein binding. The two effects offset each other, and elimination in the elderly may be similar to that seen in children and younger adults.[42]

Acetazolamide decreases the bulk flow of cerebrospinal fluid (CSF). This reduces drug elimination from the brain by CSF bulk flow resulting in an increase in brain concentration of coadministered drugs. For example, a patient on phenobarbital may experience increased drowsiness.

Adverse Effects

Dose-related Effects

Acetazolamide is generally very well tolerated. Most side effects occur at initiation of treatment and are most likely to include lethargy, dizziness, nausea, numbness, and paresthesias, which usually affect the distal part of the limbs, and less often the face. Side effects may worsen as the dose is increased. Shortness of breath has been reported but is not associated with clinically evident cardiac or pulmonary dysfunction. Reduced exercise tolerance was described in a study involving healthy volunteers.[206] Metabolic acidosis, fatigue, depression, decreased libido, and decreased appetite have also been noted occasionally.[67,189,250] An increased risk of metabolic acidosis is found in patients treated concurrently with silicates[121]; it is also more frequent in elderly patients.[211]

An interesting side effect is the occurrence of dysgeusia, or altered taste.[91,102,255] Although not usually reported spontaneously, this symptom may occur in up to 90% of patients. Acetazolamide eliminates the tingling sensation from carbonated drinks as a result of inhibition of carbonic anhydrase located in the taste buds.

Renal stones have been associated with drugs that inhibit carbonic anhydrase. The reported frequency has varied from 1 of 277 patients[145] up to 43% of patients treated for epilepsy, glaucoma, and periodic paralysis.[121,189,220]

Idiosyncratic Effects

The most serious adverse effect associated with acetazolamide is aplastic anemia, which occurs predominantly in older patients (mean age 71).[123] The prodromal symptoms in patients developing aplastic anemia were usually nonspecific: Lethargy, anorexia, and fatigue, followed by bleeding or signs of infection.[123] Other idiosyncratic reactions encountered less frequently include renal failure, thrombocytopenic purpura, and agranulocytosis.[74,123,174,186,196,228]

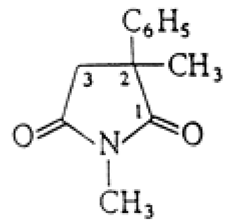
Teratogenicity

An increased incidence of congenital abnormalities has been found in animal studies. In humans, there are isolated reports of malformations associated with the use of acetazolamide during pregnancy, including microcephaly, congenital heart defects, and congenital glaucoma. However, the overall risk of malformations from acetazolamide has not been established. Thus, use in pregnancy cannot be recommended unless the therapeutic benefit to the mother clearly outweighs the potential risk to the fetus.

The Role of the Drug

Acetazolamide is an antiepileptic drug with a broad spectrum of efficacy. Efficacy has been reported in the treatment of

partial,[41,73,145,170] primary generalized tonic–clonic,[7,41,156,189] absence,[7,88,106,145,195] and myoclonic seizures.[190] Inhibition of carbonic anhydrase is the only mechanism that has been identified as the basis for the drug's antiepileptic effect. A stable acetazolamide–carbonic anhydrase enzyme complex is formed with a pharmacodynamic effect exceeding 24 hours. Once-a-day dosing is therefore realistic with acetazolamide. The main factor limiting wide use is development of tolerance, which results in diminishing efficacy over time.[7,112,144,145,156] As a result, acetazolamide is often prescribed for intermittent use. It is thus well suited to the treatment of catamenial seizures.[7,72,85,167,182,185,190,195]



METHSUXIMIDE

FIGURE 6. Structural formula for methsuximide.

How to Use the Drug

Effective plasma levels range from 8 to 14 μg/mL and 1 to 22 μg/mL.[170] The usual daily dose of acetazolamide is 10 to 20 mg/kg given two to three times daily.[129,197] When acetazolamide is used as adjunct therapy, the starting dose should be 250 mg/day to minimize sedation; the dose should then be increased as tolerated. The effective dosage varies considerably, but few patients benefit from doses above 20 mg/kg[170] or 750 mg/day.[145] Resor and Resor[189] found that patients with juvenile myoclonic epilepsy responded to acetazolamide monotherapy in doses ranging from 500 mg/day (6.7 mg/kg) to 1,750 mg/day (27 mg/kg), with an average dose of only 893 mg/day (14 mg/kg). Doses above 15 mg/kg are not usually effective and lead to a significant increase in side effects. Looking at cumulative seizure control, Oles et al.[170] found that most patients responding to acetazolamide had done so with doses of 9 mg/kg or less. Children should require higher doses than adults because of higher renal clearance. However, most reports have recommended doses of 500 to 750 mg/day (10 to 15 mg/kg/day) in children.[73,145,156]

When acetazolamide is first begun, it should be taken in the morning because it has a diuretic effect that continues for the first 3 to 5 days of treatment. As the diuretic effect abates, evening doses can be used without difficulty. Elderly patients may require adjusted doses.

Methsuximide

Structure

Methsuximide (*N*,2-dimethyl-2-phenylsuccinimide; Fig. 6) differs from ethosuximide in having a phenyl group at the 2-carbon position and a methyl group at the 5 position. Its structure is consistent with the generalization that short alkyl chains at the 2, 3, and 5 positions of the succinimide ring are associated with activity in the pentylenetetrazol model, whereas phenyl substitutes at the 2 and 3 positions confer activity in the maximal electroshock model.[30,43,176,229]

Basic Mechanism of Action

Methsuximide's mechanisms of action are unknown. Its efficacy against absence seizures may be due to an action similar to that of ethosuximide in which low-threshold calcium currents in thalamic neurons are blocked.[43,45,46,47,124,142] The drug's effectiveness in the maximal electroshock model and in partial seizures is likely mediated by changes in sodium conductance, as with phenytoin, or other ionic or neurotransmitter effects.[229]

Pharmacologic Fundamentals

Methsuximide and ethosuximide (Chapter 147) are similar in both structure and function.

Adverse Effects

Adverse effects occur in 35% of persons taking meth-suximide.[20] Dose-related side effects principally involve the gastrointestinal tract and central nervous system. Gastrointestinal effects include anorexia, nausea, hiccups, and abdominal pain. Central nervous system side effects include drowsiness, confusion, photophobia, headache, irritability, dizziness, and ataxia.[30,177,183,222,229,242] Delayed coma after overdose may reflect time required to convert the drug to its *N*-desmethyl metabolite.[30,229] Idiosyncratic reactions are rare and include rash, behavioral changes, and extrapyramidal reactions.[30,181,235] Hepatic failure has not been reported.[30] There have been rare cases of transient leucopenia, and a single case of pancytopenia was reported but the association with methsuximide was questionable.[30,229] There has been one case of reversible osteomalacia.[181] Few data are available regarding teratogenicity. However, methsuximide's metabolism by arene oxidase implies an epoxide metabolite, which may contribute to the teratogenic effects of several drugs in susceptible individuals.[259,260]

Methsuximide overdosage is characterized by stupor, coma, respiratory depression, central neurogenic hyperventilation, increased or decreased reflexes, myoclonus, and second-degree heart block. Favorable results were reported in a single case in which charcoal hemoperfusion was used.

Patients taking methsuximide in combination with phenyt-oin or phenobarbital have higher plasma concentrations of *N*-desmethylmethsuximide than patients taking methsuximide alone. The plasma concentrations of phenytoin and phenobarbital are increased appreciably when methsuximide is added. These interactions probably occur as a result of competition for the common enzyme involved in their metabolism, CYP2C9/10. A significant fall in carbamazepine level may occur with addition of methsuximide. This is probably due to induction of CYP2C9, the enzyme that metabolizes carbamazepine.[30]

Role of the Drug

In one study that looked at initial treatment of absence seizures with methsuximide, complete control was not achieved in any patient.[140] In studies in which methsuximide was used as adjunctive therapy for treatment of absence seizures, 0% to 31% of patients had complete seizure control, and 13% to 66% of patients had 50% or greater reduction in seizure fre-quency.[30,139] In comparison to methsuximide, ethosuximide (Chapter 147) has the following advantages: Higher frequency of seizure control, fewer side effects, and fewer drug

interactions. Methsuximide is indicated for absence seizures only when less toxic drugs fail to produce adequate control.

When methsuximide is used as adjunctive therapy in treating complex partial seizures, the majority of patients who have failed trials of phenytoin, phenobarbital, and carbamazepine will not have a 50% or greater reduction in seizure frequency.[30] Patients having a good initial response to methsuximide often lose the response after 4 to 7 months.[33,242]

How to Use the Drug

The usual adult starting dose is 300 mg/day, which is increased using increments of 150 or 300 mg/day every 1 to 2 weeks; the longer interval is favored by Browne[30] and others because of the long half-life of methsuximide's active metabolite, particularly at higher levels. Although this long half-life could allow once-daily dosing, as with ethosuximide, side effects are less if it is given in two or three divided doses. In children or the elderly, a lower starting dose of 150 mg/day is preferable. The target dosage is 10 mg/kg, with a maximum of 900 to 1,200 mg in adults. Several investigators[30,33,181,229,235] suggest a therapeutic range of 10 to 40 mg/L for the measured active metabolite, *N*-desmethylmethsuximide. Presently, methsuximide is available in the United States only as Celontin 300-mg tablets.

Discontinuing the Drug

As with other antiepileptic drugs, indications for drug withdrawal include unacceptable adverse effects, ineffectiveness at maximal tolerated dose, or successful long-term seizure control. In the case of an allergic reaction, methsuximide can be withdrawn abruptly, especially if other drugs are maintained; otherwise, gradual withdrawal is advisable.

Summary and Conclusions

Trimethadione is sometimes useful in treating absence seizures and Lennox-Gastaut syndrome in patients refractory to less toxic agents. Paramethadione has been withdrawn from the U.S. market. Paraldehyde is effective in treatment of status epilepticus and alcohol withdrawal seizures but is seldom used because safer drugs are available for these indications. Phenacemide is an effective but toxic drug for partial seizures that should be considered only after less toxic drugs have failed and surgical therapy has been excluded. Modest success has been reported in treating refractory tonic–clonic seizures with bromide. Bromide is one of the few antiepileptic agents that can be taken safely by persons with porphyria. Methsuximide is a second-line drug for partial seizures. In an era of new alternatives for the treatment of epilepsy, the usage of the drugs discussed in this chapter will almost certainly continue to decline.

Introduction

During the 16 years between 1989 and 2005, a number of new antiepileptic drugs (AEDs) entered the market for the add-on treatment of partial seizures as their initially approved indication. The availability of these AEDs has contributed to the management of epilepsy, either as adjunctive therapy or as monotherapy. In addition to providing more choices for the physician and his/her patients, many of these drugs have led to improved seizure control and have been shown to possess a more favorable tolerability and pharmacokinetic profile than some of the older "first-generation" AEDs. Unfortunately, for the patient with refractory epilepsy, there still remains a substantial need for more efficacious therapies. Thus, none of the AEDs currently available can claim to be capable of providing complete seizure control in a sizeable proportion of patients with refractory partial epilepsy. In addition, only small advances in the therapy of certain seizure types and epilepsy syndromes have been made. Therefore, there is still significant room for improvement.

Despite the advancements in our understanding of the pathophysiology and molecular genetics of various epilepsies, little progress has been made in the development of a therapy that targets the presumed molecular basis of a given seizure type. To this end, several of the drugs in development today evolved from a nonmechanistic approach and the use of a battery of animal seizure and epilepsy models to define their in vivo anticonvulsant profile. This is not to imply that target-driven discovery is not employed in the discovery of investigational AEDs. As reviewed here, a number of the drugs in development have emerged from very focused programs designed around a "validated" molecular target.

Many of the drugs reviewed in this chapter will likely emerge from clinical studies over the next 2 to 5 years, and at least some of these new agents will offer some level of improvement to the multitude of patients whose seizures are not fully controlled with existing anticonvulsants. Whether any of these drugs will lead to complete seizure freedom in a major proportion of refractory patients or emerge ultimately as first-line agents for the treatment of one or more types of epilepsy has yet to be determined.

Brivaracetam (UCB 34714) and Seletracetam (UCB 44212)

Structure and Chemistry

Brivaracetam, (2S)-2-[(4R)-2-oxo-4-propylpyrolidinyl]bu-tanamide, and seletracetam, (2S)-2-[(4S)-4-(2,2,difluorovinyl)-2-oxopyrrolidin-1-yl] butanamide, are two very potent levetiracetam analogs in clinical development by UCB Pharma (Fig. 1).

Pharmacology

The development of brivaracetam and seletracetam stems from the recognition that the action of levetiracetam is related to its ability to bind with a novel site identified as synaptic vesicle protein 2A (SV2A).[95] The demonstration that the efficacy of levetiracetam and a series of analogs is correlated with their SV2A binding affinity stimulated a drug-discovery program at UCB to identify compounds with higher affinity for SV2A than levetiracetam. Seletracetam and brivaracetam emerged from this effort, wherein approximately 12,000 compounds were initially screened against SV2A.[64] These two analogs were chosen from 900 that were selected for in vivo evaluation in the audiogenic seizure-susceptible mouse, and from 30 that were subsequently selected for more extensive evaluation in the kindling model.

Seletracetam appears to be a more potent analog that shares a similar anticonvulsant profile with levetiracetam. For example, seletracetam is not active in the traditional maximal electroshock (MES) or pentylenetetrazole (PTZ) seizure models but is more potent than levetiracetam in the corneal-kindled mouse (10-fold) and the genetic absence epilepsy rat from Strasbourg (GAERS) model of spike-and-wave epilepsy (25-fold). In addition to increased potency, seletracetam also appears to possess an even higher protective index (i.e., the ratio of a drug's median toxic dose to its median effective dose) in animal models than does levetiracetam.[104]

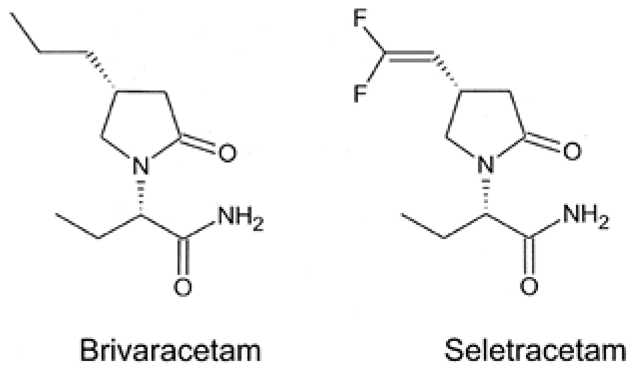

FIGURE 1. Structure of brivaracetam and seletracetam.

Brivaracetam differs from both levetiracetam and seletracetam in that it appears to possess a slightly broader activity spectrum in animal seizure models, and it is active in the

P.1722

MES and PTZ seizure tests. These effects of brivaracetam are thought to be related to its modest inhibition of sodium (Na) channels.[129,175] Brivaracetam also appears to be more effective than levetiracetam in its ability to suppress both the behavioral seizure and electrographic afterdischarge in the amygdala-kindled rat model of partial epilepsy. In addition to its more potent action against the fully expressed kindled seizure, brivaracetam also appears to be more potent and more effective than levetiracetam in preventing the acquisition of corneal kindling.[103]

At the cellular level, brivaracetam does not directly display any direct effects on γ-aminobutyric acid (GABA)-, glycine-, kainic acid-, or α-amino-3-hydroxy 5 methyl isoxazole 4 propionate (AMPA)-gated currents.[128] It has been found to exert a small inhibitory effect on the amplitude of the plateau phase of *N*-methyl-D-aspartate (NMDA)-evoked currents.[127] Seletracetam also appears to be a potent inhibitor of high-voltage activated (HVA) calcium (Ca^{2+}) currents.[121] Results from combination studies conducted with seletracetam, ω-conotoxin GVIA and ω-conotoxin MVIIC suggest that this effect of seletracetam is mediated by both N- and Q-type HVA channels. In addition, seletracetam has also been found to reverse the inhibitory effect of zinc and ß-carboline inhibition of glycine-gated currents.[127] In contrast to brivaracetam, seletracetam is inactive at voltage-gated Na^+ channels.[175]

Low concentrations of brivaracetam (1–10 µM) suppress high potassium (K), low calcium (Ca)-induced epileptiform bursting in hippocampal slices.[100] Levetiracetam has been shown to exert a similar action but requires substantially higher (i.e., 32 µM) concentrations. Brivaracetam (3.2 µM) differs from levetiracetam in that it is also capable of reducing spontaneous bursting; whereas levetiracetam is inactive at concentrations up to 32 µM. The ability of brivaracetam to inhibit spontaneous bursting may be related to its inhibitory effect on voltage-activated Na^+ currents.[176]

Brivaracetam has also been found to be effective at nontoxic doses in two models of neuropathic pain, including chronic constriction injury and streptozocin-induced diabetes.[76] Similarly, brivaracetam was found to be very efficacious in the harmaline-induced tremor model.[36]

Pharmacokinetics

To date, published clinical information is available only for brivaracetam. After single doses up to 1,400 mg and multiple doses up to 800 mg/day in healthy volunteers, brivaracetam is rapidly absorbed from the gastrointestinal tract, with a median time of peak concentration at 1 hour.[99] Plasma drug levels increase proportionally with dose.[131] Concomitant intake of food does not affect extent of exposure, but the rate of absorption is lower and peak concentrations are reduced by about 30%.

The half-life of brivaracetam in healthy volunteers is in the range of 6 to 11 hours (average 7.7 hours).[99] Only a minor fraction of the apparent oral clearance (CL/F) of brivaracetam is accounted for by renal clearance of unchanged drug.[131] Identified urinary metabolites include 2-(2-oxo-4-propylpyrrolidin-1yl)butyric acid and 2-(2-oxo-4-propylpyr-rolidin-1yl)-4-hydroxybutanamide.[99]

Efficacy and Adverse Effects

In a Phase II study in 19 photosensitive epilepsy patients, single oral doses of brivaracetam ranging from 10 to 80 mg were effective in reducing the photoparoxysmal electroencephalographic response, which was abolished in 78% of patients.[63a,99] The 80 mg dose was most effective in terms of time to reach the maximal response and duration of response. Median time to maximal response for all doses was 0.5 hours and median duration of effect was about 28 hours after 10, 20, or 40 mg, and 59.5 hours after 80 mg.

In healthy volunteers given single doses up to 800 mg/day and multiple doses up to 800 mg/day, adverse events were usually dose-related and included dizziness, somnolence, headache, nausea, and euphoric mood.[99] In the photosensitivity study, the adverse effect profile was similar to that reported in healthy volunteers.

Eslicarbazepine Acetate (S-Licarbazepine Acetate, BIA 2-093)

Structure and Chemistry

Eslicarbazepine acetate (S-licarbazepine acetate, BIA 2-093), *S*-(-)-10-acetoxy-10,11-dihydro-5H-dibenzo/b,f/azepine-5-car-boxamide, is structurally related to carbamazepine and oxcarbazepine in that it shares the dibenzazepine nucleus[53] (Fig. 2). In this respect, eslicarbazepine acetate was designed by BIAL, Portugal, to be a potentially improved alternative to carbamazepine and oxcarbazepine. However, as shown in FIGURE 2, it is important to note that oxcarbazepine is metabolized to (*S*)-licarbazepine (eslicarbazepine) and (*R*)-licarbazepine in a 4:1 ratio. Thus, the only difference between oxcarbazepine and eslicarbazine acetate is that eslicarbazepine acetate is only metabolized to the (*S*)-enantiomer with minor chiral conversion to the (*R*)-enantiomer, whereas oxcarbazepine is converted to both the (*S*)- and (*R*)-enantiomers.[a] Given that there is no evidence to suggest that the (*R*)-enantiomer is more toxic than the (*S*)-enantiomer or that it interferes with the efficacy of the (*S*)-enantiomer, it is not likely that eslicarbazepine acetate will provide any major advantage over oxcarbazepine. In fact, in the MES test, the less potent (*R*)-enantiomer displays an equivalent, if not more favorable protective index (i.e., the ratio of the median toxic dose in the rotorod test to the median MES efficacious dose) than the (*S*)-enantiomer.[15]

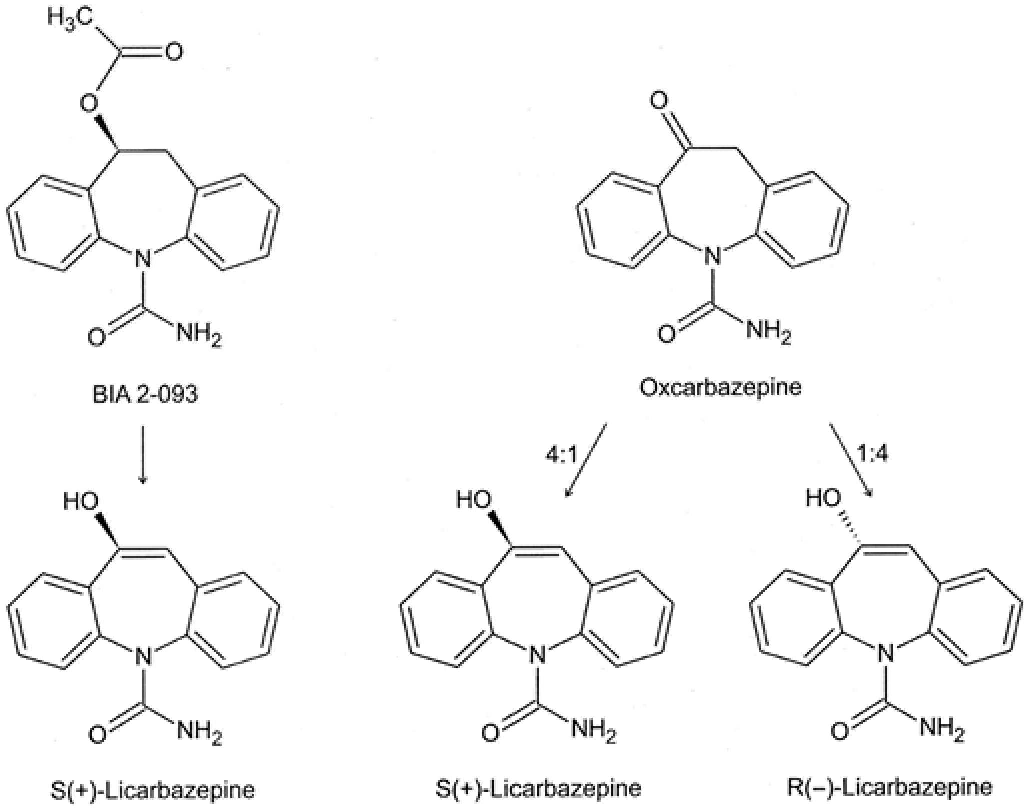

FIGURE 2. Structure of eslicarbazepine acetate (BIA 2-093) and ox-carbazepine. Eslicarbazepine is rap-idly metabolized to its active meta bolite *S*(+)-licarbazepine. Oxcarbazepine is also converted to its mono-hydroxy derivatives *S*(+)-licar-bazepine and *R*(−)-licarbazepine in a 4:1 ratio. (Modified from Rogawski MA. Diverse mechanisms of antiep-ileptic drugs in the development pipeline. Epilepsy Res. 2006;69(3):273–294, with permission.)

Pharmacology

Eslicarbazepine acetate behaves very much like carbamazepine and oxcarbazepine in animal seizure and epilepsy models.

P.1723

It is effective against tonic extension seizures induced by MES and focal seizures in the amygdala-kindled rat model of partial epilepsy.[15] Like carbamazepine and oxcarbazepine, eslicarbazepine is mostly inactive against clonic seizures induced by PTZ. This activity profile would predict efficacy in humans against generalized tonic–clonic seizures and partial seizures, respectively.[168] In these models, eslicarbazepine acetate is equipotent to carbamazepine and more potent than oxcarbazepine.

Mechanistically, eslicarbazepine displays a voltage-depen-dent block of voltage-dependent Na currents.[21] In a manner similar to other voltage-sensitive Na channel blockers, eslicarbazepine inhibits Na-dependent neurotransmitter release at concentrations similar to those observed for carba-mazepine and oxcarbazepine.[6,116]

Pharmacokinetics

After oral administration of single and multiple doses, unchanged eslicarbazepine acetate is generally undetectable (<10 ng/mL) in plasma.[4,5] Eslicarbazepine acetate is rapidly and extensively converted to (*S*)-licarbazepine, whose chemical structure corresponds to the *S*-enantiomer of 10-hydroxy-carbazepine, the active mono-hydroxy-metabolite of oxcarbazepine.[4,5,15,53] Chiral conversion of (*S*)-licarbazepine to (*R*)-licarbazepine is minor, and only about 5% of circulating licarbazepine is in the *R*-form[2,18]; by contrast, after administration of oxcarbazepine, the ratio between (*R*)- and (*S*)-licarbazepine in blood is on the order of 20% to 25%.[164]

Peak plasma concentrations of licarbazepine occur 0.75 to 4 hours after single oral doses of eslicarbazepine acetate ranging between 20 and 1,200 mg.[4] The bioavailability of licarbazepine, measured in terms of area under the curve (AUC), is about 16% greater than that observed after an equivalent molar dose of oxcarbazepine.[18] The pharmacokinetic profile of licarbazepine is not affected by coadministration of eslicarbazepine acetate with food.[98] Bioequivalence between a suspension and a tablet form has been demonstrated.[49]

During multiple doses ranging from 200 mg twice a day to 2,400 mg once daily, peak licarbazepine concentrations are usually observed 2 to 3 hours after each dose intake, and steady-state concentrations are reached within 4 to 5 days of once or twice daily administration.[5,162] The extent of systemic exposure to licarbazepine increases in an approximately dose-proportional manner after both single and multiple doses.

The half-life of licarbazepine has been estimated to be in the range of 8 to 17 hours after single doses and 9 to 13 hours after multiple dosing,[2,4,5] although an "effective" half-life of 17 to 24 hours has been inferred from the time taken to reach steady-state.[2,5] Licarbazepine is excreted in urine in free and conjugated form, with about 20% and 40% of the dose being recovered within 12 and 24 hours post-dose respectively.[3,4,5] Oxcarbazepine has been detected as a minor metabolite.[4]

In a study that compared the plasma levels of (*R*)- and (*S*)-licarbazepine after single (600 mg) and multiple doses (600 mg once daily for 8 days) in 12 young (mean age 30 years, range 18–38) and 12 elderly (mean age 70 years, range 65–80) healthy volunteers, no pharmacokinetic differences were identified between the two age groups.[2]

Drug Interactions

Because licarbazepine clearance in patients taking oxcarbazepine is known to be moderately increased by coadministration of enzyme-inducing AEDs,[106] it is reasonable to assume that a similar interaction may apply to licarbazepine derived from eslicarbazepine acetate.

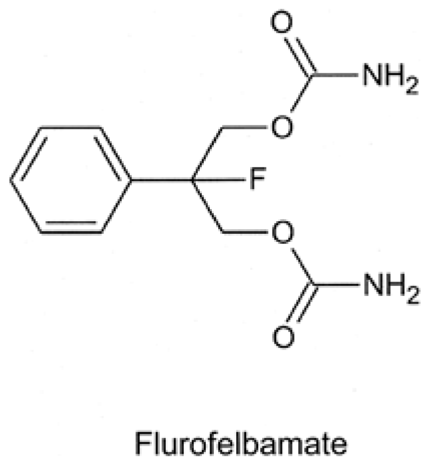

FIGURE 3. Structure of fluorofelbamate.

In healthy subjects, eslicarbazepine acetate at a dosage of 1,200 mg/day did not affect the pharmacokinetics of digoxin to a clinically significant extent.[97] Whether eslicarbazepine acetate shares with oxcarbazepine the ability to stimulate the metabolism of steroid oral contraceptives and other substrates has not been reported.

Clinical Efficacy

A multicenter double-blind, parallel-group, adjunctive-therapy study compared once daily and twice daily eslicarbazepine acetate (at escalating doses of 400, 800, and 1,200 mg/day, each for 4-week periods) with placebo in 143 patients with refractory partial seizures.[18,96] The proportion of responders (defined as patients showing at least 50% seizure reduction) during the 800- and 1,200-mg/day periods were significantly higher in the once-daily group than in the placebo group, and there were no statistically significant differences in responder rates between the once- and twice-daily group.

Adverse Effects

In healthy volunteers, single and multiple doses of eslicarbazepine acetate up to 1,200 mg and 1,200 mg/day, respectively were tolerated well.[3,5] In the adjunctive therapy trial, tolerability was rated as good or very good in 90% of patients in the once-daily group, 80% in the twice-daily group, and 83% in the placebo group.[18]

Fluorofelbamate

Structure and Chemistry

Fluorofelbamate (2-phenyl-2-fluoro-1,3 propanediol dicarbamate) is a felbamate analog designed to have the clinical efficacy of felbamate without its serious adverse effects (i.e., aplastic anemia and hepatic toxicity). Structurally, fluorofelbamate differs from felbamate in that it possesses a fluorine atom instead of a hydrogen at the 2-position of the propanediol moiety (Fig. 3). This substitution is thought to result in a more stable molecule and to prevent the production of atropaldehyde (ATPAL, or 2-phenylpropenal), the proposed toxic reactive metabolite of felbamate.[154] Fluorofelbamate is being developed by MedPointe Healthcare, Inc.

Pharmacology

Fluorofelbamate, like felbamate, is active against a variety of electrically and chemically induced seizures in animal models.[18] In addition to blocking tonic extension in the MES test, it also blocks clonic seizures induced by picrotoxin, and sound-induced seizures in the Frings mouse. Fluorofelbamate (100 and 200 mg/kg) is also quite effective in reducing the cumulative seizure duration in the perforant path model of self-sustaining status epilepticus (SE) when administered early. Slightly higher doses (i.e., 200 and 300 mg/kg) attenuated seizures in the self-sustaining status model when administered late and at a time when the status was refractory to treatment with conventional anticonvulsants.[107]

In addition to is anticonvulsant activity, fluorofelbamate has been reported to be neuroprotective in several models. For example, it decreases neuronal damage in an in vitro chemical model of ischemia (i.e., NaCN), protects against hypoxic CA1 hippocampal neuronal damage in an in vitro slice model, decreases the infarct volume in an in vivo rat pup model of hypoxia, and reduces CA1 damage associated with transient global ischemia in gerbils.[18,166]

Limited in vitro data are available regarding the mechanism of action of fluorofelbamate. Based on the electrophysiologic studies thus far reported, it would appear that fluorofelbamate is not a potent modulator of either inhibitory- or excitatory-mediated neurotransmission. It has been reported to produce a modest inhibition of kainate- and NMDA-mediated currents in mouse cortical neurons and to exert a modest inhibition of voltage-dependent Na currents in NIE-115 neuroblastoma cells.[18,129] It is not clear whether these modest effects are sufficient to account for its seemingly broad anticonvulsant and neuroprotective profile in animal models.

Pharmacokinetics

Based on evidence suggesting that a reactive metabolite, ATPAL, may be responsible for the toxicities observed during therapy with felbamate, Parker et al.[117] tested the hypothesis that fluorofelbamate would not be metabolized to ATPAL. They compared the metabolism by in vitro human liver postmitochondrial suspensions (S9) of selected felbamate and postulated fluorofelbamate metabolites and concluded that fluorofelbamate is not metabolized in vitro by S9 to ATPAL.

In pharmacokinetic studies in rats and dogs, exposure increased proportionally with dose. In dogs, peak plasma concentrations were reached in 2 to 6 hours, and the terminal half-life was estimated at 6 to 9 hours.[18] No studies in humans have been reported to establish fluorofelbamate pharmacokinetics, interaction potential, efficacy, or adverse-effect profiles.

Ganaxolone (CCD 1042)

Structure and Chemistry

Ganaxolone, 3α-hydroxy-3β-methyl-5 α-pregnan-20-one, is the 3β-methyl analog of the endogenous steroid allopregnanolone and is a potent positive modulator of $GABA_A$ receptors. It is currently under development by Marinus Pharmaceuticals (Fig. 4).

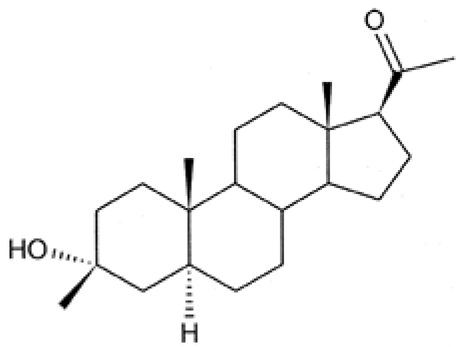

FIGURE 4. Structure of ganaxolone.

Pharmacology

In seizure and epilepsy models, ganaxolone is effective against clonic seizures induced by PTZ and bicuculline.[25] At nontoxic

P.1725

doses, ganaxolone is less active against tonic extension seizures induced by MES. It is also active against seizures induced by aminophylline, τ-butyl-bicyclo-phosphorothionate, and fluorothyl (see Perucca and Kupferberg[120a], for review and references). Ganaxolone has also shown activity in the 6-Hz model of pharmacoresistent partial epilepsy,[61] is active in acute SE models,[70] and demonstrated efficacy against partial seizures in the corneal- and amygdala-kindled rat models.[25,126] In contrast to the benzodiazepines, the anticonvulsant activity of ganaxolone in animal models is not diminished with chronic treatment.

Ganaxolone is a potent positive modulator of $GABA_A$-evoked currents. It is active at $GABA_A$ receptors containing most αsubunits, including α1, α2, α3, α4, and α6. Unlike the benzodiazepines, the activity of most neurosteroids at the $GABA_A$ receptor is not dependent on the presence of a γ2 subunit.[25] Interestingly, GABA receptors containing a δ-subunit are particularly sensitive to modulation by neurosteroids.[129,169] Because of their presynaptic and extrasynaptic localization,[43,113] δ-subunits containing $GABA_A$ receptors are ideally suited to mediate tonic currents and may represent an important molecular target for ganaxolone and other potential neurosteroids.[129]

Pharmacokinetics

Seven different studies in normal volunteers were performed examining the pharmacokinetics of ganaxolone after single (50 to 1,500 mg) and multiple dose regimens (≤300 b.i.d. for 10 days or 500 mg once daily for 2 weeks).[110] Because ganaxolone is highly insoluble in aqueous media, it has been formulated as a solution complexed with ß-cyclodextrin or 2-hydroxypropyl-ß-cyclodextrin to enhance bioavailability.

After oral dosing, ganaxolone is absorbed rapidly, and peak plasma levels are generally attained within 3 hours. Absorption is followed by a biphasic elimination phase, with a rapid decline in plasma concentration over the first 12 hours and a subsequent slower decline characterized by a terminal half-life of 37 to 70 hours.[110] Plasma concentrations after multiple doses are similar in shape to those observed after single doses, with a sharp decrease in plasma levels over the first 12 hours. Accumulation is limited, as indicated by a lack of increasing trough levels during repeated dosing. The pharmacokinetics of ganaxolone appear to be linear, with mean peak plasma levels at steady state ranging from 32 ng/mL at 50 mg once daily to 376 ng/mL at 500 mg once daily.

Drug Interactions

In children aged 7 months to 7 years with infantile spasms, no consistent changes in the serum levels of concomitant AEDs with administration of ganaxolone were observed.[66]

Clinical Efficacy

A double-blind, randomized, placebo-controlled trial to examine the safety, tolerability, and antiepileptic activity of ganaxolone after withdrawal from other AEDs during presurgical evaluations was performed in 52 patients who were randomized to receive ganaxolone (24 patients) or placebo (28 patients) for up to 8 days.[78] Ganaxolone was administered at a dose of 1,500 mg/day on day 1 and 1,875 mg/day on days 2 to 8. Dosing occurred three times per day. The primary endpoint was time to withdrawal from the trial. Intent-to-treat survival analyses revealed a trend toward efficacy with ganaxolone ($p = 0.0795$, log rank test). Kaplan-Meier curves depicted a clear separation between treatment groups, with 50% of the ganaxolone-treated patients completing the entire study, compared with 25% of patients treated with placebo. Covariate analyses revealed a significant treatment effect on survival time in men ($p = 0.03$). Post-hoc analyses focusing on patients who completed the entire study revealed a significant difference ($p = 0.04$) between treatment groups. A clear relationship between trough serum concentrations and efficacy was not evident.

A multicenter, open-label, add-on trial investigated the safety and efficacy of ganaxolone in 20 children (age 7 months to 7 years) with refractory infantile spasms, or with continuous seizures after a prior history of infantile spasms.[66] The dose of ganaxolone was increased to 36 mg/kg per day (or to the maximally tolerated dose) over 4 weeks, then maintained for 8 weeks before tapering off. The frequency of spasms was reduced by at least 50% in 33% of the subjects with spasms, with an additional 33% experiencing some improvement (25%–50% reduction in spasms frequency). In these subjects with highly variable sampling times, a ganaxolone concentration-response curve could not be established.

Adverse Effects

In normal volunteers, ganaxolone was well tolerated after single doses (≤1,500 mg) and multiple doses (≤300 mg b.i.d. for 10 days).[110] No serious or life-threatening adverse events attributed to the drug were observed. The majority of adverse events were mild (82%) to moderate (14%) and were limited to headache, dizziness, somnolence, gastrointestinal disturbances, and malaise. There was no apparent effect on electrocardiogram (ECG) or vital signs.

In the presurgical study of Laxer et al.,[78] 47 adverse events were reported in the ganaxolone group and 38 in the placebo group. Central nervous system (CNS) adverse effects occurred in both groups, with dizziness being the most common complaint. Two serious adverse events occurred; one patient receiving ganaxolone experienced agitation and depression on the first day of treatment, and one patient receiving placebo experienced postictal psychosis.

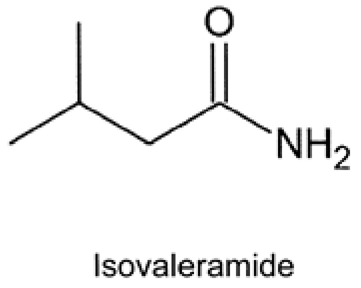

FIGURE 5. Structure of isovaleramide.

In the infantile spasms study, the most common adverse events thought to be possibly, probably, or definitely related to ganaxolone were somnolence, diarrhea, nervousness, and vomiting.[66] In another open-label pediatric study in 15 children aged 5 to 15 years treated with doses up to 12 mg/kg three times a day, adverse events included somnolence, sleep disturbances,

P.1726

nervousness, constipation, change in seizure types and, in one case, disturbed behavior and cognition.[79]

Isovaleramide (NPS 1776)

Structure and Chemistry

Isovaleramide (NPS 1776), 3-methylbutanamide, is a low-molecular-weight, branched-chain amide that displays a broad-spectrum of activity in animal models (Fig. 5). It is being developed by NPS Pharmaceuticals.

Pharmacology

In animal seizure and epilepsy models, NPS 1776 possesses an anticonvulsant profile similar to that of valproate (VPA). It is orally active against tonic extension seizures in the MES test and clonic seizures induced by PTZ, bicuculline, and picrotoxin. Furthermore, it is effective in reducing the behavioral seizure score in both the corneal- and amygdala-kindled rat models of partial epilepsy, and it reduces the afterdischarge duration in the amygdala-kindled rat. Daily dosing with NPS 1776 has also been found to delay the acquisition of kindling in the amygdala-kindled rat, thereby suggesting that this compound, like VPA, may exhibit antiepileptogenic effects. NPS 1776 is also effective in two genetic seizure models (i.e., the Frings audiogenic seizure susceptible mouse and the Wistar rat). In the Wistar rat, NPS 1776 was found to reduce the spontaneous electrographic spike-and-wave discharges. In a chronic dosing study in the Frings audiogenic seizure-susceptible mouse, no sign of tolerance was observed following daily dosing with NPS 1776 for 28 days. Overall, the preclinical anticonvulsant profile of NPS 1776 suggests that it will have broad-spectrum efficacy against partial and generalized seizures.[16,18,167] In addition to its anticonvulsant action, NPS 1776 has been found to possess antispastic, analgesic, and anxiolytic activity.[18]

To date, the mechanism of action of NPS 1776 has not been elucidated. It is inactive in in vitro binding and uptake assays against a number of receptor- and voltage-active ion channels at a concentration of 1,000 μM, suggesting that it does not exert an action through a direct interaction at the sites studied.[18]

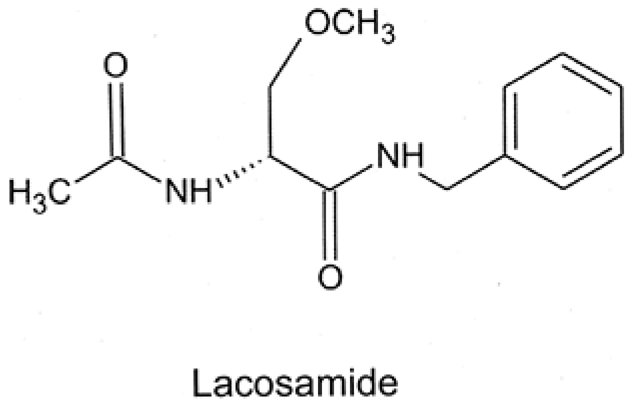

FIGURE 6. Structure of lacosamide.

Pharmacokinetics

After single and multiple doses up to 1,600 mg and 2,400 mg/day, respectively in healthy volunteers, isovaleramide is rapidly absorbed from the gastrointestinal tract.[18] The increase in systemic exposure with increasing dose is slightly more than dose-proportional after single doses, but no major deviations from linearity were observed after multiple dosing.

Isovaleramide is negligibly bound to plasma proteins and is rapidly eliminated with a half-life of 2 to 4 hours. Less than 4% of an orally administered dose is excreted unchanged in urine, and elimination is primarily metabolic. A sustained-release formulation is under development.[18]

Drug Interactions

In vitro, isovaleramide does not inhibit any of the major CYP isoenzymes.[18]

Efficacy and Tolerability

Isovaleramide has shown excellent tolerability in Phase I studies in healthy volunteers. Clinical studies have been initiated to assess its potential value in the treatment of epilepsy and in the acute treatment of migraine, but no results have been reported to date.[18]

Lacosamide (Harkoseride, SPM 927)

Structure and Chemistry

Lacosamide, also formerly known as harkoseride and SPM927, is the *R*-enantiomer of 2-acetamido-*N*-benzyl-3-methoxy-propionamide. It is currently under development by Schwarz BioSciences for the treatment of partial epilepsy and neuropathic pain (Fig. 6).

Pharmacology

Lacosamide displays broad-spectrum anticonvulsant activity in rodent models of generalized and partial epilepsy.[18,148] It is effective against audiogenic seizures in Frings mice and is a potent blocker of MES-induced tonic extension seizures in mice and rats. Lacosamide is less effective against clonic seizures induced by PTZ, but it is quite potent against limbic seizures in the 6-Hz psychomotor seizure model of pharmacoresistant epilepsy.[40] Lacosamide is also very effective in blocking both the behavioral seizure and afterdischarge duration in the hippocampal-kindled rat model of partial epilepsy. Last, lacosamide is effective in reducing the cumulative seizure duration in the perforant path model of self-sustaining SE. In addition to its effects in seizure and epilepsy models, lacosamide has demonstrated

an ability to attenuate the acquisition of amygdala kindling and displays in vitro and in vivo neuroprotective properties. For example, lacosamide has been shown to delay the development of amygdala kindling at doses of 10 and 30 mg/kg.[23] Furthermore, it decreased the infarct volume in the rat middle cerebral artery occlusion (MCAO) model of ischemia when administered 15 minutes before MCAO and for 4 hours postinfusion.[122] In contrast, lacosamide was ineffective in preventing brain damage or functional deficits in a rat model of traumatic brain injury.[122] In organotypic rat hippocampal slice cultures, lacosamide produced a concentration-dependent block of glutamate- and oxygen-glucose deprivation–induced apoptosis. These latter effects might suggest that lacosamide possesses a disease-modifying effect; however, additional studies are required to fully evaluate this potential attribute.

Lacosamide is effective in various animal models of chronic pain.[149] For example, it is active in the formalin, carrageenan model, and the adjuvant-induced arthritis models of chronic pain. The results from these studies support the ongoing clinical investigations in the treatment of pain associated with diabetic neuropathy.

From a mechanistic perspective, more can be said about what lacosamide does not do at the cellular level than what it does do. To date, little is known about the molecular mechanism underlying its broad-spectrum anticonvulsant profile.[129] Lacosamide does not directly interact with GABAergic or glutamatergic neurotransmission. It does not block sustained repetitive firing or voltage-dependent Na currents. Furthermore, it does not enhance K currents or attenuate Ca currents. Lacosamide does appear to block slow but not fast depolarization-induced action potential firing in cultured cortical neurons. Like carbamazepine, lacosamide is effective in the 4-amino-pyridine (4-AP) model of epileptiform bursting, and its activity in this model, unlike that of carbamazepine, is completely reversible.[80] The results obtained to date suggest that lacosamide has a potentially unique mechanism of action relative to a majority of the available AEDs.

Pharmacokinetics

Lacosamide is efficiently absorbed from the gastrointestinal tract, with peak plasma concentrations being achieved within 1 to 5 hours of dosing.[18,75] Oral bioavailability is virtually complete, as documented by the observation that plasma lacosamide levels after the administration of the same dose using either oral tablets or 30- or 60-minute intravenous infusions meet criteria for bioequivalence.[75,132] Concomitant intake of food has no effect on the rate or extent of lacosamide absorption,[27] and plasma concentrations are linearly related to dose over the 100- to 800-mg dose range.[132]

Lacosamide is negligibly (<10%) bound to plasma proteins.[18] The half-life is on the order of 12 to 16 hours, and elimination occurs partly by renal excretion in unchanged form and partly by biotransformation. About 40% of an orally administered dose is recovered unchanged in urine, and another 30% is recovered in the form of the inactive *O*-dimethyl-metabolite SPM 12809.[18,75,140] In a study designed to assess the potential role of CYP2C19 on lacosamide disposition, plasma lacosamide levels after oral and intravenous administration were similar in eight extensive metabolizers and three poor metabolizers for CYP2C19. However, the plasma levels of the *O*-demethyl-metabolite were markedly reduced in the poor metabolizers, suggesting that CYP2C19 contributes to lacosamide demethylation.[74]

After normalization for dose and differences in body weight, plasma lacosamide concentrations do not differ significantly between males and females. In a multiple-dose study, plasma lacosamide concentrations at steady-state in 23 elderly subjects (≥65 years, age range not stated) were about 10% to 35% higher than those observed in a similar cohort of subjects aged 18 to 45 years.[140]

Drug Interactions

In studies conducted in healthy volunteers, lacosamide pharmacokinetics were not affected by coadministration of carbamazepine 400 mg/day or valproic acid 600 mg/day.[74]

In vitro, lacosamide shows no potential to inhibit CYP1A2, CYP2A6, CYP2C9, CYP2D6, CY2E1, and CYP3A4 in human hepatocytes.[74] In studies with human recombinant CYPs, lacosamide inhibits CYP2C19, but the median inhibitory concentration (0.45 mg/mL) is greater than the anticipated human therapeutic plasma levels. Lacosamide does not induce CYP1A2 and CYP3A4 activity in human hepatocytes.

In healthy volunteers, lacosamide (400 mg/day) has been found not to affect the pharmacokinetics of carbamazepine, valproic acid, metformin, digoxin, ethinylestradiol, and levo-norgestrel. Likewise, clinical trials in patients receiving adjunctive treatment with lacosamide at dosages up to 600 mg/day did not identify any change in serum levels of carbamazepine, carbamazepine-10,11-epoxide, phenytoin, valproic acid, lamotrigine, mono-hydroxy-carbazepine, topiramate, zonisamide, levetiracetam, and gabapentin.[18,59,74]

Clinical Efficacy

Studies in Epilepsy

A multicenter, double-blind, randomized, parallel-group, placebo-controlled trial assessed lacosamide (200, 400, and 600 mg/day in two divided doses) as adjunctive therapy in 418 patients with refractory partial-onset seizures.[14,59] Lacosamide was titrated to target dose in 100 mg/day increments at 1-week intervals, followed by a 12-week maintenance phase. In the full analysis (ITT) data set, median reduction in seizure frequency (maintenance vs. baseline) was 10% on placebo, 26% at 200 mg/day, 39% at 400 mg/day, and 40% at 600 mg/day. Responder rates (proportion of patients with at least 50% seizure reduction) was 22% on placebo and 33%, 41%, and 38% at 200, 400, and 600 mg/day, respectively. Response rates at the 400- and 600-mg dose were statistically superior to placebo. The proportion of patients completing the maintenance period without major protocol deviations was 78%, 74%, and 60% in the 200, 400, and 600 mg/day groups, respectively, compared with 88% in the placebo group.[59] Follow-up observations in patients who continued open-label lacosamide after completion of the double-blind phase suggest that efficacy is maintained during long-term treatment.[35]

Studies in Neuropathic Pain

Lacosamide has been investigated in two multicenter, double-blind, randomized, parallel-group, placebo-controlled trials in patients with neuropathic pain attributed to distal diabetic neuropathy. One trial explored dosages of 200, 400, and 600 mg/day in a total of 370 patients,[170] while the second trial assessed 400 and 600 mg/day in 357 patients.[174] The study design involved gradual titration to the target dose and a 12-week maintenance period. In both studies, the best response was in the 400 mg/day dose groups. In one of the trials, the reduction in pain score in the 400-mg group was statistically significant compared with placebo,[170] while in the other the difference compared with placebo during the last 4 weeks of treatment failed to reach statistical significance.[174] Administration of a

P.1728

600 mg/day dose did not appear to confer additional benefit in reducing pain scores, and was less tolerated.

Adverse Effects

In the adjunctive-therapy placebo-controlled trial in patients with partial onset seizures, the most commonly observed adverse events were dizziness, headache, fatigue, ataxia, gastrointestinal disturbances (nausea, vomiting), and visual disturbances (blurred vision, diplopia, and nystagmus), most of which were dose-related.[14] The most common of all events was dizziness, which was reported by 24%, 26%, and 55% of patients at 200, 400, and 600 mg/day, respectively, compared with 10% on placebo. The proportion of patients withdrawing due to adverse events was 5% on placebo, 11% at 200 mg/day, 19% at 400 mg/day, and 30% at 600 mg/day. Remarkably, there were little differences in proportion of patients reporting somnolence between the placebo and any lacosamide dose group.

A formulation of lacosamide for intravenous use is being developed to allow replacement therapy for patients temporarily unable to continue oral therapy. In healthy volunteers, adverse events after infusion of 200 mg lacosamide over periods of 15, 30, and 60 minutes were similar to those observed after intake of a 200-mg tablet.[75] Likewise, adverse events associated with 30- to 60-minute infusions (up to 300 mg b.i.d. for two days) given as replacement treatment in patients with epilepsy stabilized on oral lacosamide were comparable to those observed after oral dosing.[18,132]

Studies in Neuropathic Pain

In the first trial conducted in patients with neuropathic pain, the proportion of patients discontinuing treatment due to adverse events was 8.6%, 23.1%, and 39.8% in the placebo, 200, 400, and 600 mg/day groups, respectively.[170] In the second trial, discontinuation rates were 11.3% and 23.3% at 400 and 600 mg/day, respectively, compared with 5.4% on placebo.[174] In both trials, lacosamide was generally well tolerated, with similar rates of adverse events in the placebo and active treatment groups at doses up to 400 mg/day. In the 600 mg/day group, the incidence of dizziness (29.0% in the first study and 19.5% in the second study) was considerably higher than in the other groups.

Losigamone

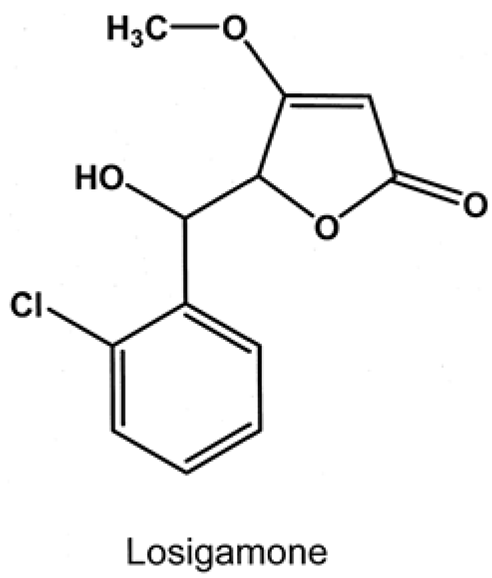

FIGURE 7. Structure of losigamone.

Structure and Chemistry

Losigamone, threo ±5(*S,R*)-5-[(2-chlorophenyl)hydroxyl-methyl)]-4-methoxy(5H)-furanone, is a racemic mixture that was synthesized at the Willmar Schwabe Company in Karlsruhe, Germany (Fig. 7).

Pharmacology

In most pharmacologic studies conducted to date, the *S*(+)-enantiomer of losigamone is more potent than the *R*(-)-enantiomer.[173] In animals, losigamone is active in blocking tonic hind limb extension induced by a number of stimuli including MES, PTZ, bicuculline, nicotine, and 4-aminopyridine but not strychnine or picrotoxin.[146] It is also effective against clonic seizures induced by PTZ, bicuculline, and picrotoxin.[146] In addition, losigamone has been shown to inhibit audiogenic seizures in rats and gerbils and to attenuate behavioral seizures in the PTZ-kindled mouse.[120]

Like many of the AEDs, the precise mechanism of action of losigamone has yet to be established. In the in vitro hippocampal slice preparation, losigamone has been demonstrated to reduce the frequency and amplitude of picrotoxin-, low Ca^{2+}/low magnesium (Mg^{2+}), and low Ca^{2+}/low Mg^{2+}/high K^{+}-induced seizure-like events in a concentration-dependent manner.[68,69,81,146] At higher concentrations, losigamone has been found to decrease the late recurrent epileptiform discharges in area CA1 and CA3 of the hippocampus and the ictiform events in the entorhinal cortex that develop following prolonged exposure to low-Mg^{2+} containing buffer.[173] Losigamone has also been shown to decrease depolarization-induced repetitive spike firing and stimulus-induced excitatory postsynaptic potentials in the entorhinal cortex slice preparation[141] and 4-aminopyridine-induced epileptiform activity in rat hippocampal slice preparation.[172] Losigamone does not appear to modify either fast or slow inhibitory postsynaptic potentials.[141]

At the cellular and molecular level, it is not clear how losigamone is exerting its effects in the in vitro slice studies that have been conducted to date. Losigamone has been shown to enhance GABA-mediated chloride (Cl) flux in vitro. For example, in the absence of exogenously applied GABA, losigamone increased Cl flux in cultured spinal cord neurons. In addition, it has been shown to enhance GABA-evoked Cl flux. These two effects of losigamone were both blocked by the Cl channel blocker picrotoxin and the $GABA_A$ receptor antagonist bicuculline. Interestingly, results from radio-ligand binding studies suggest that losigamone is not directly interacting with either the benzodiazepine or GABA receptor binding site (see Stein[70] for review and references). In addition, losigamone has been reported to decrease depolarizations induced by the glutamate agonist NMDA, but not those induced by AMPA.[144] In a separate study, *S*(+) losigamone, but not *R*(-) losigamone has been found to decrease both K- and veratridine-evoked glutamate and aspartate release from cortical slices.[60] Collectively, the results of these two latter studies suggest that losigamone may be exerting some of its anticonvulsant effects by modulating glutamate release.

Losigamone has been reported to decrease spontaneous synaptic activity in cultured hippocampal neurons and sustained repetitive firing evoked by somatic current injection.[39] In contrast to classical Na channel blockers, losigamone does not affect the fast transient Na current but instead inhibits the

P.1729

persistent Na current in hippocampal neurons.[51] This is particularly interesting given that the persistent Na current has been implicated in the fine control of neuronal excitability. For example, it has been suggested that the persistent Na current can contribute to subthreshold oscillations that can determine the behavior of neuronal networks in a number of brain structures, including the neocortex and entorhinal cortex.[159] Through its action on the persistent Na current, losigamone may be acting to "fine tune" neuronal excitability, thereby reducing hyperexcitability without the adverse effects associated with those drugs that inhibit fast Na channels (see Errington et al.[41a] for further discussion and references).

Pharmacokinetics

After single oral doses up to 700 mg and multiple doses up to 600 mg three times a day, losigamone displays linear pharmacokinetics.[19,120] The compound is rapidly absorbed from the gastrointestinal tract, is approximately 50% bound to plasma proteins, and is eliminated primarily by oxidation and conjugation.[118,156,165] CYP2A6 appears to be a major enzyme involved in losigamone metabolism.[67,156]

The mean CL/F of losigamone racemate after single oral doses in healthy volunteers is on the order of 300 to 400 mL/min. There are, however, important pharmacokinetic differences between enantiomers, due to stereoselectivity in drug metabolism: In particular, CL/F values of the (*R*–)-enantiomer are more than 10-fold greater than those of the *S*(+)-enantiomer, and the *R*(–)-enantiomer also shows more extensive first-pass metabolism after oral dosing.[118,120,156] The half-lives of the *R*(–)- and *S*(+)-enantiomer are on the order of 2.2 and 4.8 hours respectively.

Drug Interactions

In studies using nonenantioselective assays, losigamone CL/F values in patients taking enzyme-inducing AEDs such as carbamazepine and phenytoin have been on the order of 500 to 600 mL/minute, which are higher than those observed in healthy volunteers. Patients taking enzyme-inducing AEDs also show relatively shorter losigamone half-lives (about 3.8 hours) and steady-state plasma losigamone levels which are about one-third lower than in patients not taking enzyme inducers.[71] Valproic acid and lamotrigine do not affect losigamone pharmacokinetics to an important extent.[37,72]

Losigamone does not appear to have enzyme-inducing properties[19]; does not affect the serum concentration of phenyt-oin, carbamazepine, carbamazepine-10,11-epoxide, and lam-otrigine[71,120,137]; and does not influence significantly the pharmacokinetics of a combined steroid oral contraceptive.[38] Losigamone may, however, reduce slightly the serum concentration of valproic acid.[72,73]

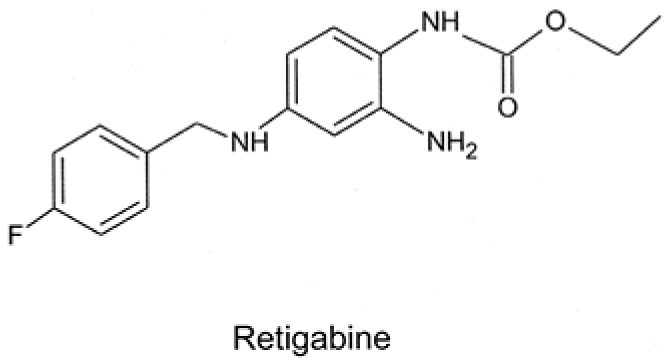

FIGURE 8. Structure of retigabine.

Clinical Efficacy

A first double-blind, multicenter, placebo-controlled study explored the potential efficacy of losigamone (500 mg t.i.d) in 203 patients with partial seizures.[11] Median percent reduction in seizure frequency was 15% in the losigamone group compared with 7% in the placebo group ($p = 0.004$); however, there were no statistically significant differences in the proportion of patients achieving at least 50% seizure reduction (losigamone, 22% vs. placebo, 15%). In a second trial using a similar design, 264 patients with refractory partial seizures were randomized to receive adjunctive treatment with placebo, losigamone 400 mg three times a day, or losigamone 500 mg three times a day for 12 weeks.[12] Median reduction in partial seizure frequency was 3% for placebo, 20% for losigamone 1,200 mg/day, and 25% for losigamone 1,500 mg/day, with the difference in both active treatment groups being significant ($p < 0.01$) in comparison with placebo. Responder rates were 12% for placebo versus 17% and 29% for the 1,200 mg/day and 1,500 mg/day groups respectively, the difference being significant ($p = 0.004$) for the higher dose group. The authors concluded “that it might be promising to study higher dosages in the future and that the potential of the drug has not yet been entirely explored.” In addition to the adjunctive therapy studies summarized here, some evidence for losigamone efficacy against partial seizures has been provided in a short presurgical monotherapy trial.[145]

Adverse Effects

In the first double-blind trial, adverse events were reported in 60% of patients in the losigamone group compared with 38% on placebo.[11] In the second trial, corresponding proportions were 59% on placebo, 66% on losigamone 1,200 mg/day, and 76% on losigamone 1,500 mg/day.[12] Adverse effects most commonly reported with losigamone include dizziness, sedation, fatigue, visual disturbances, vertigo, ataxia, and anorexia. The majority of these typically occur in less than 15% of patients, and the suggestion has been made that they might be reduced by slow dose titration.[12] An increase in serum cholesterol, γ-glutamyltransferase, and other liver enzymes has been described, but the clinical significance of these findings is uncertain.[12,120]

Retigabine (D23129)

Structure and Chemistry

Retigabine, *N*-[2-amino-4-(-4-fluorobenzylamino)-phenyl]car-bamic acid ethyl ester, is a structurally novel AED in devel-opment by Valeant Pharmaceuticals, Costa Mesa, CA (Fig. 8).

Pharmacology

Retigabine is truly a broad-spectrum AED in animal models.[133] It is effective against electrical (MES), chemical (PTZ, picrotoxin, penicillin, kainate, intracerebroventricular administered NMDA), and genetic (genetically epilepsy-prone rats and audiogenic seizure–susceptible mice) seizures (see Perucca and Kupferberg[120a] for review and references). Similarly, retigabine is effective in blocking the fully expressed behavioral seizure

and decreasing the duration of electrographic afterdischarge in the fully kindled rat.[155]

Retigabine has been found to prevent the acquisition of kindling in the amygdala-kindled rat and to enhance learning performance in a model of cerebral ischemia.[18] It is also effective in two models of neuropathic pain, suggesting that it may find utility for this additional indication.

From a mechanistic perspective, retigabine is quite novel. In the late 1990s, retigabine was found to be a "potassium channel opener" in cultured neurons.[134] Subsequent, the compound was found to specifically interact with a particular K current—the M-current, which is carried by the K-channel, voltage-gated, KQT-like subfamily (KCNQ) (see Bialer et al.[18] and Rogawski[129] for review and references). The M-current is a slowly activating current which, when activated, enhances membrane stabilization.[136] Retigabine is thought to reduce excitability by shifting the activation of the KCNQ current to more hyperpolarized potentials and to slow the deactivation and increase the activation phase.[151,152] This effect is of particular interest in that mutations in $KCNQ_{2/3}$ genes have been associated with benign familial convulsions (BFNC), an autosomal dominant epilepsy of childhood.[20,143] By enhancing M-currents, retigabine decreases neuronal excitability by inhibiting spike-frequency adaptation.[115]

In addition to enhancing M-currents, retigabine has also been found to increase GABA-mediated currents at concentrations that are only slightly higher than those that enhance M-currents.[114,135] Retigabine increases GABA-mediated currents through a nonbenzodiazepine-mediated action because its effect is not blocked by the benzodiazepine receptor antagonist flumazenil.[135]

Given the broad-spectrum anticonvulsant profile of retigabine, it is conceivable that both mechanisms contribute to its efficacy in in vitro and in vivo seizure and epilepsy models.

Pharmacokinetics

After oral intake of immediate-release formulations, the absolute bioavailability of retigabine is about 60%.[56] Retigabine pharmacokinetics are characterized by rapid absorption, moderate CL/F (0.6–0.7 L/kg), high apparent volume of distribution (6.2 L/kg), moderate plasma protein binding (about 80%), and a half-life of 5 to 9 hours.[46] In healthy subjects, the pharmacokinetics of retigabine are linear and dose proportional for doses of 100 to 700 mg, and steady-state pharmacokinetics after twice daily administration are in agreement with single-dose pharmacokinetics.[46] Food does not alter significantly the pharmacokinetics of retigabine.[17] In black subjects, retigabine CL/F and volume of distribution were 25% and 30% lower, respectively, after normalizing by body weight, leading to higher exposure in this population.[46] In a study exploring the influence of gender and age on retigabine CL/F, there were no substantial sex-related differences in the disposition of retigabine, but there was a relevant decrease in CL/F, resulting in higher exposure, in elderly patients, believed by the authors to be related at least in part to decline of renal function with age.[55] In patients with epilepsy, dose linearity of retigabine could be demonstrated up to 1,200 mg/day.[17]

Retigabine is cleared by nonoxidative metabolism and, to a lesser extent, by renal excretion in unchanged form.[17] Plasma profiling and spectroscopic analysis of two isolated urinary metabolites obtained after single oral dosing of 600 mg retigabine in healthy volunteers indicated that both acetylation and glucuronidation are major metabolic pathways in humans.[54] Two distinct inactive *N*-glucuronides have been identified as the primary metabolites.[108] Another metabolite, the *N*-acetyl derivative (AWD21-360), which is rapidly formed and cleared at the same rate as retigabine, is pharmacologically active,[17] and is found in serum at concentrations comparable to those of the parent drug.[56]

Of ten recombinant human uridin-glucuronosyl transferases (UGTs) evaluated, only 1A1, 1A3, 1A4, and 1A9 catalyzed the *N*-glucuronidation of retigabine. UGT 1A4 is considered the major isoenzyme responsible for the metabolism of retigabine in the liver and other organs.[57] It has been suggested that cleavage of the retigabine glucuronides in the gastrointestinal tract may lead to significant enterohepatic cycling.[57]

Drug Interactions

Retigabine does not appear to alter to any important extent the plasma levels of carbamazepine, phenytoin, valproic acid, phenobarbital, and topiramate.[45,48] In turn, retigabine pharmacokinetics are not altered by valproic acid or topiramate, whereas a moderate (about 30%) increase in retigabine CL/F is observed in patients receiving concomitant treatment with carbamazepine or phenytoin. This indicates that patients treated with carbamazepine and phenytoin may require higher dosages of retigabine to achieve a given retigabine concentration.[18]

Because both retigabine and lamotrigine undergo glucuronidation, a pharmacokinetic interaction study was performed.[56] Retigabine and lamotrigine exhibited a modest pharmacokinetic interaction on one another. A slight decline (13%) in retigabine CL/F after administration of a very low dose of lamotrigine (25 mg/day for 8 days) was believed to result from competition for renal elimination rather than competition for glucuronidation. An increase in lamotrigine CL/F by 22% due to retigabine (600 mg/day) was unexpected, because retigabine did not show enzyme induction in various other drug–drug interaction studies.[56]

Retigabine has been reported not to affect the pharmacokinetics of an oral contraceptive containing ethinylestradiol and levonorgestrel.[47]

Efficacy

Sachdeo et al.[138] performed an open-label dose-finding study of retigabine titrating 60 patients with epilepsy to a maximum dose of 1,200 mg/day in either a two or three times a day regimen. Median seizure rate was reduced by 21%, and 44% of patients had at least 50% reduction in seizure frequency.

Porter et al.[124] reported the results of a randomized controlled trial of retigabine in which 399 patients were randomized to daily doses of 600 mg, 900 mg, 1,200 mg, or placebo. Median monthly partial seizures decreased by 13% for placebo, 23% for 600 mg retigabine, 29% for 900 mg retigabine, and 35% for 1,200 mg retigabine. The 900 and 1,200 mg doses were significantly superior to placebo, and the 1,200 mg dose was significantly superior to 600 mg. Responder rates were 16% for placebo, 23% for 600 mg, 32% for 900 mg, and 33% for 1,200 mg; both the 900 mg and 1,200 mg doses were statistically superior to placebo.

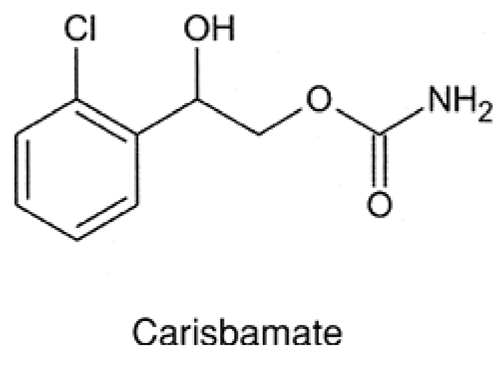

FIGURE 9. Structure of carisbamate.

Adverse Effects

In the open-label dose finding study, the most common adverse effects were dizziness, asthenia, somnolence, nausea, speech disorder, and tremor.[138] Dizziness and somnolence were the most common adverse effects that were dose limiting. Several different titration schedules were compared for 73 patients receiving retigabine in a randomized double-blind study.[1] A schedule of 150 mg increases every 7 days was associated with fewer discontinuations than increases every 2 or 4 days. The

most common adverse events were somnolence, speech disorder, ataxia, dizziness, and asthenia.

In the four-arm randomized controlled trial, the most common adverse events were somnolence, dizziness, confusion, speech disorder, vertigo, tremor, amnesia, abnormal thinking, convulsions, ataxia, abnormal gait, paresthesia, incoordination, and nervousness.[124] Most discontinuations associated with CNS-related symptoms occurred in the 1,200-mg retigabine group, suggesting that these adverse events may be dose related.

No clinically significant changes in laboratory parameters, ECG, Holter recordings, or vital signs were observed in any of the three large scale studies.[1,124,138]

Carisbamate

Structure and Chemistry

Carisbamate, 2-carbamoyloxy-1-2-chlorophenyl-ethanol, is a monocarbamate in clinical development by Johnson & Johnson Pharmaceutical Research & Development, Raritan, NJ (Fig. 9).

Pharmacology

Carisbamate is active in acute rodent seizure models including the MES, PTZ, bicuculline, and picrotoxin tests.[129] In addition, carisbamate is effective in the kindled rat model of partial epilepsy and the GAERS model of spike-and-wave seizures.[112] Carisbamate is effective against recurrent spontaneous seizures in the kainate post-SE model.[52] When tested several weeks post kainate treatment, carisbamate was found to be more efficacious than topiramate in this model, in that it rendered a larger fraction of rats seizure-free at a lower dose.

In addition to its acute anticonvulsant effects, carisbamate when administered at 1 and 8 hours, followed by twice daily dosing for 6 days after the onset of lithium-pilocarpine–induced SE, was reported to confer a neuroprotective and antiepileptogenic effect.[50] These results suggest that carisbamate may be disease-modifying in addition to being an anticonvulsant.

At present, nothing definitive can be said about the molecular actions of carisbamate that contribute to its broad-spectrum anticonvulsant profile and neuroprotective action.

Pharmacokinetics

The pharmacokinetics of carisbamate were evaluated after single doses (100 to 1,500 mg) and multiple doses (100–750 mg b.i.d.) in a total of 123 healthy volunteers. Carisbamate exhibited linear pharmacokinetics and was rapidly absorbed, with a peak concentration at 1.3 to 2.7 hours. The primary route of elimination appears to be metabolic,[171] with glucuronide conjugation being an important pathway.[30,31] The mean elimination half-life of carisbamate is in the range of 11.5 to 13.9 hours, mean CL/F values are in the range of 2.9 to 3.8 L/h,[30,31,171] and apparent volume of distribution after oral dosing (Vd/F) is on the order of 52 to 66 litres.[171]

Drug Interactions

Three separate studies were performed to evaluate the interaction between carisbamate and valproic acid, lamotri-gine, and carbamazepine.[30,31] Each of these studies enrolled 24 healthy volunteers. Carbamazepine treatment (600 mg/day) increased carisbamate CL/F by about 40%, and reduced its half-life from 10.4 to 7.4 hours on average.[30,31] Neither valproic acid (500 mg b.i.d) nor lamotrigine (50 mg b.i.d.) had substantial effects on the pharmacokinetics of carisbamate.[30,31] The pharmacokinetics of carbamazepine were not affected by carisbamate (500 mg b.i.d.).[30,31] Concomitant carisbamate (500 mg b.i.d) reduced valproic acid and lamotrigine exposure by approximately 20%, which was not considered to be of clinical significance.[30,31]

Efficacy

A small proof-of-principle study was undertaken in 13 patients with photosensitive epilepsy[63]. Ten of 13 showed some response to carisbamate at doses of 500, 750, and 1,000 mg based on photosensitivity score; three of the ten showed complete suppression of EEG photosensitivity. Reduction in photosensitivity was greatest after the 1,000 mg/day dose.

Adverse Effects

In the single-dose pharmacokinetic study in healthy subjects,[171] the most common adverse events were euphoria, hypoesthesia, dizziness, and paresthesia. These were rated mild to moderate in severity. The frequency of adverse events was greater in subjects receiving 1,000 mg and 1,500 mg than in those subjects receiving lower doses or placebo. In the multiple-dose pharmacokinetic study at doses up to 750 mg twice a day,[171] the most frequent adverse effects were somnolence, insomnia, euphoria, abnormal thinking, headache, hypoesthesia, dizziness, asthenia, malaise (n = 5), and paresthesia (n = 4). Eight subjects, including three receiving placebo, withdrew from the study because of adverse events.

In three different drug interaction studies with a total of 72 subjects, the most common adverse events were dizziness, headache, somnolence, fatigue, headache, paresthesia, hypoesthesia, somnolence, impaired concentration, and nausea.[30,31]

In the study conducted in 13 patients with photosensitive epilepsy, dizziness, nausea, and abnormal thinking were seen more commonly in those receiving carisbamate than placebo (Kasteleijn-Nolst-Trenite personal communication to M. Privitera). Adverse events were more common at doses of 750 mg and 1,000 mg compared to 500 mg or 250 mg.

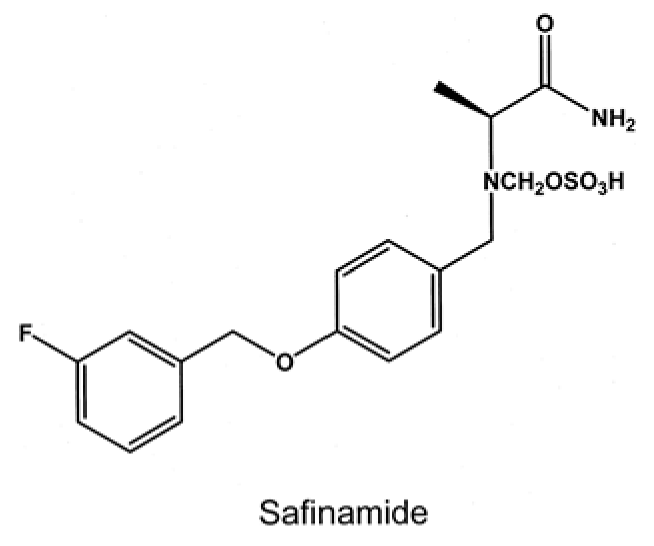

FIGURE 10. Structure of safinamide.

Safinamide (NW 1015, FCE 26743 PNU 151774)

Structure and Chemistry

Safinamide, (*S*)-(+)-2-4-[(3-fluorobenzyloxy) benzyl amino]propanamide methanesulfonate, is an alaninamide derivative

in development by Newron in Italy for treatment of epilepsy and Parkinson disease (Fig. 10).

Pharmacology

In animal seizure and epilepsy models, safinamide possesses a broad-spectrum anticonvulsant profile[18]. It prevents tonic extension-induced seizures by MES stimulation and strychnine. In addition, it is active against clonic seizures induced by bicuculline and picrotoxin. Safinamide is also effective in blocking seizures induced by the glutamate agonists NMDA and kainate. Safinamide blocks behavioral and electrographic seizures in the amygdala-kindled rat and behavioral paroxysms associated with afterdischarge-generating stimuli to the amygdala in a monkey model of partial epilepsy.[42] In addition to its ability to block kainate-induced SE, safinamide is also effective in decreasing kainate-induced neuronal cell loss. Furthermore, safinamide has been found to be neuroprotective in the gerbil model of cerebral ischemia. Based on its anticonvulsant profile, safinamide is expected to be effective in human partial and generalized seizures. Its demonstrated neuroprotective effects also suggest that it might be disease modifying in epilepsy and other degenerative disorders.

Safinamide acts by binding to the batrachotoxin recognition site of the Na channel, and it is a potent blocker of voltage-gated Na currents.[139] In addition, safinamide is a negative modulator of Ca channels and possesses a modest affinity for the σ-1 receptor. Functionally, one or more of these actions could account for its ability to prevent veratridine- and KCl-induced glutamate and aspartate release. Last, safinamide is a potent inhibitor of rat and human monoamine oxidase (MAO)-B, and this activity is thought to contribute to both its neuroprotective effects and to its potential utility for the treatment of Parkinson disease[18].

Pharmacokinetics

Safinamide is rapidly absorbed from the gastrointestinal tract, with peak plasma concentrations being achieved within about 2 hours after a single dose.[18] Concomitant intake of food reduces the rate of absorption, but peak concentrations and AUC are unaffected compared with the fasting state.[102] Both in healthy volunteers and in patients with epilepsy and Parkinson disease, plasma safinamide levels increase proportionally with the administered dose over the explored dose range of 50 to 300 mg/day.[102] Steady state is reached by day 5 of administration, and peak plasma levels during multiple dosing occur between 5 and 6 hours after intake.

Safinamide is about 90% bound to plasma proteins. In healthy volunteers and in patients not receiving enzyme inducers, the half-life is about 22 hours.[102] Clearance occurs primarily by metabolism. Approximately 70% of an orally administered dose can be accounted for by an inactive phase I metabolite, which is excreted in urine in conjugated form.[18]

Drug Interactions

The half-life of safinamide in patients comedicated with enzyme-inducing AEDs is shortened to about 16 hours, suggesting that safinamide metabolism is at least in part mediated by inducible enzymes.

In vitro, safinamide does not affect the activity of various CYP isoenzymes involved in the metabolism of other AEDs.[18,150] Preliminary observations in patients with epilepsy receiving safinamide doses up to 300 mg/day have not identified changes in the plasma concentration of concomitantly administered carbamazepine, lamotrigine, phenobarbital, or valproic acid.[18]

Because tyramine shows MAO-B inhibiting activity, studies have been performed to test potential interactions with the effects of intravenous and oral tyramine. No clinically significant interactions have been detected in these studies.[18,26]

Clinical Efficacy

In a study that assessed the response to transcranial magnetic stimulation in healthy volunteers as a surrogate marker for potential anticonvulsant activity, safinamide was found to reduce the motor evoked potential at doses of 1 and 2 mg/kg.[17] In an exploratory adjunctive-therapy trial in 43 patients with refractory epilepsy, 16 of 39 evaluable patients showed a greater than 50% decrease in seizure frequency on safinamide (at dosages up to 300 mg/day) compared with an initial prospective baseline.[18] Randomized controlled trials of safinamide in epilepsy have not been reported to date.

Safinamide is also being developed for the treatment of Parkinson disease, because of its potent MAO-B inhibiting activity.[8] In healthy volunteers, dose-dependent, progressive platelet MAO-B inhibition has been observed at single doses starting from 0.025 mg/kg, with virtually complete inhibition at 0.6 mg/kg.[102] In a multinational Phase II trial in patients with Parkinson disease, a median safinamide dose of 70 mg/day (range 40–90 mg/day) was associated with improved motor scores.[147]

Adverse Effects

In all studies conducted to date in patients with epilepsy and Parkinson disease, safinamide was generally well tolerated. The most commonly reported adverse events observed in adjunctive-therapy studies in epilepsy patients were dizziness, headache, vertigo, nausea, and blurred vision.[18]

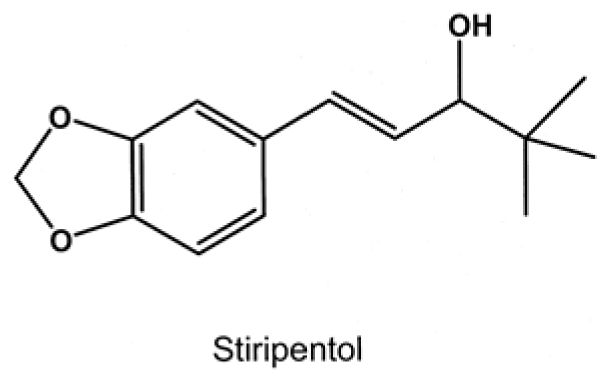

FIGURE 11. Structure of stiripentol.

Stiripentol

Structure and Chemistry

Stiripentol, 4,4-dimethyl-1-[(3,4 methylenedioxy)phenyl]-1-penten-3-ol, is an allyl alcohol that exists in two enantiomeric

P.1733

forms (Fig. 11). Stiripentol has been under clinical investigation for about 30 years, and has been made available by Biocodex for compassionate use under a special program in France and Canada for over 10 years.[32] In 2001, stiripentol was granted orphan drug status in the European Union as a potential treatment for severe myoclonic epilepsy of infancy and has been approved recently by the European Medicines Agency (EMEA) for the treatment of this condition, adjunctively to valproic acid and clobazam. In clinical trials, assessment of its potential antiepileptic efficacy has been complicated by pharmacokinetic interactions, which result in marked changes in serum levels of concomitantly administered AEDs.

Pharmacology

Stiripentol is effective against a wide range of models that include tonic extension seizures induced by MES, clonic seizures induced by PTZ and bicuculline,[91,123] and spike-and-wave discharges in genetically susceptible Wistar rats.[109] It is also effective in suppressing interictal electroencephalographic discharges in the alumina gel rhesus monkey model of focal epilepsy.[90]

Despite the long-term use of this drug, very little can be said about the molecular mechanisms underlying its anticonvulsant action. The suggestion has been made that the efficacy of stiripentol could be related to positive modulation of GABAergic inhibitory neurotransmission. For example, stiripentol has been found to inhibit GABA-transaminase and β-hydroxybutyrate dehydrogenase activity, and to affect the uptake of glycine and GABA (for review and references see Loiseau and Duche[91]).

Pharmacokinetics

Despite evidence that stiripentol enantiomers differ in pharmacologic activity[142] and that the pharmacokinetics of the drug in rodents is stereoselective with preferential accumulation of the less active *S*-enantiomer,[10] published pharmacokinetic studies of stiripentol in humans appear to have been conducted utilizing nonenantioselective assays.

Following single oral doses ranging from 300 to 1,200 mg in powder form in healthy volunteers, stiripentol is rapidly absorbed, with peak plasma concentrations being attained mostly within 2 hours.[87] Stiripentol administered as a solution was found to possess a bioavailability of only 21% ± 9% compared to the powder form, possibly due to precipitation of the drug in the aqueous environment of the gastrointestinal tract.[87]

Stiripentol distributes extensively into tissues and is avidly (99%) bound to plasma proteins.[91] After single oral doses in healthy subjects, the elimination is multiphasic, with a mean residence time of 4 hours and a CL/F of 1.3 to 1.8 L/h/kg.[83] Single-dose pharmacokinetics are not predictive of pharmacokinetics at steady-state, because a several-fold decrease in CL/F is observed during multiple dosing.[83] Repeat administration studies at dosages up to 1,800 mg/day in healthy subjects and up to 2,400 mg/day in epileptic patients clearly demonstrated that stiripentol follows Michaelis-Menten kinetics, and that steady-state serum concentrations increase nonlinearly with increasing dosage.[83,86,87,91] In patients receiving stiripentol as adjunctive therapy, dosage increments from 600 to 1,200 mg/day resulted in a 253% increase in concentration, and a further dosage increment from 1,200 to 2,400 mg/day resulted in a 397% increase in drug concentration, which corresponds to an approximately fivefold decrease in CL/F (from 1.7 to 0.35 L/h/kg) when switching from the lowest to the highest dose.[87,91]

The occurrence of Michaelis-Menten kinetics is probably due to saturation of the enzymes responsible for stiripentol metabolism. At least five different pathways and 13 metabolites have been identified, with renally excreted metabolites accounting for 73% of the dose and about 13% to 24% of the dose being recovered unchanged in the feces.[111] The major pathway appears to involve oxidative cleavage of the methylene dioxy ring to yield catechol metabolites. Other pathways include conjugation with glucuronic acid, hydroxylation of the *t*-butyl group, *O*-methylation of catechol derivatives, and conversion of the allylic alcohol side chain to the isomeric 3-pentanone structure.[91,111]

Evidence suggests that stiripentol metabolism is stimulated by concomitant administration of enzyme-inducing AEDs. At a dosage of 1,200 mg/day, stiripentol CL/F in patients comedicated with carbamazepine, phenytoin, or barbiturates is about three times as high as that observed in healthy subjects, although the degree of interindividual variability is considerable.[86,87,91] Despite the fact that in recent years stiripentol has been used mainly in the treatment of pediatric patients, information on its pharmacokinetics in infants and children is very limited. Observations by Farwell et al.[44] suggest that stiripentol CL/F is lower in children than in adults receiving equivalent dosages.

Drug Interactions

Stiripentol inhibits a variety of CYP enzymes in vitro, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4.[105,157] Inhibition of the metabolism is responsible for a significant elevation in serum levels of concurrently administered AEDs,[91] including phenytoin,[44,87,91,105] carbamazepine,[28,65,85,88,94,105] clobazam and its active metabolite norclobazam,[33] phe-nobarbital,[91,93] primidone,[13,91] and valproic acid.[84,85,89] Many of these interactions are clinically significant. For example, the increase in carbamazepine concentration after starting stiripentol may be more than twofold, and a reduction in carbamazepine dosage is usually required to minimize the risk of toxicity.[44,65,82,158] Because stiripentol inhibits the conversion of carbamazepine to carbamazepine 10,11-epoxide,[28] the serum concentrations of the latter decrease considerably in patients receiving carbamazepine in combination with stiripentol.[65,88] Another major interaction occurs with clobazam. Dose-normalized clobazam concentrations increase about twofold after adding stiripentol, whereas the increase in the concentration of the active metabolite norclobazam is about threefold.[33] The magnitude of the increase in valproic acid levels in patients comedicated with stiripentol is of a considerably lesser magnitude compared with the increase reported for carbamazepine and clobazam.[33,89] The degree of interaction with phenytoin, phenobarbital, and primidone has been incompletely characterized, but preliminary observations suggest that, at least for phenytoin and phenobarbital, dose adjustments are required to minimize the risk of toxicity.[91]

As discussed earlier, enzyme-inducing AEDs increase stiripentol elimination and decrease serum stiripentol concentration at steady state.[86,87] Potential effects of valproic acid on stiripentol pharmacokinetics do not appear to have been investigated.

Clinical Efficacy

Most studies conducted with stiripentol to date have been open-label uncontrolled trials in which stiripentol was given as adjunctive therapy in adults and children with refractory epilepsies. Maintenance dosages have been in the range of 1,200 to 3,000 mg/day in adults, and 20 to 90 mg/kg in children. Many of these trials reported a decrease in seizure frequency, including partial seizures,[93,101,125] refractory absence seizures,[44,91,94,119] and possibly other seizure types.[91] Unfortunately, these results are difficult to interpret due to lack of a control group and, in many patients, an increase in the serum concentrations of underlying AEDs. In some studies, attempts to discontinue concomitant medications resulted in prominent deterioration of seizure control, suggesting that stiripentol has little or no antiepileptic efficacy when administered as monotherapy in these patients.[91,101] A double-blind, placebo-controlled trial of stiripentol (2,000 mg/day) added on to carbamazepine (whose dosage was reduced in the stiripentol group to compensate for the effect of interaction) in 201 patients with partial epilepsy has only been reported in summary form, and results were stated to be “non conclusive because of too low a dose of stiripentol … and an insufficient reduction in carbamazepine dosage, resulting in increased plasma levels” of carbamazepine.[91,92]

In an open trial, a particularly marked reduction in seizure frequency was observed when stiripentol was added on to clobazam in 20 children with severe myoclonic epilepsy in infancy (SMEI).[119] This led to a randomized, double-blind, parallel-group adjunctive trial in which stiripentol (50 mg/kg) or placebo was evaluated over a 2-month period in a total of 41 patients (mean age 9.4 years, range 3–21 years) with SMEI. All the patients were on a combination of valproate and clobazam.[33] In seven patients, progabide was also part of the underlying regimen. Of 21 patients treated with stiripentol, 15 (71%) were responders (defined as a >50% reduction in the frequency of clonic or tonic–clonic seizures during the second treatment month vs. baseline), compared with one (5%) of the 20 patients who received placebo. Nine stiripentol-treated patients were free of clonic and tonic–clonic seizures during the assessment month, compared with none on placebo. Percent change in seizure frequency was also greater on stiripentol (-69% vs. + 6% on placebo, p <0.0001). Although the results of this trial clearly show a much better outcome in the stiripentol group, the findings may not be regarded as a conclusive demonstration of the drug's efficacy. In fact, to minimize intolerance due to drug interactions, valproate and clobazam dosages were kept within a predefined ceiling at baseline, implying that some patients may have received suboptimal dosages of these comedications. More importantly, despite a reduction in clobazam dosage in some patients, the concentration of clobazam and norclobazam increased markedly during stiripentol administration. For example, in the double-blind period serum concentration were 50% (clobazam) and twofold (norclobazam) higher in the stiripentol group than in the placebo group. Therefore, it cannot be excluded that the improvement in outcome was related at least in part to increased serum levels of comedication, rather than to an effect of stiripentol itself.[160] The authors, however, argued that the magnitude of the response was greater than expected from the elevation in clobazam and norclobazam levels.

An additional limitation of the double-blind SMEI trial is that patients were assessed under controlled conditions over a very short period. At the end of the double-blind phase, all patients went on to receive open-label stiripentol with a median follow-up of 24 months, and the authors reported a putatively favorable response in 21 of the 37 who could be meaningfully assessed. The drug was discontinued in four patients due to lack of response and in three patients because of adverse events, and two other patients died suddenly for reasons unrelated to the drug. The authors commented that "in comparison with the initial response … during the double-blind period, efficacy was maintained at last visit in 50% of the cases." A broader assessment of long-term outcome data in a total of 83 SMEI patients, including 37 from the double-blind trial described above and 46 from another trial[153] concluded that about 20% have a major benefit (fewer seizures) when stiripentol is added to inadequately effective valproate-clobazam combination therapy, and the best effects seem to be seen in the youngest patients.[9] The impact of stiripentol on psychomotor development, a major concern in this population, is unknown.

Adverse Effects

The most common adverse effects observed in patients given stiripentol include drowsiness, tremor, ataxia, hyperexcitability, insomnia, nausea, anorexia, weight loss, and occasional vomiting.[9,161] Hematologic abnormalities, including neutropenia and thrombocytopenia, have also been described.[33,161] Although some adverse effects can be ascribed to toxicity from other AEDs (whose serum levels increased following administration of stiripentol), and these abate after reduction in dosage of comedication, other effects, particularly nausea, vomiting, anorexia, and weight loss, probably reflect a direct effect of stiripentol.[119] In the double-blind trial in SMEI, CNS adverse events, particularly drowsiness, hyperexcitability, and aggressiveness, were reported in 91% of patients on stiripentol, compared with 25% of those on placebo.[33] Digestive system adverse events were reported in 67% of the stiripentol patients and 35% of the placebo patients. No patient, however, withdrew from the study because of adverse events, and many adverse events resolved after a reduction in dosage of comedication.

Talampanel (GYKI 53773; LY 300164)

Structure and Chemistry

Talampanel, currently developed by Teva, Israel, is the active (*R*)-enantiomer of the *N*-acetylated derivative of the 2,3-benzodiazepine GYKI 52466 (Fig. 12).

Pharmacology

Talampanel is effective against tonic seizures induced by MES and clonic seizures induced by PTZ.[7,17,163] Talampanel is also effective in blocking the expression of focal seizures in mouse and rat kindling models.[7,17,18,163] In combination with other AEDs, talampanel was found to potentiate their anticonvulsant action.[34] In one study, a low dose of talampanel (2 mg/kg) when administered with subtherapeutic doses of valproic acid (25–75 mg/kg) reduced the severity and duration of kindled seizures without negatively affecting long-term memory or motor coordination.[22]

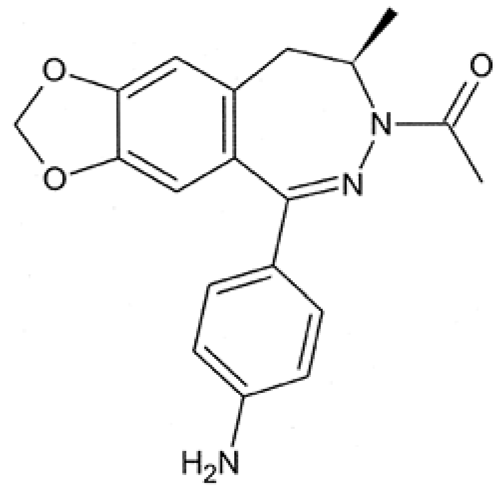

FIGURE 12. Structure of talampanel.

Talampanel is a noncompetitive antagonist of glutamate-mediated excitation evoked through the AMPA receptor.

AMPA receptors play a key role in mediating seizure spread and are implicated in seizure-induced neuronal damage. As such, AMPA receptors represent rational targets for AED discovery, and effective drugs that penetrate the blood–brain barrier at nontoxic doses may be useful for both the symptomatic treatment of epilepsy and the prevention of damage associated with chronic epilepsy and acute SE.[129,130] AMPA antagonists, unlike NMDA antagonists, do not block the induction of long-term potentiation and are thus thought to be devoid of the potential for inducing disturbances in long-term memory.[62] Through its noncompetitive interaction with the AMPA receptor, talampanel may offer some advantage over competitive AMPA receptor antagonists because its effect cannot be overcome by an excess of the endogenous ligand, such as glutamate. This is particularly important given that extracellular glutamate levels rise prior to the onset of electrographic seizure activity[41] and during excessive neuronal discharge associated with SE and other brain insults such as trauma and hypoxia-ischemia.

Pharmacokinetics

In studies conducted in healthy volunteers, talampanel is absorbed rapidly from the gastrointestinal tract, with peak plasma concentrations being observed within 3 hours after dosing.[18] Intake with a meal has no major influence on pharmacokinetic parameters. Between 67% and 88% of plasma talampanel is bound to plasma proteins, and its mean half-life after multiple dosing is on the order of 6 to 7 hours.[18] Half-life values of about 4 hours are observed after single doses of 30 to 35 mg, with longer values (about 7 hours) after 75 mg doses,[24] indicating nonlinear pharmacokinetics.

Langan et al.[77] assessed talampanel pharmacokinetics after single and multiple doses in patients taking enzyme-inducing AEDs. In these patients, plasma talampanel concentrations showed considerable interindividual variability and were on average less than one-half those seen in healthy volunteers. Mean talampanel half-life values after single doses were 3.0 hours compared to 4.2 hours in healthy volunteers, whereas mean CL/F values were 81.4 L/h compared to 26.2 L/h in healthy volunteers. After administration of multiple doses (mostly 50 mg t.i.d.) in the same patients, the half-life of talampanel increased to 5.6 hours and CL/F decreased to 39.5 L/h. The nonlinear pharmacokinetics of talampanel imply that plasma talampanel levels at steady-state increase more than proportionally with increasing dosage.

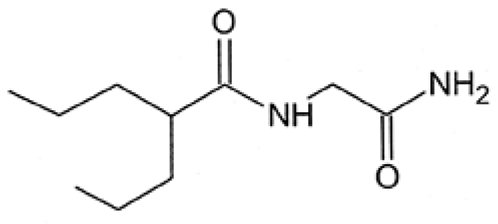
In humans, talampanel is converted to a variety of metabolites, including the 4′-*N*-acetyl, the 7-*O*-methyl catechol, and *O*- or *N*-glucuronidated compounds.[18] The *N*-acetyl metabolite has been reported to be inactive in vitro, but to be about one-third as active as talampanel in some in vivo studies, possibly because it can be deacetylated to talampanel.[18] In humans, acetylation by *N*-acetyl transferase NAT2 represents only about one-fourth of the total elimination even in homozygous fast acetylators, and therefore the impact of acetylator status on talampanel disposition is modest.[24,77] In patients taking talampanel, the plasma concentrations of the *N*-acetyl metabolite seem to be very low.[24,77]

Drug Interactions

As discussed, enzyme-inducing AEDs such as carbamazepine stimulate talampanel metabolism and decrease its plasma concentration at steady-state. In a randomized controlled trial of 49 patients[29] talampanel target doses were adjusted based on concomitant medication. Despite adjusting target doses, talampanel plasma concentrations were 66 ng/mL in patients receiving two hepatic enzyme-inducing drugs, 155 ng/mL in patients receiving one hepatic enzyme-inducing drug, and 372 ng/mL in patients receiving no enzyme-inducing AEDs. Thus, talampanel has a complex drug interaction profile that may make it difficult to predict its plasma concentrations when used as an adjunctive therapy.

Despite the fact that talampanel may inhibit CYP3A4 activity in vitro,[18] there is no clear evidence that talampanel affects to an important extent the pharmacokinetics of other AEDs. In a cross-over trial, six of 32 patients who were given talampanel in addition to carbamazepine required a reduction in carbamazepine dosage to maintain the serum carbamazepine concentration within 30% of baseline.[29] In another study, however, serum carbamazepine concentrations in 12 patients were not affected by talampanel.[77] Preliminary observations in a few patients also did not identify any effect of talampanel on the plasma concentrations of clobazam, clonazepam, topiramate, lamotrigine, primidone, and vigabatrin.[77] In the same study, the suggestion was made that talampanel and valproic acid may inhibit each other's metabolism. In fact, in one patient receiving talampanel and valproic acid (but not receiving carbamazepine), plasma talampanel concentrations and half-life were higher than previously recorded in healthy subjects. In addition, three of the four patients treated with valproic acid experienced significant increases in plasma valproic acid concentrations when talampanel was added on. In a more recent study in 10 healthy subjects, however, administration of valproic acid (500 mg/day for 5 days consisting of a total of 10 doses starting on the evening of day 2, with single 25 mg doses of talampanel administered on day 1 and 6) did not affect significantly the pharmacokinetic parameters of either talampanel or its *N*-acetyl metabolite. Administration of talampanel (25 mg) in this study caused a slight increase in trough total and free valproic acid concentrations (day 7 vs. day 6), which was not significant for total valproic acid, and marginally significant (p <0.05) for free valproic acid.[18]

A lovastatin interaction study found no changes in plasma levels of lovastatin, a CYP3A4 substrate, after 10 days of talampanel dosing of 60 mg three times daily.[17]



Valrocemide

FIGURE 13. Structure of valrocemide.

Efficacy

Chappell et al.[29] performed a double-blind, placebo-controlled, randomized, add-on crossover trial of talampanel in 49 patients

P.1736

with refractory partial seizures. Patients were titrated to the maximum tolerated dose, but there were three different target doses, determined by the patient's concomitant AEDs. Patients receiving enzyme-inducing AEDs had a target of 75 mg three times a day; those not receiving an enzyme-inducing drug or receiving an enzyme-inducing drug plus valproic acid had a target of 60 mg three times a day; those receiving valproic acid without an enzyme-inducing drug were targeted to 25 mg three times a day. While receiving talampanel, patients experienced a statistically significant median seizure reduction of 21%.

A pilot placebo-controlled study of talampanel (up to 50 mg t.i.d.) in 50 patients with amyotrophic lateral sclerosis (ALS) showed a trend towards a slower clinical deterioration in the talampanel group, but the difference versus placebo failed to reach statistical significance.[16,17]

Adverse Effects

In the pharmacokinetic study in patients conducted by Langan et al[77] no serious adverse events were reported; the most frequently reported adverse events were dizziness, ataxia, drowsiness, and headache.[78] Most patients taking enzyme-inducing AEDs did not tolerate the target dose of 75 mg three times a day, and required a dose reduction to 50 mg three times a day. The patient who was taking valproic acid without enzyme inducers was targeted to receive 35 mg three times a day, but his dosage had to be reduced to 10 mg three times a day. It was suggested that talampanel adverse effects occur at lower doses in patients taking AEDs than in healthy subjects, presumably due to the additive CNS effects of comedication.

In the randomized crossover trial, the most common adverse effects were dizziness (52%), ataxia (26%), headache (13%), and somnolence (13%), although headache and somnolence were seen almost equally in the placebo group.[29] Dizziness was reported to be mild to moderate, transient, and associated with peak plasma concentrations.

Valrocemide (TV-1901)

Structure and Chemistry

Valrocemide, *N*-valproylglycinamide, is currently under development by Shire (Fig. 13).

Pharmacology

Valrocemide is a broad-spectrum valproic acid-like anticonvulsant that was in early clinical development by Teva Pharmaceutical until 2004. Like valproic acid, valrocemide is active in many animal seizure and epilepsy models but, unlike valproic acid, it is not embryotoxic in rats and rabbits. This is likely due to the fact that the main metabolic pathway for valrocemide is enzymatic amide hydrolysis, which yields *N*-valproyl glycine.[18,58] In animal models, valrocemide is active against tonic extension seizures induced by MES, sound-induced seizures in the Frings audiogenic seizure-susceptible mouse, and focal seizures in the hippocampal-kindled rat. Valrocemide is also active in the 6-Hz model of pharmacoresistent limbic seizures. Consistent with its broad-spectrum anticonvulsant profile, valrocemide is also active against spike-and-wave seizures in the lethargic mouse and clonic seizures induced by the chemoconvulsants PTZ, bicuculline, and picrotoxin.

In addition to blocking seizure spread, valrocemide is thought to exert its anticonvulsant effect through an effect on seizure threshold. From results obtained in the intravenous PTZ seizure threshold test, valrocemide increased the dose of PTZ required to evoke a first twitch and clonus. Unfortunately, the precise molecular mechanism underlying all the anticonvulsant actions of valrocemide is not known.

In addition to its anticonvulsant effects, valrocemide has been found to reduce both the peripheral horizontal and vertical activity in the rat amphetamine-induced hyperactivity model of mania.[18] In addition, valrocemide has been found to decrease rearing in a manner similar to that observed with lithium. Thus, valrocemide, much like valproic acid, is a broad-spectrum neuromodulator that is likely to have effects against multiple CNS disorders including epilepsy and bipolar disorder.

Pharmacokinetics

Valrocemide is well absorbed after oral administration, with a linear relationship between serum concentration and dose after single doses up to 4,000 mg and multiple doses up to 1,000 mg three times a day.[17]

Valrocemide CL/F in healthy volunteers has been estimated at about 4 to 6 L/h, and the half-life is in the range of 6.4 to 9.4 hours after both single and multiple doses.[16,17]

The major metabolic route involves conversion to the inactive derivative *N*-valproyl-glycine, whose urinary recovery accounts for 40% of the administered valrocemide dose. Together, renal clearance of unchanged valrocemide and formation clearance of *N*-valproyl-glycine account for 57% to 75% of CL/F. Valproic acid has been detected as a minor metabolite and, based on pharmacokinetic parameters in healthy volunteers, it has been estimated that about 4% to 6% of a valrocemide dose is converted to valproic acid.[16,17]

Drug Interactions

Patients receiving concomitant mostly enzyme-inducing AEDs exhibit higher CL/F values (mean 8.2 L/h) and shorter half-lives (mean 4.7 hours) than do healthy volunteers, suggesting that valrocemide metabolism is mediated by inducible enzymes.[16]

Studies with human liver microsomes showed that, at clinically relevant concentrations, valrocemide and *N*-valproyl-glycine are devoid of inhibiting activity on a variety of CYP enzymes, including CP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E2, and CYP3A4, and epoxide hydrolase.[16]

Efficacy and Tolerability

In an adjunctive-therapy 13-week exploratory study in 22 patients with epilepsy, valrocemide has been up-titrated to the highest tolerated dosage or up to a maximum of 2,000 mg

P.1737

twice a day. Fourteen patients tolerated 2,000 mg twice a day, and there were no serious adverse events. The most common adverse events affected the CNS or the gastrointestinal tract. Although valrocemide was associated with a significant improvement in seizure frequency compared with baseline, the lack of a control group prompts caution in the interpretation of the results.

Summary and Conclusions

A number of investigational drugs currently are in development for the treatment of partial epilepsy. Their anticonvulsant activity was identified through the use of a battery of well-established animal and seizure models. Given the validity of the models employed, it is highly likely that most if not all of these investigational drugs will be found effective in patients with epilepsy. Because several of the drugs currently winding down the road to regulatory approval process possess a broad anticonvulsant profile, it will be of interest to see whether they will possess a similarly broad spectrum of activity in patients with multiple seizure types. In addition, an important question that remains to be answered is whether one or more of these drugs will lead to a marked improvement in seizure-free rates in patients with epilepsy refractory to current treatments.

Many of the drugs in the pipeline share a similar mechanistic profile with the marketed AEDs. On the contrary, the molecular mechanism of a few AEDs in development has yet to be defined. The inability to define a particular mechanism to a given drug suggests that it is unique relative to the other AEDs, and the hope would be that this would translate into improved efficacy over the established AEDs. It is important to note that several of the drugs in the pipeline have been found to prevent neuronal damage secondary to an acute brain insult. It is possible that this action may one day lead to the development of a “disease-modifying” therapy that slows, halts, or prevents the development of epilepsy in the susceptible individual. Such a therapy would be a major leap forward for the patient with newly diagnosed epilepsy, or even the person at risk for developing epilepsy. The challenges associated with the development of a disease-modifying therapeutic agent are immense, but worthy of pursuit.

Chapter 165

Immunoglobulin and Immunomodulatory Therapy

Flavio Villani

Christian G. Bien

Giuliano G. Avanzini

Introduction

The use of immunoglobulin in intractable epilepsy is one of its oldest applications in medicine, starting from the empirical observation of its beneficial effect on seizures.

The immune system and its associated inflammatory reactions have been implicated, by numerous experimental and clinical findings, in the pathogenesis of several forms of epil-epsy. The relationship between epilepsy, the immune system, and the inflammatory cascade is, however, exceedingly complex and possibly bidirectional.

The wide range of immune abnormalities observed in patients with epilepsy and the reported efficacy on seizure control of different immunomodulatory and/or anti-inflammatory treatments suggest the existence of different subtypes of epileptic syndromes associated with variable abnormalities of the immune system.

In this view, intravenous immunoglobulin (IVIg), with its broad immunomodulatory mechanism of action, could be effective in different forms of immune-dysregulated intractable epilepsies.

IVIg may also share nonimmunologic mechanisms of action: Its possible anticonvulsant properties and the ability of IVIg to interfere with the final common pathway of seizures at a cellular level, with a significant increase in seizure threshold, have been suggested by human epilepsy data and have been demonstrated in different experimental epilepsy models.

Although IVIg may represent a valuable resource in some drug-refractory epilepsies, and its effectiveness has important pathogenetic implications, controlled studies with the systematic monitoring of immunologic markers are needed to define more precise indications and to optimize the administration protocols.

The Central Nervous System and the Immune System

The central nervous system (CNS) is considered an immuno-privileged site because of the presence of the blood–brain barrier (BBB), its ability to accept grafts, the absence of classical lymphatic drainage, and the reduced traffic of monocytes and lymphocytes; it is, however, also considered an immunologically specialized site, because immune and inflammatory reactions do occur in the CNS, originating in the CNS itself (innate immunity), or are imported by competent immune cells from the peripheral tissues (acquired immunity).[75,92] The transition between innate and acquired immunity is mediated by a large variety of inflammatory mediators (e.g., cytokines, Toll-like receptors) not detectable or barely detectable under physiologic conditions.[3] Although such mediators are classically produced by cells of the immune system in response to infection or other pathologic stimuli, they are also produced by brain parenchymal cells such as microglia, astrocytes, and neurons, and by cells of the BBB and choroid plexus.[53,80]

It is worthwhile to note that an immune response in the CNS may be also triggered by endogenous ligands. Signals from damaged cells or arising from molecules entering the brain through a damaged BBB may initiate an immunologic response followed by an inflammatory reaction. A large spectrum of injuries, such as ischemia, trauma, and seizures, may initiate such a pathological process.[4,49]

The patterns of induction of inflammatory molecules and their time course of activation/persistence in brain tissue are related to the nature of the CNS injury and may be relevant in planning the treatment of epilepsy by immunomodulation.

Immunologic Alterations in the Epilepsies

Alterations of the immune system described in patients with different forms of epilepsy are numerous. Both humoral (predominantly IgA and IgG2 deficiencies)[29,33] or cellular[30,45,89] immunity may be impaired in these patients.

Conflicting reports have been published on serum immunoglobulin concentrations in patients with epilepsy. In a recent study serum IgA, IgG, and IgM concentrations were determined in a large cohort of epileptic patients and compared to a reference population.[76] The patients with epilepsy had lower serum IgA concentrations compared with controls. Low serum IgA levels were also found in patients taking phenytoin or who had previously been treated with that drug. No differences in serum IgG and IgM concentrations were observed between patients and control subjects.

Several recent reports have shown an increase in the markers of inflammation in serum, cerebrospinal fluid (CSF), and brain resident cells following seizures. Tonic–clonic seizures, for example, may induce a proinflammatory increase of cytokines such as interleukin (IL)-6, but may also reduce the IL-1RA/IL-1α ratio[46,68,71,72] in plasma and CSF. Experimental studies suggest that IL-1β prolongs seizure duration and, at the same time, promotes neuronal damage, whereas its effect is blocked by IL-1RA.[91] Increased levels of IL-1β and other cytokines have been observed in the experimental model of glycerol-induced seizures,[26] as well as in patients with either partial or generalized epilepsy.[64] These observations and the association of polymorphisms in the IL-1 gene complex with temporal lobe epilepsy and hippocampal sclerosis[50] and other forms of drug-refractory, localization-related epilepsies,[70] together with an increase in the expression of proinflammatory molecules in neurons and glia in brain tissue obtained from patients surgically treated for drug-resistant epilepsies,[9,23,58,77,83] are consistent with previous data suggesting a modulatory effect of cytokines and other proinflammatory molecules on neurotransmission and seizures.

P.1742

Anti-brain antibodies[61,73] or autoantibodies[11,42] have also been related to different forms of epileptic syndromes and to more complex neurologic syndromes with prominent epilepsy, such as Rasmussen chronic encephalitis (RE).

Other evidence, although indirect, of the possible role played by the immune system in epilepsy includes the immunologic abnormalities induced by antiepileptic drugs (AEDs) such as phenytoin and carbamazepine,[34,65] and the anticonvulsant efficacy of immunosuppressive drugs such as adrenocorticotropic hormone (ACTH) and corticosteroids on the intractable seizures of West's Syndrome (WS).

The inflammatory response is strictly regulated genetically: Different prevalences of human leukocyte antigen (HLA) class II haplotypes in epileptic patients, compared with the general population, have been described.[44] The analysis of IL-1β, IL-1α, and IL-1RA gene polymorphisms[69] in a cohort of drug-resistant epilepsy patients versus healthy controls suggested an association between cytokine gene haplotypes and development of intractable focal seizures, but this observation was not confirmed by other authors.[17,41]

Clinical studies underscored the role of stress hormones in epilepsy. Increased ACTH and cortisol levels have been reported in human epilepsies and in status epilepticus (SE).[18,35,36] Activation of the ACTH/glucocorticoids axis in response to antecedent injury or stress has been suggested in the pathogenesis of WS.[8]

Dysfunction of the BBB has been demonstrated both in epilepsy experimental models[101] and in human epilepsy.[22] In most cases, however, routine examination does not provide evidence of BBB disruption with normal CSF.[87,99]

Increased BBB permeability induced by seizures, inflammation, or both has several clinical implications, which include the entry of compounds with immunogenic or inflammatory potentials,[66] the upregulation in the expression of multidrug transport proteins limiting AED access to the brain,[52] and facilitation of the entry of those compounds with therapeutic potential with limited or no access to the CNS, such as immunoglobulins.

The Use of Immunomodulatory Treatments in Human Epilepsies

From a clinical point of view, although the role of the immune system in the pathophysiology of human epilepsies is still only partially understood, the possibility of treating different forms of epilepsies by immunomodulatory agents is supported by extensive evidence.

IVIg, corticotropin, corticosteroids, plasma exchange, immuno-adsorption with protein A, and interferon (IFN)-α have been applied with some success in several epileptic syndromes: The antiepileptic effect of these agents may be at least partially mediated by their immunomodulatory and anti-inflammatory effects.

The concept that immunomodulatory and anti-inflamm-atory treatments may have a beneficial effect on epileptic seizures in human epilepsy has been first suggested after the empirical observation of Pechadre et al.[67] as early as 1977; the authors observed a decrease in the frequency and severity of seizures in children with epilepsy treated with intramuscular immunoglobulin for recurrent upper respiratory tract infections. Following this observation, the old allergic theory of epilepsy[24,97] was revised, and a new immunologic approach to epilepsy was proposed. Studies on the relationship between the immune and nervous systems flourished,[78] as did attempts to treat epileptic seizures with immunoglobulin. The anticonvulsant efficacy of immunomodulatory drugs with anti-inflammatory actions has been well documented. In particular, ACTH and steroids are very effective in severe childhood epileptic encephalopathies.[27,37,39,79,84] The antiepileptic mechanisms of these drugs have not been completely elucidated: Seizure inhibition may involve, at least in part, the ability of steroids to modulate various neurotransmitters, including γ-aminobutyric acid (GABA).[51,74] Their immunosuppressant and anti-inflammatory activities may play a major role in epilepsies with an immune component, such as RE.

The Use of IVIG in Epileptology

The use of IVIg in intractable epilepsy is one of its oldest applications in medicine.[93] This application followed its use for substitution in immunodeficiency states,[16] but preceded the work of Imbach et al.[48] on idiopathic thrombocytopenic purpura in childhood and the subsequent use of this treatment in numerous non-neurologic and neurologic diseases.

IVIg Preparation

Commercial IVIg is human polyclonal IgG prepared from the pooled plasma of as many as 10,000 or more donors. For this reason, there are concerns about the quality and safety of the IVIg preparations. Although it is considered unlikely that IVIg preparations may cause infections, good manufacturing practice is of utmost importance.

IVIg in the Central Nervous System

In neurologic disorders, the access of IVIg to the nervous system is limited by the blood–nerve, blood–brain, and blood–cerebrospinal fluid barriers. Because IgG is virtually absent in the brain parenchyma, the chances of IgG entering the CNS after intravenous infusion of IVIg are low, unless some degree of barrier damage exists. The effectiveness of IVIg therapy has been related to the concentration of IgG in the CNS, as demonstrated for other neurologic disorders such as encephalitis. Investigations of the CSF in patients with intractable epilepsy before and after IVIg treatment aimed to clarify the role of this treatment in epilepsy. Van Engelen et al.[88] examined the CSF of 15 patients with cryptogenic WS and Lennox-Gastaut syndrome (LGS): None of these patients had CSF abnormalities, and all had an apparently normal blood–CSF barrier permeability. After IVIg therapy, the total serum and CSF IgG concentrations increased by 76% and 44%, respectively, demonstrating a normal transfer of IgG from blood to the CSF. Because no restrictive barrier exists between the CSF and the extracellular fluid of the brain,[96] IgG may probably reach certain parts of the brain, at least within short diffusion distances, thus favorably altering neuronal excitability in areas of the brain and brainstem adjacent to the CSF. On the other hand, IgG may reach relevant sites in epileptic patients in whom the BBB may have been focally destroyed by seizure activity, as demonstrated in an experimental model.

IVIg Mechanisms of Action

Although the role of the immune system in epilepsy is not completely clarified, the mechanism of action of IVIg in epilepsy is considered mainly immunologic.

The suggested, but not proven, mechanisms of action of IVIg therapy have been related, among others, to the compensation of possible IgG2 deficiencies, suppression of infections,[21] neutralization of pathogenic autoantibodies by anti-idiotypic interactions,[25] and interference with cytokine production.

P.1743

Nonimmunologic mechanisms of action have been also suggested, based either on human epilepsy data or on animal experimental data. One evidence for a nonimmunologic action of IVIg is related to the time course of the response to treatment of patients with different forms of epilepsy; an immediate response suggests a direct neuromodulating effect. The possible anticonvulsant properties and the ability of IVIg to interfere with the final common pathway of seizures at a cellular level have been investigated in different experimental epilepsy models. By significantly increasing seizure threshold, an anticonvulsant effect of IVIg has been demonstrated in subsets of animals in a model of kindled cats[43] and in a direct cortical stimulation model of epilepsy.

Efficacy of IVIg in the Epilepsies

The evaluation of the efficacy of IVIg treatment in epilepsy is difficult due to the heterogeneity of the available studies, with high variability in the study designs, patients' selection, treatment modalities, and outcome parameters. A publication bias must be also considered because the results of small series of nonresponders may have not been published.

Furthermore, with few exceptions,[80] most of the studies on intractable epilepsy were not double-blind and placebo-controlled, because of the obvious limitations related to the route of IVIg administration and to the problems related to a cross-over study design.

Data from noncontrolled studies suggest that IVIg may work differently in different subgroups of epileptic patients; the search for markers predictive of response is therefore important in this context.

IVIg in West Syndrome and Lennox-Gastaut Syndrome

LGS and WS are epileptic encephalopathies, characterized by severely refractory polymorphic seizures and often catastrophic effects on cognitive development. The evidence for an immune-mediated pathogenesis is mostly based on the observation of positive responses to immunomodulatory agents.

Corticotropin and corticosteroids are often more effective than AEDs in controlling seizures, thus suggesting a role for inflammation in the pathophysiology of these syndromes.

IVIg has been applied both in WS and LGS, with some encouraging results. A cumulative meta-analysis is not possible because the studies are heterogeneous and not controlled. On the other hand, if we consider the available noncontrolled studies and small case series, most authors have reported good positive response rates. In WS, seizure-free status after IVIg treatment was achieved in 40% to 60% of patients, whereas the same outcome was reached using ACTH in 20% to 70% of patients.[2] In LGS, total absence of seizures was achieved using IVIg in 10% to 44% of patients. The use of ACTH in LGS is less standardized (the reported rates of seizure-free patients ranged from 50% to 60%[1]) and because of a high rate of relapse (from 70% to 90%) during the ACTH taper, limited to phases of particularly active epilepsy. For the similar positive response rates and for the lack of potentially fatal side effects, the use of IVIg in these forms of intractable epilepsy may be considered a good alternative to ACTH.

IVIg in Landau-Kleffner Syndrome

Landau-Kleffner syndrome (LKS) is a rare, probably etiologically heterogeneous, pediatric neurologic disorder, characterized by progressive loss of language skills, behavioral problems, and, in many patients, epilepsy. It has been associated with neurocysticercosis, *Haemophilus influenzae* type B meningitis, temporal lobe tumors, demyelinating lesions, and cerebral arteritis. Several lines of evidence point to an autoimmune etiology in LKS. An autoimmune response to central and peripheral myelin has been reported by Nevsimalova et al.[62] Serum IgG antibodies to endothelial cells were found in 45% of 11 patients with an LKS variant, compared with 2% of 29 healthy children and 22 controls with non-neurologic disorders.[20]

The immunopathogenic hypothesis has also been suggested by other authors[32,54,60] following the observation of a dramatic improvement of language function and EEG abnormalities after treatment with corticosteroids and/or repeat IVIg infusions. Interestingly, in one of these cases, the pretreatment CSF IgG index was increased, suggestive of intrathecal IgG production, and this was reversed to normal after the first IVIg treatment. On the other hand, other therapeutic attempts involving AEDs and steroids have had only limited success to stop disease progression or to reverse the language deficit. Although the results with IVIg were encouraging, with long-term remission, the studies are single-case reports that do not allow one to draw definitive conclusions about the efficacy of this treatment in LKS.[32,54,60]

IVIg in Rasmussen Encephalitis

Rasmussen's encephalitis (RE) is a rare condition that typically appears during childhood and is characterized by progressive unilateral brain dysfunction, intractable partial epilepsy, epilepsia partialis continua (EPC), and inflammatory histopathology. Its etiology is unknown, but persistent chronic viral infection and a local autoimmune response have been hypothesized. Nonviral autoimmune mechanisms were first suggested by pathologic evidence of cerebral vasculitis with immune complex deposition in a child with typical RE, associated with CSF oligoclonal bands and high antinuclear antibody titres.[5] This mechanism was more strongly supported by the work of Rogers et al.: They first reported the presence antibodies directed against the neuronal glutamate receptor subunit 3 (GluR3) in RE patients, and induced seizures and inflammatory histopathologic changes, similar to those observed in RE, in rabbits immunized with GluR3.[81] Many other authors have successively confirmed Rogers' findings. Subsequent studies have provided (partly contradictory) evidence for potential mechanisms of action of anti-GluR3 in RE.

Direct evidence of the pathogenicity of GluR3 antibodies via receptor activation was demonstrated using both rabbit-derived GluR3 antibodies and serum obtained from patients with active RE. These results could not be reproduced by other groups. Instead, a complement activation by GluR3 antibodies was suggested. Levite et al. showed that GluR3 immunization of mice elicits both a humoral and a cellular autoimmune response.[56] Oligoclonal local T-cell and B-cell responses[10,57] have been found in the lesions of RE patients. Bien et al.[14] documented the in situ presence of a predominantly $CD3^+/CD8^+$ lymphocytic infiltrate in brain specimens of RE patients, suggesting that cytotoxic T cells contribute to neuronal damage in RE. Although these reports suggest the existence of an autoimmune response at the basis of RE, some observations argue against this hypothesis, and in particular the evidence that GluR3 antibodies are neither always present in the serum of RE patients nor specific for RE.[13,59,98] Bernasconi et al.[13] demonstrated the presence of GluR3 antibodies in 82% of RE patients, but also in 64% of patients with partial epilepsy.

The hypothesized immunologic basis for RE prompted clinicians to try new immunomodulatory and anti-inflammatory treatments and, although the available experience is limited, it offered further circumstantial evidence for RE as an autoimmune condition.

P.1744

Table 1 Immunomodulation in RE treatment

Papers	Type of treatments	Outcome

	(number of patients)	
Rogers et al., *Science* 1994[81]	Plasma exchange (*n* = 1)	Seizure reduction and neurologic improvement; reduction of GluR3 antibodies
Chinchilla et al., *J Neurol Neurosurg Psychiatry* 1994[19]	High-dose corticosteroids (*n* = 8)	Seizure reduction and neurologic improvement in seven patients
Hart et al., *Neurology* 1994[40]	High-dose corticosteroids (*n* = 17) IVIg (*n* = 9)	Seizure reduction and neurologic improvement in 10 patients Seizure reduction in eight patients
Antozzi et al., *Neurology* 1998[6]	Immuno-adsorption with protein A (*n* = 1)	Seizure reduction and neurologic improvement; reduction of GluR3 antibodies
Leach et al., *Neurology* 1999[55]	IVIg (*n* = 2)	Seizure reduction in both patients
Villani et al., *Neurology* 2001[95]	IVIg (*n* = 1)	75% seizure reduction, disappearance of EPC, improvement of neurologic deficits
Granata et al., *Neurology* 2003[38]	IVIg (*n* = 10 childhood-onset; *n* = 1 adult-onset) High-dose corticosteroids (*n* = 14) Plasma exchange (*n* = 5) Immuno-adsorption with protein A (*n* = 3)	50% seizure reduction and slight neurologic improvement in two children. In the adult patient (see Villani et al., 2001), the positive effect was transient, although prolonged. Transient seizure reduction and neurologic improvement in six patients Blocked SE in one patient Seizure reduction and neurologic improvement in one patient
C.G. Bien et al., *Neurology* 2004	Tacrolimus, N=7 (children and adults)	In comparison to a historical untreated control cohort, tacrolimus treated patients had a significantly better motor outcome and less tissue loss on brain MRI. There was, however, no difference in seizure frequency between the two groups.
Villani et al.,	IVIg (*n* = 6)	Transient seizure reduction and neurologic

Epilepsia 2005[94]	Immuno-adsorption with protein A (n = 4) High-dose corticosteroids (n = 7) Chronic corticosteroids (n = 9)	improvement in three patients Transient seizure reduction, improvement (two of four patients) and stabilization (two of four patients) of neurologic deficits Useful in SE Uncertain effects, but deterioration at withdrawal

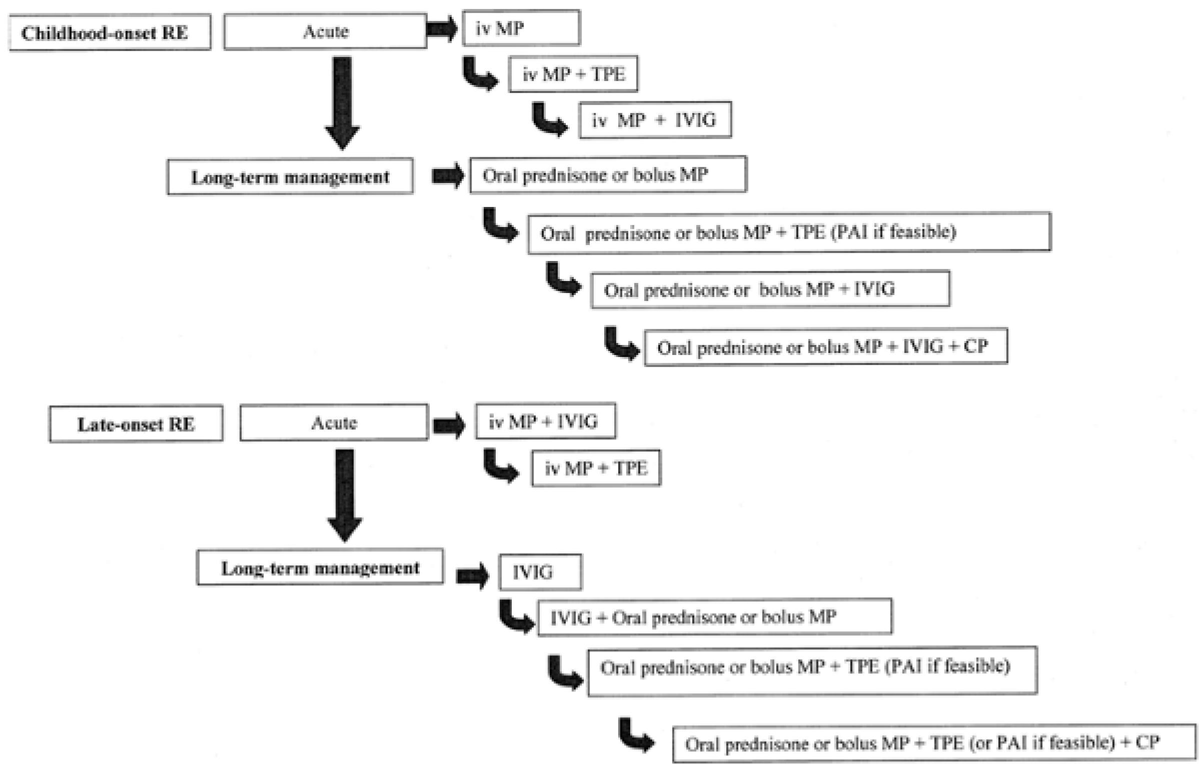

FIGURE 1. Proposed flow-chart for administration of immunomodulatory treatments in childhood and late-onset Rasmussen encephalitis (RE). MP, methylprednisolone; TPE, therapeutic plasma exchange; IVG, IN immunoglobulin; PAI, protein A immunoadsorption; CP, cyclophosphamide. (From Granata T, Fusco L, Gobbi G, et al. Experience with immunomodulatory treatments in Rasmussen's encephalitis. *Neurology* 2003;61:1807–1810.)[37]

P.1745

A number of medical treatments have been proposed, including high-dose corticosteroids, IVIg, plasma exchange, and immuno-adsorption with protein A (Table 1), particularly in the early disease stages, when patients still present mild neurologic deficits and surgery may not be the best choice (it may result in hemianopia, hemiparesis, and also aphasia when the dominant hemisphere is affected).[38]

The use of IVIg has produced encouraging results in the treatment of patients with the adult-onset variant of RE.[55,95] The less encouraging response to IVIg in the more typical childhood form of RE, along with the slow progression of adult-onset RE, may suggest different disease mechanisms in these two variants.[38] The extreme rarity of this pathology does not allow the efficacy of this treatment to be assessed in controlled trials.

Clearly, multicenter studies are necessary to investigate the indications for and timing of immunomodulatory interventions in RE. Immunomodulation may delay surgery, particularly in patients with late-onset (adolescent or adult) RE.[15,55,95] Based on these and other data[15,40,55,95] a nonsurgical approach to the treatment of RE for childhood and late-onset RE variants (Fig. 1) has been recently proposed.[38] This therapeutic scheme presents a graduated approach to the acute phases of the disease (i.e., SE and worsening of EPC) and for long-term immunomodulation in patients ineligible for surgery, and underscores the role of IVIg in this rare pathology as recommended by a European consensus proposal for the immuno-threatment of RE.[14a]

Summary and Conclusions

IVIg may exert beneficial effects in different form of epileptic syndromes, ranging from the frequently catastrophic childhood epileptic encephalopathies, such as WS and LGS, to RE, where its efficacy, maximal in the adult-onset variant, may be transient but nevertheless useful in delaying more invasive therapeutic approaches.

The favorable effect, generally attributed to an immunologic mechanism, supports the immunogenetic hypothesis for these epilepsies. Possible nonimmunologic mechanisms, involving a direct effect on membrane excitability, should also be taken into account. Although IVIg treatment may represent a valuable approach in some drug-refractory epilepsies, and its effectiveness has important pathogenetic implications, controlled studies, utilizing the systematic monitoring of immunologic markers, are needed to define its indications and to optimize the administration protocols.

Chapter 166

Overview: Surgical Therapy

Jerome Engel Jr.

Heinz Gregor Wieser

Dennis D. Spencer

Introduction

Surgical treatment for epilepsy has a long and distinguished history.[11,15,33] Trephination was practiced since prehistoric times in many parts of the world, and cauterization, a popular therapy in the European Middle Ages, persisted into the late 19th century. The modern era of epilepsy surgery was inaugurated when surgeons began to operate on "invisible" lesions based on principles of functional cerebral localization developed largely by John Hughlings Jackson.[32] Macewen, in 1879,[24] and Horsley, in 1886,[19] were the pioneers of this approach. The advent of electroencephalography (EEG) in the first half of the 20th century made it possible for Bailey and Gibbs[3] and the Montreal group led by Penfield and Jasper[20,27] to perform epilepsy surgery, predominantly anterior temporal lobectomy, based on electrophysiologic evidence alone. Much of the early neuroscience research that characterized and mapped human cortical function was derived from the work that Penfield and Jasper performed during surgery for epilepsy.[27] Nevertheless, surgical treatment was offered to only a few patients. Although this therapeutic modality has gained increasing acceptance in recent years, it remains underutilized today.

Whereas surgical intervention during the early years was constrained by the limited localizing capabilities of available diagnostic tools, initially consisting of seizure semiology and direct observation of defects in the skull and cortex, and later including EEG, pneumoencephalography, and cerebral angiography, the factors that continue to restrict epilepsy surgery today are more sociopolitical. With recent tremendous advances in our ability to accurately delineate structural and functional epileptogenic brain regions and to safely and effectively remove them, there has been a resurgence of interest in epilepsy surgery, and the number of patients undergoing surgical treatment for medically refractory epileptic seizures doubled or tripled worldwide between 1985 and 1990.[16] It has been estimated for the United States that there may be over 100,000 potential surgical candidates, with 5,000 to 10,000 added annually,[18] but only about 2,000 surgical procedures to treat epilepsy were performed in the United States in 1990. The number has not changed appreciably since then, despite a randomized controlled trial of surgery for temporal lobe epilepsy,[36] and a Practice Parameter published by the American Academy of Neurology recommending surgery for this condition.[17] This underutilization is typical of other industrialized countries as well and can be attributed in part to (a) the reluctance of third-party payers to provide support for expensive presurgical evaluation, a problem that is currently being addressed by efforts to streamline the diagnostic process where possible, and to conduct studies that demonstrate the cost-effectiveness of surgical intervention over the long run; and (b) inadequate dissemination of information concerning advances in epilepsy surgery to primary care physicians, who too often are not identifying potential candidates and referring them to epilepsy surgery centers in a timely fashion. Furthermore, when patients are referred for epilepsy surgery, it is after an average of 22 years of seizures, often too late for meaningful rehabilitation.[4,14]

Underutilization of surgical treatment for epilepsy is steadily being reversed, and surgical intervention is playing an increasingly important role in the epileptologist's therapeutic armamentarium, as evidenced by the escalating number of conferences, books, and monographs on this subject in recent years.[2,5,6,7,8,9,10,22,23,26,28,29,31,35,37,38,39,40] This is a direct result of new developments in structural and functional neuroimaging; improvements in other areas of diagnosis, particularly involving EEG and long-term monitoring; and refinements in surgical technique. However, the growth of surgical treatment is also due to a better understanding of the pathophysiology of those epileptic disorders that are amenable to this therapy, which to a large extent has derived directly from basic research conducted on the human brain in epilepsy surgery centers. Consequently, many different surgical procedures are available to treat specific individual epileptic disorders, and a variety of presurgical evaluation protocols can be applied depending on the suspected underlying epileptogenic disturbance and proposed surgical intervention. Therefore, surgical approaches are no longer dependent on the particular experience or biases of the surgical team in each center, nor are they constantly changing, with each new patient seen as a unique problem. Rather, a number of universally accepted strategies have been developed based on data derived from many epilepsy centers worldwide and validated by their results, which can be applied to categories of patients in a well-organized fashion according to predetermined criteria. Furthermore, based on years of cumulative data, reasonably reliable prognoses can be made before the recommendation of surgery, and specific surgically remediable syndromes can be easily identified for which medical prognosis is so poor and surgical prognosis so good that early surgical intervention can be deemed the treatment of choice.[13]

The chapters in this part review the current concepts of surgical treatment for epilepsy for nonsurgical physicians. The first three (Chapters 167,168,169) address identification of surgical candidates by primary care physicians, the general approaches to surgical treatment, and the basic principles of presurgical evaluation and surgical intervention. The vast majority of surgical candidates can be evaluated today using routine noninvasive electrophysiologic, neuroimaging, and neuropsychological investigative techniques, each of which is described in more detail in Section IV. With proper application of these approaches, surgical treatment for approximately one-quarter to one-half of patients with medically intractable epileptic seizures, or 5% to 10% of all patients with epilepsy, could be achieved noninvasively in a safe and cost-effective manner.

There remains a smaller number of patients with medically refractory seizures who could also benefit from surgical

treatment but who require more expensive invasive presurgical evaluation. The next several chapters (Chapters 170,171,172,173,174,175) are devoted to these diagnostic techniques, including both chronic and intraoperative intracranial recordings used to localize the epileptogenic region and intracranial recording and stimulation techniques used to delineate essential primary cortex that must not be damaged during the surgical procedure. These approaches are unique to epilepsy surgery programs. In addition, Chapter 173 discusses intra-arterial amobarbital procedures, which are semi-invasive tests that yield information about lateralization of language and memory that is important whether or not invasive testing is required.

The next group of chapters (Chapters 176,177,178,179,180,181,182) presents the specific therapeutic surgical procedures performed as a treatment for epilepsy. Although these chapters provide considerable technical detail, they are not designed for neurosurgeons, but rather to help neurologists and other potential referring physicians understand the rationale for these various approaches and the indications for their application. Therapeutic surgical interventions include procedures designed to resect epileptogenic brain regions, procedures that disconnect epileptogenic areas, and procedures that selectively remove discrete lesions. In addition, reoperation is discussed. Experimental invasive procedures such as deep brain stimulation are presented in Chapter 134.

The next two chapters are concerned with surgical results. Outcome assessment (Chapter 183) is essential to evaluate the efficacy of presurgical evaluation protocols and specific surgical procedures and provides critical information necessary for validating advances in the field. Recent emphasis has rightly moved away from seizure outcome per se and toward more global quantitative measures of quality of life. In view of the shrinking resources for health care, increasing importance is also being placed on determining which surgical approaches for epilepsy are most cost-effective. Whether surgical intervention succeeds in reversing disability, so that the patient becomes not only seizure-free but independent and capable of leading a satisfying and productive life, depends in part on early surgical intervention, but also on effective postoperative rehabilitation (Chapter 184).

The final chapter in this section addresses special pediatric considerations that are not adequately covered in the preceding chapters. Surgical treatment is becoming an increasingly important therapeutic approach for infants and children with epilepsy (Chapter 185).

Surgical treatment for epilepsy is an evolving discipline, and continuing progress, much of which is currently unforeseen, will undoubtedly occur during the lifetime of this textbook. Future directions can be divided into three parts: (a) technological advances that improve the safety, accuracy, and cost-effectiveness of epilepsy surgery; (b) application of surgical treatment in countries with limited resources, as a direct result of cost reduction; and (c) expanded use of the unique opportunities provided in an epilepsy surgery setting to conduct invasive research on the human epileptic brain.

Technological improvements will undoubtedly involve continuing advances in both structural and functional neuroimaging; more streamlined approaches to EEG monitoring; the development of noninvasive techniques for three-dimensional localization of interictal and ictal epileptiform abnormalities, such as magnetoencephalography and functional magnetic resonance imaging (fMRI); and the widespread use of advanced computer technology to coregister multidisciplinary data. New developments in these areas are expected to expand the population of medically refractory patients who can be considered surgical candidates and to result in even better surgical outcomes, but these advances will also make it possible for an increasing number of patients to undergo surgical treatment without the added expense and risk of invasive intracranial presurgical procedures. Improvement in cost-effectiveness, particularly if early surgical intervention is encouraged to maximize surgical outcome, will make surgical treatment more acceptable to third-party payers and enhance its availability. It will also contribute to the application of surgical treatment in countries with limited resources.

The burden of world epilepsy is overwhelmingly borne by developing countries, where it is estimated that upwards of 90% of people with epilepsy live.[21] Although the treatment gap in these areas of the world refers to the fact that considerably more than half of these people receive no medical therapy at all for their recurrent epileptic seizures, improving access to treatment should include surgical intervention where appropriate, as well as pharmacotherapy. As identification of patients with surgically remediable syndromes becomes easier with the application of relatively inexpensive noninvasive EEG and MRI approaches, and with the demonstration that 80% of those with surgically remediable syndromes can become seizure-free and lead relatively normal lives after early surgical intervention, surgery should become the most cost-effective approach for such patients, particularly in countries with limited resources. The establishment of at least one epilepsy surgery facility in larger developing countries, and regional centers in areas where countries are too small to support their own epilepsy surgery program, could provide service for large populations of patients. Screening patients with MRI could then make it possible to identify the best candidates as early in the course of their disorder as possible, so that presurgical evaluation and surgical intervention would proceed in a relatively inexpensive manner. Indeed, this process is already underway.[38]

It is important not to forget that much of our current understanding of the basic mechanisms of human epilepsy now derive from studies conducted on brain tissue obtained through epilepsy surgery, or by direct in vivo investigations of the human epileptic brain during the course of invasive presurgical evaluations. Expansion of the number of epilepsy surgery centers around the world has not only made surgical treatment available to an increasing number of patients, but also greatly facilitated access of basic neuroscientists to these unique research opportunities. The growth of invasive research on the epileptic human brain could tremendously enhance our future understanding of the fundamental disturbances underlying the various forms of pharmacoresistant epilepsy that are currently treated surgically. This understanding, in turn, could alter our approaches to surgical intervention, which might be more specifically directed at the structural or functional epileptogenic disturbance, resulting in procedures that are more effective and less likely to induce unwanted side effects. In addition, anatomic, chemical, physiologic, and molecular biologic research on the human epileptic brain is essential for developing new concepts for nonsurgical approaches to control disabling epileptic seizures and to prevent the occurrence of epileptic disorders.

Summary and Conclusions

Modern surgical treatment for medically refractory epilepsy has been available for well over 100 years;

however, recent technological advances in clinical neurophysiology and neuroimaging, as well as an improved understanding of the anatomic substrates and pathophysiology of a number of symptomatic epileptic conditions, have greatly enhanced the safety and efficacy of surgical intervention and markedly increased the number of patients who might be considered surgical candidates. Although this may be as many as half of all patients with epileptic seizures that cannot be controlled by pharmacotherapy, only a very small percentage of these are actually identified and referred for surgical treatment today. Surgically

remediable syndromes can now be easily diagnosed noninvasively in most cases, and 60% to 80% of patients with these disorders can expect to become seizure-free postoperatively. Many patients with more complicated epileptic conditions can also benefit from surgery, although invasive studies might be required, and prognosis may be somewhat poorer. Early surgery provides the best opportunity for complete psychosocial rehabilitation. The major purpose of this section, therefore, is to provide practicing physicians with information about surgical treatment for epilepsy that will help them to identify potential surgical candidates and refer them to epilepsy surgery centers as early in the course of their disorder as possible. The ultimate aims are to offer surgical therapy to the greatest number of patients who might benefit from this intervention, to maximize the opportunities for complete surgical cure, and to prevent the development of adverse psychiatric and social consequences of recurrent disabling epileptic seizures.

Chapter 167

Indications and Criteria for Surgical Intervention

Michael S. Duchowny

A. Simon Harvey

Michael R. Sperling

Peter D. Williamson

Introduction

The estimated lifetime cumulative incidence and prevalence of epilepsy are 3% and 0.5% respectively, with approximately 60% of patients manifesting partial seizures.[47,48] Although most patients with new-onset epilepsy have few seizures or are well-controlled, an estimated 5% to 10% of patients become sufficiently medically intractable to consider surgical therapy.[47,86] Data from a Danish registry of unselected patients with partial epilepsy suggest a cumulative incidence for intractable epilepsy of 135 per 100,000.[62] Intractable epilepsy is a major risk for personal injury, quality of life, and in some cases, mortality. Furthermore, recurrent seizures have a significant socioeconomic cost to the individual and society.

In recent decades, there has been increasing interest in the surgical treatment of patients with intractable seizures. At the second Palm Desert conference on epilepsy surgery, the number of procedures performed at major epilepsy surgery centers between 1986 and 1990 was more than twice that reported before 1985.[34] This remarkable increase has been fuelled by a combination of technological advances in neuroimaging and electroencephalography, new appreciation of the devastating personal and socioeconomic effects of recurrent seizures, delineation of surgically remediable epilepsy syndromes, and recognition of the long-term benefits of early surgical intervention.

Temporal lobe resections make up approximately two-thirds of all procedures currently performed at epilepsy surgery centers, reflecting the predominance of adult patients with intractable temporal lobe epilepsy (TLE). In pediatric epilepsy surgery centers, a greater proportion of patients undergo extratemporal, multilobar, and hemispheric resections.[54,85,126]

It is currently estimated that as many as 5,000 new patients annually in the United States might benefit from epilepsy surgery,[86] yet less than one-third receive treatment at the major centers.[34] Underutilization of epilepsy surgery is also apparent in other countries.[79,97] The education of primary care physicians to refer patients with surgically remediable epilepsies, instruction of health insurers and government health agencies regarding reimbursement for epilepsy surgery, and refinement of epilepsy surgical protocols should increase the number of patients with intractable epilepsy who may benefit from epilepsy surgery.

Who Is a Candidate for Epilepsy Surgery?

A simple statement can be made that epilepsy surgery may be considered by anyone whose seizures recur despite use of appropriate antiepileptic drugs (AEDs). For properly selected patients, surgery offers a relatively safe and effective means of either abolishing seizures, diminishing their severity, or reducing seizure frequency. Because most of the benefits conferred by surgery accrue when seizures are completely stopped, palliative surgery is a viable option only if it would improve quality of life or lessen the risk of injury or death. Surgery may seem a rather drastic measure for intermittent symptoms that may not prevent someone from living a happy and fulfilling life. However, uncontrolled epilepsy has numerous adverse medical and psychosocial consequences, some of which appear only after years or decades of illness. Surgery is performed precisely because it is effective, and its risks are generally less than the aggregate long-term risks of uncontrolled seizures.

What kinds of seizures and types of epilepsy provoke the consideration of epilepsy surgery? The most common types of seizures that lead people to consider surgery are those that cause alteration of consciousness or awareness or injury. These seizures have the greatest potential to cause injury and impair quality of life. Hence, complex partial and secondarily generalized tonic–clonic seizures are common indications for surgery because of their adverse psychosocial and medical repercussions. Loss of awareness prevents legal operation of a motor vehicle, forces people to rely upon others for transportation (which limits independence), reduces employment opportunities, diminishes educational choices, and imposes psychological burdens. Common activities, such as using pubic transportation, are fraught in ways that people who do not suffer from seizures cannot imagine. In addition, when seizures might cause someone to precipitously fall with resultant injury (e.g., tonic–clonic, atonic, tonic, and some simple partial seizures), activity is further limited. In addition, some seizures, although they might not cause injury or loss of awareness, might be so unpleasant or psychologically disruptive that surgery could still be an option. For example, seizures that either produce intense nausea and vomiting or cause socially unacceptable behavior might warrant surgical therapy. Lastly, some postictal behaviors, such as recurrent postictal psychosis and prolonged postictal confusion or lethargy, may cause more difficulty than the seizures themselves and prompt a patient to consider surgery. In general, the individual who suffers from the seizures is the only one who can state with certainty whether residual symptoms are inadequately controlled or not, although it is the physician's responsibility to assess medical risks.

How often should seizures occur to consider surgery? There is no objectively determined seizure frequency required to consider surgery. Although most people who have surgery have seizures at least once every month or so, others have had fewer seizures and decided that surgery was worthwhile. Having just one or two seizures per year prohibits the legal operation of a motor vehicle and can lead to serious medical and psychosocial consequences. In our experience, some patients with as few as two or three seizures per year have had surgery and viewed it as worthwhile; careful preoperative counseling

should always be performed so that patients will have realistic expectations.

The time at which seizures occur might also influence the decision to have surgery. Seizures that occur at predict-able times pose fewer problems than seizures that appear randomly. For example, the person who has seizures occurring only while asleep (nocturnal seizures) may drive an automobile and live a relatively unrestricted life. However, these seizures might still be psychologically disturbing, disrupt sleep, and pose medical risk so that surgical consideration is legitimate.

Last, the type of epilepsy syndrome must influence the decision to consider surgery. Some types of epilepsy are known to disappear with the passage of time, so that it would be overly aggressively to perform surgery for them. Other types of epilepsy are associated with a progressive downhill course, (e.g., progressive myoclonic epilepsy, seizure associated with malignant tumors) so that surgery will certainly not afford long-term benefit and probably should not be done. Other types of drug-resistant epilepsy (e.g., medial TLE) often favorably respond to surgical treatment, and surgery might be considered early in the course of treatment.

Rationale for Surgical Intervention

In addition to the physical harm posed by epileptic seizures, accumulating evidence suggests that chronic epilepsy results in deterioration of brain function and structure. It is recognized that many patients with epilepsy, particularly patients with seizures of temporal lobe origin, suffer a progressive decline in learning and memory.[51] The loss of verbal memory skills has particularly devastating consequences on quality of life and may lead to a significant decline in socioeconomic status. It is not altogether clear to what degree seizures, their underlying pathologic substrate, or the cumulative effects of drug treatment contribute to decline, but a longer duration of epilepsy appears to be a critical factor in cognitive decline. Helmstaedter et al.[50] performed a longitudinal neurocognitive study of 147 surgically treated and 102 medically treated adults with TLE. They found that a higher proportion of the medically treated group suffered a significant decline in memory skills between 2 and 10 years after baseline evaluation. Seizure-free patients had the best outcome, with superior recovery of both memory and nonmemory functions. Cross-sectional studies have further shown that a duration of TLE greater than two decades is associated with the greatest deterioration of cognitive ability and is independent of patient age and age at seizure onset.[61] Additional evidence suggests that frequent interictal discharges and short nonconvulsive seizures can cumulatively impair cognition and educational achievement.[2]

In parallel with studies of cognition, serial neuroimaging studies in patients with refractory seizures reveal evidence of progressive degeneration at anatomic loci remote from seizure origin. Recurrent temporal lobe seizures are associated with decreased hippocampal volume 3.5 years after seizure onset if recurrent seizures are present,[41] whereas progressive volume reduction occurs in the amygdala and entorhinal cortex ipsilateral to the atrophic hippocampus.[14] Voxel-based morphometry of unilateral TLE reveals abnormalities in the thalamus, cerebellum, and extratemporal neocortex as well as temporal and extratemporal white matter.[80] These findings collectively reveal that chronic TLE is associated with widespread secondary changes that affect multiple brain regions and the connectivity between cerebral hemispheres.

Criteria for Surgical Candidacy

Medical Intractability

The decision to refer patients for epilepsy surgery rests on the perceptions of the patient and physician that medical treatment is failing. These perceptions are based on the belief that the physician has exercised “due diligence”—she has administered optimal medications at high serum therapeutic concentrations. However, there are few established guidelines to assist the physician's choice of medications, dosing interval, duration of treatment, monitoring of serum concentration, and withdrawal of therapy. Thus, medical treatment of seizures is still largely individualized, with no unique point in time when intractability is established.

Certain risk factors dictate a low probability of seizure remission. The likelihood of persistent seizures is increased by additional factors such that patients with multiple risk factors have the poorest outcome.[21] High seizure frequency in the form of daily or weekly episodes constitutes a major risk factor for medical intractability, whereas seizure clustering increases the risk still further.[1] Early seizure onset, particularly in infancy, predicts seizure persistence,[77] and infantile hemiconvulsive status epilepticus (SE) is specifically linked to the development of TLE.[20,42,45] Motor convulsions in a nonconvulsive disorder are a risk factor independent of the number of lifetime episodes.[90] Patients with organic brain damage are less likely to undergo spontaneous seizure remission.[1,56] Thus, abnormal neurologic status by physical examination or neuroimaging criteria is associated with both a greater risk of developing epilepsy and a reduced likelihood of remission. As a rule, the more severe the brain damage, the greater the likelihood of seizure persistence.[113]

Deficient medical management may, in some cases, simulate medical intractability. Patient noncompliance or intermittent compliance may masquerade as “pseudointractable” seizures. Physician failure to administer a first-line or appropriate adjunctive antiepileptic medication, or more commonly failure to attain high therapeutic serum concentrations, is not infrequently discovered in patients referred for surgical evaluation.[43] Nonepileptic disorders and psychogenic seizures must be exposed at the outset, but approximately 10% of epileptic patients also manifest coexistent psychogenic seizures.[23] The range of conditions resembling epilepsy in early childhood is particularly broad.[104] Mistaking complex partial seizures for absence epilepsy, or failing to identify precipitating factors, such as sleep deprivation, leads to suboptimal therapy. Neurodegenerative disorders and inborn errors of metabolism are a rare but important cause of seizures that do not respond to medications, and inborn errors of metabolism may go unrecognized in patients with structural brain abnormalities. Indolent gliomas occasionally manifest as refractory epilepsy but are usually detectable with serial neuroimaging.

Seizure frequency and duration of epilepsy should not be the sole determinants of medical intractability, because infrequent seizures or short duration of epilepsy may still pose significant risks for the patient and impair quality of life. For example, yearly seizures may make it impossible for a patient to drive or perform certain occupations. Similarly, infrequent but severe seizures or recurrent bouts of SE pose a significant medical risk. Occasionally, patients with a relatively brief seizure history present with extremely frequent or disabling seizures, such as in epilepsia partialis continua or certain infantile syndromes. Medical intractability must therefore be assessed in the context of the patient's quality of life and likelihood of seizure remission.

Recent studies suggest that patients at risk for intractable epilepsy can be identified with a surprising degree of accuracy early in the course of their epilepsy. This would suggest that patients can and should be placed on a “watch list” by their treating health care providers. Epilepsy patients who have already experienced multiple seizures before seeking treatment, and who have an inadequate response to initial attempts to control seizures using AEDs are likely to have refractory epilepsy.[71] In children, for example, after adjusting for epilepsy syndrome, the occurrence of high seizure frequency, focal electroencephalographic (EEG) slowing, and acute symptomatic or neonatal SE are associated with a higher risk of intractability, whereas seizure onset between 5 and 9 years was associated with a lower risk.[10] In contrast, lack of early remission in patients who are not medically refractory is not associated with a poor outcome.[9]

Identification of a Surgically Remediable Syndrome

A significant proportion of epilepsy surgery candidates manifest seizures in the context of specific epilepsy syndromes. Candidates for excisional procedures usually have localization-related epilepsy syndromes, whereas candidates for commisural surgery typically have generalized epilepsy syndromes. Patients with surgically amenable epilepsy syndromes fall within the cryptogenic and symptomatic etiologic groups, because idiopathic epilepsy syndromes are genetically determined and are therefore unlikely to be influenced by surgical intervention. Many epilepsy syndromes are well characterized and have defined prognoses, simplifying the selection process; thus, idiopathic partial and generalized epilepsies are not surgically amenable, whereas surgery might be considered the treatment of choice for some specific epilepsy syndromes such as mesial TLE; neocortical epilepsy caused by discrete, easily resectable lesions; chronic epilepsy associated with Sturge-Weber syndrome; tuberous sclerosis; focal cortical dysplasia; hemimegalencephaly; and Rasmussen syndrome.

The Landau-Kleffner syndrome of acquired epileptic aphasia is a rare disorder characterized by regression of language in early childhood, prominent EEG abnormalities, and often seizures. In some children with impaired language who fail medical treatment, multiple subpial transection of perisylvian cortex on one side may be of benefit.[53]

The syndrome of gelastic epilepsy and hypothalamic hamartoma is another rare epilepsy syndrome for which cortical resection and anterior callosotomy are ineffective in alleviating seizures.[17] Recently, seizure remission has been achieved by hamartoma resection,[88,116] confirming seizure origin in the hypothalamic lesion. These observations suggest that other cases of intractable epilepsy syndromes associated with subcortical lesions such as subcortical heterotopias may also be surgically amenable.

Surgical treatment is advocated for some patients with infantile spasms. Infants who fail to respond to treatment with conventional anticonvulsants and corticosteroids, and who demonstrate predominantly unilateral abnormalities on EEG, positron emission tomography (PET), and magnetic resonance imaging (MRI) may be suitable for lobar or multilobar cortical resection.[22,105] Early resective surgery is also indicated in infants with catastrophic presentations of partial seizures.[28]

Loss of Quality of Life

Chronic epilepsy is associated with considerable comorbidity and deterioration in overall quality of life. Decline in social, behavioral, and intellectual domains is a prime motivating factor in seeking surgical intervention. This is especially true for children, who are at higher risk for behavioral and cognitive disturbances as well as the emergence of depression in adolescence.[29,30,86] Children with medically resistant seizures who are intellectually disadvantaged show an even greater compromise in their quality of life, irrespective of their intellectual ability level.[101]

The benefits of surgical intervention have recently been demonstrated for adults with TLE. Aydemir et al.[4] found that successful surgery improved social activities and resulted in greater independence. Similarly, Lowe et al.[78] found that long-term seizure-freedom after temporal lobectomy uniformly improved quality of life.

Earlier definitive surgical intervention would be expected to set the stage for improved self-esteem, greater social opportunity, and career advancement. Two separate studies have confirmed this hypothesis. Van Empelen et al.[118] performed a longitudinal follow-up of 21 children and found that, 2 years after surgery, children began to perceive themselves as being socially more competent and having greater self-worth. Adolescents began to improve sooner after surgery; at 2 years, they demonstrated improvement in the domains of athletic competence and romance. Sabaz et al.[102] also found improved quality of life in a prospective study of families of 35 children with medically resistant epilepsy undergoing epilepsy surgery, but significant gains occurred primarily in patients who became seizure-free.

Role of Early Intervention

The evidence for neuronal injury and subsequent epileptic and cognitive deterioration in chronic epilepsy has been discussed. The detrimental effects of recurrent seizures pose special risks to the developing brain of infants and young children. Uncontrolled seizures also jeopardize the chances for an independent lifestyle, and children with intractable epilepsy are likely to be excluded from normal schools and from social and vocational opportunities.[74,75,76] Thus, uncontrolled chronic epilepsy has the potential for irreversible cognitive, behavioral, and psychosocial problems in later life. For this reason, syndrome characterization, medical intractability and likely prognosis should be established early in patients with uncontrolled seizures, allowing the consideration of early surgical intervention. Additional consideration takes into account the neural plasticity data from lesioning studies,[65,66,67] which suggest that functional recovery from cerebral resection is superior if surgery is performed earlier in postnatal life.

Goals of Surgery

The goal of any treatment for epilepsy is to permit the patient to live as normal a life as possible. Maximizing normal function and minimizing adverse effects is part of the overall goal of therapy, whether medical or surgical. Treatment must therefore restore a sense of well-being and alleviate the psychosocial disability, medical morbidity, mortality, and risk for associated seizures. Refractory-seizure patients often have cognitive, linguistic, motor, sensory, psychiatric, and social impairments,[3,38,39,60,64,111] and treatment must also address these problems. A comprehensive rehabilitative plan is an important component in an epilepsy surgery program.

Two broad categories of surgical therapy for epilepsy, curative and palliative, define the relative success of surgical intervention. Curative surgery eradicates seizures and the need for medication, whereas palliative surgery lessens seizure severity or frequency or prevents the occurrence of some seizure types.

P.1754

These outcome measures are similar to the goals of surgery in other conditions (e.g., for cancer surgery, complete tumor removal vs. debulking).

Curative surgery should eliminate the psychosocial disability associated with seizures and therefore remains the best hope for achieving a “normal” life, including improved schooling, greater personal independence, enhanced employment opportunities and attainment of a driver's license. Studies have shown that return to a normal lifestyle after surgery rarely occurs in patients who do not achieve seizure freedom.[110] However, curative surgery may also create unanticipated psychosocial problems due to newly acquired independence or upward vocational mobility.[15]

In some patients, only one of several seizure types is cured by surgery, but this may be a worthwhile outcome. For example, patients with mixed seizure disorders usually benefit from elimination or marked reduction in the frequency of tonic or atonic seizures, due to the reduction in medical risk and attendant injuries (e.g., fractures, lacerations). Similarly, patients with TLE may benefit from abolition of complex partial seizures and tolerate occasional auras without loss of consciousness. Palliation requires a clear a priori definition of the surgical objectives, so that an intelligent appraisal of results can follow surgery.

Whenever surgery for epilepsy is contemplated, the risks and benefits must be carefully weighed. The risks of epilepsy surgery are acceptably low in the modern era, with overall mortality being less than 0.5% and morbidity 5%. Surgical complications include cerebral infarction, intracranial hemorrhage, intracranial infection, and direct cranial nerve or cerebral injury, possibly resulting in temporary or permanent neurologic deficits. Morbidity and mortality vary according to the patient's age and type of surgery; risks appear to be slightly higher in children compared with adults, and in hemispherectomy and corpus callosotomy compared to anterior temporal lobectomy and extratemporal resections.[116,117]

The risks of surgery must also be compared with the risks of continued medical treatment. At present, little data address the relative risks of medical versus surgical treatment. Risks associated with ongoing epilepsy and their medical treatments include death, injury, SE, possible detrimental effects of seizures, and adverse effects of medication. People with epilepsy have increased mortality rates compared with the general population,[73] and a preliminary report suggests that this risk might be reduced by epilepsy surgery.[119] A large prospective controlled study of patients with persistent seizures revealed that achieving complete seizure control after epilepsy surgery reduces mortality to a level that is indistinguishable from the general population, whereas seizure persistence is continues to be associated with high mortality rates.[108] Thus, given the reduced risk of death after successful epilepsy surgery, the long-term risks of medical therapy exceed the risks of epilepsy surgery in suitable candidates.

The issue of epileptic and intellectual deterioration in chronic epilepsy is controversial, but experimental and clinical studies provide evidence that seizures can produce cognitive impairment[16,55,98] and produce cellular changes.[5,81] Studies suggest the hippocampus is particularly vulnerable, especially in early childhood.[20,45,103]

Types of Surgical Treatment

Surgical procedures to treat epilepsy include lesionectomy, lobectomy, corticectomy, multiple subpial transection, corpus callosotomy, and various combinations of these procedures. For hemispheric epilepsy syndromes, various forms of hemispheric resection and disconnection are utilized. The specific type of surgery employed for a patient depends on the predominant seizure type, the location of the seizure focus, the presence of a demonstrable lesion, and the patient's cognitive and neurologic status. The timing of surgery must take into account the natural history of the epilepsy syndrome, the patient's developmental status and, in children, issues related to cerebral plasticity.

Mesial Temporal Lobe Epilepsy

Disorders of the mesial temporal lobe often give rise to seizures that ultimately become refractory to medical treatment, constituting the most common surgically remediable epilepsy syndrome. Although mesial temporal lobe epilepsy (MTLE) can be caused by tumors, vascular malformations, developmental anomalies, and other discrete epileptogenic lesions that are potentially resectable, within this condition the most common syndrome is MTLE with hippocampal sclerosis.[40,125] There is often a history of febrile seizures or other neurologic insults in early childhood,[20,45] and complex partial seizures typically begin in the first or second decade. The syndrome is additionally characterized by anterior or midtemporal spikes on EEG and hippocampal atrophy and signal abnormality on MRI.[13,57] Additionally, patients may have temporal lobe hypometabolism on PET,[31,33] temporal lobe hypoperfusion on single photon-emission computed tomography (SPECT),[71,100] and specific memory disturbances on neuropsychological testing and intracarotid amobarbital testing. Longitudinal studies of patients with complex partial seizures suggest that less than 20% undergo spontaneous remission of seizures,[44,69,77] and that a significant proportion of patients with refractory seizures experience cognitive, interpersonal, and psychiatric problems.[74,75,76] Thus, all patients with medically intractable TLE should be given consideration for surgery, early in the course of their epilepsy.

Prior to high-resolution MR and functional neuroimaging, surgical candidates frequently required invasive EEG monitoring with temporal lobe depth or strip electrodes. More recently, preoperative investigations have been limited to scalp EEG monitoring, MRI, neuropsychological testing and, at some centers, PET or SPECT.[32,109,112] Chronic subdural or depth EEG monitoring, or both, are presently advocated for patients without MRI evidence of hippocampal pathology. When language-dominant lateral or posterior neocortical temporal seizures are suspected, extraoperative functional mapping of language is recommended.

For patients with unilateral or predominantly unilateral seizures, most centers perform a standard anterior temporal lobectomy in which the amygdala, anterior hippocampus, and anterior temporal neocortex are resected.[36] Intraoperative electrocorticography and cortical stimulation are used at some centers to tailor the lateral temporal resection according to the extent of EEG abnormality and the location of the language cortex.[27,115] Selective amygdalo-hippocampectomy, sparing the lateral temporal neocortex, is performed at some centers,[106,128] while other centers perform only lateral neocortical resections, sparing amygdala and hippocampus.[70] The aim of modified temporal resections is to reduce postoperative cognitive deficits; however, the indications for these procedures are not standardized and, as a result, surgical decisions are largely based on local institutional philosophy and the results of preoperative MRI and neuropsychological testing.

Lesional Neocortical Epilepsy

Partial epilepsy associated with a discrete neocortical lesion such as a tumor, vascular malformation, or focal cortical dysplasia constitutes another surgically remediable

epilepsy syndrome.[17,91,93] In this setting, the potential exists to cure the patient's seizures with minimal electrophysiologic investigation and localized resection. However, surrounding cortex may harbor occult pathology and be epileptogenic, necessitating more thorough electrophysiologic investigation and wider resection.[11,12] For lesions that do not involve critical cortex, the surgeon can perform a generous resection that includes the lesion and surrounding cortex. When lesions are close to or directly involve language, cognitive, motor, or sensory cortex, excisional surgery may be contraindicated or may only be feasible with stereotactically guided lesionectomy,[18] corticectomy or lesionectomy guided by EEG localization and functional mapping,[12] or resection combined with multiple subpial transection.[82] Patients with large lesions, such as large areas of pachygyria, may still benefit from epilepsy surgery but only by extensive resection of the lesion and surrounding epileptogenic cortex. For patients with multiple lesions, such as patients with tuberous sclerosis or patients with multiple cavernous angiomas, successful surgery is still possible if seizures can be localized to a single lesion or group of lesions.[6,35]

An important surgical consideration is that developmental lesions in proximity to critical cortex do not necessarily displace or transfer function to the opposite hemisphere.[24,25] Complete resection of the lesion appears crucial for seizure-freedom in lesional epilepsy surgery.[37,92] Advances in MRI and functional MRI should facilitate the selection and preoperative investigation of patients with lesional epilepsy.

"Nonlesional" Neocortical Epilepsy

Patients with "nonlesional" partial epilepsy are the most challenging group of surgical candidates and are typically evaluated at specialist centers. Many have extratemporal epileptogenic regions and present with a wide spectrum of simple partial, complex partial, or secondarily generalized seizure types. When the seizure semiology suggests a well-localized site of onset, the scalp EEG shows localized discharges, and the patient's neurologic examination and cognitive profile do not suggest extensive cerebral dysfunction, surgery is a reasonable consideration. By contrast, surgery is often unrewarding in patients with poorly localized electroclinical findings or evidence of pervasive cerebral dysfunction.

A detailed description of the patient's aura and careful attention to the ictal behavioral sequence on video monitoring may suggest the lobe and side of seizure onset. Interictal and ictal EEG monitoring with special electrodes or extra closely spaced electrodes may further localize the field of electrographic abnormality or reveal discharges from basal or interhemispheric cortex that may not be obvious from the routine EEG.[83] Ictal SPECT is particularly useful in nonlesional extratemporal epilepsies, often revealing discrete neocortical regions of activation not appreciated by EEG monitoring or MRI.[46,52] Interictal SPECT and PET are usually unrewarding in aiding localization of "nonlesional" extratemporal epilepsies. Once a putative epileptogenic region is identified, repeat MRI using thin coronal slices and optimized pulse sequences through the suspected region may identify a previously occult lesion.

In patients with no demonstrable cortical lesion, intracranial EEG recording of seizures using subdural or depth electrodes or a combination of both is often necessary to plan the resection.[26,127] Occasional patients with a discrete epileptogenic region may benefit from localized corticectomy, but many patients require large resections due to either poorly demarcated areas of epileptogenicity or evidence of widespread epileptic dysfunction. Alternatively, some centers perform a generous lobectomy or multilobar resection in patients with nonlesional extratemporal epilepsy, based on noninvasive preoperative data and intraoperative electrocorticography. Seizure outcome in this difficult group of patients again depends on the ability to resect the epileptogenic region.[60]

Hemispheric Epilepsy Syndromes

Several neurocutaneous disorders, cerebral malformation syndromes, and acquired cerebral pathologies are manifest by intractable seizures of hemispheric origin. Specific examples include Sturge-Weber syndrome, hemimegalencephaly, Rasmussen syndrome, and infantile hemiplegia with unilateral cerebral atrophy or porencephaly. In the developmental and early acquired syndromes, seizures often begin in early infancy and are associated with developmental slowing, arrest, or regression. In this group, early surgical intervention not only offers relief from seizures but also permits attainment of the child's full developmental potential. Early hemispherectomy for patients with Rasmussen syndrome is advocated by some centers.[121]

Hemispherectomy is generally indicated in patients with widespread unilateral EEG abnormalities, diffuse unilateral structural abnormality, and clinical evidence of hemiparesis and hemianopia. In young patients, hemispherectomy may be performed in the absence of all these features in hopes of greater seizure-freedom and more complete transfer of function to the other hemisphere. Detailed preoperative EEG monitoring and functional neuroimaging are usually unnecessary to lateralize seizures but may help to exclude contralateral seizure onset and confirm the functional integrity of the contralateral hemisphere.

Various surgical techniques are employed to treat hemispheric epilepsy syndromes, and these include anatomic hemispherectomy, functional hemispherectomy, hemispherectomy, and hemidecortication. The choice of technique depends in part on the patient's age, the type of lesion, the size of the hemisphere and lateral ventricle, and the surgeon's expertise.

Secondary Generalized Epilepsies

The symptomatic/cryptogenic generalized epilepsies, such as the Lennox-Gastaut syndrome, bilateral cerebral dysfunction, and bilateral seizure onset, usually preclude focal cortical resection. Atonic, tonic, and tonic–clonic seizures may, in some patients, respond to corpus callosotomy, the rationale being interruption of the rapid secondary bilateral synchrony that underlies these seizures types.[89,107] The indications for corpus callosotomy are not standardized, but patients with “drop attacks” usually respond best. Recurrent episodes of convulsive SE are also eliminated in most cases.[98] The influence of intelligence, EEG abnormalities, and MRI abnormalities on outcome is variable.

Preoperative investigations are usually limited to EEG monitoring and MRI to exclude focal onset of seizures and therefore possible benefit from focal cortical resection. Neuroimaging studies often reveal lateralizing abnormalities, but may also reveal lesser but potentially significant problems in the good hemisphere. Both ictal and interictal EEG may be uninformative and, in some cases, actually misleading by indicating greater abnormalities over the good hemisphere.[122] Documenting seizure types may add useful lateralizing information even in the absence of EEG confirmation.

Debate exists as to the superiority of anterior versus total corpus callosotomy with respect to seizure control and postoperative neuropsychological status. Corpus callosotomy is occasionally performed in patients with nonlocalizable partial epilepsies in whom secondary generalization and falling

P.1756

occur. Timing of surgery is not an issue in patients with infantile hemiplegia, but may be more problematic in disorders such as Rasmussen syndrome, in which children are generally normal at the outset and then slowly deteriorate. If there is concern for neurologic functions in hemispherectomy candidates, corpus callosum section should be considered. Corpus callosotomy has been offered as an alternative to hemispherectomy in infantile hemiplegia syndromes and remains a viable option.[124]

Contraindications to Surgery

Absolute contraindications to epilepsy surgery include underlying degenerative or metabolic disorders or supervening medical illness. Progressive neurologic disease must therefore be diagnosed at the outset, because these disorders are unlikely to benefit from surgical therapy.

Benign epilepsy syndromes for which seizure remission is anticipated at a later date constitute another absolute contraindication to epilepsy surgery. Benign rolandic epilepsy and benign focal epilepsy of childhood with occipital spikes are the most common idiopathic partial epilepsies, and present with characteristic clinical and EEG features.[49,94] However, some patients with atypical rolandic or occipital seizures may be difficult to differentiate from patients with occult lesional epilepsies.

Relative contraindications to surgery include medication noncompliance, interictal psychosis, and severely dysfunctional family dynamics. Mental retardation is a potential surgical contraindication, but has little practical importance for resective procedures, and is a not a factor in determining candidacy for corpus callosotomy. Medication noncompliance is considered by some to be a contraindication to surgery, because noncompliance compromises the establishment of medical intractability and predicts postoperative noncompliance. Persistent interictal thought disturbance in a patient with intractable epilepsy is a controversial surgical contraindication, because psychotic patients still fare better if their seizures can be controlled.[114] Although mental retardation indicates pervasive cerebral dysfunction, retarded patients also benefit from the elimination of recurrent seizures and medication. Finally, families that are psychodynamically dysfunctional rarely tolerate the intensive or prolonged hospitalizations required for epilepsy surgery and may also be unable to rationally evaluate its attendant risks or work with the epilepsy surgery team members.

Cost-Effectiveness as a Criterion for Surgery

Economic considerations are important when considering epilepsy treatments. Patients who are resistant to medical therapy suffer most from the detrimental economic and social impacts of the condition. Whereas the most refractory patients comprise only a small proportion of those with epilepsy, they account for a large share of the total costs imposed by epilepsy. One study estimated that the 15% of patients who are most refractory account for at least 50% of the total costs of the illness.[8] Another found that cost correlated with the severity of the illness, and that intractable patients cost eight times more that those with controlled epilepsy.[60] The added expense comes from both medical (direct) costs and nonmedical (indirect) costs. Medical expenses include the cost of physician visits, emergency room visits, hospitalizations, medications, diagnostic laboratory testing. These are much higher in patients with recurrent seizures than in controlled patients. Indirect expenses, which account for up to 75% of total costs, include lost productivity from unemployment, underemployment, or lost work time; excess mortality; transfer payments (e.g., disability pension); and lost work by relatives or friends to care for the ill person.[8,59]

Murray et al.[84] estimated the lifetime cost analyses of refractory epilepsy in the United States in the mid 1900s, which were estimated to comprise 29% of adult cases. Indirect costs included lost wages due to unemployment and underemployment and lost caretaker earnings. Transfer payments and mortality costs were excluded. Prevalence analysis found direct costs of $912,553,518 and indirect costs of $2,992,629,945, with a total annual cost of nearly $4 billion (USD) ($11,745/person). Indirect costs accounted for 77% of the total.

In another analysis, Begley et al.[8] estimated the 1995 costs of epilepsy in the United States at $12.5 billion. The direct costs included were direct medical costs. Lost wages and mortality were included in indirect costs. For incident cases, those with intractable epilepsy represented 25% of all cases, but accounted for 79% of estimated costs; indirect costs accounted for 88% of the total expense. For prevalence cases, patients with intractable epilepsy comprised 43% of all cases, but accounted for 80% of estimated costs; indirect costs accounted for 84% of the total cost.

The foregoing analyses all show that refractory patients are far more expensive than well-controlled patients, and one could infer that successful treatment of refractory patients—that is, making them seizure-free—would reduce costs in the long run. Several analyses have been performed to assess the cost-utility or cost-effectiveness of epilepsy surgery.[68,71,95,96] Similar conclusions have been drawn from all analyses, that epilepsy surgery is cost-effective. King et al. calculated that the cumulative discounted benefit from temporal lobectomy was 1.1 quality adjusted life years (QALYs), equivalent to 1.1 extra years in good health. They found that surgical evaluation and treatment had an average marginal cost of $29,800 per patient, yielding a cost-utility ratio of $27,200 per QALY. Langiftt et al.[71] determined that surgery conferred an improvement of 1.61 QALY, for a cost of $15,581 per QALY for surgery.

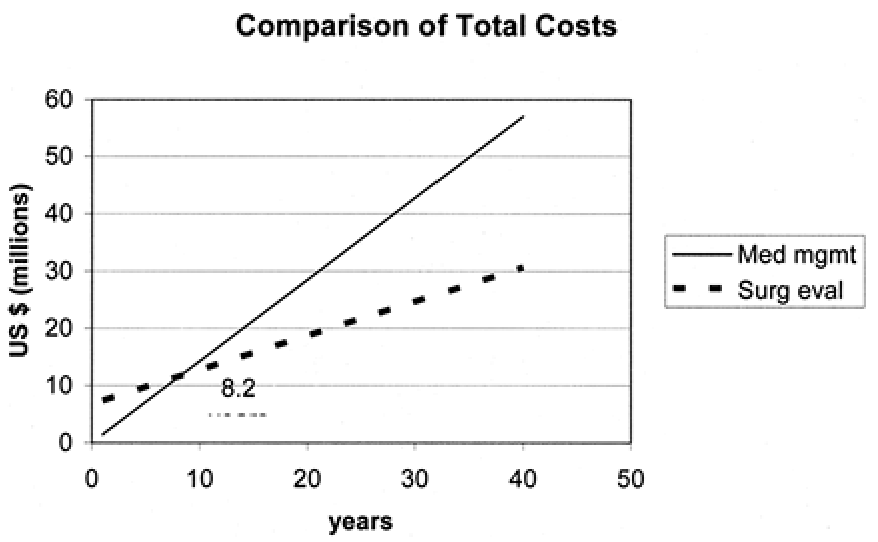

FIGURE 1. Medical management (*solid line*) has a higher per annum cost than surgical treatment. Although cheaper in the early years, the cumulative effect is that net costs over many decades are considerably higher than for surgical treatment (*dashed line*). (From Platt M, Sperling, MR. A comparison of surgical and medical costs for refractory epilepsy. *Epilepsia*. 2002;43(Suppl 4):25–31, with permission.)

Several studies have compared the costs of medical and surgical therapy. Wiebe et al.[123] modeled long-term direct medical costs in two cohorts each containing 100 patients: One treated medically, and the other evaluated for surgery. For a 35-year period, they estimated that the cost for treating the medical group were $10,741,425, whereas the cost for treating the surgical group was $8,117,911. Sensitivity analyses did not change the findings. This study did not estimate nonmedical direct costs nor indirect costs, and therefore the dollar amounts reflect only a portion of the overall costs in medical and surgical therapy. Platt and Sperling[96] performed an analysis comparing medical and surgical costs in an American cohort, and concluded that surgical treatment of TLE is cheaper than medical therapy, although this clearly requires a long-term societal perspective. When all indirect costs are combined with direct costs (Fig. 1), the total costs for the surgical group were less than the medical group 8.2 years after assignment, approximately 45% less time than if only direct costs are used in the calculations. The disparity in costs increased further with the passage of time. More recently, Picot et al.[95] evaluated a French cohort and had remarkably similar findings—that cost-effectiveness is demonstrated between 7 and 8 years after surgery. Whereas surgery has much higher costs in the first year, due to the expense of testing and hospitalization, the long-term benefit is substantial since patients who favorably respond to surgical treatment have much reduced costs in the long run.

P.1757

Summary and Conclusions

The different medical and psychosocial backgrounds of the patients, the variety of investigational modalities available to the physician, and the number of potential surgical procedures detract from the precision of the selection process. Nevertheless, efforts are underway to delineate selection criteria and preoperative protocols for the surgical treatment of the more common surgically remediable epilepsy syndromes. If it can be demonstrated conclusively that recurrent seizures are harmful to the developing or fully developed brain, it is likely that surgery will be considered at an earlier point in the treatment time-line. Early surgical intervention in appropriately screened patients is likely to benefit long-term neurobehavioral status, in addition to controlling seizures, and thus improve overall quality of life and costs to the patient and community.

Chapter 168
Surgically Remediable Syndromes

Jerome Engel Jr.
Gregory D. Cascino
W. Donald Shields

Introduction

The safety and efficacy of surgical treatment for epilepsy have improved greatly in recent years as a result of major advances in diagnostic technology, particularly long-term electroencephalographic (EEG) monitoring and neuroimaging, as well as refinements in surgical procedures.[21,24,32,56] The vast majority of patients can undergo surgical intervention without the need for chronic invasive recordings, which contributes greatly to a decrease in morbidity, mortality, and cost, and more accurate localization of the epileptogenic region has resulted in better surgical results, leaving 80% to 90% seizure-free in some series of carefully selected patients. These developments have led to an important conceptual advance in epilepsy surgery: The view that surgical intervention need not always be considered a therapy of last resort but, rather, an early treatment of choice for certain well-defined surgically remediable syndromes.[23,24,29] Surgically remediable epilepsy syndromes are disorders for which (a) the pathophysiology is understood; (b) the natural history is reasonably well known to be medically refractory or even progressive once the major first-line antiepileptic drugs (AEDs) fail; (c) presurgical evaluation can be accomplished noninvasively; and (d) surgery offers an excellent chance that disabling seizures will be completely eliminated.

The prototype of a surgically remediable syndrome is mesial temporal lobe epilepsy (MTLE), the form of temporal lobe epilepsy (TLE) that is often, but not always, associated with hippocampal sclerosis (HS).[91,92] Neocortical epilepsies caused by well-circumscribed solitary lesions[13] and a variety of unilateral but relatively diffuse hemispheric disorders in infants and young children[78] are also in this category.

Arguments for Early Intervention

Uncontrolled epileptic seizures can severely impair activities of daily living. In MTLE, complex partial seizures are usually prominent in adolescence and early adulthood, when they disrupt schooling and the acquisition of the social and vocational skills necessary to lead a normal, productive, and satisfying life. Frequent seizures in infants and young children can have an even more disastrous effect on psychomotor development. The avoidance of irreversible psychosocial consequences of epilepsy, therefore, is a strong argument for early intervention in surgically remediable epilepsies. There is, however, additional evidence for direct deleterious effects of certain seizure types on the brain.[84] The progressive nature of epilepsy, although controversial, has been well demonstrated by phenomena such as kindling[38] and secondary epileptogenesis,[59] seen in experimental animal models. If similar processes exist in human epilepsy, they could result in a worsening of epileptic seizures, manifested as more frequent or more severe seizures, more medically refractory seizures, or perhaps even surgically refractory seizures. Enduring disruption of normal cerebral function and the appearance of interictal behavioral disturbances could also result from these progressive changes or appear as a side effect of those natural, protective seizure-suppressing mechanisms that develop to maintain the interictal state.[26]

What is the evidence that progressive processes exist in the surgically remediable epileptic syndromes? In MTLE, seizures usually do not become medically refractory until many years after onset of the habitual events,[8] and interictal behavioral disturbances are reported to be common in this disorder.[25,92] Furthermore, some evidence suggests that surgery is less likely to produce complete freedom from seizures when performed late in the course of the disorder.[27] In lesional neocortical epilepsy (LNE), late surgical intervention also decreases prognosis for elimination of all ictal events.[60] In both these disorders, cognitive function improves following surgical treatment, particularly the material-specific memory function of the temporal lobe contralateral to an anterior temporal lobectomy.[70] Reversal of developmental delay by surgery for diffuse hemispheric epileptogenic disturbances in infants and young children[79] is particularly remarkable because children with these disorders who continue to have seizures almost invariably develop mental retardation and often require institutional care. These observations strongly support the view that at least some types of epileptic seizures can themselves induce progressive cerebral dysfunction and provide a strong case for early surgical intervention.[25]

Because complete freedom from seizures early in the course of the disorder can prevent the development of disabling psychosocial consequences of epilepsy as well as interictal behavioral disturbances that might result directly from seizures, early surgical intervention for the surgically remediable syndromes offers the best opportunity for achieving a normal postoperative quality of life (88). Also, because the cost of presurgical evaluation and of the surgery itself is the same whether performed early or late, and early intervention is most likely to eliminate future medical expenses and result in an independent, tax-paying individual, this approach is certainly more cost-effective.

To practice early intervention, however, it is necessary to redefine the concept of medical intractability, and this requires further study. At present, for adolescents and adults, failure of two or perhaps three of the most appropriate AEDs as monotherapy at maximum tolerable doses seems to be an adequate definition, whereas the use of second-line medications and multiple-drug combinations would unnecessarily delay a potentially definitive therapy. The need for rapidly establishing surgical candidacy may be even more urgent for infants and young children with very frequent seizures and developmental

delay. Specific ages at which a timely decision might be particularly critical are (a) 5 to 7 years, when the plastic properties of the developing brain begin to decrease sufficiently to cause concern that hemispherectomy or multilobar resection will cause additional neurologic disability, particularly for language; and (b) early adolescence, when continuing seizures have a negative effect on social development and academic achievement.

Recognition that a patient might have a surgically remediable epilepsy syndrome as soon as possible after the onset of seizures and expedient trials of the most effective AEDs to establish medical intractability in a timely manner provide the best opportunity for early surgical intervention and optimum postoperative results. To achieve this goal, it is necessary for primary care physicians and practicing neurologists in the community to know how to identify these patients so that crucial years are not lost pursuing ineffective pharmacotherapy. The remainder of this chapter is devoted to the best-defined surgically remediable epilepsy syndromes.

Specific Syndromes

Syndromes to be Excluded from Early Surgical Intervention

It is important to note at the outset that many epilepsy disorders that are not surgically remediable syndromes can be easily identified early in their course. Obviously, patients with benign idiopathic epilepsies are not candidates for surgical treatment; most of these disorders are characterized by generalized seizures that are easily controlled by medication. An old argument against early surgical treatment for TLE in children, however, was that temporal lobe seizures often disappear in adolescence. Now that the syndrome of benign childhood epilepsy with centrotemporal spikes and related disorders can be readily distinguished from TLE,[50,51] it is believed that most patients previously thought to recover spontaneously from TLE[52,53,54] actually had idiopathic localization-related epilepsy. Because the clinical and EEG presentation is so characteristic, and the seizures are so responsive to medication, children with idiopathic localization-related epilepsy that will resolve spontaneously are easily excluded from a presurgical population. At the other extreme are patients with clearly intractable seizures who do not meet the criteria for having a benign idiopathic syndrome, but who have either no abnormalities on structural or functional neuroimaging or diffuse bilateral lesions.

These patients may well ultimately become surgical candidates; however, if the epileptogenic region can be defined only electrographically, the surgical results are not as good as for patients with surgically remediable syndromes, and the need for invasive monitoring greatly increases the risk and cost of presurgical evaluation.[87] It is reasonable, therefore, to pursue additional AEDs alone and in combination for much longer periods before such patients are referred for surgical treatment.

Mesial Temporal Lobe Epilepsy

Most patients considered candidates for surgical treatment today have localization-related symptomatic epilepsies, with seizures resulting from an epileptogenic lesion that is limited to one hemisphere and is potentially resectable. Lesions in the limbic system, particularly those involving mesial temporal structures, give rise to complex partial seizures with a relatively characteristic semiology as a result of preferential propagation patterns that are reasonably well understood. Because anterior temporal resections are the most commonly performed surgical treatment for epilepsy, a considerable amount of basic research has been done on mesial temporal tissues taken from patients with medically refractory complex partial seizures, and a common pathophysiologic substrate has been described for many. This consists of HS,[7] the most common lesion found in patients with epilepsy.[75] Most workers now recognize a syndrome of MTLE with HS (MTLE-HS) that has characteristic clinical features, often gives rise to medically refractory complex partial seizures, and responds well to surgical intervention (Table 1).[23,91,92] Sixty percent to 80% of patients with this disorder can expect to become free of disabling seizures following anterior temporal lobectomy.[31,32,90]

HS is characterized by a specific pattern of cell loss and neuronal reorganization that is presumed to underlie the epileptogenicity.[6] Although structural changes are concentrated in the hippocampus, amygdala, and adjacent limbic cortex, functional disturbances are much more extensive. Hypometabolism on positron emission tomography (PET) usually involves the entire temporal lobe and frequently includes the ipsilateral thalamus and, less often, other ipsilateral cortical and subcortical structures,[30,40] and contralateral mesial temporal abnormalities are evidenced by the common appearance of contralateral interictal EEG spikes[31] and material-specific memory disturbances.[69] It is unclear to what extent these abnormalities reflect mechanisms that contribute to epileptogenicity and to what extent they reflect disruption of normal function caused by propagation of epileptic activity. Although merely resecting the anterior and mesial portions of the temporal lobe, and in some cases only the amygdala and hippocampus, can abolish disabling seizures, auras tend to persist in this group of patients, supporting a view that the epileptogenic region is widespread.[91]

The fact that habitual seizures in MTLE-HS most commonly begin within the first decade of life and are usually responsive to medication for several years, with events characteristically becoming refractory to medication in adolescence,[8] suggests some progressive nature of the epileptogenic process. The commonly encountered family history and presence of microdysplasias in this disorder suggest a familial and/or congenital predisposition to the development of HS, given a specific cerebral insult early in life.[91] The frequent occurrence of prolonged febrile convulsions can be seen as evidence of a preexisting epileptic diathesis but also could serve as a HS-inducing insult. Other early insults are common in this disorder,[57] and it is conceivable that, in some children, seemingly innocuous events, such as common childhood viruses, are sufficient to set the epileptogenic process in motion. The resultant characteristic cell loss and neuronal reorganization are accompanied by the development of a propensity to generate spontaneous epileptic seizures. This presumably takes many years, accounting for the latent period between the initial insult and the onset of habitual ictal events.[37] It would be unreasonable to assume, however, that this epileptogenic process would suddenly cease at this point; rather, it is more logical to suggest that these underlying aberrant neuronal changes continue to some extent and account for a worsening of the epileptic condition and the eventual appearance of medically refractory seizures.[28] Similar progressive changes might also account for the even later appearance of interictal behavioral disturbances.[26] For this reason, and because 60% to 80% of patients can expect to become seizure-free following appropriate anterior mesial temporal lobe resection, early surgical intervention as soon as monotherapy with the two or three preferred AEDs has failed would offer the best opportunity for relief of seizures, complete psychosocial rehabilitation, and a normal, productive lifestyle.[23,24,25,32]

Table 1 The Syndrome of Mesial Temporal Lobe Epilepsy with Hippocampal Sclerosis (MTLE-HS)[a]

History

Increased incidence of complicated febrile convulsions

Increased incidence of a family history of epilepsy

Onset in latter half of first decade of life

Auras common and occur in isolation

Secondarily generalized seizures occur infrequently

Seizures often remit for several years until adolescence or early adulthood

Seizures often become medically intractable

Interictal behavioral disturbances can occur (most commonly depression)

Clinical seizure

Aura is usually present: most common is epigastric rising, often other autonomic or psychic symptoms, with emotion (e.g., fear), can be olfactory or gustatory sensation (several seconds)

Complex partial seizure: often begins with arrest and stare, oroalimentary automatisms and complex automatisms common; posturing of one upper extremity can occur contralateral to the ictal discharge (1 to 2 min)

Postictal phase: usually includes disorientation, recent memory deficit, amnesia for the event, and dysphasia if seizures begin in the language-dominant hemisphere (several minutes)

Neurologic examination

Usually normal

Can have recent memory deficit

EEG

Unilateral or bilateral independent anterior temporal spikes, maximum amplitude in basal electrodes

Can have intermittent or continuous rhythmic slowing in one mesial temporal area

Extracranially recorded ictal activity appears only with complex partial symptoms, usually initial or delayed focal onset pattern of 5- to 7 per second rhythmic activity, maximum amplitude in one basal temporal derivation

Depth electrode recorded ictal onset most often high-amplitude rhythmic spikes or sharp waves, less commonly low-voltage fast or suppression

Propagation to contralateral side is slow (>5 sec, but may be minutes) or does not occur at all

Focal functional deficits

Usually temporal lobe hypometabolism on interictal FDG-PET, often involves ipsilateral thalamus and basal ganglia

Usually temporal lobe hypoperfusion on interictal SPECT and characteristic pattern of hyper- and hypoperfusion on ictal SPECT

Usually material-specific memory disturbances on neuropsychological testing and amnesia with contralateral intracarotid sodium amobarbital injection

Mesial temporal EEG slowing and attenuation of normal rhythms can be seen with scalp/sphenoidal electrodes but more common with depth electrodes; exacerbated by intravenous pentobarbital test

Structural imaging

Usually has small hippocampus on one side on MRI

Usually has increased hippocampal T2 signal on one side on MRI

Can have small temporal lobe on one side

Can have enlarged temporal horn on one side

Can have reduced NAA on MRS

Pathophysiology

Hippocampal sclerosis (>30% cell loss with specific patterns)

Sprouting of dentate granule cell mossy fibers

Selective loss of certain hilar neurons (somatostatin- and NPY-containing cells)

Gliosis

Dentate laminar dispersion

Hamartomas and heterotopias can occur as "dual pathology"

Microdysgenesis common

Seizures usually originate in sclerotic hippocampus, but much larger area appears to be included in the epileptogenic region

Features that place diagnosis in doubt

History of severe head trauma, encephalitis, or other specific causal events after the age of 5

Focal motor or specific sensory symptoms at seizure onset or postictally

Interictal focal neurologic deficits other than memory disturbance

Marked cognitive impairment on neuropsychological testing

Bilaterally synchronous, generalized, or extratemporal focal EEG spikes

Diffuse or extratemporal focal EEG slowing

Cerebral lesion other than hippocampal sclerosis on MRI

Modified from Engel J Jr. Update on surgical treatment of the epilepsies. *Neurology.* 1993;43:1612–1617, with permission.

MTLE-HS can usually be suspected early in the course of this disorder from the typical history and characteristic simple and complex partial seizures (see Table 1). Referral to an epilepsy surgery program should be made once habitual seizures become disabling and are resistant to at least two appropriate AEDs at maximum tolerable doses. At most

P.1763

P.1764

epilepsy surgery centers, demonstration with long-term EEG video monitoring that the habitual seizures originate electrographically from one mesial temporal area and either magnetic resonance imaging (MRI) evidence that the hippocampus on that side is damaged or PET evidence that the temporal lobe on that side is hypometabolic is sufficient to recommend surgery, provided there are no conflicting findings such as atypical initial seizure semiology, other suspicious lesions on MRI, or evidence of a nonconcordant localized functional deficit. Surgical treatment for MTLE-HS, as well as MTLE due to most other causes, is particularly cost-effective because the presurgical evaluation can almost always be performed noninvasively, and the chances of restoring the patient to a completely normal lifestyle are high, making this an ideal surgically remediable syndrome.

Lesional Focal Epilepsies

The pathologic finding underlying the epileptogenic zone in approximately 30% of patients undergoing epilepsy surgery is a *substrate-directed* abnormality, such as a tumor or vascular malformation.[13] Identification of the epileptogenic lesions by MRI is imperative in patients with pharmacoresistant seizures because of the demonstrated beneficial effect of surgical treatment.[11,12] MRI has increased the identification of structural alterations in patients being considered for surgical treatment of intractable focal epilepsy.[12,74] Surgically remediable epilepsy syndromes associated with substrate-directed focal epilepsy includes patients with MTLE related to HS (see previous section) and lesional epilepsy syndromes.[13,90] Selected patients with lesional focal epilepsy may be highly favorable candidates for surgical treatment. The surgical pathologies in patients with lesional focal epilepsy include primary brain neoplasm, vascular anomaly, and a malformation of cortical development (MCD).[13] The common tumors identified at the time of surgical excision of the epileptogenic cortex include low-grade gliomas, gangliogliomas, dysembryoplastic neuroepitheliomas (DNETs), and mixed glial neoplasms.[11,12,62,82] The cavernous hemangioma with remote hemorrhage is the most frequently resected vascular anomaly in patients with medically refractory focal epilepsy.[13] Focal cortical dysplasia is an increasingly important etiology of lesional focal epilepsy because of the increased diagnostic yield of structural neuroimaging techniques and the performance of epilepsy surgery in younger patients.[63,81] The outcome of epilepsy surgery depends on the pathology and location of the epileptogenic lesion.[13] Approximately 80% of patients with a low-grade glial neoplasm, ganglioglioma, DNET, or cavernous hemangioma are rendered seizure-free following surgical treatment. Resection of a focal MCD in individuals with lesional focal epilepsy is less effective in reducing seizure tendency.[14,63,81] Patients with MTLE are more favorable candidates to achieve a seizure remission than are those individuals with neocortical (mainly frontal lobe) focal seizures.[62,90,91]

The electroclinical presentation and response to AED therapy in patients with lesions in medial temporal structures are indistinguishable from those with focal seizures caused by HS.[34,93] Patients with lesional epileptic syndromes, however, may not have all the clinical features of MTLE shown in Table 1, although this remains to be clearly demonstrated. The ictal semiology of patients with lateral temporal or extratemporal neocortical lesions can also be similar to that of individuals with HS if there is propagation of seizure activity to the amygdala and hippocampus. In these patients, the initial ictal symptom or aura may provide a clue as to the neocortical onset of the seizures. Complex partial seizures associated with a visual aura suggest an occipital lobe onset, and those with an auditory or vertiginous aura suggest a lateral temporal onset.[1] Not uncommonly, however, the ictal semiology in patients with lateral temporal lesions reflects spread into the amygdala or hippocampus, which does not allow differentiation from MTLE related to HS. Neocortical epileptogenic lesions that do not produce a spread of ictal discharges into the mesial temporal structures give rise to partial seizures with clinical features different from MTLE. Neocortical focal seizures more commonly are associated with secondarily generalized tonic–clonic seizure activity.

Importantly, the neuroimaging findings alone should not be used to determine operative candidacy and surgical planning.[12,74] Certain lesions, such as focal cortical dysplasia, may fail to be identified by MRI or may be multifocal, which does not allow determination of the site of seizure onset.[13,63] Imaging alterations consistent with venous angiomas and small-vessel cerebral infarction are less likely to be epileptogenic. A consensus exists at present that a comprehensive epilepsy presurgical evaluation should be performed in patients with a suspected substrate-directed focal epilepsy associated with pharmacoresistant seizures to establish a relationship between the MRI-identified lesion and the epileptogenic zone.[35] Long-term EEG monitoring is considered necessary because of the possibility that the lesion can be remote from the ictal onset zone.[13] Subtraction ictal single photon emission computed tomography (SPECT) coregistered with MRI (SISCOM) has been shown to be useful in the operative strategy of patients with substrate-directed focal epilepsy and in planning the placement of intracranial EEG electrodes for identification of the ictal onset zone.[12,63] The rationale for chronic intracranial EEG recordings in patients with lesional epileptic syndromes is predominantly to determine the location of essential cerebral cortex that should not be damaged during surgery.[13,35] The most effective operative strategy in patients with lesional epilepsy includes a total lesionectomy with cortical margins.[35] Lesions involving essential cortex can be safely resected using extraoperative or intraoperative cortical functional mapping.[64] Lesionectomy alone based on stereotactically derived operative techniques can render some patients seizure-free, although removal of cortical margins increases the chances of a beneficial seizure outcome.[13,15,35] Postoperative MRI should be performed to confirm the extent of lesion excision. Residual or recurrent structural abnormalities can be associated with focal seizure activity and prompt a consideration for surgical reoperation.[82]

Diffuse Hemispheric Epilepsies

Some epileptic disorders, such as Rasmussen encephalitis, Sturge-Weber syndrome, and hemimegalencephaly, are associated with epileptogenic structural disturbances that tend to be limited to one hemisphere. These give rise to severe medically refractory epileptic seizures that are typically unilateral. However, the seizures can appear to be bilateral although they are caused by an abnormality in a single hemisphere. The structural pathology is usually associated with a contralateral hemiparesis and, in such cases, the removal of the entire epileptogenic hemisphere causes little or no additional neurologic deficit and offers an excellent chance of seizure remission.[3,78]

In 1950, Krynauw reported 12 children in whom he performed hemispherectomy to treat medically intractable epilepsy.[48] The initial reports were very encouraging because the children had markedly improved seizure control and, as a bonus, had improved behavior and cognition. Over the next decade, more that 50 hemispherectomies were performed with similar results. However, in 1966, the first report of a serious long-term complication was published, indicating that 7 to 11 years after hemispherectomy, some children developed recurrent intracranial bleeds with fatal consequences.[65] Some centers found that this occurred in as many as 30% of the

P.1765

patients.[94] The enthusiasm for hemispherectomy waned until improved surgical techniques were developed. This complication is no longer a significant problem, and hemispherectomy is now one of the most successful surgical procedures used in the treatment of intractable epilepsy.[67] The procedure is typically performed in patients with Rasmussen encephalitis, Sturge-Weber syndrome, infantile hemiplegic epilepsy, or severe developmental defects such as hemicortical dysplasia or hemimegalencephaly. These disorders are reviewed briefly, as they relate to surgical therapy.

Rasmussen encephalitis was first reported in 1958.[68] It is a sporadic disease of unknown cause. Most patients are entirely normal until the onset of seizures, generally around 5 years of age. They typically begin with focal seizures that become increasingly frequent and medically intractable, culminating in nearly continuous seizures (epilepsia partialis continua). The majority develop progressive hemiparesis and moderate dementia if seizures are not controlled. Rarely, progressive hemiplegia can precede the onset of seizures or can be the only indication of Rasmussen encephalitis.[46] Hemispherectomy is currently considered the treatment of choice. However, there have been reports indicating the presence of antibodies to the brain receptor GluR3 in some Rasmussen encephalitis patients,[72] but GluR3 antibodies do not occur in all patients.[89] Autoantibodies to *N*-methyl-D-aspartate (NMDA)-type GluRepsilon2 have also been reported.[85] Because of the implication that autoimmunity to specific receptors may underlie Rasmussen encephalitis, plasmapheresis and/or high-dose intravenous immunoglobulin (IVIG) therapy have been touted as possible therapies, but no convincing evidence suggests that such therapy is successful in the long-term.[33] Immunomodulatory therapy can slow disease progression for a time and can be considered in patients with late-onset disease in the dominant hemisphere or in patients with bilateral involvement.[39] In most cases, resective surgery should be considered as soon as the diagnosis is confirmed and some degree of hemiparesis has developed. Although most patients will require hemispherectomy, an occasional patient can benefit by a more localized cortical resection. In other patients, the disease is more diffuse throughout the hemisphere, but significant hemiparesis has not developed, and the question of timing of hemispherectomy arises. If the patient is old enough to begin to lose plasticity for language, has involvement of the language-dominant hemisphere, and the diagnosis has been confirmed (usually by biopsy), it may be necessary to perform the hemispherectomy, thus causing a new hemiparesis but preserving maximum potential for language recovery.

Sturge-Weber syndrome is characterized by angiomatosis of the leptomeninges over the posterior area of the hemisphere, resulting in progressive injury to the subjacent cortex. Thus, most patients have gyriform calcification of the ipsilateral occipital/parietal cerebral cortex (usually after 2 years of age), contralateral seizures and hemiplegia, mental retardation plus associated ipsilateral facial angiomatosis, and glaucoma. If patients have severe, uncontrolled epilepsy in the first year of life, cortical resection is indicated. Although hemispherectomy is often required, if the cortical involvement is limited to the occipital/parietal areas, then a more limited resection can be possible, thereby preserving motor function. Early surgery can prevent progression with consequent damage to frontal structures and can also result in improved cognitive outcome in those patients with early-onset seizures that are medically intractable.[4] In one study, poor developmental outcome correlated best with high seizure intensity in the early period rather than with age of onset or degree of hemiparesis.[47] Some authors suggest that surgery should be performed as soon as the diagnosis is confirmed, but others suggest that surgery should be reserved for patients with intractable seizures. Because many patients with Sturge-Weber syndrome will do well developmentally if seizures can be controlled with anticonvulsant drugs, surgery may create an unnecessary neurologic deficit. Surgery should be reserved for patients who have demonstrated medical intractability.

Although infantile hemiplegic epilepsy is not a recognized syndrome, the term describes a group of children noted to have hemiparesis early in life, and who develop intractable focal and secondarily generalized seizures. Many of these patients have encephaloclastic lesions such as porencephalic cyst, often in the distribution of the middle cerebral artery, suggesting an early-onset stroke. Some patients have developmental disorders such as hemimegalencephaly or schizencephaly, while others have the hemiconvulsion, hemiplegia, and epilepsy (HHE) syndrome characterized by acute-onset focal seizures followed by the appearance of hemiplegia and intractable epilepsy. Whatever the cause, severe hemiparesis associated with medically intractable seizures should trigger consideration of hemispherectomy. Many children also have involvement of the visual system, with partial or complete hemianopsia. It has been noted that in such cases, using the term “hemispherectomy” to describe the surgery is not entirely accurate; “tidying up what Mother Nature has done” more accurately reflects the character of the surgery.

The decision to perform hemispherectomy or hemispherotomy is relatively straightforward in some patients (e.g., severe hemiplegia with frequent and intractable partial seizures); in others, it can be quite difficult (e.g., infantile spasms with only generalized electrographic seizures). The epilepsy syndromes that are amenable to hemispherectomy usually are associated with severe, very frequent seizures, failure to acquire normal cognitive abilities if the seizures begin very early in life (e.g., Sturge–Weber syndrome), or loss of intellect if a later onset of seizures occurs (e.g., Rasmussen encephalitis). Because hemispherectomy always results in hemiparesis with loss of fine motor control of the affected hand, the hoped-for improvement in seizure control, cognition, and language must be balanced against any surgically induced loss of motor function. In cases with established moderate or severe hemiparesis, there is little motor ability to be lost, so the decision to perform surgery is relatively easy. However, in patients with a progressive disorder such as Rasmussen encephalitis, the decision can be more difficult. As a general rule, the patient should have, as a minimum, some loss of hand function before hemispherectomy is considered. But the decision process can be further compounded by potential loss of language skills if the dominant hemisphere is involved and the child has acquired language. In patients less than 6 or 7 years of age, the side of language dominance is not critical because "plasticity" will allow for development of language in the remaining hemisphere. After that age, the plasticity gradually decreases. It is not clear at what age language could not be recovered, but patients as old as 11 years have had left hemispherectomy with recovery of substantial language ability.[33] When the patient has involvement of the dominant hemisphere, surgery should not be unnecessarily delayed once it is clear that hemispherectomy is the treatment of choice, even though the surgery may result in significant loss of motor function.

Secondary Generalized Epilepsies in Infants and Small Children

Symptomatic generalized epilepsies have, in the past, been considered to be the result of diffuse, bilateral brain disturbances, and thus, the patients were not candidates for treatment by cortical resection. It is now clear that some children have generalized seizures as the result of localized cortical abnormalities. Initial studies indicated that patients with infantile spasms were the primary candidates for this approach. However, recent

P.1766

reports indicate that some young children with catastrophic childhood epilepsies other that infantile spasms are also surgical candidates. Because the attention has been directed to infantile spasms, many other children with other seizure types and significant developmental failure were not referred until much later in their course. In a recent report, the developmental outcome was better in the patients with infantile spasms who had been referred for surgery early compared with patients who had similar pathology but did not have infantile spasms, because the latter patients were referred later in their course.[44]

The concept that generalized seizures could result from a localized brain abnormality is not entirely new. Indeed, there have been a few published cases of patients with focal brain abnormalities in whom a surgical procedure resulted in cessation of infantile spasms. For example, infantile spasms ceased after surgical resection of a right temporal astrocytoma in one case,[58] by resection of a choroid plexus papilloma in another,[9] and by fenestration of porencephalic cysts in four cases.[66] Since these reports, it has become clear that many patients with generalized seizures have a localized cortical disturbance that is amenable to surgical intervention.[17,18,77,78,79,80] Other workers have now made similar observations. Uthman et al.[86] reported that an 18-month-old child with infantile spasms was successfully treated by surgical resection of a porencephalic cyst. Similarly, Carrazana et al.[10] reported that six children with identified localized cortical disturbances associated with infantile spasms had good response to surgery. The cortical disturbance has been called the *zone of cortical abnormality* (ZCA) by the University of California Los Angeles (UCLA) group to distinguish it from the concept of the epileptogenic region. This distinction is necessary because the seizures may be generalized in onset, despite being caused by a localized cortical abnormality and, as such, identification of the electrographic area of seizure onset may not be relevant.

Recent reports indicate that another generalized seizure disorder associated with developmental decline is amenable to effective surgical intervention. Hypothalamic hamartoma has long been recognized as a cause of gelastic seizures. Most patients start having seizures early in life and suffer moderate developmental consequences. Anticonvulsant medications are rarely helpful and surgical interventions via the subfrontal or temporal approach have had high morbidity and poor seizure control. Improvements in surgical techniques and approach have markedly improved both seizure control and developmental outcome.[51a,75,95a]

The identification of appropriate candidates for the evaluation for epilepsy surgery can be more difficult among patients with infantile spasms or other generalized seizure disorders than among those suffering from partial seizures. The "gold standard" for most epilepsy surgery candidates is the identification of the area of seizure onset. Because patients with infantile spasms typically have generalized seizures, this approach cannot be used. However, almost all patients with infantile spasms who ultimately had cortical resection to control seizures had evidence of focal cortical abnormalities prior to the formal surgical evaluation. Many patients with infantile spasms caused by a ZCA had focal seizures and/or focal cortical abnormalities detected by EEG, x-ray, computed tomography (CT), or MRI.

It has long been recognized that other seizure types can be associated with infantile spasms, including focal seizures.[43,45,55,95] Carrazana et al.[10] reported 16 children in whom consistent focal seizures preceded the onset of infantile spasms, and Donat and Wright[20] reported 11 patients with focal seizures that occurred simultaneously with infantile spasms. Indeed, even the characteristic hypsarrhythmia pattern can be asymmetric or unilateral.[42] Careful observation can reveal focal disturbances more frequently than had been previously appreciated; Riikonen[71] observed focal abnormalities in 110 of 149 cases. Focal abnormalities can be easier to detect in the early EEGs. Once the hypsarrhythmia is established, it is easy to miss relatively subtle EEG abnormalities, such as focal slowing or decreased β activity. In addition, the relationship between infantile spasms and focal seizures can become less apparent with time. Carrazana et al.[10] noted that the relationship between focal seizures and infantile spasms was lost in 11 of 12 patients followed for more than 6 months. Thus, early identification of localized EEG abnormalities may be critical.

Structural defects detected by CT or MRI are less common but may be more obvious than the EEG abnormalities.[83] Alvarez et al.[2] reported three children with porencephaly who developed infantile spasms. They proposed that the porencephaly was the cause of the infantile spasms. Cusmai et al.[19] found CT evidence of focal abnormalities in 17 of 174 cases. Sankar et al.[73] reported that MRI is able to detect very subtle focal gray matter disorders by developmental changes in the subjacent white matter. Chugani et al.[16,18] first reported that PET could detect cortical disturbances, in some cases even when the MRI and CT are normal. However, advances in MRI imaging have greatly improved our ability to identify subtle focal cortical dysplasias that were not able to be detected in the past. PET scan remains an important adjunct in many cases. Magnetoencephalography (MEG) is also playing a role in some difficult cases.[67a] It is especially useful in patients with tuberous sclerosis who have numerous cortical tubers but only one or two that are responsible for the seizures.

Because the goal of the evaluation is to identify the ZCA, it would seem likely that patients who are surgical candidates have evidence of the presence of a ZCA prior to the formal surgical evaluation. Indeed, many patients do demonstrate clear evidence of a localized brain disturbance. The characteristics of patients with infantile spasms who may be considered for surgical evaluation are noted in Table 2.

At the conclusion of surgical evaluation, children are recommended for surgery if there is a confluence of historical, EEG, closed-circuit television (CCTV)/EEG, CT, MRI, PET, and/or MEG data indicating the presence of a ZCA (a single lobe, contiguous multilobes, or one hemisphere). No single abnormal test is sufficient to lead to surgery. Surgical resection of the ZCA results in complete or near-complete control of the seizures, including generalized seizures, in about 75% of cases. More important, perhaps, is the observation that the developmental outcome can be improved.[5,44] The improvement is related to age at surgery (earlier being better for development) and to severity of developmental delay at the time of surgery. Not surprisingly, children who had better development at the time of surgery had the best developmental outcomes.

Table 2 Profile of Patients with Infantile Spasms Who May Be Considered Candidates for Evaluation for Epilepsy Surgery

1. The seizures are medically intractable
   - As a minimum, the child should have failed adrenocorticotropic hormone (ACTH) or prednisone, plus one or two other anticonvulsant medications; early evidence suggests that vigabatrin can be particularly effective in this group of patients and should be administered prior to surgical consideration if possible (it is not approved in the United States as of this writing)
2. Evidence of localized brain abnormality
   - The most useful is a localized abnormality on neuroimaging (cortical disturbances are best seen with MRI or PET, but CT and SPECT can also be very helpful); and/or
   - There are focal seizures that precede, follow, or occur simultaneously with the infantile spasms; and/or
   - The interictal EEG shows evidence of localized cortical disturbance such as:
     - Unihemispheric or localized delta activity
     - Unihemispheric or localized decreased or absent beta activity
     - Localized interictal epileptiform discharges including hemihypsarrhythmia
     - Unilateral sleep spindles
   - The ictal EEG is localized;[76] generalized seizures such as infantile spasms can be preceded or followed by consisently localized epileptic activity; and/or
   - There is an abnormal neurologic examination with localized features

Other Situations in Which Surgical Treatment Can Be Considered

Surgical treatment can be very effective in patients who do not have obvious surgically remediable syndromes. All patients with symptomatic epilepsy who have disabling, medically refractory seizures should be considered *potential* surgical candidates; however, if they do not have one of the recognized surgically remediable syndromes, it is quite likely that chronic intracranial recordings will be necessary to delineate the epileptogenic region for surgical resection, and chances for complete cure may be relatively small. Consequently, surgical intervention is often not as cost-effective as it is for the surgically remediable syndromes, and trials of second-line AEDs, as well as polypharmacy, may be justified before surgical referral is considered. This includes patients with diffuse or bilateral

P.1767

structural lesions in whom only one small part of the structural abnormality might be epileptogenic, as is sometimes the case with schizencephaly,[49] or in patients who have ictal EEG onsets that are poorly defined or appear to be coming independently from both hemispheres. Corpus callosotomy remains a surgical option for patients with disabling drop attacks that do not respond to AEDs or vagal nerve stimulation.[36] Multiple subpial transection is an alternative surgical approach that spares cortical function when the epileptogenic region involves essential cortical areas, as is the case, for example, in Landau-Kleffner syndrome.[61]

When electroclinical data indicate that focal seizures are of neocortical origin, but no structural lesion can be identified, surgical treatment is based on electrographic delineation of the boundaries of the epileptogenic region, and results are often poor.[87] In these patients, seizures could be caused by (a) structural lesions similar to those that produce LNE but are too small to be identified; (b) pathologic processes similar to those that occur with HS, which can not be detected by available histochemical techniques; or (c) an entirely different, and as yet unknown, epileptogenic pathologic process. It is likely that more than one explanation for this condition exists. The relatively poor results encountered under these circumstances could be related to failure to delineate accurately the epileptogenic region and adequately remove it or to the possibility that the underlying disturbance is actually very widespread. If the latter is the case, the associated functional disruption would appear to be subtle compared to that observed with MTLE because a large region of hypometabolism is rarely encountered with interictal PET in nonlesional neocortical epilepsy, as opposed to its common association with MTLE.[41]

Summary and Conclusions

Early surgical intervention for medically refractory epilepsy provides the best opportunity for complete freedom from seizures and avoidance of irreversible psychosocial consequences of disabling illness. As a result of recent advances in presurgical diagnosis, as well as improvements in the safety and efficacy of surgical treatment for epilepsy, an excellent postoperative outcome can be confidently predicted in appropriately identified surgical candidates. For this reason, surgical intervention is no longer considered a last resort but rather an early treatment of choice for certain well-defined surgically remediable syndromes for which (a) the pathophysiology is understood; (b) the natural history is reasonably well known to be medically refractory or even progressive; (c) presurgical evaluation requires only noninvasive studies; and (d) surgery offers a 60% or greater chance of abolishing disabling seizures. Examples of surgically remediable syndromes include MTLE-HS; focal epilepsy caused by discrete structural lesions that can be resected without introducing additional neurologic deficit; and catastrophic unilateral or secondary generalized epilepsies of infants and young children that result from disturbances confined to one hemisphere, such as hemimegalencephaly, Sturge-Weber syndrome, Rasmussen encephalitis, and relatively large but unilateral developmental abnormalities such as cortical dysplasias and porencephalic cysts. These conditions can be treated with anteromesial temporal lobectomy, localized cortical resection, hemispherectomy, hemispherotomy, or multilobar resection. The best results with respect to subsequent seizures, psychosocial readjustment, and quality of life are obtained when surgery is performed as soon as it can be established that high-dose first-line AEDs as monotherapy have failed.

Chapter 169

Presurgical Evaluation: General Principles and Methods

Gary W. Mathern

Michael R. Sperling

Introduction

Epilepsy surgery is considered when seizures are incompletely controlled by medication and it is apparent that further medical therapy will be futile. Surgery is typically offered to patients who have uncontrolled seizures that are disabling, cause loss of awareness, pose risk of injury, impair quality of life, or are psychologically disruptive. When the question of surgery arises in such cases, a presurgical evaluation should be performed. The evaluation is carried out by multidisciplinary teams composed of epilepsy specialists in neurology, neurosurgery, neurophysiology, neuroradiology, psychiatry, and neuropsychology, with additional input from professionals in social work and nursing. This chapter reviews the basic objectives, methods, and principles of the presurgical evaluation. A brief overview of the testing generally included in presurgical evaluations is provided, with full details about each method referred to in subsequent chapters.

Timing of Referral for Presurgical Evaluation

The goal of any treatment for patients with epilepsy is "no seizures, no side effects," as advocated at the National Institutes of Health (NIH)-sponsored meeting Curing Epilepsy: Focus on the Future; A White House-Initiated Conference on Epilepsy (CURE).[48,94] For most patients, even a rare seizure can be an unacceptable level of control because of restrictions on driving and the impact on social and vocational status.[96,103] While the CURE group acknowledged that complete seizure control cannot be achieved in all patients, it recognized that complete absence of seizures made such a difference in a person's quality of life that this objective should be as close to the standard of care as possible.

Physician experts in epilepsy care recommend that patients with refractory epilepsy, defined as failure of two to three appropriate antiepileptic drugs (AEDs) or disabling medication side effects, should be referred to a comprehensive epilepsy center for a further evaluation that includes surgery as one of the therapeutic options.[5,13,26] The purpose of the referral is to verify that patients have a correct epilepsy diagnosis (i.e., exclude nonepileptic seizures and improper seizure classification that may affect treatment recommendations) and to consider all potential further therapies, such as surgery, that might be employed in an attempt to stop seizures. Of course, not every patient referred to an epilepsy center will have surgery.[9] Changes in medical management can often substantially improve seizure control or even eliminate seizures so that patients can be returned to their community physicians. Likewise, additional nonsurgical therapies, such as the ketogenic diet and vagus nerve stimulator (VNS), can be considered at the time of a presurgical evaluation.[37,39,99]

There is now irrefutable evidence that uncontrolled seizures are associated with progressive anatomic and functional changes, neurologic compromise,[52,67,88,97] and higher than expected mortality rates.[74,78,90] Although there still continues to be some debate as to the definition of therapy resistant,[8,10,68] these considerations have led to the recommendation that therapy-resistant patients should be referred to an epilepsy center for presurgical evaluation once they have failed initial AED therapy.[12,14,33,35] This recommendation is especially important for infants and young children, who are at greatest risk of epilepsy-induced encephalopathy.[29,53,54] It has even been advised that children with uncontrolled seizures or infantile spasms under age 2 years should be referred to a specialty center regardless of magnetic resonance imaging (MRI) findings.[26] MRI-demonstrated lesions should also be referred to an epilepsy center for presurgical evaluation, regardless of seizure control, as these substrates may eventually lead to therapy-resistant seizures, or the lesion itself may prove to be progressive.[28,85] In addition, intractable focal epilepsy can result from low-incidence etiologies that require the special experience of a comprehensive epilepsy center. Examples of these pathologies include adolescents and adults with focal cortical dysplasia and hippocampal sclerosis, and children with hemimegalencephaly,[82] Rasmussen syndrome,[11] Sturge-Weber Syndrome,[31] tuberous sclerosis complex,[31] Landau-Kleffner syndrome,[73] hypothalamic hamartomas,[45,66] and polymicrogyria.[3] The upper limit at which surgery should be considered is not certain. We have had successful experience with surgery for patients in their 60s who are otherwise in good health.

Goals and Types of Surgical Considerations

The goal of a presurgical evaluation is to characterize a patient's epilepsy thoroughly and completely. In doing so, the multidisciplinary epilepsy team determines what type of seizures and epilepsy syndrome the patient has and the likelihood that it can be treated successfully with surgery. At the completion of the process, the team should be able to provide the patient and his or her family with a comprehensive assessment of the risks and benefits of different treatments and the risks that may be associated with the natural history of the epilepsy syndrome. If surgery is an option, a detailed description of the proposed surgical procedure, surgical risks that may be encountered, and long-term seizure control that can be anticipated from medical therapy alone should be provided. This information must be

P.1772

communicated effectively to patients and their families so they can make informed decisions about subsequent management. The epilepsy team cannot tell the patient what to do, but it can provide sufficient information and education, in a manner that patients can understand, so that they and their families are informed about all the options and can make decisions about their care. It should also be noted that there are no age restrictions in considering patients as possible candidates for epilepsy surgery.[43,69]

The types of surgical procedures can be divided into two general categories.[69] *Resective* operations are those where the intent of the surgery is to remove the epileptogenic brain area. The goal of resective surgery is to eliminate seizures completely and, hopefully, improve cognitive and psychosocial outcomes (see Chapter 167). Most resective procedures involve removal of cerebral cortex, and they can be subclassified as focal (lesion and surrounding cortex, Chapters 176, 177, and 179), lobar or multilobar (Chapter 178), or hemispheric (hemispherectomy, Chapter 178). Resections can also involve removal of subcortical lesions, like hypothalamic hamartomas[35,36] (Chapter 250). Also included under this category are procedures like radiosurgery, where focused x-ray beams destroy defined epileptogenic regions of the brain, and multiple subpial transections (MSTs; Chapter 182), which are thought to disconnect epileptogenic zones selectively from the rest of the cortex.[72] With *palliative* procedures, the intent of therapy is to stop the most disabling seizures and/or reduce seizure frequency, but not necessarily eliminate all seizures. The most common palliative operations are corpus callosotomy[40,65,77] (Chapter 180) and VNS[7,37] (Chapter 131). Most callosotomies involve sectioning of the anterior two thirds to four fifths of the callosum, although a complete callosotomy is occasionally done in individuals with a major unilateral deficit or after failure of initial anterior resection.

Localized Cortical Resections and Cerebral Hemispherectomy

The ideal candidate for resective surgery is a patient with therapy-resistant epilepsy due to a clearly demarcated localized brain abnormality (symptomatic epilepsy) where removal of the pathologic lesion has a high probability of producing seizure control with acceptable or no side effects.[33,34] The precise identification and localization of the responsible epileptogenic brain region is the goal of the presurgical evaluation.[44] Thus, the evaluation aims to (a) identify discrete structural abnormalities using modern neuroimaging and, inferentially, from associated functional deficits; (b) provide convincing evidence that seizures arise at or near the structural lesion; and (c) establish whether eloquent brain regions that support speech and motor-sensory functions are at risk. If these objectives are satisfied, then there is a high likelihood of a good postoperative seizure control. However, these aims may be modified in some patients with well-defined seizure syndromes or in individuals at risk for seizure-induced cognitive deficits. For example, patients with MRI-demonstrated unilateral hippocampal sclerosis may have multiple areas of interictal or ictal abnormalities on electroencephalography (EEG) but still respond well to anterior lobe resection. Similarly, infants and children with symptomatic epilepsy may present with what appears clinically and electrographically to be generalized epilepsy, but they nonetheless sometimes respond well to surgical removal of an identified cortical abnormality such as cortical dysplasia.[23,24] Perhaps the ultimate localized cortical resection is cerebral hemispherectomy, an operation that has evolved considerably over the years.[25,30] The basic objective in evaluating patients for hemispherectomy is similar to that in focal resection, namely, to identify an area of brain that can be removed safely to eliminate seizures. The presurgical evaluation in patients who are candidates for hemispherectomy aims to establish the following: (a) a unilateral structural abnormality; (b) widely distributed abnormal excitability in that hemisphere; and, in older children and adults, (c) significant impairment of motor and sensory function (and perhaps language) in that hemisphere.

Palliative Surgery

Corpus callosotomy and VNS can be useful when the realistic therapeutic goal is to reduce the burden of epilepsy without stopping all seizures. As a consequence, the clinical approach to such patients and the surgical risk–benefit ratio are different than for patients being considered for resective surgery. When epileptogenic areas of the brain are widespread and involve both hemispheres, localized cortical resection is not usually a viable option. However, interruption of the interhemispheric connections via corpus callosotomy or stimulation of the vagus nerve (VNS) can often palliate seizures in such patients. This is especially true for patients that suffer injuries from generalized tonic, atonic, and tonic–clonic seizures. Corpus callosotomy and VNS may also benefit patients with complex partial seizures who are not candidates for focal resection.[6,83] For palliative procedures, the evaluation should determine if there is (a) evidence of generalized epilepsy or nonlocalizable partial epilepsy with abnormal generalized or multifocal discharges on the EEG, (b) lack of suitability for a resective procedure, and (c) presence of tonic, atonic, tonic–clonic, or therapy-resistant complex partial seizures. Neuroimaging is less critical in planning palliative operations unless it strongly suggests a discrete lesion, in which case consideration should be given to a focal resection.[93]

The Conceptual Approach to Defining Epileptogenesis

The overriding principle of the presurgical evaluation is to define abnormalities of structure and function that can be attributed to abnormal cortical areas and EEG-determined pathologic excitability, and then remove those cortical areas in which all relevant data are concordant. Historically, our concepts of what constitutes the cortical region(s) that should be removed to control seizures have been determined by the evolving tools available for clinical use.[34] Over time, a series of terms that embody these concepts have been developed.[32,81] They are recapitulated and described here based on the current state of our understanding and their application to the evaluation process. In general, the greater the degree of overlap among the different tests, the higher the likelihood of accurately defining the epileptogenic zone and achieving a good postsurgical result.

Epileptogenic Zone

Identifying the epileptogenic zone is the fundamental goal of the presurgical evaluation. The epileptogenic zone is defined as that area of cortex that is indispensable for the generation of clinical seizures and that, if removed in its entirety, would abolish seizures. Clinicians use various diagnostic tools to try to define this zone, including analysis of seizure semiology, interictal and ictal EEG recordings, and neuroimaging (MRI, ictal single photon emission computed tomography [SPECT], ^{18}F-fluorodeoxyglucose positron emission tomography [FDG-PET]). However, each of these methods defines cortical zones

that are associated with different aspects of epileptic symptomatology. At the present time, there is no direct way to define the epileptogenic zone definitively. Rather, inferences about the boundaries of the epileptogenic zone are inferred from the composite picture that is pieced together through an understanding of the sensitivities and specificities of each of the diagnostic methods described below.

Irritative Zone

This is the cortical area that is capable of generating interictal EEG discharges.[86] The interictal spike is usually closely related to the brain area that generates seizures but it is not identical to it. Interictal spikes often appear beyond the region that needs to be removed for seizure control; can be more limited in spatial extent than the epileptogenic zone; or may be entirely absent over a discrete structural or functional lesion.[76] Moreover, the location and extent of the irritative zone depends on the EEG method employed. For example, because of the disparate volumes of cortex sampled by scalp, intracranial electrodes, and magnetoencephalography (MEG)/magnetic source imaging (MSI), the irritative zone is defined somewhat differently by each.[4,79] The duration of EEG recording; whether sleep is recorded and, if so, what stages are included; seizure frequency; and timing of the EEG in relation to monthly hormonal cycles can all influence localization of the irritative zone.

Ictal Onset Zone

This is the cortical area from which seizures arise as recorded by EEG or MEG/MSI. It also is not congruous with the epileptogenic zone, which is often a larger region of cortex. While the ictal onset zone provides an approximate indication of the brain region involved in seizure generation, resection of the ictal onset zone alone may not result in elimination of seizures. As with the irritative zone, the ictal onset zone is typically defined by scalp and intracranial EEG.[87] MEG/MSI, however, is increasingly used to determine the area of ictal onset.[58,104] The delineation of the ictal onset zone is methodology dependent, in that extracranial EEG often provides a somewhat different picture than intracranial EEG, which in turn may differ from results obtained by MEG/MSI. Moreover, whether intracranial EEG is recorded by depth or strip electrodes can also influence the identification of the ictal onset zone because of bias introduced by the amount of spatial sampling of the EEG, the frequencies measured, and the size and number of electrodes used.

Although it seems logical that removal of the cortical tissue in which seizures start would abolish them, even careful extirpation of a precisely defined area of seizure onset offers no assurances that seizures will stop. The potential ictal onset zone is a manifestation of a complex nonlinear system with predilections for certain topographic regions.[61,71] Resection of just the observed area of ictal onset without addressing the underlying histopathologic substrate may simply enable a new cortical region to become the preferred zone of seizure origin. Because of these variables, the spatial extent of the irritative zone is not as precisely delineated as might be hoped.

Epileptogenic Lesion

The epileptogenic lesion is the structurally abnormal area of brain that presumably causes the epilepsy; it is best identified using high-resolution MRI.[18,19,80,101] Although complete excision of a structural lesion usually ensures a good postoperative result, it does not guarantee success.[64] Sometimes the structural lesion is incidental and unrelated to the epilepsy. Thus, it is important to confirm the epileptogenicity of a lesion using EEG before presuming it is the cause of the seizures.[18] Alternatively, the visible structural lesion may comprise only a portion of the histopathologic abnormality. For example, developmental tumors, cavernous angiomas, or subtle cortical dysplasia (Palmini type I)[75,84] may be accompanied by a tandem sclerotic hippocampus located distant from the tumor (dual pathology), or microscopic disease may occupy cortical areas more extensively than indicated by the macroscopic lesion.[98] It is also important to note that a portion of the epileptogenic zone may contain anatomically normal but functionally abnormal tissue that must be excised for seizure relief.[19]

Functional Deficit Zone

This is the area of cortex that produces interictal dysfunction, such as abnormalities found on neurologic examination, deficits discovered with cognitive testing, regions of impaired perfusion or metabolism defined by nuclear medicine scanning (e.g., PET, SPECT), or a focal nonepileptiform EEG abnormality, among others.[70,100] Determining this zone is useful because it is presumed that such functional deficits are related to an underlying structural abnormality or physiologic derangement of the brain. This information provides confirmatory evidence to support the identity of the ictal onset zone and epileptogenic lesion. The scope of the functional deficit zone depends greatly on the tests used. Some measures may overestimate the size of the epileptogenic zone, whereas others may underestimate it. For example, FDG-PET scans often reveal extensive temporal, nontemporal, and subcortical abnormalities in patients with mesial temporal lobe epilepsy who respond to an anteromesial temporal resection. Nonetheless, information gained by testing for a functional deficit is an important component of the presurgical evaluation as it helps physicians and patients understand the extent of abnormalities that exist before surgery and that may not be improved after surgery.

Symptomatogenic Zone

The symptomatogenic zone is the area of cortex that, when activated by a seizure, produces the initial symptoms and signs of a seizure.[81] Because it is impossible to tell whether the first ictal symptoms arise from the ictal onset zone or from propagation of the seizure to more distant cortex, and because seizures often arise in "silent" cortex, early features of the seizure are only moderately reliable as an indication of localization. Production of clinical symptoms and signs by secondary spread are probably more common. They can still be helpful if propagation routes are known. For example, an aura consisting of a rising epigastric sensation is moderately specific for a mesial temporal lobe seizure, although it actually may arise elsewhere. Likewise, forced head version, unilateral ictal dystonia, postictal aphasia, postictal nose wiping, unilateral eye blinking, and ictal vomiting are other ictal manifestations that have localizing value.

Overview of Presurgical Methods

As already noted, different methods and tests are used to define the epileptogenic zone, and no single presurgical test provides definitive information on which surgery can be based. Rather, data from multiple tests are integrated to form a hypothesis regarding the likely location and extent of the epileptogenic zone. Some tests are benign and pose little or no risk. Others

can cause discomfort or risk of injury. With the remarkable technologic advancements that have occurred over the past two decades, most patients now proceed to surgery without an invasive presurgical evaluation, and the future should see a further increase in the proportion of these patients where the presurgical evaluation is nearly risk free.

Table 1 Tests Used in Evaluation of Patients

Noninvasive tests
Tests of structure
MRI including DTI
Tests of excitability
Interictal and ictal video-EEG
Ictal SPECT and PET

Interictal and ictal MEG/MSI

Ictal functional MRI

Tests of functional deficit

Interictal EEG

Interictal PET

Interictal SPECT

Wada test

Neuropsychological testing

Interictal MEG

Interictal functional MRI

Magnetic resonance spectroscopy

Tests of cortical function

Wada test

Functional MRI

Magnetic stimulation

PET

MEG

Invasive tests

Tests of excitability

Intraoperative ECoG

Chronic interictal and ictal semi-invasive and intracranial EEG

Tests of functional deficit

Interictal EEG

Tests of cortical function

Intraoperative electrical stimulation

Extraoperative electrical stimulation

DTI, diffusion tensor imaging; ECoG, electrocorticography; EEG, electroencephalography; MEG/MSI, magnetoencephalography/ magnetic source imaging; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single photon emission computed tomography.

Tests can be broadly categorized as noninvasive or invasive (Table 1). Certain noninvasive tests, like EEG (Chapters 73 and 74) and MRI (Chapter 79), are routinely used in the presurgical evaluation of all patients. Other noninvasive tests, like ictal SPECT (Chapter 81), FDG-PET (Chapter 80) and neuropsychological examinations (Chapters 90 and 91), supplement EEG and MRI and are used on an as-needed basis. Invasive testing, which refers to EEG recordings made from implanted intracranial electrodes, are reserved for patients in whom the results of noninvasive testing are inconclusive or conflicting, or who need careful delineation of specific areas of cortical function before a resection can be offered. The degree to which different noninvasive tests are used, the access to different technologies, and the experience of the epilepsy team vary somewhat from one epilepsy center to the next, and these considerations usually play a role in whether invasive EEG monitoring is recommended.[105]

It must be emphasized that the most important part of the presurgical evaluation takes place before any tests are performed. The neurologic history provides the critical elements, and all subsequent testing must be considered in light of the patient's history. Knowledge of the patient's early development, a history of any neurologic injury or febrile convulsions, need for special education, the age when seizures started, the tempo at which the epilepsy developed, the existence of a latent period, the types of seizures experienced and whether they generalize, seizure duration, the time of day that seizures occur, their relation to monthly hormonal cycles, characteristics of the aura and its evolution, features of the postictal period, response to medications, and family history is critical to determining if surgery will be feasible and what the chances of success are. The neurologic examination can also provide useful information. Consider the following example. A child had a history of a prolonged febrile convulsion at age 1, development of afebrile seizures at age 8, and a latent period without seizures from ages 12 to 16, followed by the development of uncontrolled epilepsy. Seizures were characterized by an initial rising epigastric aura leading to diurnal complex partial seizures with postictal speech difficulty. There were no secondarily generalized seizures. The patient had difficulty learning new material, and neurologic examination showed a diminished right nasolabial fold. This information alone points to an almost certain diagnosis of mesial temporal lobe epilepsy, probably of left-sided origin. For this patient, further testing is useful but will likely only validate the clinical diagnosis. Furthermore, this clinical information implies that the postoperative prognosis is excellent, although additional testing will help confirm that opinion. Thus, while there is no question that technology has made surgery available to a larger number of patients and improved outcome, it must supplement, not supplant, clinical judgment. Experienced epileptologists and neurosurgeons should recognize those features of the neurologic history and examination that are key to making correct diagnostic and treatment decisions.

Noninvasive Tests

Electroencephalography

Despite its clinical introduction more than 70 years ago, EEG remains an essential tool in evaluating patients for epilepsy surgery[57,76] (Chapter 73). When combined with the history and neurologic examination, the interictal EEG often suggests the diagnosis of the epilepsy syndrome and whether it can be treated surgically. For example, observing generalized slow spike-and-wave activity or widespread multifocal spikes in a patient with significant developmental delay raises the possibility of Lennox-Gastaut syndrome, where corpus callosotomy and VNS are more likely to be used if any operative procedure is indicated. Persistent interictal frontal lobe spikes are usually correlated with frontal lobe epilepsy, as anterior temporal lobe spikes are with temporal lobe epilepsy.[49,50,91,92] However, the limitations of interictal EEG are well known, and it is hoped that more sophisticated EEG techniques being developed will be of even greater help in epilepsy diagnosis.[36,106] Likewise, the presence of nonepileptiform abnormalities, such as a focal interictal slow-wave disturbance, also helps in identifying functionally abnormal areas of the brain and assist in understanding clinical phenomenology and planning surgery.

The ictal scalp EEG remains the definitive method of establishing the diagnosis of epilepsy (Chapter 74). Epileptic seizures have now been sufficiently characterized by video-EEG monitoring that different ictal EEG patterns have diagnostic value in helping classify the type of epilepsy. Moreover, the ictal scalp EEG often accurately suggests the site of seizure origin, although it sometimes lacks sensitivity and specificity.[62] An ictal EEG may be obtained with continuous monitoring performed

either on an outpatient or an inpatient basis. However, inpatient monitoring offers more flexibility and substantial technical advantages, especially for managing antiepileptic medications and obtaining video studies of behavior (Chapter 93).

Analysis of ictal behavior has an important role in the presurgical evaluation. In epilepsy monitoring units, video monitoring is routinely used to record behavior. It accurately documents ictal semiology, and this is helpful in confirming the origin of the seizures.[81] In addition, focal postictal deficits, such as aphasia, provide valuable localizing information.

Structural Brain Imaging

Advances in structural brain imaging have revolutionized our concepts of surgically treatable epilepsy syndromes and reduced the need for intracranial EEG recordings.[42] Because identification of a structural abnormality is one of the key objectives of the presurgical evaluation, neuroimaging, especially using high-resolution MRI with newer techniques like diffusion tensor imaging (DTI), has become irreplaceable (Chapter 79). The routine availability of high-resolution MRI has substantially increased identification of tumors and cortical malformations as well as cortical dysplasia and atrophic lesions such as hippocampal atrophy.[1,2,20,21,47,82] Additionally, some preoperative MRI findings, such as hippocampal atrophy, have been correlated with seizure relief and cognitive status after surgery.

Functional Neuroimaging

Several techniques provide additional physiologic information, thereby helping to define the functional deficit zone or area of ictal onset. PET scans using FDG and other ligands show localized defects in the brain's metabolism[55,56,70,100] that often correspond to the epileptogenic zone (Chapter 80). PET has particular value in infants and children with neocortical epilepsy, as EEG and MRI may not fully reveal the spatial extent or even the presence of a localized epileptogenic zone in such cases.[24] SPECT shows characteristic changes in perfusion in the interictal state, during seizures, and postictally that help identify sites for resection.[46,59] Its highest yield appears to be in the ictal or immediate postictal states, and ictal subtraction SPECT can provide important localizing information (Chapter 81). Functional MRI can also show localized perfusion abnormalities in focal epilepsy (Chapter 83). Magnetic resonance spectroscopy and MEG/MSI are other tools that are capable of demonstrating localized or lateralized deficits in focal epilepsy, and they are assuming a larger role in defining zones of interictal functional deficit[38,95] (Chapter 82). Because the presurgical evaluation obtains different types of information that can be used collectively to make a surgical decision, neuroimaging has acquired great importance as a result of its versatility.

Neuropsychological Testing

Neuropsychological evaluation provides information about the patient's baseline cognitive, linguistic, and other higher cortical functions[41,60] (Chapter 90). The localizing value of neuropsychological testing is more variable in patients with intractable epilepsy beginning in early childhood, as cortical functions may have reorganized or developed in atypical ways. Consequently, neuropsychological testing in children with epilepsy requires special expertise and flexibility, as usual and traditional rules regarding localization of brain function may not apply (Chapter 91).

Psychiatric Evaluation

The patient's psychiatric status has a bearing on outcome, and therefore most patients ideally should have a psychiatric evaluation before surgery, preferably by a psychiatrist experienced with the particular emotional and psychiatric symptoms and conditions in this patient population (see Chapter 209). As a practical matter, appropriate preoperative diagnosis can avert, or at least anticipate, possible psychiatric decompensation around the time of surgery. While major psychiatric disorders used to be considered a contraindication for epilepsy surgery, more flexibility is now the rule as centers have gained substantial experience in managing psychiatric disorders.[16,17] Some have argued that epilepsy surgery may have the additional benefit in children of reducing or preventing the likelihood of future behavioral and psychiatric problems.[26]

Wada Test

The intracarotid amobarbital procedure (Wada test) is used to assess hemispheric dominance for language and evaluate the contribution of each hemisphere to supporting long-term memory (Chapter 173). In separately anesthetizing each hemisphere with an intracarotid amobarbital injection, this test is not entirely risk free, although the chance of a permanent serious complication is low. As a localizing tool, the test is used mainly in temporal lobe epilepsy patients to compare recognition memory in each hemisphere and determine the risk of postoperative global amnesia. It also helps define the functional deficit zone and assists in predicting seizure relief after surgery.[63,92]

Functional Magnetic Resonance Imaging and Magnetoencephalography

Newer noninvasive techniques are increasingly being applied to map cortical function in relation to epileptogenic cortex. Functional MRI (fMRI) provides discrete localization of motor, sensory, visual, and cognitive functions (Chapter 83). MEG/MSI can help identify cortex capable of initiating seizures and also map sensory and language cortex (Chapter 78).

Invasive Tests

Intracranial EEG recordings are obtained in circumstances when resective surgery is being considered and noninvasive tests have failed to define the presumed epileptogenic zone unambiguously. Intracranial EEG affords the opportunity to record the beginning of a seizure without the limitations of scalp EEG. Currently, it is used in about one third of patients undergoing resective epilepsy surgery.[9] To obtain intracranial EEG requires surgically placing electrodes within or over the brain (Chapter 171). Although it is reasonably safe, the operation carries a small risk of complications.[15] Also, the principle of offering surgery based on concordant data of different types (e.g., structural, epileptiform, and nonepileptiform functional) from the noninvasive surgical evaluation is modified when intracranial EEG is performed. With intracranial EEG, the decision to offer surgery rests primarily on the ictal EEG findings. If seizure onset is well localized, resective surgery is recommended. If it is poorly localized or multifocal seizure onsets are detected, then resective surgery is often not advised.

It must be recognized, however, that the value of intracranial EEG is limited.[51] Removal of the ictal onset zone determined by intracranial EEG, no matter how well defined, does not always result in abolition of seizures. To optimize the chance of finding a resectable ictal onset zone, the surgical team must have a well-framed hypothesis regarding its possible location that guides the placement of intracranial electrodes. Here, the noninvasive evaluation plays a key role in establishing a few reasonable possibilities. Answers are then sought to the following questions: Is there a single ictal onset zone, and where is it located? What is its extent? Is it near a structural lesion or functional area of the brain? What is the function of the cortex in that region, and will its removal lead to a permanent deficit?

Intracranial Electrodes

These are discussed in detail in Chapter 171, and only comments need be made here. The main types of electrodes used are intracerebral or depth electrodes, subdural electrodes, and epidural electrodes. Depth electrodes are placed within the substance of the brain and find their greatest use in recording from buried cortex such as hippocampus. Subdural and epidural electrodes are best suited to record from the neocortical surface of the brain, whether over the convexity, in the interhemispheric fissures, or from basal surfaces. Depth and subdural electrodes may be used in combination, depending on the questions posed, to allow the surgical team to map the ictal onset zone and trace the route of ictal spread. These electrodes are used for chronic EEG recording lasting from several days to several weeks. The main purpose of chronic monitoring is to record seizures, characterizing the ictal onset zone and patterns of seizure propagation.

Intraoperative electrocorticography (ECoG) can be performed in the interictal state during surgery to further define the area to be resected, either as an independent procedure or to supplement chronic intracranial recording (Chapter 172). The major limitation of this ECoG is that of time, because it is restricted to the operation.

Semi-invasive Electrodes

These include foramen ovale electrodes and epidural pegs (Chapter 170). Insertion of these electrodes is somewhat less painful than that of intracranial electrodes, although the complication rate of foramen ovale electrodes may be similar to that of more invasive types. These electrodes provide more localizing EEG information than scalp electrodes, because they are closer to the source generators. However, they have not achieved wide popularity, and their ultimate fate in the presurgical evaluation remains to be determined.

Functional Mapping Using Intracranial Electrodes

If the region to be resected appears to contain or be near eloquent cortex whose resection would result in an unacceptable neurologic deficit, electrical stimulation can be used to map the function of that cortex and its relation to the ictal onset zone. Surgery can then be carried out sparing critical tissue, or at least with the knowledge that a particular deficit will likely occur. Intracranial electrical mapping is less important in mesial temporal lobe epilepsy or in operations on “silent” areas such as the frontal pole, but it is critical in posterior frontal, anterior parietal, mesial occipital, and posterior temporal resections, especially those involving the dominant hemisphere. It has limited utility in small children, where it may be necessary to remove large portions of brain (e.g., hemispherectomy) in order to obtain seizure control. Electrical stimulation can be done with chronically implanted electrodes (Chapter 175) or acutely in the operating room at the time of resection (Chapter 174). Typically, chronically implanted subdural grids are used for extraoperative functional mapping, but other electrode types can be used on occasion.

Synthesis and Patient Counseling

At the completion of the presurgical evaluation, the surgical team should be able to provide the patient and family with reasonable estimates of the chance of becoming seizure free following surgery.[22] Particular features in the MRI, Wada test, PET scan, and other tests influence the prognosis. For example, a patient with MRI-demonstrated unilateral hippocampal atrophy has a 75% to 80% chance of becoming seizure free after anterior temporal lobe resection, whereas a patient with symmetric hippocampi has perhaps only a 50% chance of becoming seizure free.[49,89,102] Despite all the modern presurgical tests, prediction for individual patients after epilepsy neurosurgery still has its uncertainities, and patients and their families must be aware of the potential risks and benefits of different therapeutic options (see Chapter 183). In the final analysis, it must be remembered that patients seek surgery to improve the adverse psychosocial consequences of epilepsy as much as, or more, than the medical repercussions, and this need must be addressed.[27]

Before undertaking a presurgical evaluation, the patient should be informed about the risks of the tests. Some tests are basically risk free, such as MRI, neuropsychological testing, ictal SPECT, FDG-PET, and scalp EEG. However, invasive and semi-invasive EEG recording, the Wada test, and intracranial mapping all carry some risk, albeit low, and must be justified by the need for the information they provide. A general statement can be made, however, that the riskier evaluation procedures such as intracranial EEG recording are warranted in appropriate cases. Evaluation with intracranial electrodes has allowed hundreds of patients to have surgery who otherwise would not have been offered an operation. A large percentage of those patients have benefited from their operations, with reduction in their long-term medical risk from epilepsy and psychosocial improvement.

Summary and Conclusions

The decision to evaluate a patient for epilepsy surgery has potentially significant long-term medical and emotional consequences. The aim of the evaluation is to determine if a patient is a candidate for surgery, establish the type of operation that should be performed, and assess its potential benefits and risks. The evaluation should seek to obtain multiple lines of evidence, both structural and physiologic, that can be used to formulate the best surgical option. Improved methods of defining the epileptogenic zone are still needed, and as these are developed, our understanding of epilepsy and seizure-related phenomena will be enhanced.

Chapter 170

Foramen Ovale and Peg Electrodes

Heinz Gregor Wieser

Introduction

The foramen ovale (FO) electrode recording technique was developed in Zürich in 1983.[26] Its goal was to make less invasive and simplify the neurophysiologic part of the presurgical evaluation protocol for candidates for selective amygdalohippocampectomy (AHE). Before 1983, stereoelectroencephalography (SEEG) had been used for the majority of patients being evaluated there for epilepsy surgery.[21,23] The accumulated SEEG experience revealed that the mesial temporal lobe (TL) structures, in particular the hippocampus, the parahippocampal gyrus, and the amygdala, play important roles as seizure-generating structures in most patients with temporal lobe epilepsy (TLE). As a consequence of these findings, in 1975, the so-called *transsylvian AHE*[33] was developed and has since become the operative approach of first choice for surgical treatment of mesial TLE (MTLE) in Zürich as well as in many other centers.

Peg electrodes were developed at the Cleveland Clinic in 1988.[2,3] They are usually used as sentinel electrodes, often in combination with other invasive techniques, for obtaining epidural ictal recordings.

Data obtained from Engel's survey carried out before the 1992 Palm Desert conference showed that, at that time, 15 centers (15%) used FO electrodes and four centers used epidural pegs. FO electrodes had been used only in 5% of all reported patients operated on from 1986 to 1990 (n = 7,664), but in 21% of 662 reported AHE patients.[7] Since then, FO electrodes seem to be used increasingly in more centers,[1,6,12,15,18,34] whereas peg electrodes are presently used by only two epilepsy surgery centers.

FO and peg electrode recording techniques have been labeled an intermediately invasive or semiinvasive approach.

Indications

Peg electrodes allow artifact-free recording of the electrocorticogram in relatively small but widely separated regions of the cortical convexity. They were designed to determine surgical suitability in patients in whom the clinical, electrographic, and neuroimaging information did not localize the epileptogenic zone well; that is, they were used in circumstances in which exact placement of a subdural grid array was uncertain from the clinical, neuroimaging, and scalp electroencephalogram (EEG) data. Often they were inserted as sentinel electrodes contralateral to subdural grid placement, to confirm that ictal discharges were not beginning contralaterally. Depending on the particular clinical circumstances, peg electrodes may be used with other electrodes including FO electrodes, depth electrodes, and subdural grid arrays.

FO electrodes record from the mesial aspects of the TL. Compared with intracerebral depth electrodes, subdural grid electrodes, and most probably also subdural strip electrodes, FO electrodes are less invasive, but nevertheless the possibility of complications is inherent in the FO electrode technique. Therefore, its use should be restricted to presurgical evaluation of possible candidates for epilepsy surgery. Moreover, it is obvious that its main indication is for patients with TLE, in particular for patients suffering from the syndrome of MTLE.[25] Today FO electrodes are mainly used in patients with suspected MTLE with ambiguous seizure onset lateralization or with other noncongruent findings. Bilateral hippocampal sclerosis (HS) and/or bilateral independent interictal spiking are the second most often encountered reasons to insert FO electrodes. HS is the neuropathologic substrate most often found in MTLE. Vossler et al.[22] found that marked hippocampal atrophy (HA) and high-grade HS are associated with initial ictal discharges (IID) restricted to the hippocampal formation, whereas low-grade HS and absence of HA are associated with slower (2–4 per second) scalp IID frequencies and with lobar or regional seizure onsets not restricted to medial structures. Therefore, FO electrodes are particularly useful in patients without marked HS and when AHE is intended. However, in such constellations, the combination with subdural strip or grid electrodes is often necessary.

Table 1 Types of FO electrodes and combinations with other invasive recording technique (*n* = 264)

		Bilateral	**Unilateral**				**Number of electrode contacts**		
	Total	R+L	R	L	1	3	4	8	10
Patients	264	253	6	5	34[+]	1	138	7	84
FO with thermoelement	14	6	5	3

		+**SEEG**	+**Strip**	+**Strip + Grid**	+**Grid**				
Patients	49	14	32	2	1				
%	18.6	5.3	12.1	0.7	0.4				

R= right hand side; L= left hand side.

[+] First FO EEG was recorded from a patient with trigeminal neuralgia.

44 DIXI Electrodes (DIXI microtechniques, France), the remaining were designed in our own laboratory.

Thermoelement for research purpose (Landolt et al., 1995).

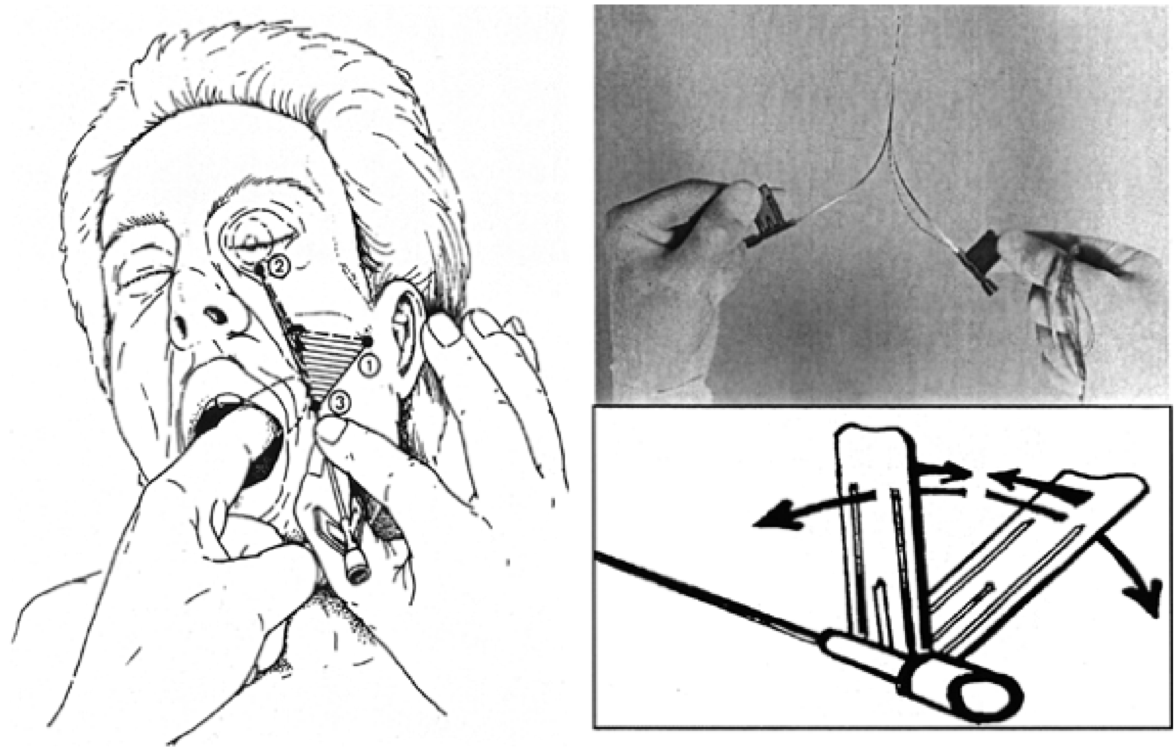

FIGURE 1. *Left:* Insertion technique of foramen ovale electrodes according to the technique of Kirschner (1932) using the landmarks of Härtel (1914). *1* is a point 5 cm anterior to external auditory meatus. *2* is the medial pupillary point. *3* is the electrode entry side, 3 cm lateral to oral commissure. The index finger is in the pterygoid fossa. The needle is inserted as described in the text, and then the special splittable cannula is withdrawn and broken.

Techniques

Foramen Ovale Electrode Design, Insertion, Removal, and Recording

In recent years, several types of FO electrodes have become commercially available. Until June 1999, the FO electrodes used in Zürich were site-made.[28] In brief, these FO electrodes consisted of Teflon-insulated, helically wound silver or platinum wires (diameter 0.1143 mm [0.0045 inches]) ending in four, eight, or ten poles. They were mounted on a "surgical" (highly corrosion-resistant) stainless steel wire 0.1 mm in diameter. This carrier, isolated with a special varnish, had adequate mechanical properties. It was flexible enough and had a special end to avoid penetration of the arachnoidal-pial layer. Each pole consisted of 90 parallel windings and was 2 or 4 mm long. The distance between two contacts was 2 to 5 mm, depending on the type of electrode (Table 1). The external diameter of the FO electrode types was such that it passed through a special split Table 18-gauge cannula (produced and marketed by Medialimed SA, CH-1604 Puidoux, Switzerland). This splittable cannula is still in use (Fig. 1). It has an external diameter of 1.23 mm and an internal diameter of 0.93 mm and permits the multipin connector to be mounted and soldered, and the stabilizing insulator poured in well before implantation. The site-made electrode impedance ranged from less than 200 ohms to a maximum tolerated 700 ohms, respectively, whereas the DC offset potential was less than 2 mV. These electrodes could be armed with other specific recording devices.

P.1780

Temperature-sensitive devices have been used in 14 patients[14] (see Table 1), and special ictal and interictal DC recording with monopolar silver FO electrodes were carried out in five patients (Fig. 6).[20]

Insertion

Insertion of the FO electrode can be done under local anesthesia. Currently, however, the procedure is done in Zürich under general anesthesia. With the stylet inside it, the special cannula is inserted 3 cm lateral to the oral commissure and directed along the intersection of two orthogonal planes: (a) the plane defined by the insertion point, a point on the lower eyelid corresponding to the medial border of the pupil, and the tip of the electrode directed toward the foramen ovale; and (b) a plane defined by the insertion point, a point 5 cm anterior to the external meatus acusticus, and the tip of the electrode directed toward the FO (Fig. 1).

The patient usually responds to the passage of the needle through the FO with a wince and a brief contraction of the masseter muscle. After withdrawal of the stylet, some cerebrospinal fluid usually leaks, and the electrode can then be carefully positioned under radioscopic control. In most instances, the tip of the electrode slips without any resistance into the caudal

end of the ambient cistern (Fig. 2, see Fig. 7). After the splittable cannula has been withdrawn and broken off, the freed electrode is fixed to the skin by a special clamp. Gauze and adhesive tape cover the electrode where it penetrates the skin. Antibiotic protection is given throughout the recording period and is continued for 3 days after the removal of the electrode.

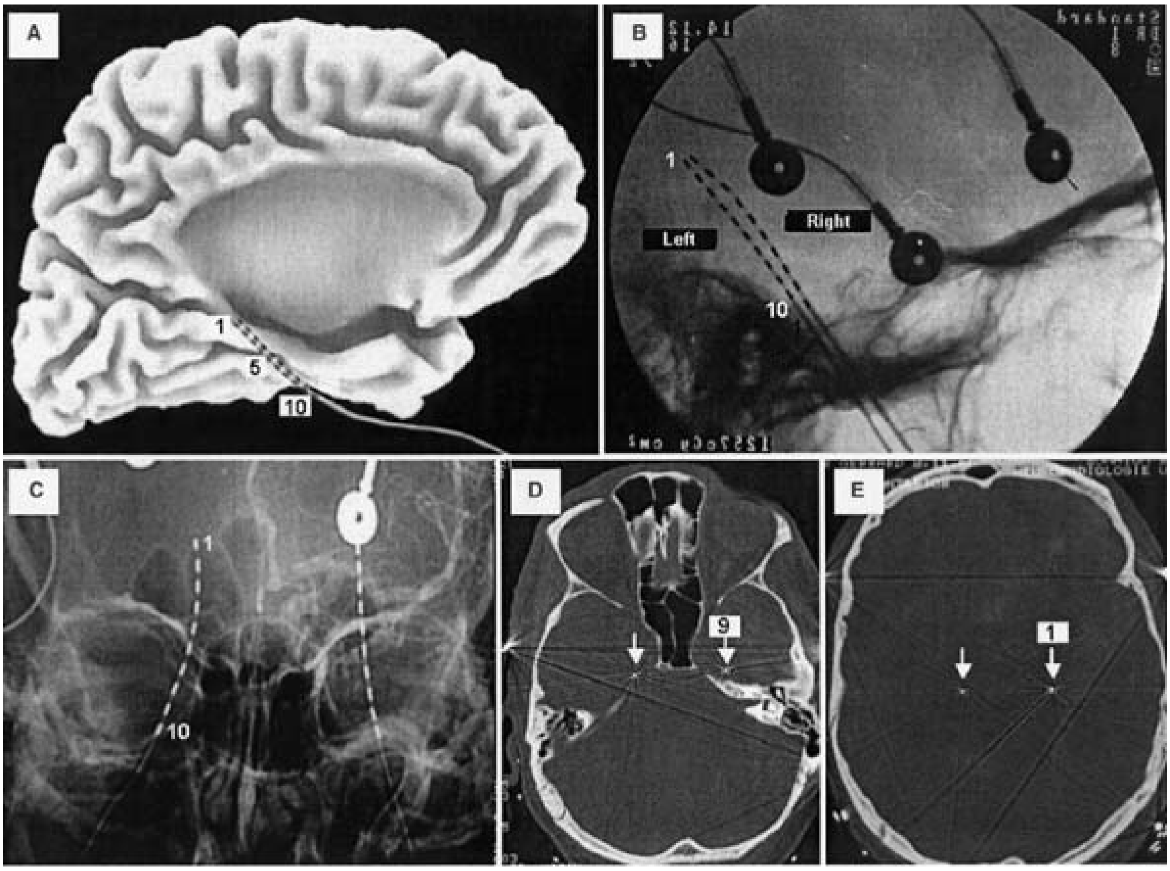

FIGURE 2. Schematic illustration of implanted 10-contact foramen ovale electrodes (**A**), as depicted by lateral (**B**) and AP x-ray (**C**) and CT imaging (**D, E**). Electrode contacts are numbered 1 to 10. **A** is used with permission of Dr. Dominik Zumsteg.

Removal

For the removal of the FO electrode, anesthesia is not necessary. During the withdrawal of the electrode a brief painful sensation in the ipsilateral teeth is relatively common. Therefore, the patients should be informed about this possibility before the explantation.

Montage, Recording, and Analysis

Sophisticated DC recording with FO electrodes has been done hard-wired with 32 channels in the laboratory, but seizure monitoring in AC mode is now realized by 64 or more channels with the patient on the ward. For routine monitoring, an uninterrupted bipolar montage connecting the ten contacts of both FO electrodes is recommended, as shown in FIGURE 3. The other channels are used for simultaneous scalp EEG and other intracranial EEG records, as well as polygraphy, if indicated.

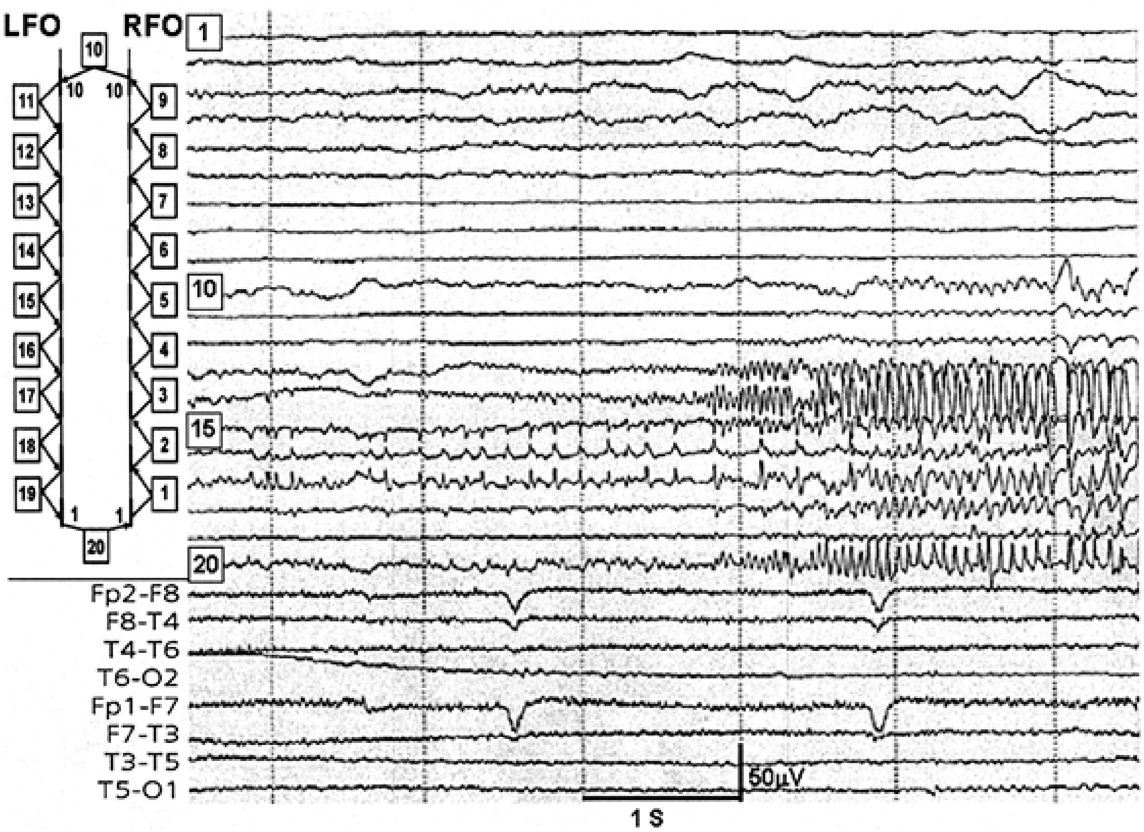

FIGURE 3. Example of a 10-contact foramen ovale (FO) electrode recorded seizure onset at contact 5 of the left FO electrode (phase reversal between channels 15 and 16) with repetitive 7/sec sharp waves and evolving rhythmic more wide-spread spike discharges of 19/sec. Note that the scalp-EEG channels do not show the seizure onset. At the *left* the montage for recording from 10-contact FO electrodes is shown. For routine long-term seizure monitoring, we prefer the depicted closed chain with 20 channels (number in boxes).

Patient Data of the Zürich FO Electrodes Series

With two exceptions (the first FO electrode patient had no epileptic seizures, but trigeminal neuralgia, and one patient had aggressive outbursts thought to reflect limbic seizures), all patients who underwent FO electrode implantation in Zürich had medically refractory complex partial seizures with or without secondary generalization. In most of these patients, before FO electrode implantation, there was rather strong suspicion of mesiobasal limbic seizure onset, as evidenced from the seizure semiology, interictal and ictal scalp EEG, neuropsychological examinations, and structural (computed tomography [CT], magnetic resonance imaging [MRI]) and/or functional (single positron emission computed tomography [SPECT] and positron emission tomography [PET]) imaging. These patients were evaluated with the aim of demonstrating a unilateral mesiobasal limbic seizure onset with a degree of confidence sufficient for surgical intervention. In recent years, FO electrodes were only used in patients with less clear evidence for mesiobasal TL seizure onset; that is, in patients with some contradictory findings pointing to lateral TL or extra-TL seizure onset, and in patients in whom lateralization was a problem (bilateral MTLE). At the beginning of the use of FO electrodes in Zürich, the majority of these patients were evaluated

simultaneously with FO and stereotactic depth electrodes. In recent years, FO electrodes were often combined with strip and sometimes with grid electrodes. In a small proportion of our FO electrode patients, mesiobasal limbic seizure onset was rather unlikely. These patients underwent long-term monitoring with FO electrodes to rule out mesiobasal limbic seizure onset definitively (in which case they would no longer have been candidates for surgical treatment) or to prove a possible secondary pacemaker role of one mesiobasal TL (in which case a so-called *palliative AHE* would be considered a treatment option).

In Zürich, during the period from 1970 to 1983, a total of 94 patients underwent SEEG exploration, and this resulted in a total of 69 operations (73%). From 1984 until today, FO electrodes were used in a total of 264 patients, in 18.6% FO electrodes were combined with other invasive recording techniques. Table 1 lists details in this respect.

The analysis of the therapeutic actions after presurgical evaluation in the last consecutive 100 patients with FO electrodes in Zürich (May 1995 to November 2005) reveals that 73 patients had AHE and eight had resection in TL and/or adjacent areas, other than AHE. Two patients underwent reoperation in TL, five patients underwent temporal lobectomy outside our center, two patients received a vagal nerve stimulator, and 10 patients had no surgery. Sixty-six of these last 100 patients had presurgical evaluation with FO electrodes alone. In 34 patients, FO electrodes were used in combination with other intracranial electrodes: FO *and* strip (n = 29); FO *and* grid (n = 2); FO *and* grid *and* strips (n = 2); FO *and* SEEG (n = 1).

It is interesting to have a look at the Zürich AHE series, which started in 1975. This series now contains a total of 517 AHE patients. Two-hundred seventy-six (53.4%) had intracranial EEG monitoring, 32 (6.0%) had SEEG only, 198 (38.3%) had FO electrodes only, 46 (8.9%) had combined intracranial electrodes (SEEG and FO, FO and strips/grids). The remaining 241 (46.6%) had AHE without intracranial recordings. Table 2 shows the obvious trend for less invasive presurgical evaluation in candidates for AHE: In recent years, the percentage of AHE without intracranial presurgical evaluation amounted to 69.6%.

Table 2 Amygdalohippocampectomies performed in Zürich and type of presurgical EEG evaluation tabulated for four time periods (*n* = 517)

	1975–1985		1986–1992		1993–1999		2000–Nov 2005		Total	
	n	%	*n*	%	*n*	%	*n*	%	*n*	%
Number of AHE	103		151		115		148		517	
AHE with SEEG alone	31	30.1	1	0.6	0		0		32	6.0
AHE with combined intracranial electrodes (SEEG + FO; FO + strips/grids)	7	6.8	3	2	32	27.8	4	2.7	46	8.9
AHE with FO alone	3	2.9	84	55.6	70	60.9	41	27.7	198	38.3
AHE with noninvasive EEG	62	60.2	63	41.7	13	11.3	103	69.6	241	46.3

Despite the overall less-invasive presurgical evaluation, the seizure outcome at 1 year after AHE improved steadily over time. In the 1975 to 1992 period Engel Classes I to IV were 69%, 9%, 13%, 9%, respectively (*n* = 254); in the period 1993 to 1999, the respective numbers are 75%, 10%, 13%, 2% (*n* = 115); in the period 2000 to 2001, the preliminary outcome assessment for 50 AHE patients revealed 89%, 11%, 0%, 0%.[30]

In this context, it is important to remember that, since 1978, CT emerged as an imaging technology; since 1985, MRI; since 1987, SPECT and 31P-MRS; since 1988, PET; and since 1993, proton magnetic resonance spectroscopy (1H-MRS) at the Zürich center.

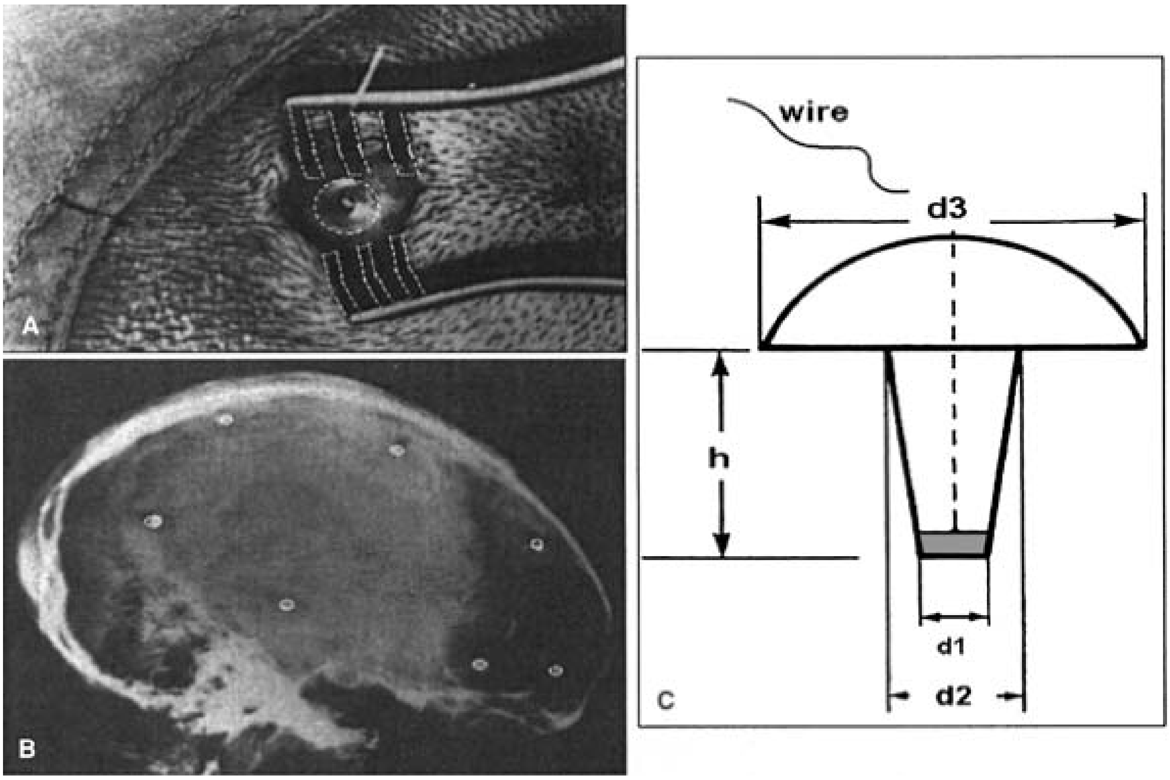

FIGURE 4. Epidural peg electrodes. **A**: The electrode consists of a stainless steel or platinum disc embedded into a mushroom-shaped silastic housing. The stalk has a gradual taper from a maximum diameter (d2) of 4.7 mm to a tip diameter (d1) of 4.5 mm. Stalk heights (h) range from 3 to 19 mm in 2-mm increments to match skull thickness. The cap has a diameter of 12.7 mm (d3) and a height of 2.5 mm (MDX4-4210, Dow Corning Corp. Midland, MI). The peg is implanted via 1.5 cm scalp incision and burr-holes (**B**). **C**: Lateral skull radiograph with epidural peg electrodes. (Modified from Wieser HG, Quesney LF, Morris HH III. Foramen ovale and peg electrodes. In: J. Engel Jr., ed. *Surgical Treatment of the Epilepsies*, 2nd ed. New York: Raven Press; 1993:331–339, with permission; original sources from Awad IA, Assirati JA Jr, Burgess R, et al. A new class of electrodes of "intermediate invasiveness": preliminary experience with epidural pegs and foramen ovale electrodes in the mapping of seizure foci. *Neurologic Res*. 1991;13:117–183; and Barnett GH, Burgess RC, Awad IA, et al. Epidural peg electrodes for the presurgical evaluation of intractable epilepsy. *Neurosurgery.* 1990;27:113–115.)

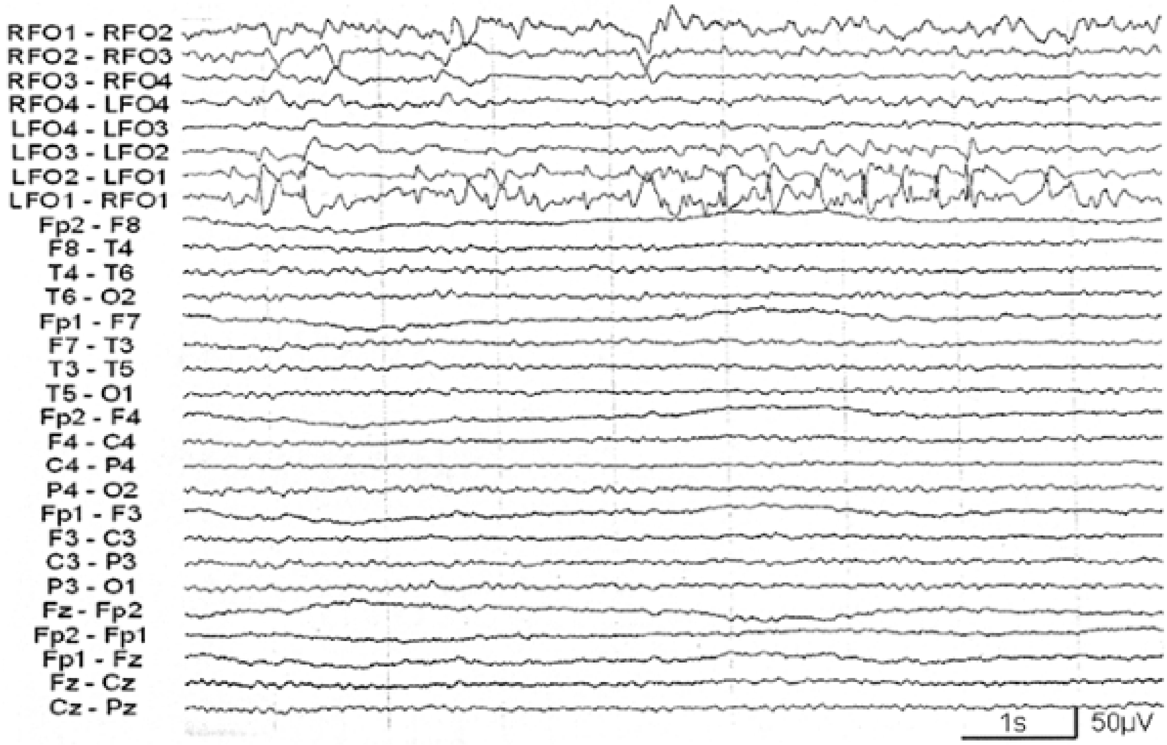

FIGURE 5. The four-contact foramen ovale (FO) electrode recorded infraclinical left posterior mesial TL seizure discharge (LFO1) not detected in the scalp EEG.

Epidural Peg Electrodes Design

Epidural peg electrodes (Fig. 4) are mushroom-shaped composites of Silastic plastic with a "cap" diameter of 12.7 mm, a

P.1783

slightly tapered stalk, and a tip consisting of a 4.5 mm disc electrode made of either platinum or stainless steel. The electrodes are made with different stalk lengths to adapt to different skull thicknesses. A 1- to 1.5-cm scalp incision is made to expose the skull at the predetermined electrode positions. A twist drill with a "stop" is used to create a 4.5-mm burr hole; the electrodes are then inserted by hand into the hole. The 38-gauge Teflon-coated steel wire from the electrode is threaded through a surgical needle and exits the scalp approximately 2 cm distant to the electrode itself. The scalp over the electrode is then sutured. The Bethel Epilepsy Center has reported on a slightly smaller version of the original epidural peg electrode.[10]

P.1784

Comparison of FO Electrodes with Sphenoidal Electrodes and Other Noninvasive Recording Techniques from the Temporal Lobe

The value of the sphenoidal electrodes is controversially discussed.[4,5,11] From his extensive review of the studies comparing sphenoidal electrodes with other basal electrodes, and with scalp electrodes, both interictal and ictal, Schomer[16] came to the conclusion that "it is not clear that the sphenoidal electrode offers a substantial benefit over other "basal" electrodes, such as the minisphenoidal electrodes, the T1/T2 electrode, the zygomatic, or the anterior temporal electrode." If, however, the standard sphenoidal electrode is placed with "great care just inferior to the foramen ovale, it may be able to differentiate laterality of temporal lobe seizure onset better than the more superficial "basal" electrodes."[11]

Advantages of Foramen Ovale Electrodes

FO electrodes provide a definite advantage over scalp EEG and over sphenoidal electrodes. In several instances in which the Zürich group used sphenoidal and FO electrodes simultaneously, they found FO electrodes to be superior in detecting epileptiform activity from the mesial aspect of the TL. In several patients, specially constructed FO electrodes were implanted, which had equally spaced intracranial and extracranial contacts (see Fig. 7); the distribution of the peak amplitudes for various epileptiform graph elements, recorded referentially against Cz, were measured. From this study,[24] it became clear that most spikes could not be reliably detected in the extracranial electrodes, because of a very steep voltage gradient. Zumsteg et al.[35] averaged FO electrode and scalp EEG spikes for representative interictal epileptiform discharges (IED) and studied the cortical activation during the ascending phase of the FO electrode–recorded spike using statistical low resolution electromagnetic tomography (LORETA) solutions. In 11 of 15 studied patients, 19 of 30 (63%) IED patterns showed a very restricted activation of ipsilateral mesial temporal lobe that could be detected in the scalp EEG, but only after averaging. A widespread neocortical activation involving frontal and temporo-posterior structures, which could be reliably detected in the scalp-EEG without averaging, occurred in five of 15 patients (representing 6 of 30 [20%] IED patterns). Very restricted mesial temporal spike that could not be detected in the scalp EEG despite averaging occurred in four of the 15 patients (representing five of 30 [16.7%] of IED patterns). Epileptiform discharges originating in the posterior hippocampal formation are usually not detectable in the scalp EEG. The epileptiform activity, depicted in FIGURE 5, originates at the posterior contact of the left four-contact FO electrode and is neither seen in the simultaneously recorded scalp EEG nor in the anterior contacts of the FO electrode. Because the anterior contact of FO electrode is situated close to the foramen ovale, it may well be comparable to an optimally placed sphenoidal electrode.

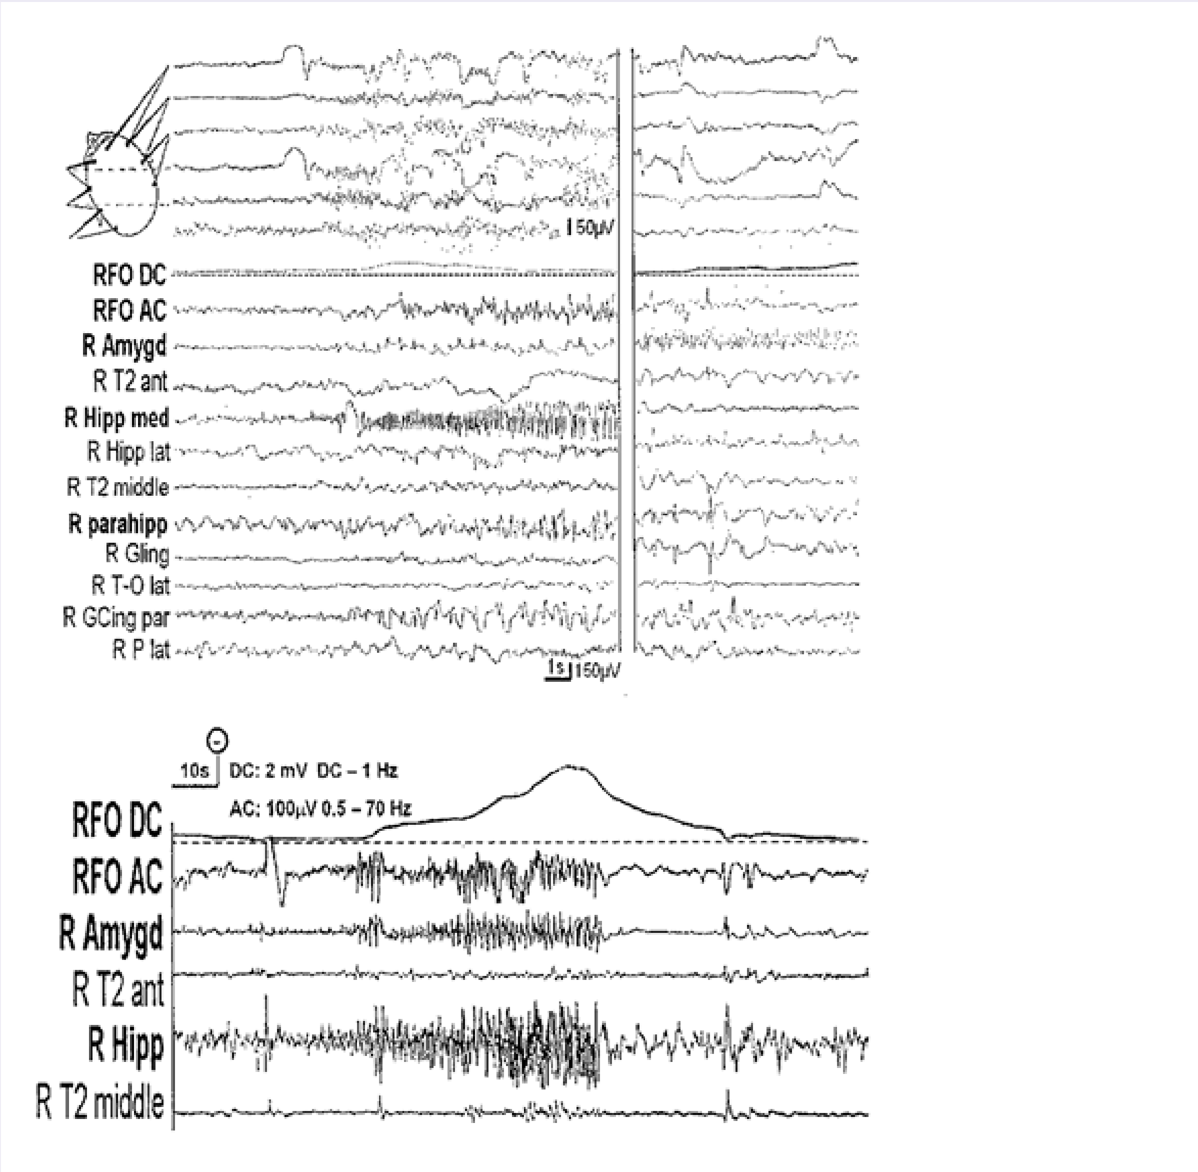

FIGURE 6. *Upper part*: Stereoelectroencephalographically recorded right hippocampal (R Hipp) seizure discharge onset (*left*) with moderate spread to ipsilateral amygdala (R Amygd), right parahippocampal gyrus (R parahipp) and posterior cingulate gyrus (R G Cing par). Note that the right foramen ovale electrode (RFO) recording in AC mode reliably depicts this discharge, which is accompanied by a negative DC shift in the FO DC recording (RFO DC). The amygdala discharge *(right)*, however, is accompanied by attenuation without clear spikes. *Lower part*: The seizure discharge in right amygdala and right hippocampus is very well depicted by the right foramen ovale electrode recording in AC mode (RFO AC) and accompanied by a marked negative shift in the DC recording.

Compared to stereotactic depth electrodes, FO electrodes reliably pick up epileptiform activity generated or involving the hippocampal formation. This is illustrated in FIGURE 6. Song et al.[19] reported on eight patients who had intraventricular recordings with an electrode endoscopically placed along the

lateral margin of the hippocampus. Seven of these patients also had subdural grid or strip electrodes, and four had FO electrodes. One complication occurred (thalamic contusion) and, in another patient, the tip of the electrode was misplaced into the frontal horn of the lateral ventricle instead the temporal horn. The authors illustrate two seizure onsets from two patients. In both, the intraventricularly recorded hippocampal discharge is well depicted by the FO electrodes. The depicted discharge pattern looks very similar in both recording techniques, but exhibits a phase reversal between the intraventricular and the FO electrodes.

Pure amygdala discharges, however, may escape detection in the scalp and FO electrodes, as illustrated in the upper right part of FIGURE 6 and in FIGURE 7.

An advantage of FO electrodes is that they explore the mesial temporal lobes symmetrically and thus allow studying the seizure spread to the opposite hemisphere (Figs. 8 and 9). Because of their good spatio-temporal resolution, multicontact FO electrodes also allow the study of various types of seizure patterns and interictal epileptiform discharges (Figs. 9 and 10). Finally they are very helpful for monitoring the time course of amobarbital-induced slow δ-wave activity and/or other mesial TL EEG changes in selective TL amobarbital tests with inactivation of the territory of the anterior choroidal artery. It has been shown[29] that an appropriate intracranial EEG recorded from depth electrodes or FO electrodes in combination with a scalp EEG is indispensable for a reliable interpretation of the amobarbital effects of selective tests. The increase of δ-wave activity is judged as the most typical amobarbital-induced EEG effect. Other amobarbital-induced EEG patterns are the isoelectric line, the burst suppression pattern, and the high- and low-voltage β-activity. In the Zürich selective TL amobarbital series (106 patients), the δ-increase, the "activation phenomenon," and spike reduction were observed. The activation phenomenon and the spike reduction were only reliably detected using intracranial EEG recording techniques. As expected, δ-wave increase at the site of amobarbital action was the most commonly observed EEG pattern, and was present in 75%.

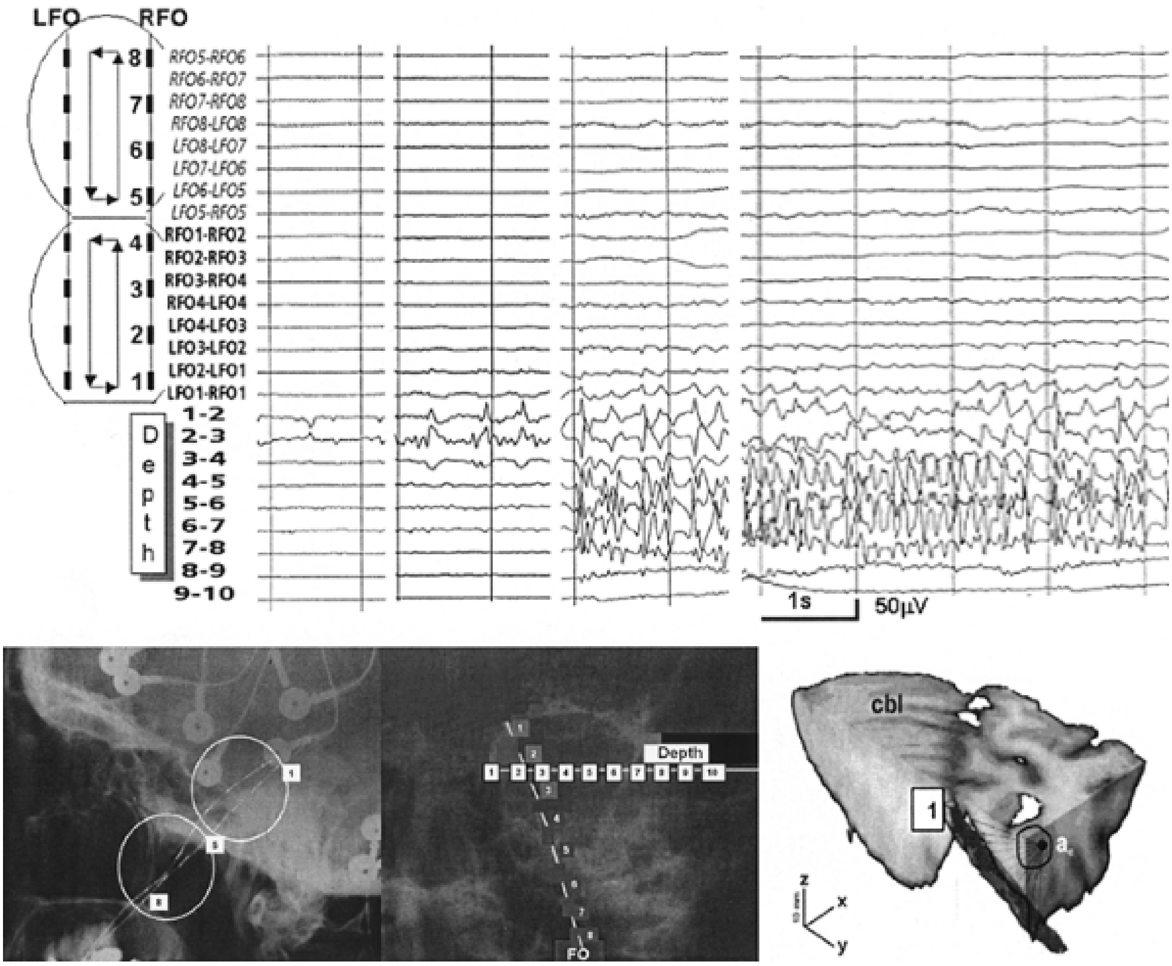

FIGURE 7. *Top:* Four sections of an amygdala seizure, recorded with specially constructed eight-contact foramen ovale (FO) electrodes, which have contacts 1 to 4 intracranially situated, and contacts 5 to 8 extracranially situated (see radiograph, *bottom, left*) and a stereotactically implanted multicontact depth electrode orthogonal insertion, with its tip (contact depth 1) in the left amygdala (*bottom, middle part*). At the *bottom, right*, the 3-D reconstructed topographic relationship of a FO electrode to the amygdala is shown. A minimal distance of 15.9 mm of the nearest contact to the center of the amygdala (a_c) was measured. *cbl, cerebellum.* The deepest contact 1 (rectangulated) is at the end of the ambient cistern. The depicted seizure discharge was accompanied by abdominal pain. Note that (a) the amygdala seizure onset is not reliably picked up in the FO electrode contacts, and (b) the extracranially located contacts of the FO electrode—with contact 5 representing an optimally placed sphenoidal electrode—do not even show the late discharge which, however, is well reflected by repetitive sharp waves in the intracranial left FO electrode recording (contact 2, *LFO2*). Recordings from intracranially placed FO electrode contacts are indicated in bold. Parts of this figure are modified from Eschle D, Siegel AM, Wieser HG. Amygdala seizure onset characterized by severe abdominal pain. *Mayo Clin Proc.* 2002;77:1358–1360 (*upper part*); and Wieser HG, Schwarz U. Topography of foramen ovale electrodes by 3D image reconstruction. *Clin Neurophysiol.* 2001;112:2053–2056 (*bottom, right*).[31]

In a comprehensive study,[29] in which the amobarbital-induced memory performance was correlated with the amobarbital-induced EEG changes, a significant correlation between the dosage and the duration of the EEG changes ($p < 0.05$) was found, but there was no significant correlation between the dosage and the EEG pattern. Moreover, the appearance of an "activation phenomenon"; that is, the evocation or increase of spikes (or other epileptiform graph elements) predisposed to a marked decrease of the memory performance not only for material specific for the side of injection, but also for material specific for the contralateral, noninjected hemisphere.

Combined FO electrode and scalp EEG monitoring during selective TL amobarbital tests is therefore very important for correct interpretation of the test results.

Limitations

FO electrodes have definite limitations: The nature of the FO electrode recording technique implies that only restricted questions can be answered by this technique, namely: (a) Do the seizures originate at the mesiobasal TL structures? If yes, (b) are they constantly lateralized? In addition, (c) information is obtained as to whether the seizure origin is more anterior or posterior. However, if the seizures do not originate at one mesiobasal TL, the patient is by definition no longer a suitable candidate for curative selective AHE, and it must then be decided whether further evaluation is indicated with a view toward more extensive TL or even extratemporal surgery.

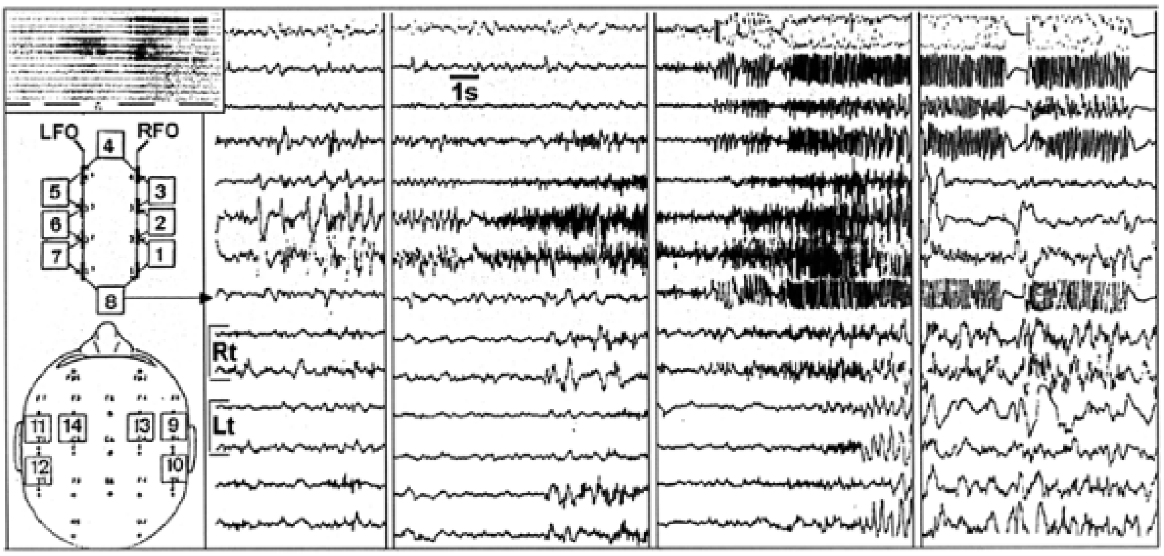

FIGURE 8. Illustration of a prototypic four-contact foramen ovale (FO) electrode-recorded MTLE seizure with left mesiotemporal onset (phase reversal at contact 2′ of left FO electrode (LFO) (i.e., between channels 6 and 7). *Section 1 (left)* shows repetitive 1/sec sharp waves resembling the “hypersynchronous seizure onset pattern”; *section 2,* the high-frequency spike discharge; *section 3,* the subsequent spread to the right mesial temporal lobe (i.e., the bilateral mesial temporal discharges); *section 4 (right),* the cessation of the left temporal discharge in the anterior FO electrode contacts but with some ongoing discharge in the deepest contact 1 (channel 7), and the end of the seizure. Channels 1 through 8 record from the FO electrodes (closed chain montage), channels 9 through 14 are selected bipolar scalp EEG recordings, as indicated in the scheme with numbers in rectangular boxes. Bars in the insert indicate sections 1 through 4.

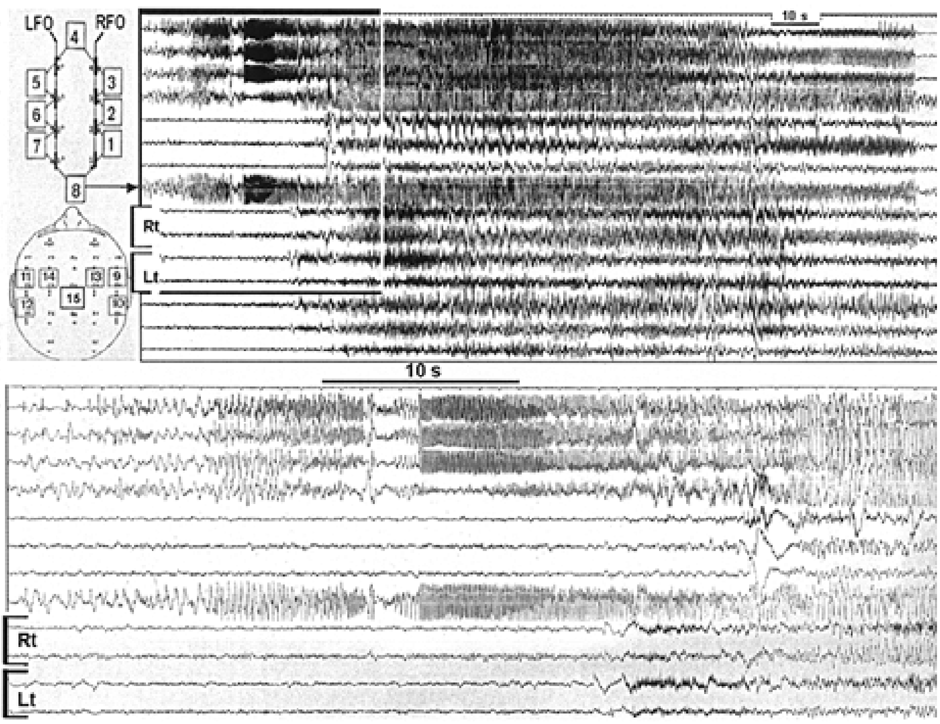

FIGURE 9. Combined four-contact foramen ovale (FO) and scalp recordings of a seizure with right mesial temporal lobe onset lasting 2.7 minutes and with spread to the left mesial temporal lobe (*upper part*). The *lower part* depicts the beginning of the seizure (marked) with better time resolution. Note the dynamics of the discharge with the intermediate 2.5 seconds long paroxysmal pattern shift (lower part) and that the selected scalp EEG channels from the right temporal (Rt) and left temporal (Lt) do not reliably pick up the seizure onset, but show the late seizure discharge.

Evidently a risk exists of falsely localizing an apparent seizure origin in the mesiobasal TL and missing the true origin outside these structures when the FO electrode technique is used. The best way to minimize this risk is to carefully study the clinical features accompanying the seizures by recording the occurrence of the subjective auras and/or the objective signal symptoms and correlating these with the simultaneously

P.1787

recorded EEG. In addition, as already mentioned, FO electrodes can be combined with other recording techniques, such as subdural strips.

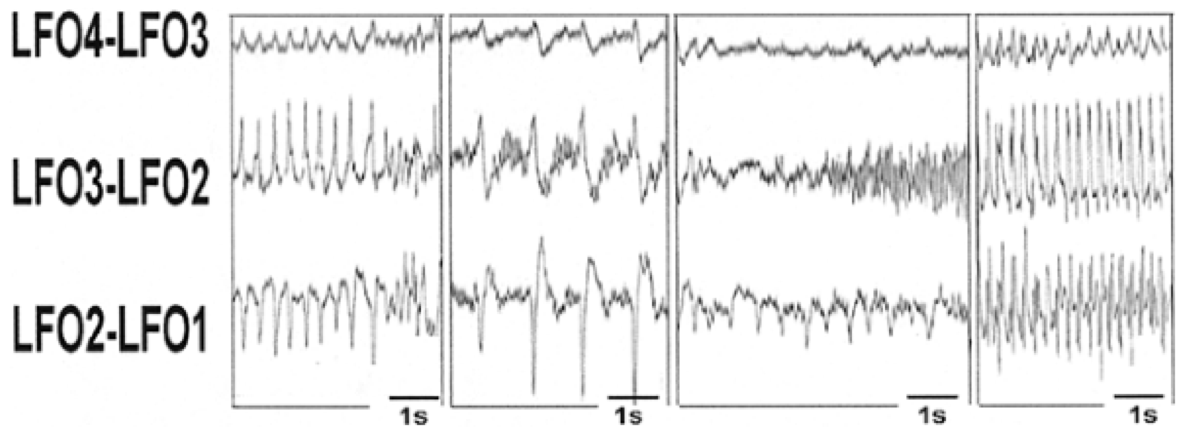

FIGURE 10. Four sections of a left foramen ovale (LFO) electrode recorded seizure with typical discharge patterns. *From left to right:* Electropositive "hypersynchronous" recruiting rhythm at contact 2 (LFO2); "afterdischarge-like" polyspike-slow complexes; critical decrement and high-frequency low-amplitude ("tonic") discharge pattern with crescendo-like increase of the amplitude at LFO3; and 4/sec rhythmic discharge. (Modified from Wieser HG. Stereoelectroencephalography and Foramen Ovale Electrode Recording. In: Niedermeyer E, Lopes da Silva F, eds. *Electroencephalography: Basic Principles, Clinical Applications, and Related Fields,* 4th ed. Baltimore: Williams & Wilkins; 1999:725–740, with permission.)

The most reliable seizure onset patterns recorded with the FO electrodes are the high-frequency, low-amplitude discharge pattern and the so-called hypersynchronous seizure onset pattern.[27] In the absence of these patterns, the localization of the seizure focus should be questioned. A well-localized decrement at the FO electrodes was the most frequently observed initial seizure pattern in the Zürich FO

electrode series. When followed within 3 to 5 seconds by a high-frequency discharge at the same localization, it was also a reliable pattern. From analysis of simultaneous recordings from depth electrodes inserted directly into limbic structures, such as the amygdala, anterior and posterior hippocampus, and parahippocampal, as well as the fronto-orbital and cingulate gyri, and from FO electrodes, it became evident that a well-localized initial flattening of the EEG record from the FO electrode was nearly always associated with a high-frequency, low-amplitude discharge observed in the stereotactic depth recordings from the hippocampal formation and/or amygdala.

The FO electrodes usually pick up mesial TL epileptogenic activity very reliably.

Only in the very rare cases of prolonged discharges totally confined to the amygdala and not affecting the hippocampal formation may the FO electrode miss the discharge. This is because the amygdala behaves as a closed electrical field. In the SEEG series, however, amygdala seizures accounted for only about 3% of all psychomotor seizures.

The limited placement of peg electrodes represents their main limitation. The use of the epidural peg electrodes at the Cleveland Clinic has declined significantly over the past years. In part, the changes reflect surgical preference, but to a large extent they reflect improvements in noninvasive evaluations, including (a) high-resolution MRI scans, (b) volumetric analysis of the hippocampus, and (c) digital EEG allowing reformatting and filtering of data. It has also become apparent that, in the evaluation of a patient with a focal epilepsy whose studies include no focal MRI abnormalities and no localizing EEG abnormalities, epidural peg electrodes are unlikely to demonstrate a clear epileptogenic focus. In other words, they are not very helpful in a "fishing expedition."

Complications

The risks of insertion of FO electrodes and peg electrodes are considerably less than those for depth and subdural strip and grid electrodes.

In 1987, we had one serious complication in the Zürich FO series: A subarachnoid hemorrhage that led to a transient upper pontine syndrome. MRI-documented subarachnoid hemorrhages without any neurologic deficits occurred in two other patients. Meningitis occurred in two patients and was treated by intravenous antibiotics without sequelae. Placement of FO electrodes may be associated with transient morbidity, especially facial pain. Temporary facial pain has occurred in 19% of our patients. Two patients reported mild transient temporomandibular joint dysfunction. Recurrence of labial herpes was seen in 5%. A transient hypo- or dysesthesia, localized in one corner of the mouth, was reported in 9% of the cases. No other side effects or complications, and, in particular, no persisting trigeminal impairments occurred in Zürich.

One patient pulled out one FO electrode in a postictal confusional state; one patient injured one electrode during shaving. Since the information gathered was not sufficient, both electrodes had to be reimplanted.

At the Palm Desert Epilepsy Surgery Conference, it was reported that a few other severe complications had occurred at other centers.[17]

Complications of Epidural Peg Electrodes

By the end of 1993, approximately 77 patients had over 500 epidural peg electrode insertions and studies at the Cleveland Clinic; at the Bethel Epilepsy Center, 36 patients underwent evaluation using approximately 420 epidural peg electrodes. No major complications were seen in these patients. In one Cleveland patient, a single cortical contusion was discovered on CT scan.

Culturing the peg electrodes at time of removal yielded a bacterial colonization rate of approximately 22% in the Cleveland Clinic series; no patient had a clinical infection attributable to these electrodes. The lack of clinical infection was in part a result of prompt treatment with appropriate antibiotics if the electrode cultures proved positive.

Costs

The cost of FO electrodes and their insertion are considerably less than that of other invasive electrode techniques. Although general anesthesia is usually preferred, insertion of FO

electrodes can be done under local anesthesia and does not require a sophisticated neurosurgical theater or a neuroradiological examination under stereotactic conditions. Usually no intensive care unit is necessary, and patients with FO electrodes alone can be evaluated outside very specialized units. Likewise, the cost of insertion of peg electrodes is less than that of grid electrodes. However, the major expenses derive from the long-term monitoring, and they are similar whether the electrodes are semi-invasive or invasive.[7]

Future Directions

Whereas FO electrodes may be viewed as a major step in making TL surgery less invasive, the usefulness of peg electrodes remains limited. It is our guess that FO electrodes will be increasingly used in nonlesional TLE patients being evaluated as candidates for mesial temporal lobe resections, and the use of peg electrodes might decline further. Arguments for this prediction are that, in TLE, very effective standardized surgical procedures are available and the main goal of the preoperative evaluation in patients is to answer the question of whether a patient is a suitable candidate for one of these standardized surgical procedures. In MRI-negative extratemporal epilepsies, however, exact localization and determination of the extent of the epileptogenic area still remain a very demanding and difficult task requiring a tailored approach with invasive intracranial techniques in almost all cases.

Summary and Conclusions

On the basis of the Zürich experience, with strict indications, the semiinvasive technique of FO electrode recording is suitable for the evaluation of potential candidates for AHE. Because AHE has virtually abolished larger TL resections in Zürich, a considerable proportion of patients considered for surgical treatment of TLE are candidates for bilateral FO electrode evaluation. The aim of the FO electrode insertion is to record and study the patient's spontaneously occurring habitual seizures.

Epidural peg electrodes are a useful and safe addition to the surgical epileptologist's toolbox. However, they should be seen as being complementary to other invasive electrodes and not as replacement for them.

Introduction

Reports and experience worldwide have shown that resection of the epileptogenic area of brain in uncontrolled epilepsy patients with stereotyped partial seizures can cure the epilepsy, or at least prevent recurrent seizures.[30,57,81] The corollary of this statement is that if the surgery fails, the area removed was incorrect or incompletely resected or was only one of several cerebral regions responsible for seizures. Accordingly, accurate definition of the location and limits of this epileptogenic area has become a major preoccupation among epileptologists.

The first need is to define *epileptogenic area,* a term synonymous with epileptogenic region or epileptogenic zone. This is defined as the area of brain necessary to generate seizure activity,[31] resection of which (or inactivation or complete disconnection of which) will result in cessation of seizures. We seek to differentiate this epileptogenic zone from the irritative zone (of interictal spiking), the ictal onset zone (where the electroencephalogram [EEG] shows spontaneous seizures to arise), the symptomatogenic zone (activation of which produces initial ictal symptoms or signs), the zone of functional deficit (with evidence of reduced or abnormal metabolism, blood flow, and cognitive ability), and the epileptogenic lesion (demonstrated by structural imaging).[74] Although those areas usually overlap, they do not precisely coincide with the epileptogenic zone and, at times, appear to diverge. We might eventually develop techniques that allow visualization of the epileptogenic zone in other ways, but currently the demonstration of electrographic seizure onset offers the most logical means of verifying its approximate location,[36] except in childhood catastrophic epilepsy, in which the ictal onset zone is typically reported to be generalized even if the causative, epileptogenic zone is localized.[72] (An exception to this is the occasional case of childhood catastrophic epilepsy in which intracranial recording has demonstrated intrinsic epileptogenicity of a lesion, such as hypothalamic hamartoma.)[48] Because the latter cases are not likely to be studied with intracranial electrodes, this chapter concentrates almost exclusively on the evaluation of partial seizure disorders.

The electrographic delineation of the epileptogenic zone can be supported by delineation of the irritative zone, the symptomatogenic zone, the area of focal functional deficit, and the epileptogenic lesion such that the complementary nature of the respective studies allows one to infer the limits of the epileptogenic zone from less precise electrographic information, a scenario most often found when an epileptogenic lesion is roughly colocalized with a surface EEG recording abnormality.[32,33,83] In other situations, however, particularly in the absence of compelling data to characterize the epileptogenic lesion, irritative zone, and zone of functional deficit, the ability of the surface EEG to determine the ictal onset zone is suboptimal. For the purpose of designing an effective resective procedure for uncontrolled epilepsy, intracranial electrodes are then used to localize ictal onset as well as interictal spike distribution; this information is then used with the other data to infer the location of the epileptogenic area.

Intracranial EEG recording fills a specific need only in the context of a specific question. Extensive knowledge of seizure patterns, surface EEG expression of the ictal onset and irritative zones, and functional and structural abnormalities accompanying the epilepsy is necessary to properly design an intracranial EEG study. The nature of the procedure requires that its risk be sufficiently balanced by the possibility of useful gain in the localization, definition, and understanding of the uncontrolled epilepsy. In addition, the appropriate intracranial techniques must be used to answer the questions posed.

Intracranial EEG is indicated in the setting of uncontrolled epilepsy considered for resective surgical treatment when (a) there is likely to be a single region of seizure onset; (b) localization of this region is insufficiently precise or impossible based on the combination of ictal clinical manifestations, noninvasive EEG, and tests of focal functional deficit and structural abnormalities; and (c) the spectrum of findings in the individual allows a hypothesis about the suspected region or regions of seizure onset to be further investigated.

These considerations are important because intracranial recording has significant limitations, costs, and risks.[91] Implanted electrodes necessarily record from a limited volume of cortex. They must therefore be placed appropriately to address the questions at hand. Furthermore, because chronic implantation carries the known risks of hemorrhage and infection and the unknown risks of cognitive effects and epileptogenic potential, it is desirable to restrict the number of implanted electrodes to as few as possible. This must be done without compromising the ability to detect the zone of seizure onset with sufficient precision to use in the determination of the epileptogenic area for subsequent surgery.

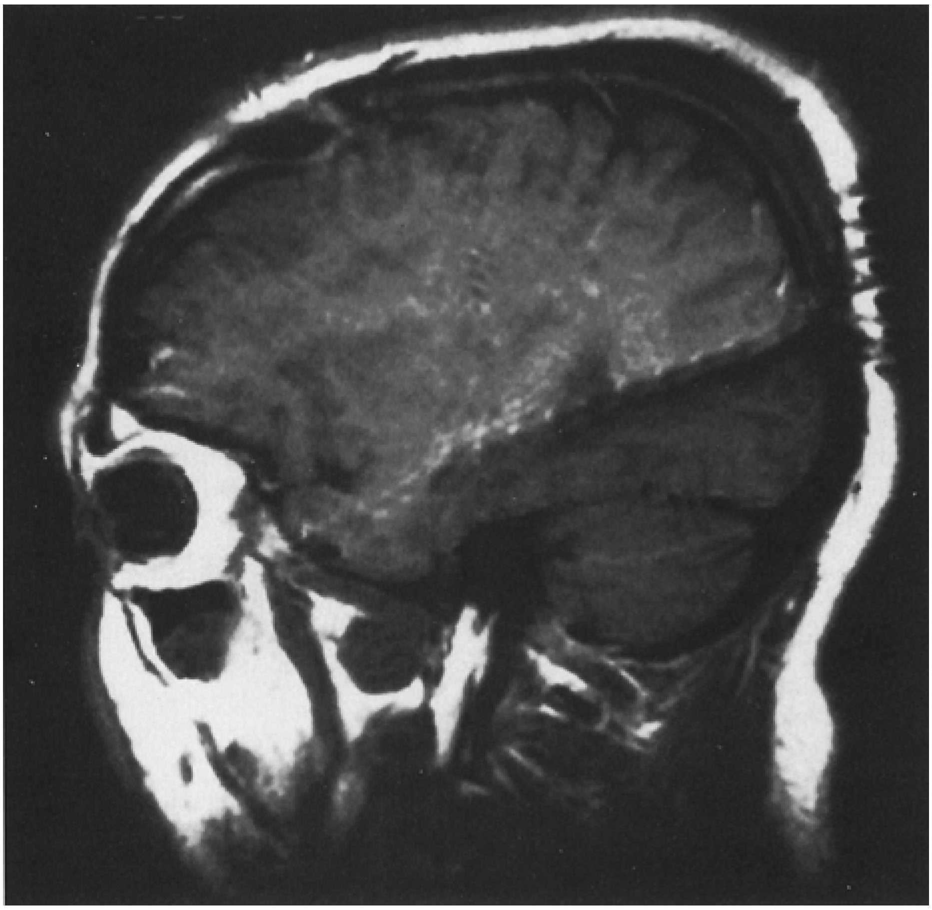

FIGURE 1. Sagittal magnetic resonance imaging (MRI) view of temporal lobe depth electrodes inserted by a posterior approach, illustrating multiple contacts.

Technological advances have altered the use of intracranial recording over the past decade in several ways.

High-quality neuroimaging, with qualitative and quantitative magnetic resonance imaging (MRI) at the forefront, has improved our detection of macrostructural abnormalities in epilepsy, including certain gliomas, developmental abnormalities (cortical dysplasia, hamartomas), and restricted atrophic lesions such as hippocampal atrophy. As accumulated experience has supported significant correlations between excision of these lesions and seizure relief, finding evidence for a structural lesion has assumed increasing importance in the localization of the epileptogenic zone for epilepsy surgery.[16,20,83,89] Now, the presence of certain "lesions" more often allows the less precise scalp EEG localization of the ictal onset zone to suffice because the additional information required to infer the localization of the epileptogenic area is provided by the MRI. Although scalp EEG localization to the region of the structural abnormality is still considered imperative to prove that the lesion is epileptogenic,

localization by interictal surface EEG without discordant information from ictal surface recording has become acceptable for this purpose at most centers. The opinion that only imaging might be sufficient to define a cortical region of epileptogenesis has been voiced, but some patients are known to have coincidental structural lesions irrelevant to the electrically abnormal area.[34,84] In Yale's recent experience, patients with discordant MRI and overall EEG localization represent approximately 10% of those with hippocampal atrophy, tumors, or developmental lesions.[34] About half of these patients have had surgery based on ictal onset localization, with cure of seizures. This means that, although the MRI is highly sensitive in localizing epileptogenic structural lesions in uncontrolled epilepsy patients and these lesions are often where uncontrolled seizures begin, the structural abnormality does not necessarily indicate the epileptogenic zone.

The increasing sophistication of imaging has also been responsible for generating a new population of patients for intracranial study who may not have been considered candidates before. These are patients with bilateral hippocampal atrophy or with so-called "dual pathology" such as a tumor or cortical developmental abnormality with hippocampal atrophy. In these situations, experts agree that intracranial recording is essential to determine which potentially epileptogenic lesion is indeed responsible for the uncontrolled seizure disorder.[34] In one recent study, patients with bilateral hippocampal atrophy were found to be good candidates for cure of seizures after temporal lobe resection, with the side of resection based on intracranial ictal onset EEG localization and not on the severity of the atrophy.[51] An MRI demonstration of dual pathology is also not always synonymous with dual epileptogenesis, although it might be.

Intracranial EEG has been in use since the 1950s. It was initially applied infrequently, mainly in patients with poorly localized surface EEG or evidence for bitemporal EEG abnormalities, who comprise 10% to 15% of surgical candidates. In the late 1960s and 1970s, some centers used intracranial EEG in all surgical candidates before resecting tissue for seizure control. This practice generated considerable historical and practical information but is no longer necessary. Now, some form of intracranial EEG investigation is performed on approximately 15% to 45% of adult patients at most centers that do epilepsy surgery. The proportion of patients considered for intracranial investigation depends on the referral population. In the pediatric population, both the need for and the practicality of intracranial recording diminish with decreasing age. Although invasive recordings can be done in infants,[127] they are rarely necessary.[23]

Intracranial EEG is obtained with depth electrodes (Figs. 1 and 2), subdural strip electrodes (Figs. 3,4,5), subdural grid electrodes (Fig. 6), and/or epidural electrodes. They are multicontact, usually flexible electrodes that require an operative procedure for insertion in preselected locations based on prior evaluation. All of them can be used for chronic or acute recording over 1 to 4 weeks (rarely up to 8 weeks) for the purpose of localizing the epileptogenic zone by recording multiple spontaneous ictal events. They differ predominantly in the parts of brain that can be recorded. Only depth electrodes penetrate brain tissue directly. They are therefore best suited for recording from deep, buried structures such as amygdala and hippocampus (Figs. 1 and 2), planum temporalis, and insula. These electrodes are also well suited for recording from sulcal cortex, as well as near lesions in deep cerebral locations. Subdural electrodes are best suited for recording from the cortical surface, including dorsal, basal, and interhemispheric regions, and provide a method for safe, extensive cortical sampling. Subdural strip electrodes and depth electrodes can be inserted to record from multiple lobes and areas in both hemispheres. Subdural grid electrodes are restricted in insertion to previously defined zones.

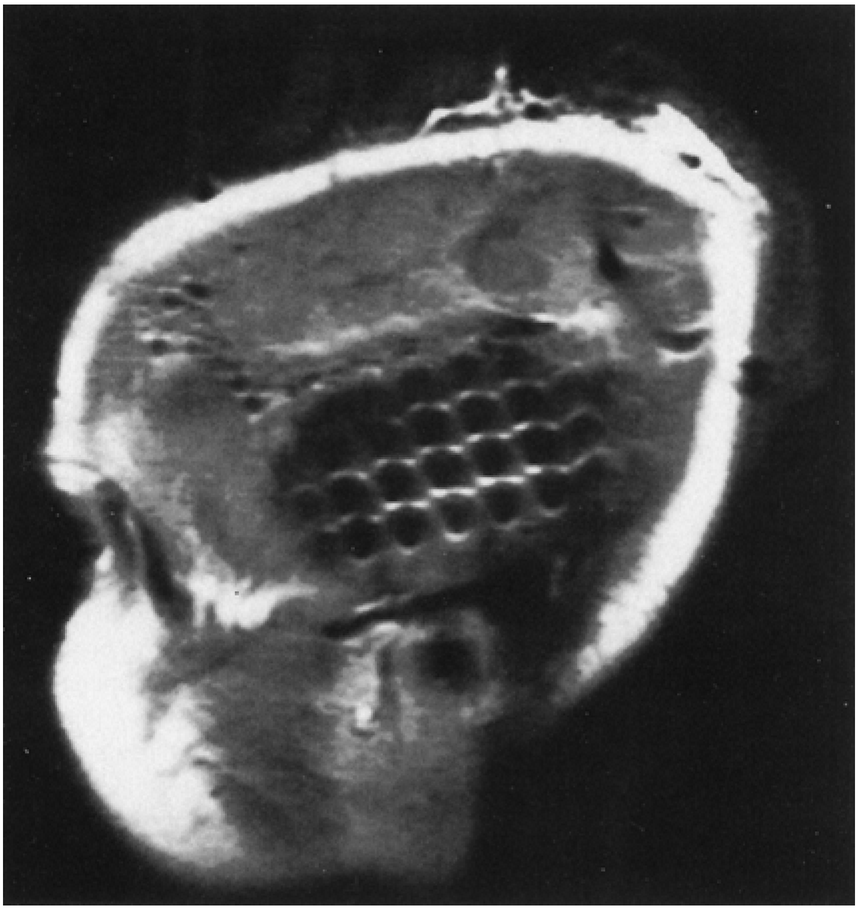

FIGURE 6. Sagittal magnetic resonance imaging (MRI) view of subdural grid placed to record from temporal neocortex.

The electrodes differ in the method of insertion, and with these differences come predictable differences in safety profiles. Depth electrodes are inserted with stereotactic MRI or computed tomographic (CT) guidance such that the trajectory, termination point, and location of each contact can be accurately predetermined.[62,87,91] These electrodes are usually inserted bilaterally, and accurate symmetric placements can be routinely achieved, not an insignificant accomplishment when comparison of the homotopic areas for onset and propagation of seizure activity is paramount in interpretation (see Depth Electrodes, Interpretation further on in this chapter). The strategy for selection of target locations of depth electrode placement differs somewhat in North American and certain European centers. The differences are partly a result of the more frequent combination of depth with additional implanted (subdural) electrodes in North America, thus allowing a more restricted use of depth electrodes for only some of the regions to be studied. The approach at some European centers developed from the stereo-electroencephalography method of Talairach and Bancaud, and aims to simultaneously and three dimensionally display all areas potentially involved in the onset, propagation, and clinical manifestations of the ictus, using only depth electrodes.[11,12,25,47,64,103,104] Both are based on hypotheses developed from noninvasive study. The European approach may incorporate more regions of suspected propagation and evolution, a consideration that influences the surgical approach of those centers. Subdural strip electrodes are inserted with the least precision because they are passed through burr holes and "slid" in the subdural space to the desired target (Figs. 3,4,5). Adhesions caused by prior surgery, infection, or injury often deflect the desired placement, and thus strict precision and homotopic sampling are rarely achieved. Depth and subdural electrodes can be removed at the bedside. Subdural grid electrodes require craniotomy for insertion and removal and can be placed accurately. Subdural grid electrodes are usually placed only when a reasonably well-defined epileptogenic zone is known, and they serve to aid in precisely defining the limits of resection. They provide optimal cortical coverage for functional mapping with stimulation if seizures begin near language, motor, or sensory cortex.

Increasingly, the intracranial EEG methods are combined to achieve optimal sampling of all suspicious areas for seizure onset. They can all be used at any age, although the range of indications tends to be more restricted in young children, especially infants. The specific indications, construction, insertion, interpretation, limitations, risks, cost, and accuracy of each of these methods are the subjects of the remainder of this chapter.

Indications for Intracranial Electrodes

Intracranial electrodes are indicated when it is reasonable to believe that a therapeutic resective procedure could be performed but the noninvasively obtained data are inadequate and more information is needed. Intracranial electrodes are then used to precisely identify the location of the ictal onset zone and can also delineate functionally important tissue that should be spared at the time of resection. Some protocols, particularly in certain European centers, also strive to delineate other regions of initial or early involvement that can be incorporated in designing the resection. Exact criteria for what constitutes sufficient concordant or discordant data vary somewhat from one epilepsy center to another.

Specific indications for intracranial electrodes in the evaluation of patients with refractory epilepsy include the following:

1. Insufficient concordance of noninvasively obtained data such that there remains uncertainty regarding the localization of the epileptogenic zone. Circumstances

   leading to intracranial electrode use include the following:

   a. An MRI showing an atrophic, developmental, or space-occupying lesion with nonlocalized interictal and ictal EEG.

   b. A normal or nonlocalized MRI with insufficient evidence of localized functional deficit and localized abnormality of excitability in a single region.

2. Discordance of noninvasively obtained data, so that the existence of a single epileptogenic zone must be proven and better localized.

3. Occupation by the epileptogenic lesion of territory within or immediately adjacent to vital cortex (e.g., motor strip, language areas) so that invasive functional mapping must be performed before resection in conjunction with precise localization of the epileptogenic zone.

Although there are no set criteria that can be systematically used to decide whether intracranial recordings should be performed, these statements give broad guidelines. Factors such as the presence of a lesion and the type of epilepsy (temporal versus extratemporal) influence to various degrees the need for invasive recordings. In the great majority of cryptogenic cases, for instance, the use of intracerebral recordings remains essential.[65] In temporal lobe epilepsy, although diagnosis of mesial temporal lobe seizures and the side of ictal onset is now possible in the majority of patients using noninvasive investigation, additional long-term monitoring with intracranial electrodes is appropriate when the side of mesial temporal ictal onset is unclear, if neocortical or extratemporal ictal onset is considered possible, or when electroclinical arguments suggest that the epileptogenic zone extends outside the boundaries of a more traditional approach to the mesial temporal lobe resection. The delineation of extratemporal epileptogenic networks is much more difficult than that of temporal lobe regions of seizure origin, so that many more patients with extratemporal epilepsy undergo invasive EEG recordings: There are no clear extratemporal epilepsy “syndromes,” there is no equivalent of hippocampal sclerosis on MRI, scalp EEG is often mislocalizing and even mislateralizing, and there are no standardized resection techniques.

Certain electrode types are more suited to some locations than others and are therefore indicated under different circumstances. Because depth electrodes penetrate the substance of the brain, they are indicated when EEG recording is needed from buried cortex (e.g., hippocampus, amygdala, or basal or interhemispheric cortex inaccessible to subdural electrodes). In practice, depth electrodes are often used to record from the mesial temporal lobes when mesial temporal lobe epilepsy is suspected. They are also useful for recording from other deep cortical structures that can be involved (insula, planum temporalis). They are also essential for targeting deep regions of suspected seizure onset, for example, one or several heterotopic regions of gray matter.[2,76,105] Subdural electrodes overlie the surface of the brain and are most suited for bilateral neocortical EEG recording, often in combination with depth electrodes. Subdural grids are ideal for functional mapping of cortex, though regional preoperative localization is needed to select the (restricted) sites for placement. In practice, subdural strips are also often used additionally with grids for better sampling of other lobes ipsilaterally or contralaterally.

Depth Electrodes

Construction

Most commercially available depth electrodes are multicontact with platinum contacts. In the past, nichrome alloy and stainless steel were also used.[87,91] These kinds of electrode contacts are all considered safe for postplacement MRI documentation of electrode contact positions with respect to anatomic landmarks,[129] although high-resolution CT is often used for this purpose, with later MRI coregistration to improve localization in relation to anatomic definition. These multicontact electrodes carry 4 to 12 contacts along their length, usually spaced 5 to 10 mm apart at variable or constant intervals. Others have up to 18 contacts with 1.5 mm spacing. Exact locations of contacts along the shaft can be varied to start and terminate at predetermined locations. The electrodes are commercially available from several vendors. They are flexible and are inserted with a rigid introducer that lies alongside or within the electrode. Rigid electrodes are also used.

Insertion

Insertion of depth electrodes is now routinely done by standard stereotactic methodology utilizing a Todd Wells, BRW, or Lexell frame[63,79]; more recently, frameless stereotactic methodology has been used. Electrodes enter through burr holes with usual targets of medial temporal and medial frontal regions (Figs. 1 and 2); deep, extratemporal locations are also targeted. The total number of electrodes varies but rarely exceeds 15, the total depending on the hypotheses generated and the array of electrodes selected to adequately address those. Electrodes can be inserted parasagittally or orthogonally such that, for example, they traverse the occipital lobe and occipitotemporal junction or lateral temporal lobe en route to medial temporal regions. Because the electrodes sample multiple locations, additional areas of preferred sampling can also determine which approach is used; some centers use either parasagittal or orthogonal placements, depending on the individual situation, but most have a preference for one or the other approach based on prior experience. Some centers use a computer-driven robot for electrode implantation,[15] particularly when nonorthogonal implantation is preferred either because of anatomic constraints or particular targets (insula, gyrus rectus). Neither approach is reported to be associated with a higher risk of complications. Lateral (orthogonal) placement is more common.

Recording

Commercial digital recording equipment allows referential recording and reformatting with desired electrode combinations, filter settings, and bipolar and referential display montages. This provides considerable flexibility. Most commercial equipment now allows sampling at 200 to 800 Hz; recent work in patterns of seizure onset suggests a potential benefit of using higher sampling rates. The multiple contacts, especially with combined procedures, usually require at least 64 channels of simultaneous EEG recording to display and interpret the information adequately, and often twice that number or more are optimal.

Electroencephalographic recording is done in parallel with continuous audiovisual correlation. The main goal is localization of the region of ictal onset recorded during spontaneous seizures. It is critical to scrutinize all electrode contacts carefully in relation to one another and in relation to the time of synchronized clinical seizure activity.

Seizures are precipitated by controlled withdrawal of antiepileptic medications during continuous recording. Current literature suggests that carbamazepine, phenytoin, valproate, or lamotrigine withdrawal does not produce false localization or atypical seizures[59,90,94,111]; the other, newer antiepileptic drugs have not been assessed in this regard. Barbiturate and benzodiazepine withdrawal should be avoided

because they can produce unreliable and/or false locali-zation.[116] Usually, spontaneous seizures are recorded within 7 to 10 days despite the patient's inactivity; seizures that occur earlier or later during the session do not have different profiles or accuracy for confident localization of the epileptogenic zone. Most centers prefer at least three seizures for analysis, and some require up to ten for the study to be considered complete. No rules can be developed, however, because seizures vary in their frequency, intensity, similarity to the usual clinical events, and similarity to one another. To this is added a variable number of subclinical seizures, recording mishaps, immediate postictal seizure onsets, immediate postoperative seizure onsets, insufficient clinical examinations, and other confounding variables that make the protocol and the interpretation as much an art as it is a science.

Although the recording of spontaneous seizures remains the best way to assess the extent of the epileptogenic zone, some centers, mostly in Europe, use electrical stimulation, particularly when ictal discharges are poorly defined, multifocal, or widely extended from the onset of the seizure. Observation of a complete and habitual seizure sequence after such stimulation is the goal, to provide insight into the spatial organization of the epileptogenic zone and other structures. The activation of regions removed from the specific site of electrical stimulation, however, that are unsampled by the electrodes represents a difficult, potentially confounding aspect of interpretation. Chemical stimulation is generally avoided because of its potential to precipitate nonhabitual seizures.[12]

Risks

The risk of intracerebral hemorrhage after depth electrode study ranges from 1% to 4%.[110] The use of intraoperative angiography, visualization of the cortical surface, and MR guidance might have reduced the hemorrhage rate, but insufficient information is available to conclude this definitively. Intracerebral hemorrhage is the most serious complication of intracranial electrode study and is reported only after use of depth electrodes, with several deaths as a result. Infection also occurs, but fatalities and long-term morbidity are rare.

Whether rigid electrodes have more potential for damage to normal cortical tissue than flexible ones is not established. One study reviewed the MRI appearance of 210 stainless steel depth electrode tracks 1 to 64 months after electrode removal.[63] Of 57 patients studied, 33 had rigid electrodes and 24 had flexible ones, all inserted in paramedial locations from occipital or frontal entry points targeted to medial temporal and frontal locations. Punctate 1- to 2-mm hyperintensities along the electrode track were the most common abnormality, found in 41% of cases. Four tracks (2%) showed punctate signal voids consistent with microhemorrhage, and one patient had a macroscopic occipital lobe hemorrhage. The authors did not note any difference between rigid and flexible electrodes with respect to these findings. Another comparison study of complications from depth and subdural electrodes found consistent moderate to severe multifocal inflammatory reactions to subdural electrodes and only mild to moderate reaction to depth electrodes. Although depth electrodes were on occasion associated with clinically unsuspected hematoma formation, microhemorrhage was much more common under subdural electrodes. Smooth, blunt construction with adequate insulation between contacts is essential.

There seems to be no substantive long-term risk of depth electrodes to otherwise normal cortical tissue.[3,102] They do not appear to cause epilepsy. Centers routinely employing a bilateral depth electrode study before surgery for epilepsy have similar short- and long-term success rates for seizure control to those that do not. Long-term relapse after apparent seizure cure occurs occasionally whether or not depth electrodes were part of the preoperative evaluation. Occasionally, the depth electrodes themselves (or the procedure under general anesthesia) seem to “cure” the epilepsy, an observation made on <0.5% of patients at several centers.[91] These considerations suggest that depth electrodes are indeed not epileptogenic. With respect to clinically significant damage to the function of underlying tissue, in the absence of other complications or subsequent surgery, the literature does not document any negative functional effects of depth electrode investigation.[87,91]

Interpretation

Background

Background activity in depth electrodes conforms to expected rhythms on scalp EEG. Interpreters must remember, however, that because of the loss of frequency filtering from scalp and skull, and because recording is from a smaller volume of tissue, the waveforms are sharper and higher frequencies are noted, and some normal activity takes on an unusual appearance if not an unusual location. For example, high-amplitude potentials in motor cortex can mimic spikes. Occipital alpha activity, central mu rhythm, frontal beta predominance, lambda waves, and sleep spindles are seen as on surface EEG. Asymmetric activity, especially slowing, has the same significance as on scalp recording. Asymmetric or localized flattening of the recording as well as slowing can suggest progressive hemorrhage, fluid collection, or infection. However, a focal depression of activity might be seen with electrodes in white matter. In addition, some slow activity can occur in the first 48 hours after implantation and resolves spontaneously.

Interictal Activity

Interictal spikes are more widespread in intracranial EEG recording than in scalp EEG recording.[79.91,114] Although interictal spiking rates often are higher in the area where seizures begin, for example, in medial temporal lobe epilepsy, this relationship does not always hold. Furthermore, multifocal extratemporal interictal spikes in both temporal and extratemporal epilepsy with a single ictal onset zone are common. Accordingly, most experts agree that interictal spikes recorded with depth electrodes (or any intracranial electrodes)

are less important for localization of the epileptogenic region than ictal onset.[66] However, although only some of the interictal spikes recorded intracranially are associated with the epileptogenic area, *some* interictal spikes are generated there, and the ability to reliably distinguish those, perhaps because they are associated with particular background changes or have unique morphology, could advance localization. Accordingly, interictal paroxysmal abnormalities are always scrutinized because they can provide additional confirmation of localization, and eventually may prove of even more important localizing value in certain settings. This seems to be true, for example, in focal cortical dysplasia of Taylor, in which the interictal spikes can be a good marker of the extent of dysplastic cortex that needs removal to abolish the seizures.[22,106]

Gotman and Koffler[37] reported an increase in spikes postictally; other authors confirmed this observation.[49] It can be well demonstrated with intracranial recording. Gotman and Marciani did not localize the postictal spikes to the region of seizure onset,[38] but Katz and Spencer[49] felt that certain populations of postictal spikes do emanate from the area of epileptogenesis. This issue requires resolution in larger numbers of temporal and extratemporal epilepsies recorded with surface and intracranial electrodes. Certainly, many interictal spikes recorded with depth electrodes (or any intracranial electrodes) cannot be seen with any noninvasive technique, and further work to investigate their significance is needed to assess what determines their expression on surface EEG as well.

Based on earlier work in epileptic rat hippocampus, recent investigators using microelectrodes examined higher sampling rates and recorded high-frequency oscillations termed “ripples” (96 ± 14 Hz) and “fast ripples” (250 to 500 Hz) in hippocampus and entorhinal cortex of patients with mesial temporal lobe epilepsy. Whereas ripples were considered physiologic oscillations, fast ripples were predominant in the areas of seizure onset, suggesting that they might reflect pathologic hypersynchrony in epileptogenic tissue.[101] High-frequency oscillations were also described (60 to 100 Hz) in neocortical areas, and they sometimes appeared in anticipation of seizure onset.[123] Investigation of this potentially important pattern is ongoing.

Ictal Activity

Onset.

Although the goal of intracranial recording is widely accepted to be localization of the ictal onset zone, the criteria for interpretation of ictal onset in intracranial EEG have been slow to evolve.[50] A variety of EEG patterns and frequencies occur at the start of seizures, but certain patterns predominate in particular locations. Spencer and Spencer[92] found that medial temporal lobe seizure onset, often termed hippocampal seizure onset, tends to vary in exact location and morphology, appearing in hippocampus or entorhinal cortex in different seizures, in patients with mesial temporal sclerosis. The medial temporal lobe (hippocampal/entorhinal) onset pattern is distinguished by a 10- to 16-Hz rhythm. Medial temporal lobe seizure onset can also present as a characteristic pattern of slow (1 to 2 Hz), periodic spike activity in the same location as the 10- to 16-Hz onset rhythm but before it begins (Fig. 7).[107] This periodic pattern can last from 5 to >100 seconds. This periodic pattern is seen almost exclusively in the hippocampus and is inversely related to CA1 cell loss, one marker of mesial temporal sclerosis.[86] Sperling also observed a peculiar high-amplitude triangular wave pattern at the onset of seizures arising in amygdala.[98]

Ictal onset patterns appear to be more reproducible and consistent in location from seizure to seizure in neocortical epilepsy.[85] Neocortical seizure onset is characterized by a combination of often superimposed slower (4- to 10-Hz) and faster frequencies at seizure onset (Fig. 8).[39,50,85] Although Spencer et al. reported that the fast frequencies were in the vicinity of 40 to 50 Hz, other studies suggest that the frequency of recorded neocortical seizure onset can approach 200 Hz.[4,35,39,50,85,113] Isolated low- or high-frequency seizure onset recorded from neocortex or medial temporal structures, however, might represent a propagation pattern rather than actual ictal onset.

In any cerebral location, apparent rhythmic activity or frank ictal discharges differing from background can develop focally but not propagate or produce symptoms. This so-called subclinical seizure activity has been correlated with an excellent outcome after surgery,[100] specifically surgery in the area of the subclinical seizure discharge.[108] It may have a somewhat different morphology or location than the clinical ictal discharge or appear identical to the early parts of clinical seizures. The recording of such subclinical discharges does not substitute for the recording of the full clinically typical seizures on which localization is based for purposes of resection.[10]

Propagation Patterns.

Successive involvement of cerebral regions in the rhythmic patterns characteristic of seizure discharges has often been called propagation, although no physiologic mechanism is implied for the term used in this context. Propagation time from one hippocampus to the other has been studied by several authors, all of whom found that long (>20 sec) interhippocampal propagation time correlated with excellent outcome after medial temporal lobe resection, implying that it signified a true epileptogenic zone in the medial temporal region (Figs. 7 and 9).[53,54,88] Spencer et al.[88] found that interhippocampal propagation time correlated inversely and significantly with CA4 cell counts. Because CA4 is the origin of the main interhippocampal commissural connection, cell loss there might indeed prolong the process of seizure propagation. Fewer than 25% of medial temporal lobe onset seizures propagate first to the contralateral hippocampus; most initially propagate to ipsilateral temporal neocortex or frontal lobe, and both of these patterns are fairly common (Figs. 7 and 9).[1,50,96,97,98,99] The spread pattern can vary depending on the exact region of medial temporal origin; Chabardes et al.[21] found that temporal/polar seizures propagated to superior temporal gyrus/periopercular cortex, whereas other mesial temporal seizures propagated to basal and lateral temporal cortex. Parietal and occipital lobe seizures can show variable propagation by infra-Sylvian or supra-Sylvian routes, with subsequent temporal or frontal electroclinical evolution.[119,122] Seizure propagation recorded with intracranial electrodes follows known pathways but can be modified by damage to these pathways or their origins. Thus, frontal lobe seizures often show very rapid propagation to the contralateral frontal lobe, often too rapid to allow determination by visual EEG inspection of which frontal lobe triggered the seizure.[91,120,121] It is these situations that stand to benefit most from computerized EEG analysis.

Termination.

Termination patterns of seizures recorded intracranially have been neglected in research and the literature. There are three typical patterns: (a) sudden cessation of seizure activity diffusely or focally; (b) gradual decrease in frequency and increase in amplitude, usually focally; and (c) decreased frequency of a burst-suppression-like pattern, usually diffusely. The focal pattern of termination is the most common, with seizures often ending earlier in the temporal lobes than in the frontal lobes. Termination in the temporal lobe of onset recently has been correlated with cure of seizures after resection of that temporal lobe.[93] Seizure duration has not been correlated with hippocampal cell counts, suggesting that cell loss and contribution of existing pathways are not as important as other mechanisms in the termination of spontaneous human seizures.

Anticipation.

Various linear and nonlinear quantitative EEG approaches to depth electrode recorded signals have been used to identify changes in the EEG that precede and herald the oncoming seizure but cannot be appreciated by visual interpretation. Such methods fall in the purview of seizure prediction but might also be viewed as more sensitive approaches to seizure detection or detection at an earlier stage. Early investigators applied nonlinear dynamical approaches: Le Van Quyen and colleagues found that a measure of phase synchronization could define a pre-ictal state in mesial temporal lobe epilepsy; Litt and colleagues used a measure of signal energy to predict seizures; and Martinerie and colleagues applied a measure called correlation density.[52,55,56,60] Although one approach might not fit all seizures and patients, the collected work and evidence supports the conclusion that detectable changes based on quantitative EEG analysis are likely to appear 10 to 30 minutes before visually identified seizure onset. Developments in this field depend on continued analyses of intracranial EEGs and are likely to expand our approaches to, and knowledge of, the process of seizure generation.

Advantages and Limitations

The obvious advantage of depth electrode recording, an advantage shared with other intracranial recording over scalp EEG, is its ability to demonstrate an early electrical signal that

P.1799

P.1800

P.1801

P.1802

P.1804

precedes clinical seizure onset and is devoid of signal artifact. Depth electrodes are ideally suited for studying medial temporal lobe onset seizures. Depth electrodes demonstrate hippocampal/entorhinal seizure onset before medial temporal subdural strips, and both show this activity considerably before scalp EEG.[97,99] Access to buried cortex makes depth EEG the only method capable of detecting the earliest electrographic changes from seizures arising in these regions. Depth electrodes are also unique in the accuracy with which they can be placed as a result of stereotactic methodology. The major limitation of depth electrodes is limited spatial sampling. One cannot be certain that the earliest activity truly comes from the area where it was recorded.

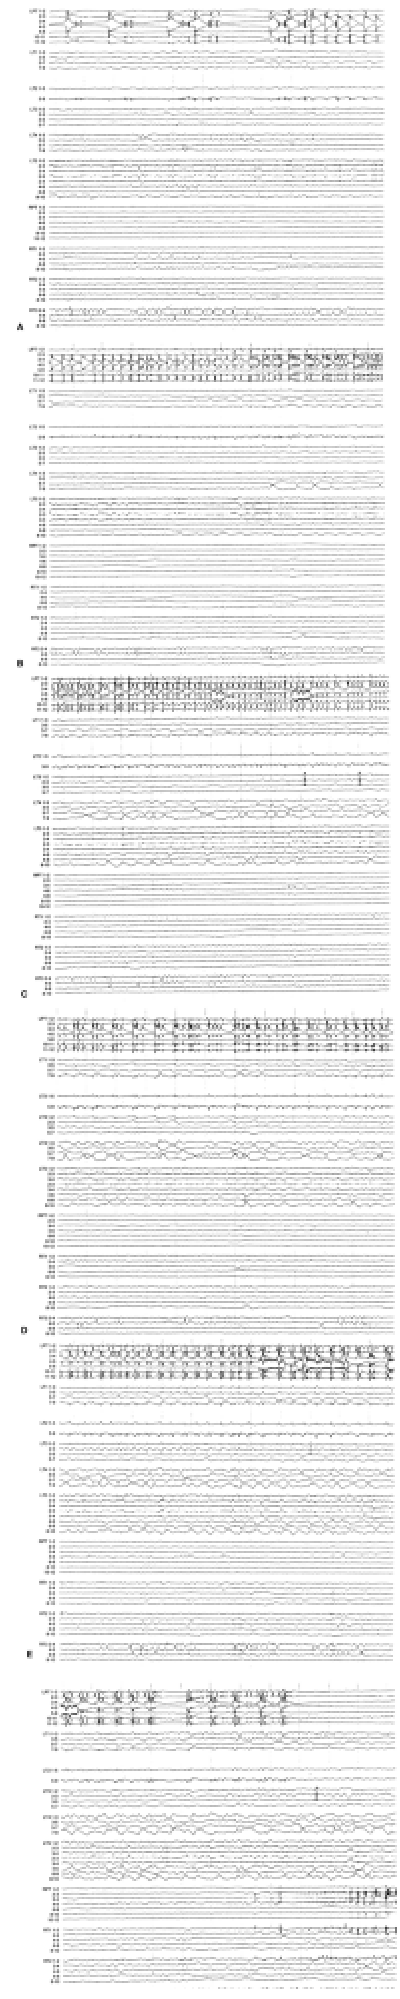

FIGURE 7. Continuous segments of electroencephalogram recorded with depth electrodes in hippocampi (LPT, left; RPT, right) and multiple subdural strips over temporal neocortex bilaterally, including anterior (LT1, LT2, RT1), middle (LT3, LT4, RT2), and posterior (LT5, RT5) locations. **A:** Before onset of spontaneous seizure, showing the slow periodic spike pattern characteristic of medial temporal lobe seizures associated with CA1 cell loss, in the left hippocampal depth electrode (LPT); note absence of abnormality in medial contacts of left anterior temporal strips (1 to 3 on LT1, LT2, LT3). **B:** The periodic pattern in LPT is accompanied by the lower-voltage, 10- to 15-Hz discharge characteristic of medial temporal seizures. **C:** The rhythmic left hippocampal activity slows, and left medial temporal neocortical rhythmic activity is reflected in subdural strips LT1, LT2, and LT3. The more posterior temporal neocortex is also involved (see LT4 and LT5) in segments **D** and **E**. Only a full minute after seizure onset (**F**) does the right hippocampus (RPT) become involved. This is the prolonged delay characteristic of interhippocampal propagation in medial temporal lobe epilepsy. Each division, 1 s; electrode positions are numbered distal (1) to proximal.

FIGURE 9. Continuous electroencephalogram segments of spontaneous seizure recorded from left and right hippocampal depth electrodes (LPT, RPT) and multiple subdural strips over frontal (LF, RF), anterior temporal (LAT, RAT), midtemporal (LMT), and temporoparietal (LTP, RTP) neocortical areas. Onset in the right hippocampus (RPT 7) with 8-Hz activity is followed rapidly by rhythmic activity in the left hippocampus (LPT, LAT). Such short propagation times to the contralateral medial temporal region raise doubt about true hippocampal onset; absence of the periodic pattern and very slow onset are also atypical (compare Fig. 7). This patient failed to achieve seizure control after temporal lobectomy.

Yield and Accuracy

Most centers select patients for depth electrode study carefully enough that they report 60% to 85% yield of focal seizure onset detection in this population.[80,82,91] The yield obviously depends on the population studied and the acumen with which the study sites are selected. In 1980 and again in 1990, in reviewing the literature and personal experience, Spencer found an equivalent proportion of all depth-EEG-studied patients to be localized.[82] Depth EEG produced a change in management of 50% of patients studied. The yield has been fairly constant despite advances in patient evaluation that have changed the population of patients who have depth electrode studies. We do not have information on patients studied after 1990 to examine whether MRI, by reducing the need for depth electrode study among the large group of lesional and hippocampal atrophy patients, has reduced the overall yield of depth electrode localization; experience suggests that this might be true, at least at some centers. A recent retrospective study of depth electrode investigations in 211 patients, however, suggests that the yield for localization might be steady (it was 87% in this report, highly comparable to results in earlier decades).[25] The yield of these studies of course depends on the sites selected for electrode placement, the specific kinds or combinations of electrodes used, and the referral population of the center.

The concept of yield is really of no value, however, without scrutiny of its accuracy. The reported surgical success and seizure cure after patient selection for operation with depth electrodes approximates the success without them in older studies.[80,82] This does not imply that such studies are unnecessary, but, rather, it probably reflects the fact that they permit more complicated patients to benefit from surgery who would have been rejected according to noninvasive protocols. This might also be because the patients studied with depth electrodes were often suspected of having medial temporal lobe epilepsy and confirmed as such, and this group of patients has a known high surgical success rate. The experience at some centers suggests, however, that seizure outcome after resections based on depth electrode localization might not be as high as for patients selected by noninvasive EEG criteria. Similar to the previous comments on the yield, the outcome of resection based on these results depends on many factors that differ among centers and patient populations. It is even more difficult to assess the accuracy of depth electrodes compared to other intracranial electrode studies because depth electrode studies are done in a special group of patients, among them those suspected of having medial temporal lobe epilepsy, whereas grids and strips are typically employed in more difficult, neocortical cases. Depth electrodes (and other intracranial methods) have also been responsible for the diagnosis of unlocalized or multifocal epilepsy in 10% to 20% of patients thought to have a reasonable possibility of localization based on noninvasive electrical, functional, and structural studies.[80,82] These patients

P.1805

are then excluded as surgical candidates by the intracranial EEG results. Although it is conceivable that poor electrode positioning, inappropriate electrode site selection, or inadequate interpretation obscured focal onset and deprived some of these individuals from potentially successful surgical treatment, this is rather unlikely: In one study, surgical success was poor when the depth EEG was not localized and the resection site had to be determined based on other data.[80] The accumulated evidence suggests that depth EEG has been and continues to be an accurate method with reasonable yield for localization of the epileptogenic zone in an otherwise untreatable population, and that these figures are not changing dramatically.

Cost

Forty-five thousand dollars is not an overestimate of the cost of a depth electrode study, considering the hospitalization, operating room, and technical and professional fees involved. This cannot be justified if simpler means enable similar treatment at comparably high success rates. For the otherwise untreatable, unlocalizable patient, however, this cost pales in comparison to the cost of a lifetime of unemployment, disability, and medical expenses. Even if only one fourth of depth electrode studies produce productive lives from totally dependent ones, the net gain to society and the individuals involved is substantial.

Subdural Electrode Strips

Construction

Subdural electrode strips are flexible strips of Silastic or Teflon into which are embedded platinum, stainless steel, or silver contact disks spaced 5 to 10 mm apart.[124,126] The arrangement can include bisurface electrodes; up to ten contacts can be arranged in one or two rows. These electrode devices are often MRI compatible, and many varieties are commercially available.

Insertion

Through burr holes, subdural strip electrodes are manually manipulated to the desired target areas in the subdural space. These commonly include medial inferior temporal and interhemispheric regions of frontal, parietal, and occipital cortices and any other lateral neocortical surface location (Figs. 3,4,5).[5] The operation is usually done under general anesthesia. Up to six, but usually two or three, electrodes are inserted through one burr hole with different planned trajectories, and some surgeons use an expanded “trough” to accommodate implantation of more strips (Fig. 3). Subdural strip electrodes can be inserted bilaterally, with an attempt at roughly homotopic placement, or asymmetrically, depending on clinical need. With appropriate experience, medial inferior temporal lobe structures including the entorhinal cortex can be adequately sampled with subdural strips (Fig. 4). Accurate placement, however, can be difficult because of adhesions or bridging veins, especially in basal and medial regions, and multiple strips might be needed to fully sample medial temporal locations from anterior to posterior.

With the advent of MRI-compatible electrodes, precise anatomic correlation of electrode locations is possible after implantation. The appearance of subdural strips on MRI in several planes as they curve around, however, as well as the use of multiple strips and arrangements can create a challenge in assigning which electrode contacts of which strip are represented at each cortical location. Meticulous attention to detailed reconstruction is necessary to assure valid interpretation.

Subdural strip electrodes can be removed without significant discomfort in the patient's room at the conclusion of the recording session. Even study extending up to 8 weeks does not create sufficient inflammatory reaction to prevent removal, although sometimes more prolonged recording is associated with the (rare) need to reopen the operative site.

Recording

The comments on depth electrode recording procedures with respect to medication withdrawal, appropriate activation procedures, the duration of the study, the number of necessary seizures, and the importance of electroclinical correlation apply equally well to subdural strip recordings and are not reiterated here. Because digital recording and reformatting with appropriate gain and filter settings is commonplace, cautions and recommendations on recording parameters are less cogent than for analog recordings. Every attempt should be made to record from all contacts simultaneously. In studies involving ten strips or more, 128 channels offer such a distinct advantage that this recording capacity is an almost necessary option for the equipment.

Risks

No mortality and relatively infrequent (predominantly infectious) morbidity (1% to 2%) are reported after subdural electrode study, and these risks are lower in experienced hands.[73,125] Although hemorrhagic complications are known, mainly from tearing of bridging veins in medial temporal and interhemispheric regions, they are rare. When multiple nearly adjacent strips are used such that the array approximates a subdural grid, cerebral edema is a conceivable complication but is unusual. Epileptogenic potential and damage to functional cerebral tissue are not a consideration here in the absence of bleeding because the brain is not penetrated.

Interpretation

The comments regarding depth electrode interpretation also apply to subdural strips. Strip recordings give increased sensitivity to interictal spikes compared to scalp EEG.[26,58,71] Seizure onset within the hippocampus is detected earlier in depth electrodes than in subdural strips, however, even when the latter are placed very medially (Fig. 7).[97,99] The characteristic periodic spike pattern of hippocampal seizure onset is less often appreciated in medial temporal subdural strip recording, and the 10- to 16-Hz onset is rare. When seizure onset is recorded from subdural strips in medial temporal locations, it more often is characterized by faster (>16 Hz) activity. Weinand et al.[112] found that medial temporal seizure onset recorded with subdural strips in patients who became seizure free after medial temporal resection usually took the form of "fast spike trains" but could be characterized as low-voltage fast activity.[112] Neocortical seizure onset characteristically shows adjacent or colocalized slow (4- to 7-Hz) rhythm in addition to the faster frequency.[85,87,91] As already mentioned, seizure onset can be characterized by faster frequencies, and some such onset patterns can be invisible to certain equipment sampling rates. Neocortical locations of onset are detected more readily by these subdural strip arrays.

As with depth electrode recording, subdural strip electrodes can demonstrate variability of the seizure onset pattern in medial temporal structures, and more consistent morphology is

observed in seizures that begin in neocortical regions.[87,91,112] Prolonged time to interhemispheric seizure propagation and onset of electrical activity frequently preceding clinical signs are also characteristics shared by the depth and subdural electrode studies of medial temporal lobe epilepsy.[112] Blume and Kaibara[19] described the "start–stop–start" phenomenon in subdural-strip-recorded seizures; it is characterized by a short-lived, localized rhythmic ictal discharge, a period of 1 to 10 sec of normalization, and resumption of ictal discharge, usually but not always in the same location, which is then followed by clinical seizure activity.[19] The initial "start" location was correlated with the location of onset in seizures in the same patient that did not show this phenomenon. The pattern was interpreted as aberrant seizure evolution, not origin; interpretation of subdural ictal onset should take these observations into account.

Some early reports documented false lateralization of medial temporal lobe epilepsy with subdural electrodes[99]; usually, with adequate medial extent of strip termination, localization of the side of medial temporal lobe seizure onset is accurate, but their reduced sensitivity prevents detection of many subclinical seizures in the hippocampus[97] and occasionally results in nonlocalizing subdural studies when depth studies are localizing.

Advantages and Limitations

An advantage of subdural strips is the ability to perform cortical mapping of functional activity by stimulation through these electrodes. This role is better filled by subdural grids (their main advantage; see later discussion) but has been successfully accomplished with subdural strips as well, particularly when adequate numbers of contacts cover the cortex in question. Stimulation at up to 15 mA can also invoke afterdischarge or clinical seizure activity, although these stimulated seizures might not serve to accurately localize the epileptogenic zone. Subdural strip electrodes have low morbidity, which remains an advantage.

The main limitations of subdural strips are their inaccurate and unpredictable placement by virtue of the insertion technique, a limitation that is only partly overcome by the skill and experience of the surgeon. Despite less sensitivity for study of medial temporal lobe structures, they provide better representation of neocortical areas.

Yield and Accuracy

The yield of subdural strips has been reportedly high, as has surgical success based on this localization,[82] but determining the specific yield of strips in current practice is complicated by the increasing use of simultaneous depth and subdural electrode recording. The best distillation of available evidence indicates an acceptably high and accurate yield of subdural strips for localization of the epileptogenic zone based on seizure outcome after resection, with an excellent risk-to-benefit ratio, limited only by the selection of implantation and recording sites. As in the case of depth electrodes, it might be true that surgical success is lower in patients localized in this way (or with other intracranial methods), but formal studies do not support this conclusion.

Costs

Subdural electrode recording has similar costs to depth electrode recording because it requires the same intraoperative placement, chronic audiovisual/EEG monitoring, medication withdrawal, electroclinical correlation, and recording of multiple spontaneous seizures. With even lower risk and acceptable yield, societal expense is thus more than justified.

Subdural Grids

Construction

Subdural grids are simply expanded subdural strips. They are sheets of inert material, usually Silastic or Teflon, into which are embedded multiple platinum, silver, or stainless steel electrode disks with variable contact spacing (usually 1 cm) to create grids that record from the large areas of cortex over which they are placed. The grid can be 4 × 5 or 8 × 8 cm or any other selection; irregular shapes are also possible, as are combinations of grids to cover predetermined cortical regions; these are fashioned intraoperatively. Grids are commercially available and MRI compatible such that verification of locations with respect to lesions and cortical surface anatomy is easily and accurately accomplished.[87]

Insertion

Because of their size, subdural grid electrodes require a craniotomy for insertion and removal (Fig. 6). Accordingly, placement is accurate. The bone flap can be replaced or left off for the duration of the study; the latter has the potential advantage of avoiding some of the complications of cerebral edema that can occur with extensive cortical grid coverage. This is a particular safety concern with children, in whose heads a given size of grid takes up proportionately more space than in an adult head. One or more grids can be inserted over a hemisphere. Subdural strips can be inserted in conjunction with grids, usually to sample interhemispheric or medial temporal regions simultaneously. Because of technical considerations, grid insertion is usually unilateral, although they can be used bilaterally. In those circumstances, smaller grids are used contralateral to the area of predominant interest.

Recording

As with all intracranial methods, localizing seizure onset with clinical correlation is the main goal of subdural grid recording, with the added possibility of functional mapping. Continuous recording during antiepileptic drug withdrawal to record a number of spontaneous seizures (usually at least three) is pursued as with other intracranial recording techniques. Recording parameters are generally equipment driven, and because reformatting of montages to bipolar or referential forms with variable filters is possible, the relative advantages or disadvantages of specific settings are not pertinent. Display of spontaneous seizure onset with different filters and gains can optimize one's ability to detect both the slow and fast components of the activity characteristic of spontaneous neocortical seizure onset. Recording sessions with subdural grids tend to be lengthier than those with other intracranial EEG methods. There might be several reasons for this observation. Functional mapping is time consuming and is often postponed until spontaneous seizures have been recorded, at which time medications are resumed. There is no evidence that this practice inhibits one's ability to stimulate functional cortex because of adhesions or reactive changes around the inserted electrodes. In addition, large electrode arrays situated in the subdural space can lessen the rate of spontaneous seizure occurrence. Neither the operational mechanism nor the predictable occurrence of this phenomenon has been systematically investigated, but it seems to be a repeated observation.

Risks

The risks of a subdural grid study are weighted toward infection and cerebral edema; these occur in up to 4% of patients who undergo subdural grid study, sometimes with significant prolongation of hospital stay and morbidity. Very rarely mortality or intracranial hemorrhage has been associated with grid recording. More extensive cortical coverage is associated with an increased risk of cerebral edema.

Interpretation

Background and interictal interpretation suffer from the restricted cerebral sampling obtained with grid studies, with the resultant inability to compare homotopic signals in various regions, assess the presence or absence of the expected normal rhythms in unsampled locations, or evaluate propagation patterns and timing.[87] Because of this, absolute background rhythm assessment is less useful than changes that occur during the recording session. Progressive slowing or attenuation is a significant predictor of metabolic or structural interference and can appear before other evidence of such intervening complications. Interictal spike distribution can be extensive, covering large portions of the grid, or can be restricted. Complete absence of interictal spiking or its relative paucity is not known to be a negative prognostic factor for ictal onset localization.

Ictal onset recorded in subdural grids can be quite focal, starting in one or two contacts, or can be widespread in nonadjacent contacts. The more focal the onset changes, the higher is the degree of confidence in the ictal localization. The characteristic pattern of neocortical seizure onset—a high-frequency discharge with adjacent simultaneous, or immediately superimposed, slow theta rhythm—is seen in subdural grid or strip recordings or depth electrodes. Eventually, all grid contacts become involved in high-frequency seizure activity, and this successive involvement and the manner in which it evolves are more rapid and less useful, with our current knowledge, than the propagation patterns across lobes or hemispheres. It is important to interpret subdural grid recordings (and all intracranial EEG recordings) with clinical correlation to ensure that electrical changes precede or are at least simultaneous with clinical involvement, for the diagnosis of ictal onset location.

Advantages and Limitations

Subdural grids are better suited than any other intracranial recording method for mapping of functional cortex near a suspected epileptogenic zone before resection. The density of contacts and the accuracy of placement are unsurpassed. Multiple subdural strips cannot control the locations of contacts with the same precision to achieve the desired array for ideal mapping.

The extensive regionalized array of contacts so ideal for mapping restricts placement of other electrodes when subdural grids are used. This limitation is the main disadvantage. In addition, physiologic effects of large subdural grids can affect the quality or character of recorded signals. The Yale group found poor yield (see later discussion), delayed electrical seizure onset, a remarkably high incidence of initial electrical change at the edge of the grid, and occasional difficulty in recording spontaneous ictal events at all. Whether these difficulties reflect insufficient sampling is questionable because grids often overlie structural lesions whose proximity to seizure onset is undeniably demonstrated by the commonly observed success in seizure cure after the lesion is removed. The "blanketing" of cortex by the subdural grid might alter the pathophysiology and the criteria by which we should interpret these EEGs, but the current state of knowledge affords no means of knowing when this might occur or how to proceed.

Yield and Accuracy

Use of subdural grids for localization of the epileptogenic zone has not been proven accurate or reliable.[109] The application of grids to localization stems from their utility for functional cortical mapping combined with a logical extension of the ability of subdural strips to provide useful localizing information about the ictal onset zone. Subdural grid recording might not be as useful as subdural strips or depth electrode study for electrical confirmation or demonstration of the ictal onset zone (Fig. 10).

"Accuracy" has a different meaning in this context; it is difficult to judge because grids are placed over areas already suspected of being epileptogenic on the basis of other localizing studies; often a structural lesion is present. Because the location of a (single) lesion on structural imaging procedures in uncontrolled epilepsy patients is often highly correlated with the region of epileptogenesis, the selection bias rather than the grid recording might be responsible for the accuracy of localization as judged by seizure cessation after lesion removal. Masuoka and Spencer[61] studied 25 patients who underwent 26 separate subdural grid studies employing chronic recording with 20 to 64 contacts. Computerized and visual analyses of digitized electrical data recorded during spontaneous seizures with electroclinical correlation were used to identify the location of the ictal onset zone. Adequate location of seizure onset was possible in only 4 of the 26 studies, and the remainder of the patients showed spontaneous seizures to be accompanied by diffuse or regional electrographic seizure onset in most or all grid contacts, lack of EEG change, or clinical onset preceding electrographic alterations in the grid recording (Fig. 10). Fourteen of the 25 patients had structural lesions, and the grid was placed over the lesions. Two of those patients had subdural EEG localization to the lesion site, and the other 12 were not localized. Six of the 12 unlocalized lesional patients have been seizure free for >2 years after resection of the lesion. These observations suggest that subdural grid recording infrequently localizes seizure onset in the absence of other localizing information and should not be promoted for that purpose alone.

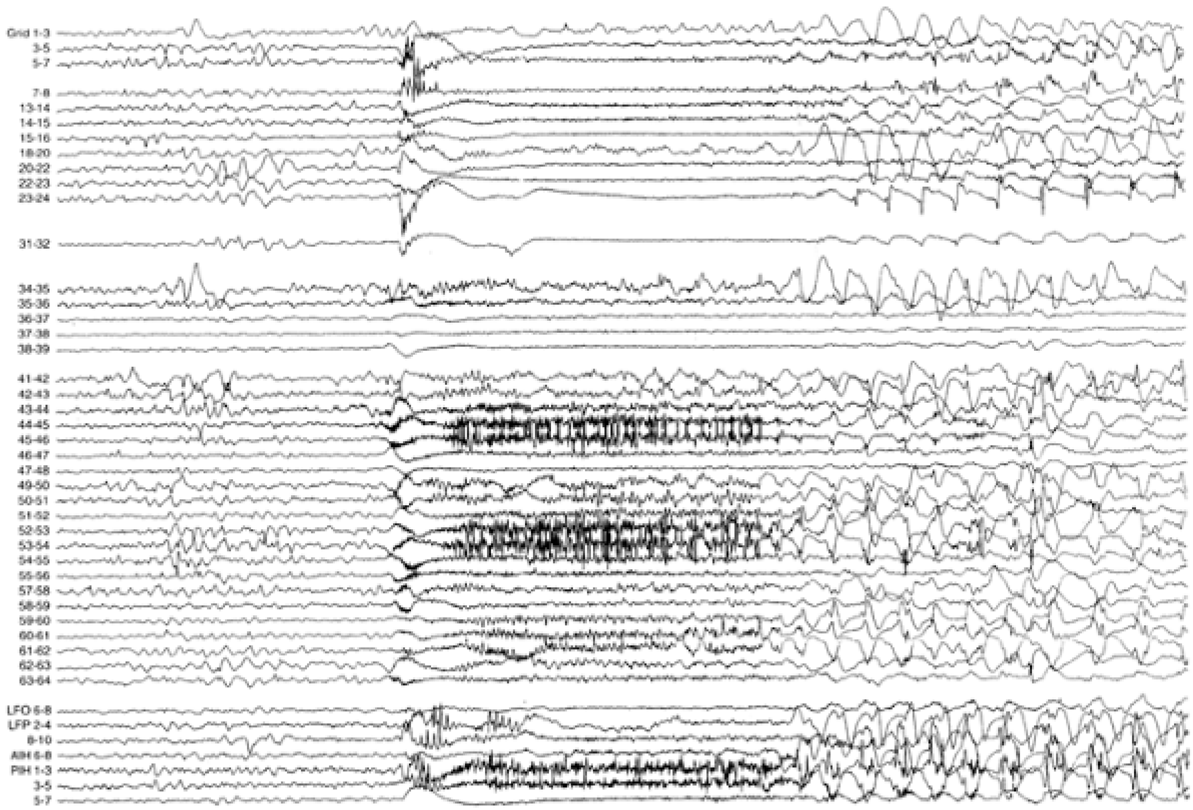

FIGURE 10. Spontaneous seizure recorded with subdural grid. Diffuse high-frequency discharge without clear localization is often a problem of subdural grid recording; there is a suggestion of slightly earlier onset in grid contact 43.

Awad et al.[9] reported 47 patients with chronic grid recording in association with lesions on neuroimaging in whom an epileptogenic "focus" was defined as the zone of maximal interictal activity "from which the patient's seizures arose." The patients were classified into three groups: (a) seizure "foci" in the region of the lesion, (b) seizure "foci" extending beyond the lesion, and (c) one or more "foci" of ictal onset remote from the lesion. Resection was performed to include the lesion and the "focus" when possible. Although the ability of grids in this study to localize the epileptogenic zone is hard to determine because interictal activity was mainly used to denote the "focus," these authors also found that only 11 of the 47 patients had "foci" exclusively in the lesion location and that complete resection of the lesion but not of the "focus" was associated with seizure control. Such data support the contention that localization of the epileptogenic zone by subdural grid recordings is a tenuous concept without proven support. Jennum et al.[45] reported that tailored resection using grids and intraoperative electrocorticography to guide resection produced best results if the "ictal field" was included in the resection.

Costs

The cost of subdural grid recording is similar to that of other intracranial recording methods but can be higher if recording lasts longer (see earlier discussion). Chronic extraoperative mapping represents an additional cost, but mapping would otherwise be necessary intraoperatively. Removal of subdural grids, however, must be done in the operating room at additional cost and risk.

Combined Studies

Frequent mention has been made of combined intracranial recording methods, usually depth electrodes and subdural strips. This combination has already become the standard for adequate intracranial EEG in many situations. Risks are additive, but cost and time are equivalent, and additional sampling theoretically allows improved accuracy of localization.[91,97] Combined studies have also allowed clinical investigation of patterns of seizure evolution, onset, propagation, and termination with correlative studies providing insights into the pathophysiology of human epilepsy that have themselves produced useful modifications of the methods used to study epilepsy. Thus, findings that have depended on the simultaneous use of depth electrodes and medial temporal subdural strip electrodes include the demonstration of frequent subclinical seizure activity in hippocampus proper, not seen in nearby medial temporal subdural strips[99,100] (Fig. 7); the interaction between entorhinal cortex and hippocampus demonstrated by depth electrode/subdural strip combinations[92]; and the initial propagation of medial temporal lobe seizures to temporal neocortex, frontal lobe, or contralateral hippocampus with its implications for anatomic alterations and for a functional hippocampal commissure in humans[96] (Figs. 7 and 9). European approaches using only depth electrodes can provide similar information in many cases if an ample number of electrodes are implanted with careful tailoring of placement by using information from multiple superficial as well as deep recording contacts.

Subdural grids can be part of combined procedures. Subdural grids and strips are often used in combination, and grid and depth electrode combinations are used less often.[14] The practical difficulty of placing grids at craniotomy, with the stereotactic apparatus required for depth electrode placement, means that usually if depth electrodes are to be combined with subdural grids, they are placed freehand with much less precision, negating one of their main advantages; frameless stereotaxic insertion can avoid this problem.

Special Considerations in Infants and Young Children

Indications

As mentioned already, invasive monitoring is indicated much less frequently in young (e.g., <5 years old) pediatric surgical candidates than in adults or older children. This is because there is a much higher relative incidence of epilepsies caused by discrete lesions (congenital or perinatally acquired) that are identifiable and localizable by structural and functional

imaging in the very young population. Of course, surgical candidacy assumes that evidence from clinical signs, seizure semiology, and noninvasive electrophysiology are topographically convergent or at least noncontradictory. Other authors provide a more complete discussion of some of the uniquely pediatric concepts of preoperative evaluation (see Chapter 185).[29,69,70,72,78] This section focuses more on certain technical and clinical considerations in the performance of these recordings.

In very young children, invasive monitoring is indicated in the fairly small minority of cases of intractable localization-related epilepsy in which doubt remains about the causal relationship between an evident structural lesion and the patient's habitual seizures. Examples might include a case of dual or multiple pathology in which one of the lesions is suspected to be the epileptogenic culprit but this cannot be deduced with sufficient certainty to justify resection (e.g., in tuberous sclerosis[8]) or a single lesion in which the electroclinical aspects of the seizures are insufficiently localizing or even lateralizing and the epileptogenicity of the lesion is uncertain. These concepts are similar to those that apply in adults.

It should be emphasized that collective experience with intracranial recordings in this age group is relatively limited. Most of the literature concerning invasive recordings in "childhood" involves adolescents and older children; very few centers have applied these techniques to infants or even "young" children (<5 years old).[43,127] Patterns of usage among these centers vary considerably and probably relate in great part to the availability and type of functional neuroimaging. For example, interictal positron emission tomography (PET) scanning provides better spatial resolution and specificity for the epileptogenic zone than interictal single photon emission computed tomography (SPECT),[17,23,24] so that centers with PET tend to use intracranial recordings less frequently than those without it. Much remains to be learned about indications, safety, and efficacy in this age group. There has been little experience with invasive recordings in infants with catastrophic generalized seizures secondary to a "zone of cortical abnormality," which is usually localized by the convergence of noninvasive indicators plus intraoperative electrocorticography.[29,72,78] Recently, Asano and colleagues reported findings from subdural recordings in infants and children with epileptic spasms.[6,7] The following discussion pertains to young children with intractable *partial* seizures.

If a suspected epileptogenic lesion is near functionally important cortex and an invasive study is indicated, additional useful information can be obtained from functional mapping through cortical stimulation, keeping in mind developmental factors that affect the optimization of stimulus parameters.[40,41] Although extraoperative cortical stimulation can be performed in infants, less information is obtainable than in adults because of the limited repertoire of clinical responses and the inability of the patient to cooperate or to report subjective sensations. In addition, these patients have an apparently increased incidence of eliciting afterdischarges at stimulation intensities substantially below the current level required for eliciting functional responses. Because localization of the primary sensorimotor strip can be accomplished intraoperatively by means of evoked potentials, it seems that functional mapping would rarely, if ever, be a determining reason to perform intracranial monitoring in an infant.

The type of invasive monitoring most appropriate for young children also differs significantly from that in adults. Whereas depth electrodes are used very often in adult epilepsy surgery centers, they are seldom indicated in young children for several reasons. First, from a purely technical point of view, the infant skull is too thin to anchor rigid depth electrodes, and there is little experience in the stereotactic placement of flexible depth electrodes in infants.[46] Second, the clinical contexts in which depth electrodes are often indicated in adults—mesial temporal lobe epilepsy of unclear lateralization or limbic epilepsy of unclear localization or lateralization—are quite uncommon in young children. Although infants do have temporal lobe seizures,[27,28,128] the etiology is hardly ever hippocampal sclerosis, but rather is some kind of neocortical congenital tumor, hamartoma, or malformation, for which localization and lateralization are typically straightforward. Third, as a corollary, because one of the main structures for which depth electrodes are superior to subdural strips—the hippocampus—is rarely the main diagnostic issue, there seem to be few situations in which depth electrodes would provide critical information that subdural strips or grids would not.

Therefore, the remainder of this section focuses on subdural electrodes. The use of depth electrodes in older children with limbic epilepsy is not essentially different from their use in adults.

Surgical Aspects

Because of the small head size, far fewer subdural electrodes can be placed in young children than in older ones and adults. On the other hand, for the same reason, a relatively greater proportion of neocortex can be sampled by a given number of electrodes. In the context of encephaloclastic lesions such as porencephalic cysts, there might be adequate intracranial room for the electrode arrays, but they might also be more difficult to keep anchored in the desired place for the duration of a monitoring session.

The greatest risks specific to this age group are anesthetic rather than surgical. Such procedures should be limited to institutions with expertise in pediatric anesthesia and intensive care. Small children easily become hypothermic in the typically cold operating rooms. Their fluid and electrolyte balance is more precarious, and apparently small amounts of blood loss can deceptively correspond to a significant proportion of total blood volume. Blood vessel walls are thinner, and bridging veins are more easily torn through excess traction or friction against the edge of a strip during insertion (particularly interhemispheric). In infants with still-unfused sutures, the risks of cerebral edema and increased intracranial pressure are lessened, although not eliminated, by the flexibility of the skull.

Nursing Aspects

Perhaps the most important differences about invasive pediatric monitoring are in the area of nursing. For children who are mature enough to communicate, preoperative preparation by means of explanations, acting out procedures with dolls, visiting the intensive care unit, and so on is important both for humanitarian reasons and for obtaining optimal recordings through maximal cooperation. A dedicated Clinical Nurse Specialist or Child Life Specialist is an element of the pediatric epilepsy team whose importance cannot be overemphasized.[29]

Unlike adolescents and adults, who are generally highly motivated to be rid of their epilepsy, younger children have less impulse control, and their cooperation cannot be relied on at all times despite their degree of motivation. For this reason, patient safety requires that monitoring be conducted with one-to-one nursing care, and preferably with a parent or closely related adult in attendance as much of the time as possible. Monitoring can take place either in a relatively private zone of a pediatric intensive care unit using portable recording equipment or in an epilepsy monitoring unit that is adequately equipped and staffed for young patients. Creativity and patience are

necessary for keeping a cranially tethered child occupied throughout waking hours and as happy as possible under the circumstances. Pain control is an aspect of care that often receives insufficient attention, especially with infants or developmentally delayed children whose discomfort cannot be verbalized but manifests itself only as irritability. Extra analgesia rather than mere sedation might be called for.

Timely recognition of postoperative complications such as cerebral edema, expanding hematoma, or infection requires personnel skilled in pediatric intensive care. The early clinical signs can be subtle and evolve more insidiously than in adults, who can report subjective symptoms more reliably and whose neurologic examinations include a greater variety of potentially localizing signs. Early signs of increased intracranial pressure, for example, might be nothing more specific than increased fussiness, easily attributable to boredom and frustration, or lethargy, easily attributable to postoperative state or sedative medications.

Fortunately, the duration of intracranial recording sessions is typically much shorter in young children than in older patients because the former typically have much more frequent seizures and because cortical stimulation, if performed at all, is less elaborate. A typical duration of monitoring is a few days to a week, in contrast to adults, in whom it typically lasts one to several weeks.

Interpretive Aspects

The challenges and caveats in determining the zone of ictal onset already discussed apply at all ages—difficulties related to incomplete spatial sampling, regional or diffuse “onsets” that probably represent spread patterns from some unsampled site, and “onsets” at the edge of a grid, which also could represent spread from an adjacent unsampled area.[44] Very rapid spread tends to be less of a problem, however, because of the immaturity of myelination of intercortical connections.

The repertoire of ictal patterns is much richer and more variable than in older patients. Although the classic low-voltage fast discharge that slows, grows, and converts into rhythmic spiking is common, repetitive spiking or merely slowly repetitive stereotyped waveforms from the onset can also be seen. Sometimes it is difficult to discern ictal onsets from background activity: A focal discharge might be obvious after having undergone considerable evolution, but it seems to emerge imperceptibly out of the background, and its moment of onset is impossible to pinpoint within the order of seconds, tens of seconds, or, rarely, even minutes.

In their considerable experience with subdural recordings in children, Jayakar et al.[42] described an ictal phenomenon that they consider a significant indicator of the epileptogenic zone—the intraictal activation of a secondary focus. This is a discrete ictal discharge that seems to arise de novo in a disparate location during the course of evolution of the primary discharge and persists beyond the termination of the primary discharge. Inclusion of these secondary foci in the resection resulted in improved seizure outcomes.

Palmini et al.[68] described a pattern believed to be characteristic of cortical dysplasia, consisting of trains of continuous or nearly continuous spiking at varying frequencies, which the authors described as "ictal" or "ictal-like," although at times a more classically evolving ictal pattern emerges out of the same location, perhaps suggesting an interictal nature of the spikes.

Apart from this apparently specific pattern, the more usual kind of sporadic, often multifocal, interictal spikes are even less localizing for the epileptogenic zone in children than in adults and should not be relied on as the sole or even main criterion for determining the margin of resection.

Comparative Assessments

Depth Versus Subdural Strip Electrodes

As noted, this combination has become standard, with good reason: Multiple studies showed that complementary information and improved ability to interpret actual localization of the ictal onset zone result without increased risk. Complementary information from interictal recording has also been documented,[71] although its utility in planning extent of resection is questionable. From analyses of these combined studies, there is little question that depth electrodes are more sensitive to epileptogenic disturbances in hippocampal and medial temporal lobe locations; subclinical seizure discharges, pre-ictal spikes, and early seizure activation are regularly seen in these depth electrode contacts, although simultaneous subdural strips extending medially in the temporal lobe do not show them.[97,99] On the other hand, subdural strips typically detect the seizure discharge before scalp recording and before clinical seizure activity and can provide satisfactory data most of the time. Rare instances of false contralateral temporal lobe localization by subdural strips have been documented.[99] In extratemporal locations, no strict comparison studies have been reported, probably because most placement protocols in suspected neocortical epilepsy use subdural strips or grids but no depth electrodes. It should be possible to compare the relative yield of depth and subdural electrodes in medial occipital, parietal, and frontal areas, but this has not been reported. In our experience, either one can detect the earliest manifestation of the seizure, even in nonlesional extratemporal epilepsy, but the yield is lower than in temporal lobe epilepsy, probably as much due to sampling locations as to any superiority of one technique or the other.

Depth or Subdural Strips Versus Grids

As emphasized earlier, because grids record from a restricted, predetermined area, their role is not strictly comparable to that of subdural strips and depth electrodes. For localization of ictal onset, even if the region is suspected, we still have the impression that the broader although sparser spatial sampling afforded with depth electrodes and subdural strips conveys a significant advantage in addition to differences in the physiology of the recording procedure itself.

Depth or Subdural Strip Versus Scalp Electrodes

Intracranial electrodes detect an artifact-free epileptic signal much earlier than scalp electrodes. Any single depth or subdural study is sufficient to prove their markedly superior sensitivity to scalp electrodes. Depending on the referral population, scalp ictal EEGs provide minimal or insufficient localization of the ictal onset zone in 50% of patients; however, 75% of depth or subdural studies provide ictal onset localization in that unlocalized group.[82] Furthermore, although localization might be apparent on surface ictal EEG, it can be unreliable and usually occurs after clinical seizure activity has begun.[95] Although the lateralization of temporal lobe ictal discharge is still usually appropriate, temporal versus extratemporal localization must be confirmed by other means, usually structural or functional abnormalities. When ictal onset localization is obtained by scalp EEG in frontal lobe locations, it tends to be widely distributed, and subdural EEG provides much more precision.[75]

Depth or Subdural Electrodes Versus Pegs

Minimal information is available with respect to the comparison of depth or subdural electrodes and epidural pegs, a novel form of EEG recording first reported by Barnett et al. in 1990.[13] Pegs are mushroom-shaped individual electrodes inserted in the skull to sample the epidural EEG, providing a signal with less muscle artifact than scalp recordings and avoiding the confusing aspects of surface recording in the setting of skull defects. This potential improvement over scalp EEG has not been formally tested but appears to be logical. The limited sampling of only dorsolateral cortical locations by this method prevents such electrodes from providing access to signals from the deep or medial locations that depth and subdural electrodes can sample. It is unlikely that peg electrodes provide resolution of temporal lobe abnormalities superior to that from sphenoidal electrodes, but they might be another approach to semi-invasive examination of extratemporal electrical activity associated with the ictus. They are most profitably used to sample EEGs from several lobes and confirm lack of activity in those regions not thought to be part of the epileptogenic zone.

Depth or Subdural Electrodes Versus Foramen Ovale Electrodes

In 1985, Wieser et al. described the use of an electrode inserted through the foramen ovale (subsequently modified to include four contacts) for chronic ictal recording. It is inserted freehand under local anesthesia.[117] Although it is semi-invasive, the technique is considered simpler than depth or subdural electrode study and has relatively low morbidity and no reported mortality. Its morbidity, however, might not be lower than that of depth or subdural electrodes. The most frequent serious complications are brain stem syndromes and subarachnoid hemorrhage. The electrodes allegedly record from mesial basal aspects of the temporal lobe. Accordingly, they are used in patients considered for medial temporal lobe resective procedures as an alternative to chronic intracranial recording. Comparisons with depth electrodes, subdural strips, and scalp electrodes in dogs with hippocampal foci suggest that ictal discharge and interictal spikes from the hippocampus are accurately reflected but restricted abnormalities and early seizure discharges, especially from the anterior hippocampus and amygdala, are not well demonstrated.[118] Although no difference was seen in postoperative seizure control between patients selected for amygdalohippocampal resection by foramen ovale electrodes or depth electrodes, patients studied by foramen ovale electrodes were a selected sample without complicated profiles.[115] One comparison of patients with foramen ovale and depth electrodes and subdural strips noted occasional false lateralization of seizure onset with foramen ovale recording, suggesting the need for caution in interpretation.[18]

Chronic Depth or Subdural Electrodes Versus Electrocorticography

Electrocorticography refers to acute intraoperative direct cortical recording. This is performed with a subdurally placed multicontact electrode grid similar to that used for chronic grid recording, multiple subdural strips, or a series of wick or ball electrodes suspended from a frame. No direct comparison of acute and chronic subdural recording has been reported, but because the manner of recording is so similar to that with subdural grids, many of the previous comments with respect to depth or subdural electrodes versus grids apply. The major disadvantage of electrocorticography is its duration, limited to brief intraoperative periods and often complicated by anesthetic effects. A review of results of electrocorticography and correlations with postoperative outcome and other EEG methods is beyond the scope of this chapter, but the usual absence of ictal recording is a major disadvantage of that technique compared to chronic ictal EEG recording methods. The ubiquity of interictal spike activity on intracranial EEG and its inconsistent correlation with ictal onset location indicate that limited interictal recording is likely to be of minimal benefit in localization of the epileptogenic zone for the purpose of resection. Successful prediction of postoperative seizure control in this context is likely to be an epiphenomenon related to selection of the site for electrocorticography (usually based on a structural lesion) rather than to the utility of the electrocorticogram itself. Electrocorticography might play a greater role in the operative planning in children with "catastrophic generalized" epilepsy, in which nonepileptiform abnormalities of the interictal recording are the focus of attention.[67,70,77,78]

Grid Versus Scalp

Although grids reduce artifact, the restricted spatial sampling they provide is a major disadvantage compared to the scalp EEG. The scalp EEG, however, reflects ictal activity long after propagation and involvement of multiple sites and well after clinical activity has occurred. No formal comparison of ictal grid versus ictal scalp EEG has been published.

Synthesis

General Indications

Intracranial EEG recording, regardless of the specific technique, is used when precise localization of the epileptogenic zone (the area necessary and sufficient to cause spontaneous seizures) is required to plan surgical resection for treatment of medically uncontrolled seizures and/or when precise localization of functional cortex is required in planning safe resective procedures for epilepsy with or without a lesion. Because it carries a 1% to 4% risk of significant morbidity and possible mortality, it can be considered appropriate only when sufficient conclusions about localization cannot be obtained by less invasive methods. Furthermore, because restricted sampling of cortical regions is desirable, the clinical situation must allow a reasonable a priori hypothesis as to which areas need study.

Distinctions Among Techniques

Whether depth, subdural strip, or subdural grid recordings are used for this localization depends on the specific questions being asked and the areas involved. Depth electrodes and subdural strips are preferable for bilateral cortical recording that can be analyzed with regard to onset, delay, propagation, and termination patterns. Subdural grid recordings, like electrocorticography in the operating room, are limited to circumscribed regions that are also studied for functional localization. Each technique has advantages in specific situations, and selection must consider technical limitations as well. Current practice almost always dictates combined types of intracranial electrodes for maximal advantage in one recording session, an approach that is not known to increase morbidity.

Techniques for Specific Situations

On the basis of worldwide published experience, technical details, the evolution of other localizing and diagnostic techniques, and the kinds of questions that are most often approached with intracranial study, the following recommendations are proposed to address specific topographic epilepsy syndromes. One must bear in mind, however, the unique problem presented by each individual patient.

Temporal Lobe Epilepsies

Whether lateralizing medial temporal lobe seizure onset, distinguishing between medial and lateral temporal lobe seizure onset, or differentiating temporal lobe from orbital frontal, medial parietal, or medial occipital seizure onset, the approach must account for what is known about the intracranial EEG patterns of medial temporal lobe epilepsy. Recording from anterior, middle, and posterior hippocampus bilaterally with orthogonally or parasagittally placed depth electrodes, combined with bilateral anterior, middle, and posterior temporal neocortical recording from orthogonal depth electrodes or multiple subdural strips, should be considered a minimum to adequately assess subclinical seizure discharges in hippocampus, pre-ictal spikes, propagation patterns, propagation time to contralateral hippocampus, and the EEG morphologic characteristics that allow accurate diagnosis of medial temporal lobe epilepsy and its distinction from neocortical regions of seizure onset. In any event, because increasing evidence suggests that the distinction between medial and lateral temporal discharges is an oversimplification and that medial temporal lobe epileptogenic zones can incorporate a participatory network that extends beyond these traditional confines, spatial sampling needs to be generous to allow information that permits adequate definition of the region for resection. When the laterality of temporal lobe onset is not questioned but the intratemporal location is a concern, the depth and subdural strategy might be exchanged for a temporal grid with medial subdural strip placement, especially in the dominant hemisphere, when language mapping needs to be performed.

Because medial frontal, parietal, or occipital lobe seizures can begin silently and propagate to medial temporal lobe structures, masquerading as temporal lobe seizures on scalp EEG, temporal lobe studies are ideally complemented by additional depth or subdural electrodes placed bilaterally in medial parietal, occipital, and/or frontal regions of concern. Additional data from functional imaging, functional testing, historical data, or structural abnormalities on MRI can suggest the need for this and other, additional intracranial sampling. Subdural strips are well suited for studying most interhemispheric locations as well as other extratemporal neocortical regions, and rarely are depth electrodes necessary except to complement the subdural strips when deeper regions appear to require study because of abnormal structure. Simultaneous recording with scalp or peg electrodes can provide important information that places the restricted information from intracranial electrodes into broad perspective.

Frontal Lobe Epilepsies

Successful localization is poor without imaging and behavioral clues in frontal regions because frontal lobe seizure semiology is so diverse and sampling of this large structure is always so limited. Because contralateral propagation occurs with startling rapidity, lateralization is often very difficult even if frontal lobe ictal onset localization can be obtained. In addition, the level of experience and the kinds of guidelines for interpretation that are available for temporal lobe epilepsy are not available for frontal lobe seizures, nor is any specific frontal lobe location considered the most common area of seizure onset. Clinical clues can direct study to primary motor area, supplementary sensorimotor area, dorsolateral, orbital, or polar frontal regions. Seizures with limbic characteristics suggest cingulate or orbitofrontal origin.

For most patients thought to have frontal lobe seizure onset, study is usually done with multiple subdural strips bilaterally but concentrated on one side, primarily in motor or supplementary motor versus lateral or polar regions, as suggested by clinical seizure characteristics. When structural and functional assessment clearly places seizure onset in one frontal lobe region, grids can be used. When prior evaluation suggests cingulate or orbital frontal complex partial lobe seizures, depth electrodes might be an alternative. They are usually placed bilaterally, especially because lateralization of the seizure characteristics can be difficult in nonmotor frontal areas. The area of any structural lesion thought to be important for epileptogenesis should be included in the design of the electrode array. Both depth and subdural electrode sampling can be fruitful in these locations. The experience in Europe suggests that use of multiple depth electrodes to target regions of frontal lobe and their connections can also be effective, based on carefully formulated hypotheses. Thus, for example, to study suspected orbitofrontal seizure origin, oblique electrodes sampling gyrus rectus, orbital cortex, and frontal pole and electrodes recording activity in lateral frontobasal cortex, anterior cingulate, and anterior temporal lobe are used.

Parietal and Occipital Lobe Epilepsies

The comments about frontal lobe localization apply equally to parietal and occipital seizure onset. Imaging clues or primary sensory or occipital symptomatology can help to guide the study, but even with those, rapidity of contralateral or rostral propagation, seizure onset in silent regions, and lack of interpretative standards contribute to the commonly observed difficulty in localization of ictal onset areas in these lobes. Although depth electrodes alone can be used for these studies, a large number will be needed for sufficient sampling, for the aforementioned reasons. Occipital lobe seizures can propagate variably to frontal and to medial temporal lobe areas bilaterally and independently and be mistaken for temporal lobe epilepsy or multifocal epilepsy, which will be undetected without extensive bilateral study. Thus, a combination of subdural strips and depth electrodes is commonly used, bilaterally because of rapid propagation and because some of the pathologic entities causing seizures in these locations (e.g., cortical dysplasia) tend to have bilateral epileptic manifestations. Seizures might appear in the general vicinity of a lesion but not the exact location; this is characteristic of occipital lobe epilepsy.

Screening Studies

A patient with uncontrolled and stereotyped complex partial seizures might have minimal localization by scalp EEG, normal MRI, nonlocalizing auras and seizure semiology, and no significant historical features to allow an educated guess with respect to localization of seizure onset. The patient deserves surgical treatment if possible, but intracranial study demands that specific questions be addressed. In these situations, the question can be reshaped in a broader sense: Can we define a single cerebral region for further intracranial study? Sometimes this is possible by sampling medial and lateral temporal lobes and frontal, parietal, and occipital neocortex with subdural strips and depth electrodes; analysis of seizure onset and propagation patterns can be used to design a second intracranial study with more focused questions and electrodes that eventually enable a resective procedure. The yield of this approach, however, to define even an area for further invasive study is lower than when more information is available to guide the selection of the

intracranial electrode array in the first place, so it is considered an option only in very few and special situations.

Lesional Patients

Implicit in the foregoing discussion was the targeting of neocortical and deep tissue in the vicinity of MRI-identified structural lesions in patients with uncontrolled epilepsy. In many lesional patients (for these purposes usually including tumors and hippocampal atrophy), the frequent concordance of scalp EEG with the lesion location allows the additional information from functional studies to suffice for excision without the need for intracranial EEG. In certain other lesions (some cortical dysplasias and atrophic regions), particularly when the process might be multifocal, and in all patients with "dual pathology" of a lesion and hippocampal atrophy (combined cortical dysplasia and hippocampal atrophy, tumor and hippocampal atrophy, or bilateral hippocampal atrophy), intracranial EEG is nearly always needed to differentiate among several areas of possible epileptogenesis. A combination of subdural strips and depth electrodes allows safe and representative sampling of the hippocampus and the vicinity of the lesions; depth EEG study as in the stereo EEG approaches in Europe can also suffice with sufficient electrode coverage. Grid recordings are reserved for patients in whom a single lesion consistent with scalp EEG localization is close to functional cortex.

Summary and Conclusions

We have watched neuroimaging revolutionize the diagnosis of epileptic disorders, allowing more precision in diagnosis, classification, and treatment. This is especially applicable to the surgical treatment of epilepsy. Probably half as many patients require intracranial EEG as did only a decade ago, and of those who do, success in localization is improved by structural and functional clues to the regions of abnormal brain. Will advances in functional and structural imaging eventually reduce or eliminate the need for intracranial EEG? This is doubtful because more sensitive imaging reveals multiple lesions more often, and these demand intensive electrical study to distinguish the ones with epileptogenic potential. The marriage of new technologies opens the door for increased understanding of brain physiology in epilepsy while enabling improved diagnosis and treatment; it might in fact herald the need for more intracranial studies than are currently done.

Chapter 172

Intraoperative Electrocorticography

Mark D. Holmes

Gian-Emilio Chatrian

Introduction

The method of recording electrical potentials directly from the cerebral cortex (electrocorticography [EcoG]) or from the cerebral cortex and subjacent structures was pioneered in humans by Berger, who detected these activities with electrodes placed over the dural surface in patients with skull defects[15] and with a needle inserted through the cortex and underlying white matter of a patient with a distant brain tumor.[16] Subsequent work continued to be aimed at validating the cortical origin of scalp-recorded electroencephalogram (EEG) rhythms and demonstrating alterations of electrocerebral activity caused by brain tumors,[2,42,98,116] but direct brain recordings soon became established primarily as aids in the surgical treatment of medically refractory partial epilepsy.[7,44,54,55,57,63,78,114] The initial role of intraoperative ECoG in defining sites of ictal origin has been supplanted in recent decades by advances in continuous EEG-video monitoring (both noninvasive and invasive) and by developments in neuroimaging. The role of intraoperative ECoG has evolved primarily as a tool for better understanding the likely boundaries of the epileptogenic zone and as guide to determining the extent of surgical resection. Despite the changing role of ECoG, the technique and interpretation of direct brain recordings during surgery has changed little during the last six decades. This review summarizes traditional technical and interpretive principles of intraoperative ECoG and highlights evolving concepts of this method. The original work of Jasper[55] and the comprehensive reviews of Bates,[13] Ajmone-Marsan and O'Connor,[8] and Gloor[46] are sources of additional information.

Indications

In patients afflicted by chronic, medically intractable partial seizures, the ECoG is performed during surgery (Fig. 1) following preoperative studies that have identified an epileptogenic region in the hemisphere targeted for surgery. Intraoperative ECoG is intended to (a) identify the limits of the epileptogenic zone, (b) guide the extent of resection, and (c) assess its completeness.

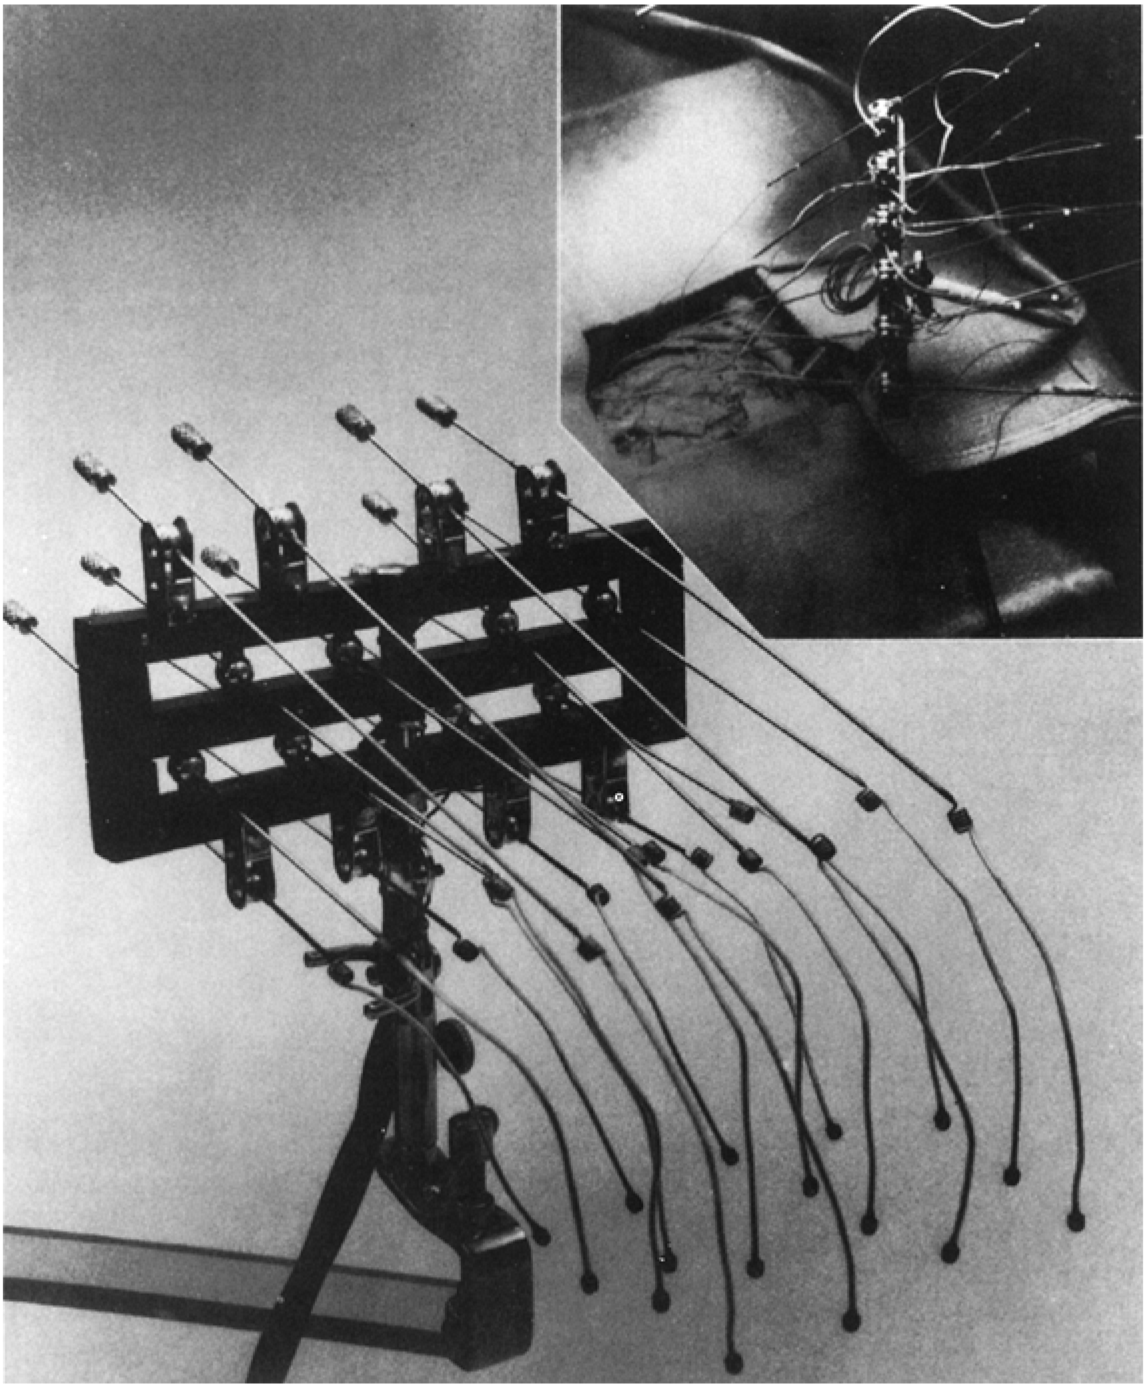

FIGURE 1. Sixteen-electrode ECoG set used at the University of Miami and at NINCDS, modified from an original design of the Montreal Neurological Institute. **Inset:** Set in place, with holder clamped to the bone edge of the craniotomy and electrodes in contact with the exposed cortex. New York: Raven Press, 1990;535–560, with permission.)

Identification of the Epileptogenic Zone

Determination of the site of the epileptogenic zone by intraoperative ECoG relies on several factors, including demonstrating an area of brain that (a) displays interictal epileptiform discharges, (b) shows susceptibility to repetitive electrical stimulation, and (c) gives rise to the initial, or all, manifestations of the patient's habitual seizures when electrically stimulated. In fact, however, it is rare that, seizure onset can be determined only by ECoG.

The Interictal Spiking Area

Because intraoperative ECoGs are of relatively short duration, electrographic seizures are rarely recorded except in some particular conditions,[11,46] and spontaneous epileptic activity consists almost exclusively of interictal discharges, that is, spikes, sharp waves, and their variants. For the sake of brevity, these are referred to in this chapter as "spikes." Because of this limitation, the utility of the ECoG during epilepsy surgery depends on the following assumptions: (a) that intraoperatively recorded interictal spikes are reliable markers of the epileptogenic process and (b) that they provide dependable information on the site and extent of epileptogenic tissue to be removed to successfully control the patient's attacks. The following observations suggest that both of these assumptions have limited validity:

1. It is impossible to distinguish with assurance in ECoG recordings primary epileptiform discharges arising from a given brain location from secondary discharges propagated from a distant epileptogenic site.[27,55,59]
2. The extent of the intraoperatively determined interictal spiking area can be increased or diminished by a number of anesthetic, analgesic, and other medications commonly administered during surgery and by the intrusion of drowsiness or non–rapid eye movement (REM) sleep in the waking ECoG.[66,96]
3. In many patients with medically intractable partial seizures, multiple interictal spiking areas are demonstrated by EcoG.[48,72,105,109,110] This finding precludes attempts to delineate a single interictal spiking zone with distinct boundaries.

Localized Electrical Stimulation of the Brain

Because the topographic extent of interictal ECoG discharges provides limited assistance in defining the boundaries of the surgically relevant epileptogenic zone, attempts have been made to identify this area by localized repetitive electrical stimulation of the brain. When of sufficient intensity, this excitation elicits an "afterdischarge," that is, a seizure discharge that typically begins at the stimulated site and subsequently either remains restricted to this location or spreads to adjacent or wider cortical regions as well as to subcortical structures (Fig. 2). Afterdischarges vary widely in duration from <1 sec to as much as 90 sec or longer and are frequently followed by postictal depression, which is in turn succeeded by slow activity of variable duration, often most obvious at the site of stimulation.[55,114] Localized stimulation of the brain of patients with chronic, intractable partial seizures was originally undertaken with the hope that (a) human epileptogenic tissue might display increased susceptibility to this stimulus in the form of afterdischarges of lower threshold, longer duration, or both, relative to nonepileptogenic tissue, and (b) the afterdischarge so elicited would be accompanied by clinical changes reproducing the initial, or all, manifestations of the patient's

P.1818

habitual seizures. However, intraoperative as well as extraoperative studies have demonstrated that afterdischarge thresholds and durations vary among cortical areas[55,114] and even within the same area from day to day[114] and from one stimulation to the next.[3] Their thresholds were elevated shortly after a prolonged afterdischarge[114] and were altered by structural changes in the area stimulated, although conflicting results were obtained by stimulating normal and sclerotic human hippocampi.[17,26] In addition, afterdischarges could be especially prominent and long-lasting at locations not demonstrating interictal spikes,[46] were not consistently related to the site of spontaneous ictal onset,[17] and sometimes occurred solely, or persisted longer, at sites distant from those stimulated.[55]

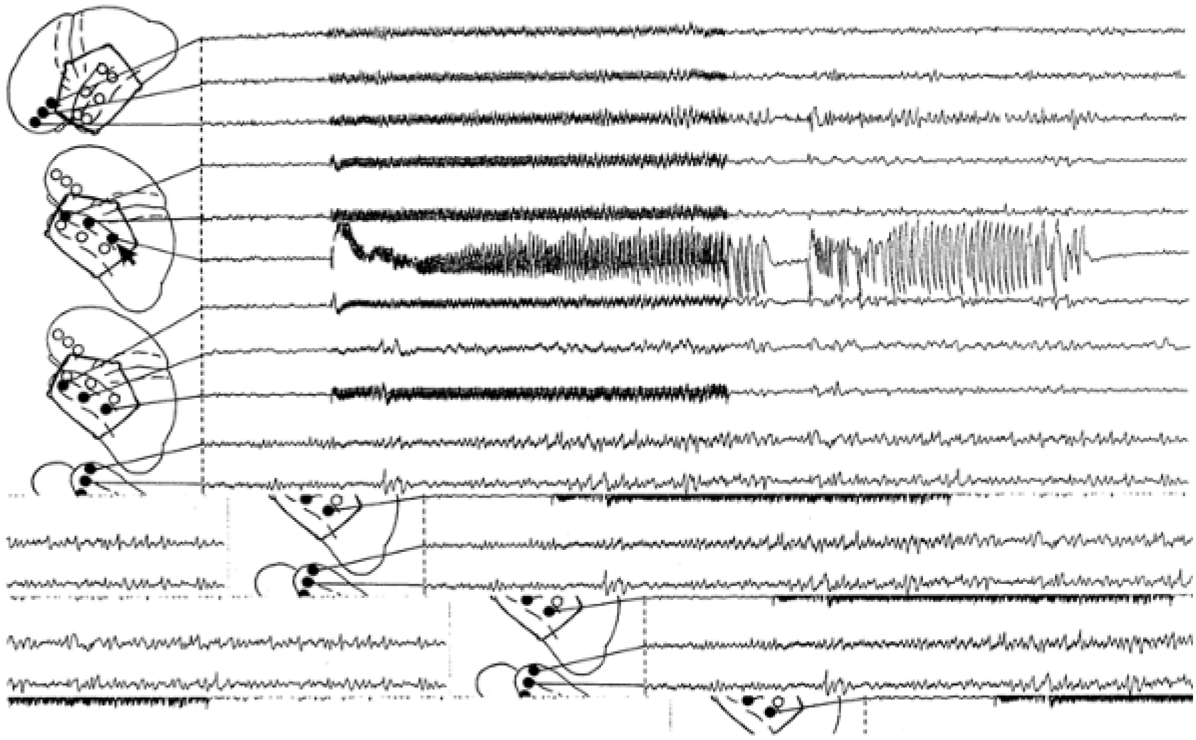

FIGURE 2. Brief, localized afterdischarge (channel 6) unaccompanied by clinical changes is elicited by electrical stimulation of the posterior portion of the left superior temporal gyrus (rectangular diphasic pulses, 0.3 msec, 60 Hz, 4 mA, 6.5 sec) in a patient with temporal lobe seizures arising from the medial and anterolateral temporal cortices.

Penfield and his associates[37,46,83,94] among others made extensive use of localized electrical stimulation of the brain to reproduce in waking patients undergoing surgery the initial, or all, manifestations of their habitual partial seizures. The ability of this technique to localize the epileptogenic zone depended on the validity of the assumptions that (a) the initial manifestations of partial seizures, that is, the "auras," indicated the site of the brain from which the seizures developed and (b) the reproduction of these manifestations by electrical stimulation of a restricted area of the brain confirmed this localization. Conflicting opinions were expressed on the localizing significance of the aura,[5,82,105,114] and attempts to reproduce it intraoperatively or extraoperatively by electrical stimulation of cortical

and subcortical structures provided evidence that, in many instances, the aura did not reflect an ictal discharge arising at the site stimulated but resulted from spread of seizure activity at a distance from this location.[12,34,114,120] The results of one study[40] indicated that the electrically elicited initial manifestations of the patient's habitual seizures, whether occurring in the presence of a localized afterdischarge or at the very onset of a spreading afterdischarge, lacked lateralizing or specific localizing value and at best suggested the most likely lobar origin of the patient's spontaneous attacks. Clinical manifestations appearing during the course of a spreading afterdischarge were likely related to the involvement of brain areas other than that stimulated.

The available information indicates that the topography of intraoperative interictal spiking, the afterdischarge threshold and duration, and the reproduction of the clinical manifestations of the patient's seizures by localized electrical stimulation of the brain do not consistently identify the epileptogenic zone.

Functional Mapping

Additional assistance in determining the boundaries of "tailored" resections of epileptogenic tissue is offered by the identification in waking patients of motor and sensory cortices and the delineation of regions involved in speech and memory functions, which are achieved by localized electrical stimulation of the brain at intensities mostly subliminal for afterdischarge (see Chapter 174, Intraoperative Functional Mapping).

Technique

Electrodes and Instrumentation

ECoG electrodes[8,13] must be capable of detecting the electrical activities of the cortex exposed by craniotomy and of adjacent as well as more remote areas of the lateral, inferior, and medial surfaces and, at times, subcortical areas of the hemisphere undergoing surgery. Most commonly, electrode-holder assemblies (Fig. 1) are used that typically incorporate 16 insulated silver wires. The distal ends of these wires terminate with a carbon ball[32] or a silver/silver chloride ball covered with cotton soaked in physiologic saline solution, which makes contact with the exposed cortex. Their proximal ends are connected by coiled springs to thin stainless steel rods, which are mounted on the universal ball joints of a holder clamped to the bone edge of the craniotomy. Wires from these joints lead to the inputs of the recording system. An alternative technique uses variously shaped assemblies of 4 to 64 or more small platinum, silver, or stainless steel disk electrodes embedded 10 to 15 mm apart in soft, flexible, clear, silicone plastic (Silastic) sheets.[121] These strips or grids can be laid over the exposed cortex or introduced from the edges of the craniotomy over or under adjacent lateral, inferior, and medial cortical regions.

A common practice is to use holder-supported electrodes to record from the exposed cortex and Silastic-embedded electrodes to explore more remote cortical areas simultaneously.[109] During temporal lobe surgery, single or multicontact needle electrodes are often inserted freehand transcortically into the regions of the amygdala and hippocampus that are inaccessible

by noninvasive means.[34,46,48,59,63,86,104] An alternative approach to hippocampal, but not amygdalar, recording requires making either an incision in the lateral temporal cortex or an anterolateral temporal lobe resection to expose the hippocampus through the opened lateral ventricle and allow placement of individual electrodes[59,60,75] or a multicontact Silastic strip[86,110] over its ventricular surface. Various reference leads can be used for intraoperative brain recordings, including two interconnected electrodes on both sides of the neck[109,110] or an alligator clip attached to a muscle near the edge of the craniotomy. Grounding of the patient usually is provided by a metal clamp attached to the post of the electrode holder or to the bone edge of the craniotomy. The ECoG electrode sets require cleaning and appropriate sterilization after each surgery to prevent transmission of agents highly resistant to decontamination,[73] whereas commercial Silastic-embedded and intracerebral electrodes generally are disposable.

In most centers, the ECoG is recorded digitally with a 16- or 21-channel electroencephalograph ideally located in a gallery adjacent to, but separate from, the operating room.[54] A large glass window enables the clinical neurophysiologist to view the operating field, and an intercom system provides verbal communication between the neurophysiologist and the neurosurgeon. Photographs of the operating field can be taken through a tilted mirror. A recording system bandpass of 0.5 to 70 Hz (-3 dB) ensures appreciation of both epileptiform discharges and background activities. Further limiting the low-frequency response of the instrument is neither necessary nor justified except during electrical stimulation. In the course of this procedure, a low-frequency cutoff of 1.6 Hz or even 5.0 Hz helps to diminish the duration of amplifier blocking following discontinuation of the stimulus. Because activities recorded directly from the cortical surface are about 2 to 60 times larger than those detected on the scalp,[1] instrumental sensitivities of 10 to 50 μV/mm are most commonly used for ECoG recordings. Modifications of the traditional instrumentation and physical arrangement for ECoG are suggested later in this chapter.

Recording and Electrical Stimulation

Preresection ECoGs survey, in a systematic order, cortical regions within and outside the area of exposure. In patients undergoing temporal lobectomy, recordings must include exploration of infratemporal and orbital frontal cortices, the hippocampus, and the amygdala; ECoGs omitting the assessment of these structures are both inadequate and potentially misleading.[109,110] Postresection ECoGs examine the cortices surrounding the ablation as well as more distant structures. Following temporal lobectomy, these typically include the remnants of the hippocampus and parahippocampal gyrus, the insula, and neighboring extratemporal cortices. Total duration of preresection and postresection ECoGs, including monitoring of the effects of electrical stimulation but excluding functional mapping, is generally about 1 to 2 hours and sometimes longer. Both before and after resection, ECoGs can be obtained either bipolarly or referentially, but recording referentially expedites the interpretation and improves its accuracy.

Protocols followed in most centers for intraoperative electrical stimulation designed to elicit afterdischarges (Fig. 2), reproduce clinical manifestations of the patient's habitual attacks, or both entail delivery of 0.5- to 2-msec diphasic pulses applied at 50 to 60 Hz over 1 to 5 seconds between two ball electrodes that terminate a pencil-shaped probe held by the surgeon.[8] The stimulus can also be delivered between adjacent Silastic-enclosed electrodes. Individual stimulus trains are separated by at least 15 seconds,[3] but longer intervals up to several minutes are necessary following a prolonged afterdischarge producing temporary refractoriness.[3] Different stimulus parameters can be used for intraoperative functional mapping (Chapter 174).

Activation and Effects of Anesthesia

When no or rare interictal spikes are detected in the preresection ECoG, "activation" techniques can be used to elicit or enhance them. These procedures commonly consist of the intravenous administration of a general anesthetic such as thiopental sodium,[18,34] methohexital,[11,39] etomidate,[43] or propofol.[52] In the appropriate dose, these agents often cause the appearance or increase the rate of interictal spiking. However, the area displaying spikes, if any were present before the injection, frequently expands to wider cortical regions, and focal discharges can appear in noncontiguous, previously silent areas outside the anticipated margins of the resection. Thus, some results of the activation used with these agents, if not critically appraised, can encourage excessively wide surgical excisions. However, in a proportion of cases, the activation is restricted to a limited cortical area shortly after the injection, becomes again confined to this region as the action of the drug declines, or both (Fig. 3).[10] In these instances, it is possible that the site displaying the earliest and the last drug-induced activation represents the patient's epileptogenic area, although proof of the correctness of this inference is lacking. Over the last several years newer agents, specifically the short-acting opioids alfentanil[71,91] and remifentanil,[117] have been introduced for activation purposes during ECoG and may show greater promise for reliably identifying the epileptogenic zone, specifically in cases of temporal lobe epilepsy. Alfentenil has been reported to result in marked increases in spikes in hippocampus and parahippocampal regions and, to a lesser extent, in basal and lateral temporal cortex.[91] Electrographic seizures triggered by this agent have also been shown to be concordant with spontaneously recorded clinical seizures.[91] On the other hand, remifentanil can increase spikes in epileptogenic zone while suppressing discharges in the surrounding "normal" brain.[117] Nevertheless, in the absence of unequivocal criteria reliably differentiating between drug-induced spiking indicative of an epileptogenic area to be removed and spurious drug effects that can be safely neglected, the results of activation procedures should be interpreted with caution.

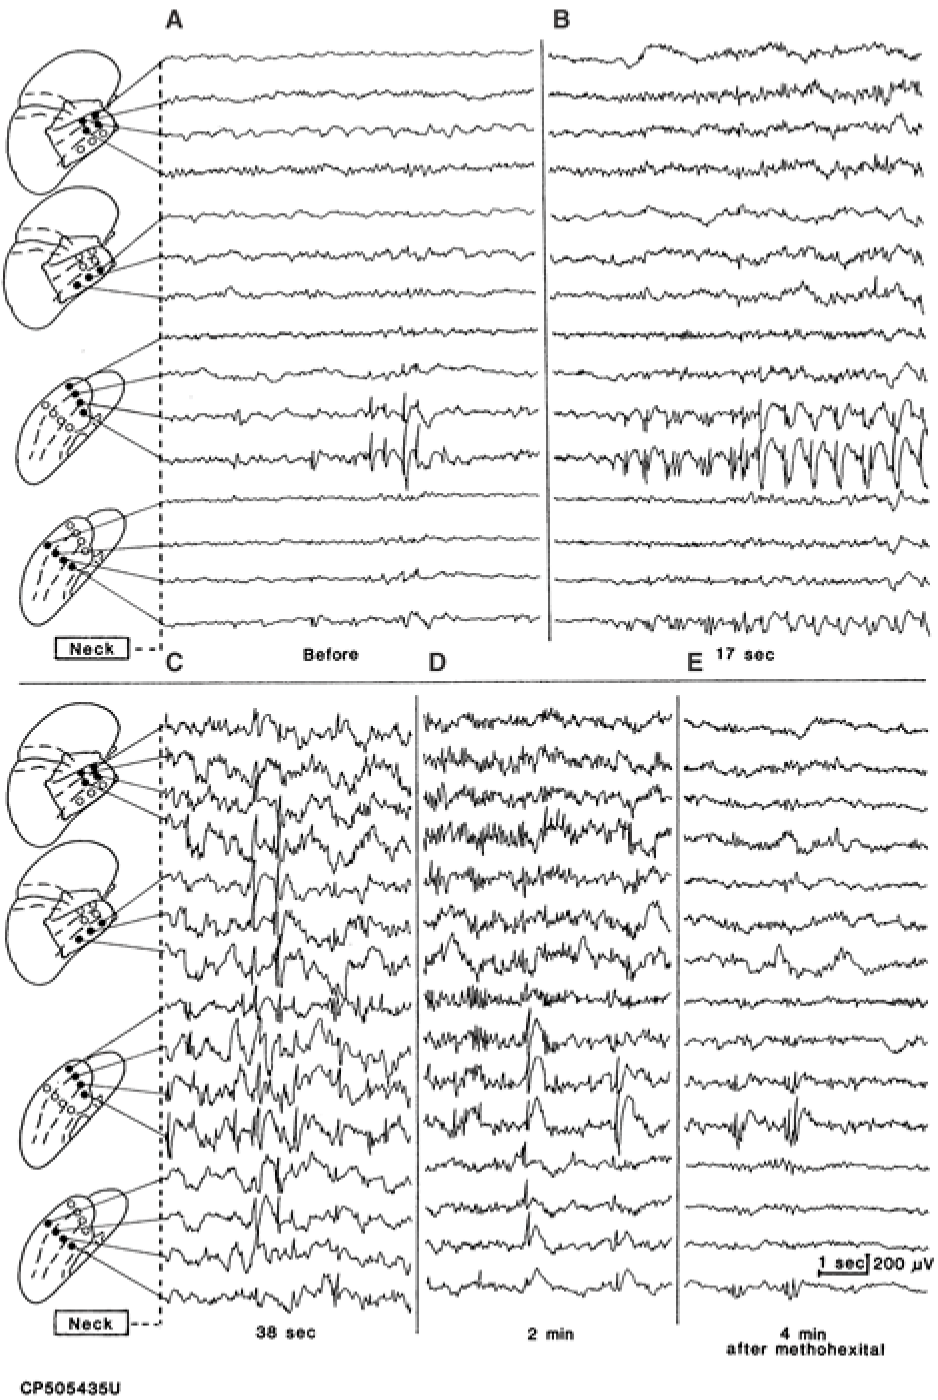

FIGURE 3. Twenty-three-year-old man with seizures characterized by feeling of weightlessness followed by loss of awareness and complex automatisms. Scalp EEGs showed sharp waves over the right anterior temporal and inferior frontal areas with some spread to adjacent regions. Before activation, intraoperative preresection ECoG shows right anterior inferomesial spike-and-slow-wave activity maximal over the uncus/anterior parahippocampal gyrus (**A**). After rapid intravenous injection of 100 mg of methohexital, the recording successively demonstrates repetitive spike-and-slow-wave activity in the same location as in **A** and beta activity in all areas surveyed (**B**); spikes and delta waves occurring diffusely or multifocally within the cortices explored (**C**); spiking confined to anterior infratemporal surface as well as decreased delta and increased beta activities (**D**); multiple spike-and-slow-wave activity restricted to the areas involved before activation, and further diminution of beta and delta

potentials (**E**). Patient fell asleep, and no ictal manifestations accompanied these ECoG changes. The hippocampus was slightly sclerotic with minor anterior herniation.

General anesthetics can influence epileptiform activity not only when rapidly injected intravenously to activate the EcoG, but also when used in relatively stable concentrations to produce general anesthesia.[66] However, even when anesthetics do suppress spikes, the intraoperative ECoG may still reliably reflect the awake interictal spiking pattern, provided that the spike frequency is >1 spike/min.[10] The opioid analgesics commonly administered during epilepsy surgery, whether performed under local or general anesthesia, can influence interictal spiking and offer no clear advantages over fentanyl.[20,45,66] On the other hand, neither propofol[102] nor nitrous oxide[51] is described as interfering with the awake ECoG. Large-dose propofol used as the sole anesthetic does not appear to trigger electrographic seizures in epilepsy patients.[25] These effects should be taken into consideration in choosing the anesthetic and analgesic agents to be used during epilepsy surgery.

Propofol is a particularly popular agent for conscious sedation during epilepsy surgery.[68] It produces a dose-dependent suppression of the EEG similar to barbiturates, and despite the role it might play in treating status epilepticus, it does not usually completely suppress spikes. It can enhance epileptiform discharges in some patients, and can produce burst suppression and electrical silence at high doses. Because of rapid metabolism, propofol can be used to induce sleep during the early portions of the craniotomy. Subsequent awake testing

and ECoG are then possible because of rapid elimination of the drug.[68]

Interpretation

Relationships Between Scalp Electroencephalogram and Electrocorticography Recordings

The intraoperative ECoG has peculiarities that distinguish it from the scalp EEG. In the absence of gross structural pathology, the same normal rhythms that characterize scalp recordings can be detected from the cortical surface. However, these potentials usually are much larger in amplitude and more sharply demarcated on the cortex than on the scalp.[8,46,55] In addition, because in the transmission of cortical potentials to the scalp, higher-frequency activity is attenuated to a greater extent than that of slower frequencies,[84] most rhythms tend to have a much sharper appearance in ECoG than in scalp recordings, and, in general, the ECoG contains more prominent and abundant beta potentials than the scalp EEG.[8] The presence of very sharp-appearing alpha and mu rhythms, variably reactive to eye opening and to contralateral limb movement,[58] sometimes makes it difficult for even experienced interpreters to distinguish individual components of these rhythms from spike discharges.

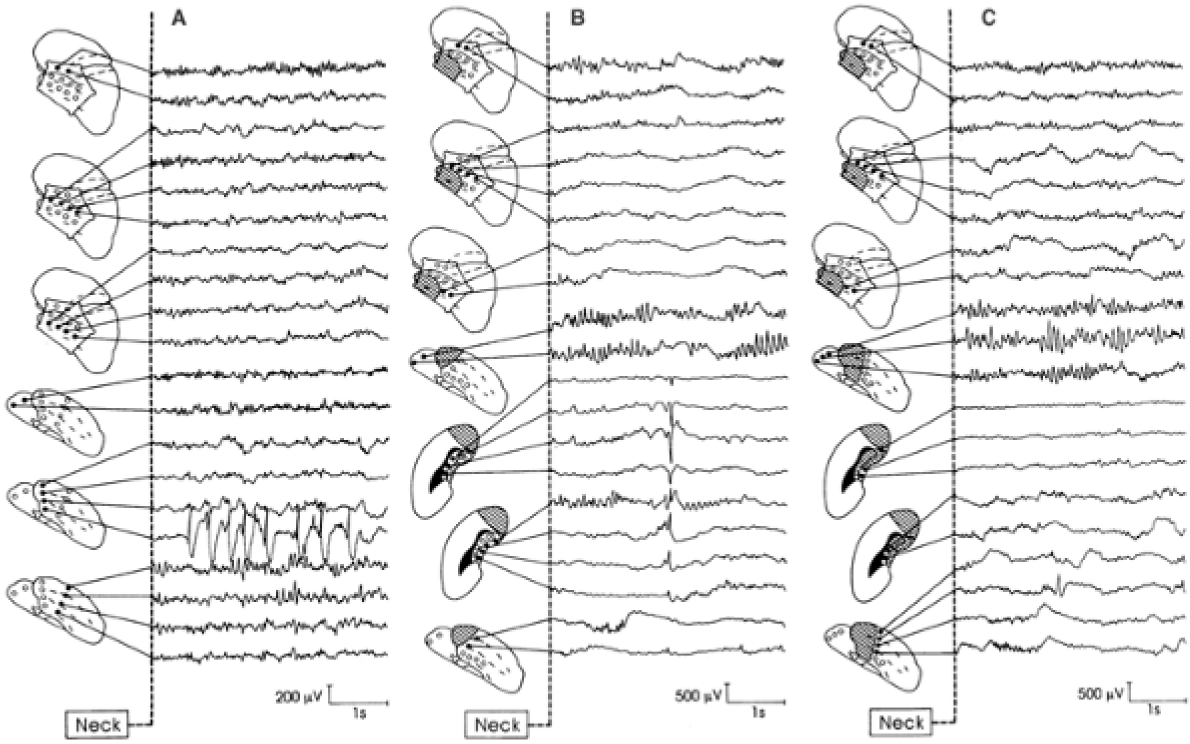

FIGURE 4. Thirty-three-year-old man with episodes of strange feeling, automatisms of hands, loss of awareness, and occasional tonic–clonic generalization. Scalp EEGs demonstrated spikes over the left mid- and posterior temporal regions. In the preresection ECoG, bursts of 2- to 3-Hz spike-and-slow-wave activity were detected over the uncus/anterior parahippocampal gyrus (**A**). After anterolateral resection, spikes occurred simultaneously over the hippocampus and the parahippocampal gyrus, with a major component that was positive on the former and negative on the latter (**B**). Following final ablation including 2.5 cm of hippocampus and parahippocampal gyrus, infrequent spikes and sharp waves occurred posteriorly to the inferomedial margin of the excision (**C**). Three years after surgery, patient was seizure-free.

Among the abnormal patterns recorded in the ECoG, interictal discharges, that is, spikes, sharp waves, and their variants, have features resembling those that characterize them in scalp recordings. However, cortically recorded spikes often attain amplitudes as large as 0.5 to 1 mV and can have durations as brief as 10 to 20 msec.[8] Special difficulties can be posed by the interpretation of areas of low-amplitude activity that can be caused by equipotentiality of electrodes linked in bipolar derivations, the shunting effect of pooling of saline solution, or structural pathology in the underlying cortex.[8] Similarly, in

P.1822

the absence of visually apparent structural alterations, it can be difficult to determine whether areas of arrhythmic delta activity apparent in preresection recordings are caused by surgical trauma, such as that related to division of adhesions, or by preexisting pathology.[6] In contrast, the finding in postresection ECoGs of similar alterations at and close to the margins of the resection can be more confidently attributed to the trauma of the excision.[8] Generally, artifacts caused by improper electrode contact, the electrocardiogram, pulsating blood vessels, or respiratory movements are easily identified, as are those related to surgical manipulations, including the spraying of saline solution and the use of electrocautery equipment.

ECoGs require instant, unhesitant interpretation that can have major consequences for the conduct of surgery, and they must be interpreted by an experienced clinical neuro-physiologist.[6]

Electrocorticography in Temporal Lobectomies

Patients with long-standing, medically intractable temporal lobe seizures most commonly demonstrate in their intraoperative preresection ECoGs interictal spikes whose distribution varies in a continuum from individual, relatively restricted, to widespread, often multiple areas of the temporal lobe (Fig. 4) and can variably extend into neighboring cortical regions, especially, but not exclusively, the frontal cortex[31,34,59,63,90,105,115] (Fig. 5). In a quantitative study,[109] 81% of spikes recorded before resection involved the infratemporal surface, 18% the lateral temporal, and 1% the orbital frontal regions. In this group of patients as a whole, interictal epileptogenicity decreased from inferomedial to lateral and from anterior to posterior portions of the temporal lobe, attaining a maximum over the uncus and the anterior portion of the parahippocampal gyrus. In keeping with observations by others,[18,86] following anterolateral temporal lobectomy sparing the hippocampal complex and providing access to the ventricular surface of the hippocampus, all patients in this study displayed interictal spikes over the hippocampus and the parahippocampal gyrus with temporal and polarity relationships suggesting that they were generated within either or both structures[110] (Fig. 4B).

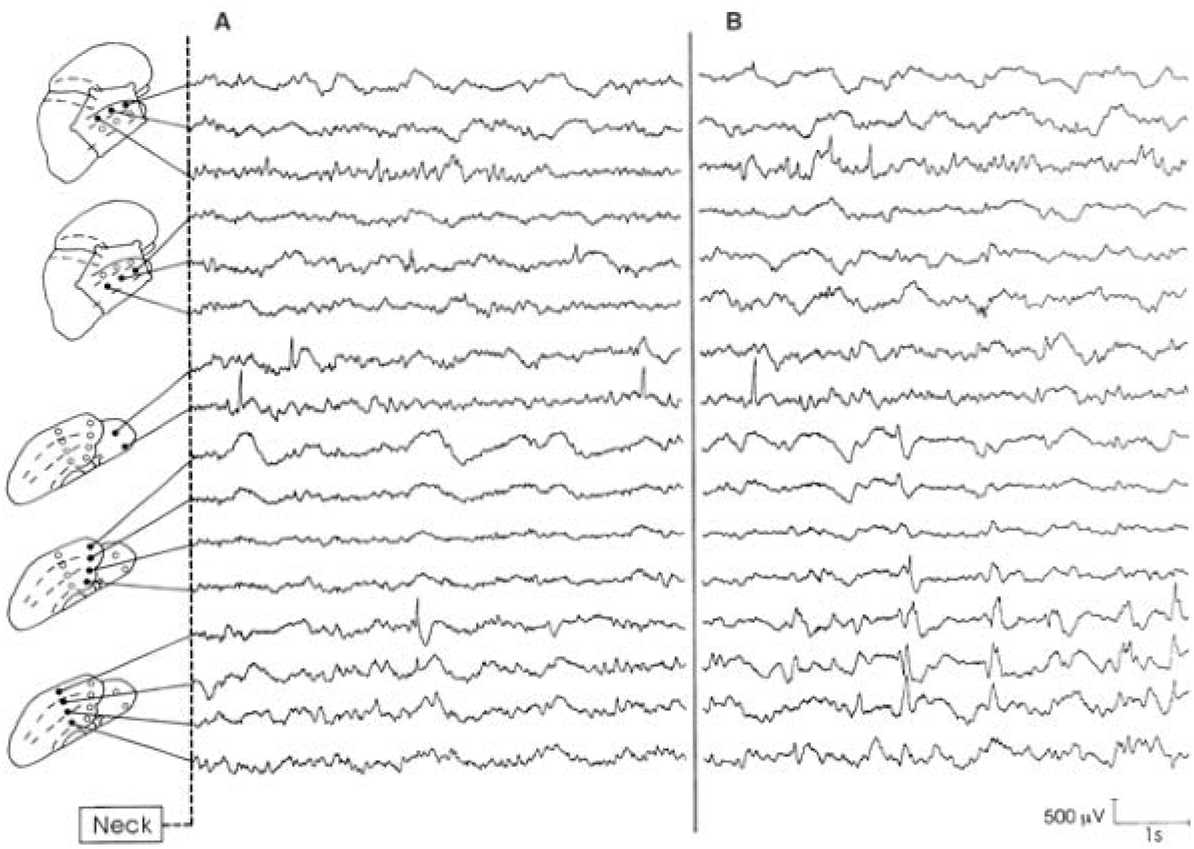

FIGURE 5. Thirty-one-year-old woman with episodes of dizziness, déja vu, automatisms of the upper extremities, loss of awareness, and occasional generalized tonic–clonic seizures. In preoperative scalp EEGs, sharp waves occurred over the inferior frontal and anterior and midtemporal regions. Interictal and seizure discharges detected in long-term subdural recordings arose from the infratemporal surface of the right temporal lobe. Intraoperative preresection ECoGs demonstrated spikes and sharp waves involving the right temporal and orbital-frontal cortices multifocally, as in this figure. (From Tsai M-L, Chatrian G-E, Pauri F, et al. Electrocorticography in patients with medically intractable temporal lobe seizures: I. Quantification of epileptiform discharges prior to resective surgery. *Electroencephalogr Clin Neurophysiol.* 1993;87:10–24, with permission.)

Although epileptiform activity is frequently detected and predominates in some patients, in extrahippocampal locations, spikes involving the hippocampal complex are the most common finding in the intraoperative ECoGs of patients undergoing temporal lobe resections. This is in harmony with the notion, long established by acute and chronic depth recordings, that the vast majority of temporal lobe seizures develop from the hippocampus, the amygdala, or both.[9,12,23,29,64,87,98,104,111,120] However, there is evidence that the demonstration of interictal hippocampal spikes in intraoperative ECoGs does not per se differentiate between mesial and neocortical temporal lobe epilepsies[18,75,110] and that no relationship exists between lateral or inferomesial and anterior or posterior temporal locations of the sole or primary ECoG spiking area and the type and location of pathology within or outside the mesial temporal region.[72]

Over the last six decades, numerous authors have variously expressed the belief that in patients suffering from chronic, medically intractable temporal (as well as extratemporal) epilepsies, the topography of intraoperative preresection spiking provided guidance in deciding the extent of excision of epileptogenic tissue.[7,14,38,48,59,83,92,105] Other investigators have disagreed with this view, and some have even advocated and successfully performed anatomically standardized temporal lobectomies without ECoG control.[28,36,103,106] Several observations[31,72] demonstrated lack of relationships between the presence of preresection spikes outside the ordinary limits of temporal lobectomy and seizure outcome. However, by far the strongest argument against the need to excise all or most of the preresection spiking area has been provided by the therapeutic success of amygdalohippocampectomy, which removes only a small portion of the region displaying spikes in individuals afflicted by mesial temporal lobe epilepsy.[72] The evidence suggests that the limits of the interictal spiking area in the preresection ECoG do not offer reliable clues regarding the amount of epileptogenic tissue to be excised to ensure the success of resective surgery in patients with medically intractable temporal lobe epilepsy, whether of mesial or neocortical origin.

The proportion of patients demonstrating spikes in their ECoGs after temporal lobectomy varies widely in different reports, from 22% to 85%,[7,31,38,110] although postresection spiking areas generally are significantly less numerous and less extensive and attain smaller maximal voltages than they did before resection[110] (Fig. 4C).

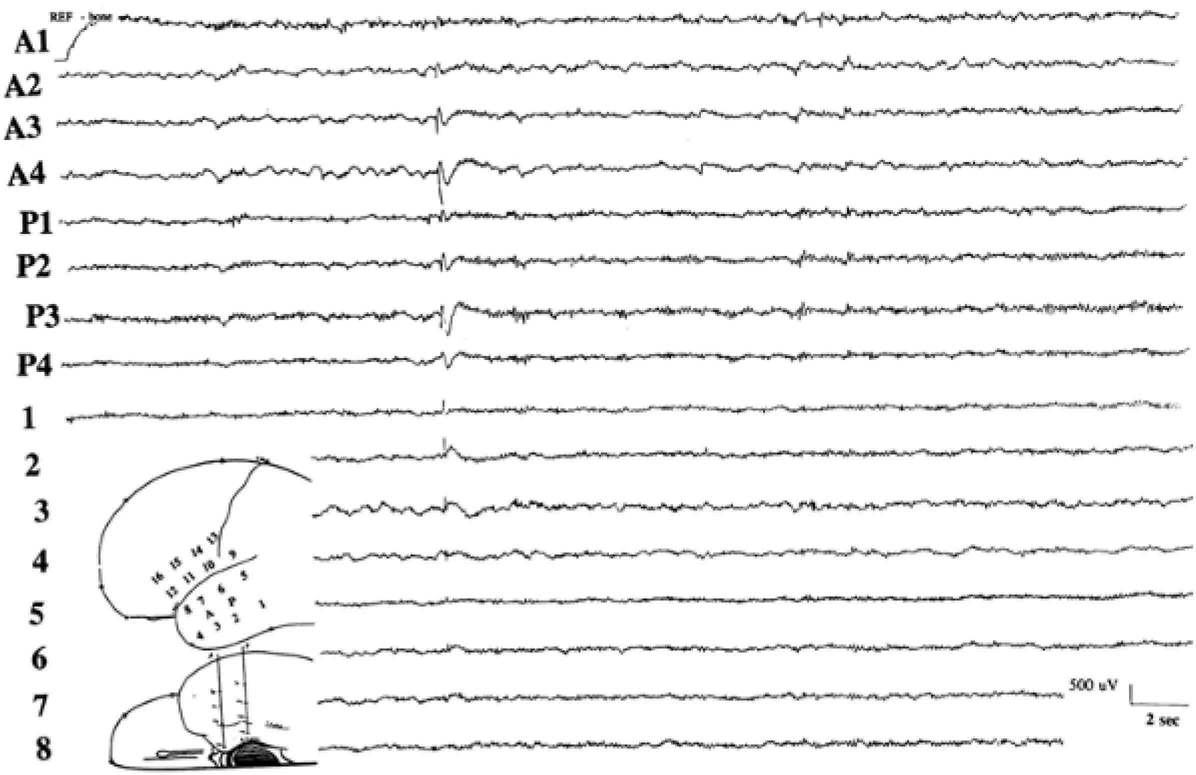

FIGURE 6. Thirty-six-year-old man with temporal lobe seizures. The EEGs demonstrated left temporal

interictal spikes, and MRI showed left amygdalar and hippocampal atrophy. Intraoperative preresection ECoG displays infrequent spikes involving most prominently the left inferior temporal gyrus, the amygdala, and the hippocampus, apparently simultaneously. A1–A4 and P1–P4, progressively deeper contacts along anterior and posterior depth electrodes inserted manually through the midtemporal gyrus and aimed at the amygdala and the anterior hippocampus, respectively. (From Cendes F, Dubeau F, Olivier A, et al. Increased neocortical spiking and surgical outcome after selective amygdalo-hippocampectomy. *Epilepsy Res.* 1993;16:195–206, with permission.)

The concept that the postresection ECoG can contain information predictive of postoperative seizure outcome has also been the subject of controversy for decades. Numerous authors affirmed the existence of a relationship between presence or absence of ECoG spiking after resections and poor or satisfactory postoperative seizure control, implicitly or explicitly advocating resection of as much spiking tissue as is compatible with avoidance of neurologic deficits,[4,6,8,14,46,55,56,57,59,65,101,105,112] whereas no such association was found in other series.[7,18,21,31,33,35,48,72,93,99,108] A more recent concept has evolved according to which in "tailored" temporal resections intraoperative hippocampal ECoG can be used to predict the extent of hippocampal resections.[61,68,74] In one study[74] of 140 consecutive patients who underwent an intraoperative tailored strategy for mesial temporal lobe epilepsy based on ECoG-guided hippocampal resection, no correlation was found between size of resection and outcome in the group as a whole or when stratified by pathologic subtype (mesial temporal sclerosis [MTS] vs. non-MTS). Individuals with large resections (>2.5 cm) were not more likely to have better outcomes than those with smaller resections, and the presence of postresection hippocampal spikes portended significantly worse outcomes in both MTS and non-MTS patients. These studies suggest that hippocampal ECoG can be used to maximize the probability of seizure-free outcome while

simultaneously possibly sparing functionally important hippocampus. There are also reports that ECoG can be very useful in guiding the extent of subcortical ectopic gray matter resection in cases of medial temporal epilepsy with this concomitant pathology.[76]

Electrocorticography in Amygdalohippocampectomy

The ECoG changes incident to selective amygdalohippocampectomy (sAHE) differ from those following temporal lobectomy. In patients with mesial temporal epilepsy whose preresection intraoperative ECoGs demonstrate variable amounts of interictal spiking, either confined to mesial temporal structures or also involving the lateral temporal surface (Fig. 6), sAHE is followed by a marked increase in frequency and a distinctive change in pattern of the epileptiform discharges most evident over the anterior temporal cortex (Fig. 7).[22,72,79] Increased spiking following this surgery is probably related to acute disconnection of preserved neocortical from excised mesial temporal structures and shows no significant relationship to the amount of epileptiform activity in postoperative scalp EEGs or to the degree of seizure control.[22] These observations strongly argue against the validity and general applicability of the concept that undiminished or increased epileptiform activity in the postresection ECoG presages unsuccessful seizure outcome following sAHE. On the other hand, a recent series of consecutive patients who underwent sAHE suggests that the preresection distribution of spikes on ECoG might predict outcome. Patients with spikes restricted to basal-mesial temporal lobe may be more likely to be seizure free than those with spikes on lateral temporal cortex as well.[24]

Electrocorticography in Extratemporal Resections

The intraoperative ECoG of patients afflicted by chronic, medically intractable neocortical epilepsies of extratemporal origin offers variable assistance in determining the location of the epileptogenic process and estimating the boundaries of the surgically relevant epileptogenic zone. Because of anatomic and functional peculiarities, the interictal spiking detected in the ECoG of patients with frontal lobe epilepsies varies in a continuum from localized to regional, multilobar, or even bilateral frontal or widespread distributions, with no clear relationship to the amount of epileptogenic tissue the removal of which would yield successful seizure control[89] (Fig. 8). Epilepsies arising in centroparietal cortices are also frequently associated with widespread epileptiform activity in intraoperative EcoGs,[88] and occipital epilepsies often generate discharges that spread variably to adjacent posterior temporal and parietal regions.[95] The distinctive tendency of epileptiform activity to be broadly distributed in the

P.1825

ECoGs of patients with uncontrollable extratemporal epilepsies is emphasized by observations indicating that interictal spikes extend outside subsequently resected tissue in as many as 75% of patients who underwent frontal lobectomy and in 91% of individuals treated by corticectomies in various locations, as opposed to 40% of patients in whom temporal lobectomies or amygdalohippocampectomies were carried out.[18,72]

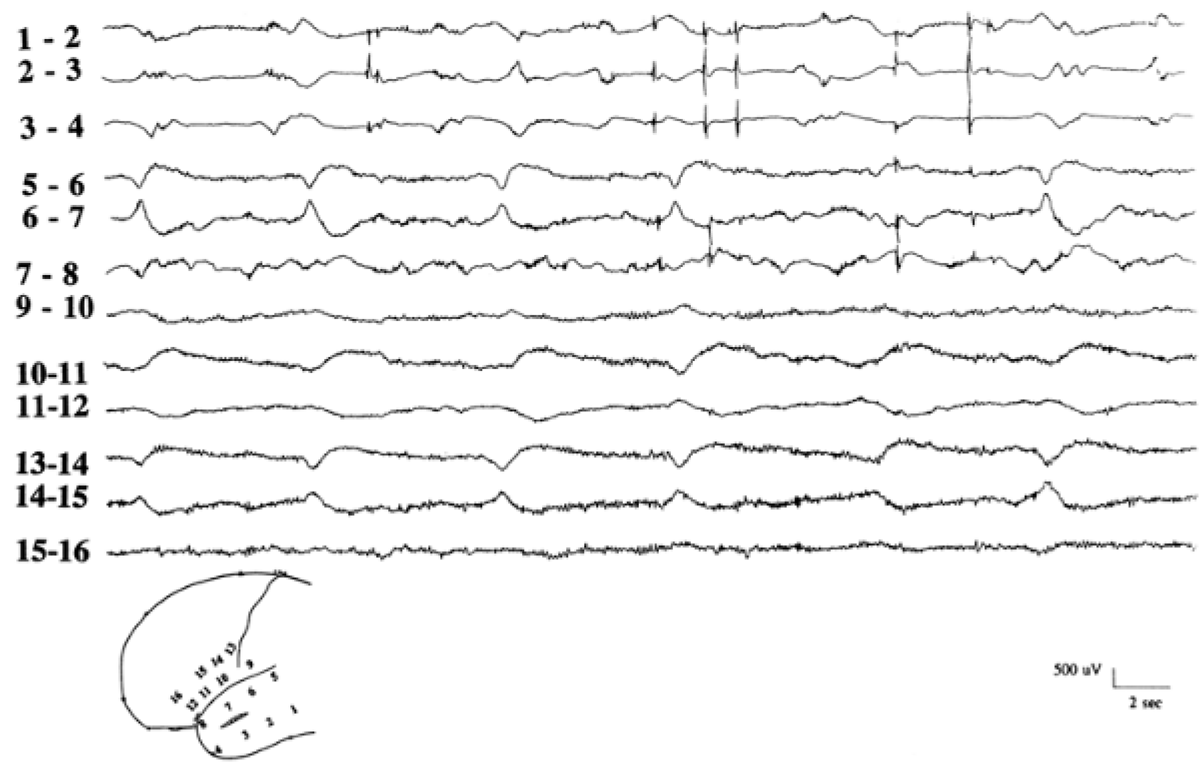

FIGURE 7. Same patient as in FIGURE 6. The ECoG after transcortical amygdalohippocampectomy shows frequent spikes over lateral temporal and suprasylvian cortices, with intervening periods of voltage depression and slow waves. (From Cendes F, Dubeau F, Olivier A, et al. Increased neocortical spiking and surgical outcome after selective amygdalo-hippocampectomy. *Epilepsy Res.* 1993;16:195–206, with permission.)

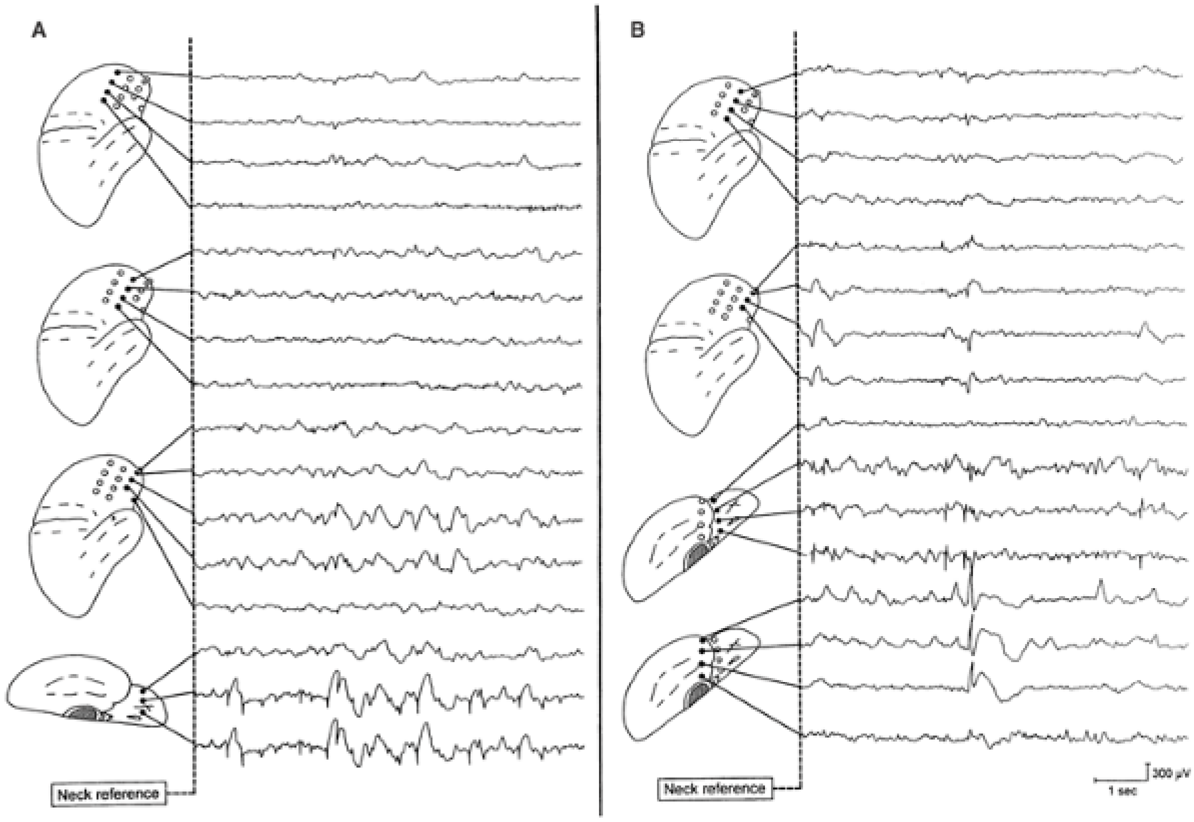

FIGURE 8. Thirty-one-year-old man with seizures characterized by body numbness and tingling, queasy feeling in stomach, frightened expression and vocalizations, gross body movements and flailing movements of arms and legs, and infrequent minor automatisms, followed by prompt recovery of responsiveness and denial of having lost consciousness. Occasionally, seizures were followed by tonic–clonic generalization. Scalp EEGs demonstrated frequent bilaterally synchronous spike-and-slow-wave activity maximal over the right frontopolar region and rare right temporal discharges. In long-term subdural strip recordings, interictal discharges involved and seizures developed from the right frontal lobe, multifocally or diffusely, both frontal lobes, or the right infratemporal surface. Intraoperative ECoG depicted here showed frequent spikes and sharp waves over the right orbital frontal and inferior frontal cortices, with complex polarity and temporal relationships, and spike-and-slow-wave activity and sharp waves over the right infratemporal surface. Two years after surgery, patient was seizure-free.

Although the precise boundaries of the surgically relevant epileptogenic area cannot be determined by ECoG, there is evidence that in frontal lobe epilepsy, ECoG findings do have prognostic significance. In both nonlesional and lesional frontal resections, when preresection spikes are restricted in distribution to no more than two gyri and postresection spikes are absent, a favorable outcome can be anticipated.[118,119] Removal of ECoG-identified, dispensable epileptogenic cortex on the margins of highly epileptogenic neoplastic, developmental, malformative, or cicatricial lesion in any location yields better seizure control than lesionectomy alone.[19,85,97,107] Cortical resection guided by ECoG in cases of porencephaly can result in effective seizure control while preserving motor and visual function.[53] Studies also indicate that the ECoG demonstration of frequent or continuous discharges over neuroimaging- or histologically identified cortical dysplasias characterizes highly and intrinsically epileptogenic cortex the ablation of which successfully controls the patient's seizures in an appreciable proportion of cases[50,81] (Fig. 9). In contrast, direct cortical recordings contribute some information that can be helpful but is not essential in the resection of large hemispheric lesions by hemispherectomy, hemidecortication, or multilobar removals.[113]

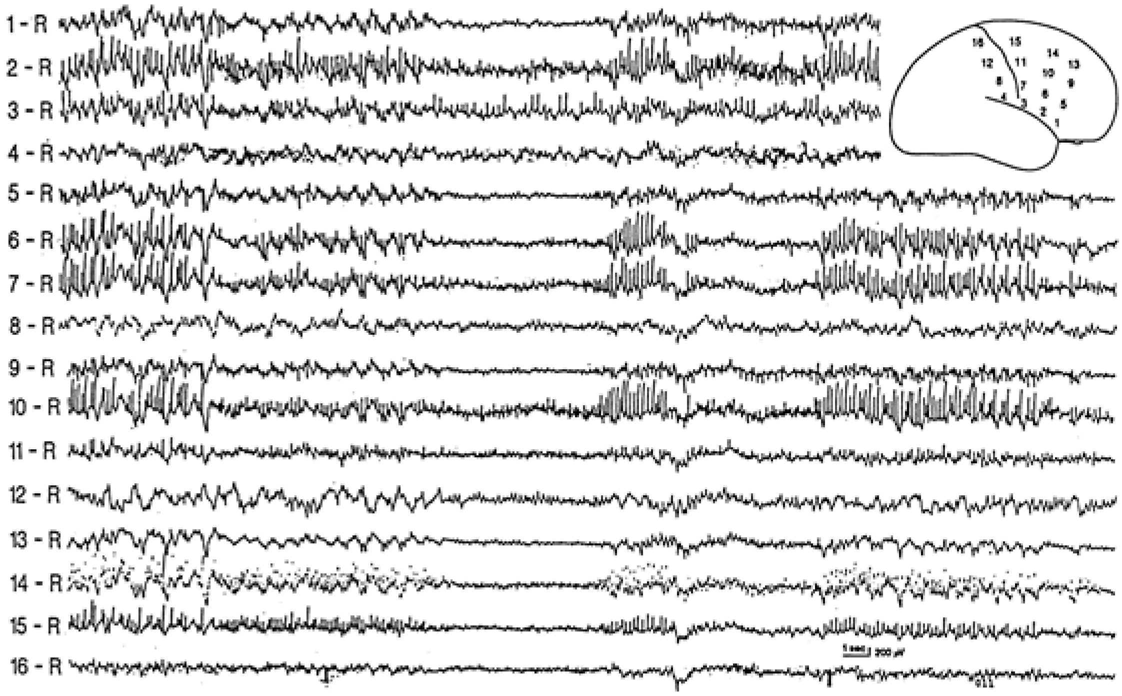

FIGURE 9. Seven-year-old girl with quasi-continuous spikes and sharp waves over the right frontocentral region in her scalp EEG and a right frontocentral dysplastic lesion demonstrated by MRI. Her intraoperative ECoG shows bursts of spikes of variable amplitude and duration detected diffusely from the right frontocentral cortex, as in this figure. (From Palmini A, Gambardella A, Andermann F, et al. Intrinsic epileptogenicity of human dysplastic cortex as suggested by corticography and surgical results. *Ann Neurol.* 1995;37:476–487, with permission.)

Electrocorticography in Cortical Disconnection Surgeries

The utility of the ECoG in cortical disconnection surgeries, including multiple subpial resection and corpus callosotomy, is not clearly established. Morrell et al.[77] reported that following multiple subpial transections performed to relieve intractable partial seizures caused by epileptogenic processes encroaching on nonresectable cortical regions, the ECoG from the transected area generally demonstrated immediate depression of all activities followed by recovery of background rhythms but not of epileptiform discharges. In contrast, in a preliminary study, Binnie et al.[18] reported that ECoG spike rates following this surgical procedure varied from complete abolition to 200% increase without demonstrable relations to either seizure outcome or completeness of transection.

Binnie et al.[18] used ECoG recordings to determine the effects of successive stages of callosotomy on the bilateral synchrony of epileptiform discharges detected before the procedure. Although a better clinical outcome was observed among patients in whom the bilateral synchrony of epileptiform activity was disrupted by callosal section, they questioned the validity of this result because of possible biased preresection findings in their small series. A recent report of children with Lennox-Gastaut syndrome who underwent anterior callosotomy disclosed that blockage of bisynchronous discharges in ECoG during callosotomy was not correlated with a prognosis that differed significantly from cases in which blockage did occur.[69] Thus, there is no adequate evidence that ECoGs are more reliable than surface EEGs in monitoring the immediate effects and prognosticating the results of corpus callosotomy.

P.1826

Advantages and limitations of Intraoperative electrocorticography

Advantages

1. Intraoperative ECoG allows entirely flexible placement of recording and stimulating electrodes within the surgical exposure and on accessible adjacent cortices.
2. Intraoperative ECoGs detect large numbers of interictal discharges that are not apparent in EEGs, whether recorded with conventional scalp electrodes only or combined with auxiliary scalp or facial leads and nasopharyngeal, sphenoidal, or foramen ovale electrodes.
3. ECoGs offer the opportunity to perform direct electrical stimulation of the brain to elicit afterdischarges, possibly reproduce clinical manifestations of the patient's habitual seizures, and delineate functionally eloquent cortical areas.
4. When performed with the appropriate technique, ECoGs are free of many of the artifacts that hinder recordings not taken directly from the brain.
5. New electrode placements can be devised at each stage of the procedure to answer the questions raised by findings of the previous stage.
6. Recordings can be taken before and after each stage of resection to determine the presence or absence and features of postresection spikes.
7. ECoG findings, particularly when combined with the results of functional mapping (Chapter 174), can offer guidance in determining the extent of resection.

Limitations

1. Intraoperative ECoG requires previous lateralization and at least broad localization ("regionalization") of the epileptogenic process.
2. With some notable exceptions, no spontaneous ictal activity is recorded intraoperatively.

3. Interictal spiking might be absent entirely, or the full extent of the interictal spiking area might not be observed in the course of a relatively brief ECoG. This can lead to performance of surgery without ECoG monitoring and use of activating procedures the results of which can raise interpretive problems.
4. It is not possible to survey during surgery the lateral and inferior temporal lobe surfaces simultaneously with the amygdala and hippocampus without violating the integrity of these structures. In addition, medial and inferior hemispheric surfaces are not accessible through standard craniotomies designed for temporal lobe resections.
5. The background activity and ECoG spiking rate and distribution are variably influenced by general and local anesthetics, opioid analgesics and other drugs, surgical trauma, and state of the patient (wakefulness, drowsiness, or sleep). These factors can raise difficulties in interpretation.
6. Waking intraoperative ECoGs might not be suitable for uncooperative adults and children.
7. The method requires additional equipment, personnel, and expenditure of time.

Complications

Prolongation of surgery and cortical exposure by about 90 minutes could conceivably result in some increase in morbidity, but this has not been demonstrated and quantified. The occurrence of a fully developed partial seizure with prolonged confusional state is likely to cause delay or abandonment of further ECoG and cognitive testing. In addition, the possible precipitation by electrical stimulation of a generalized tonic–clonic seizure possibly carries risks because of the development of acute edema and herniation of the brain through the open craniotomy. However, we found no information in the literature on the frequency of these complications.

Future Directions

The availability of computer-based digital recording systems and networking technologies offers the opportunity to modify the traditional instrumentation and promote new approaches to the analysis of the intraoperative ECoG. By using an instrumental setup such as that suggested in FIGURE 10, one can survey as many as 64 to 128 brain sites simultaneously. These recordings are displayed on high-resolution monitors at multiple locations, including the operating room gallery, the operating theater, and the EEG suite. A closed-circuit color television system can provide both the clinical neurophysiologist and the operating room staff with a detailed view of the surgical field at the same locations, and an intercom system can allow communication between the clinical neurophysiologist and the neurosurgeon while a microphone records the patient's verbalizations. The synchronized ECoG, surgical field images, and verbal communications are stored on appropriate media for later retrieval. The digitized, referentially recorded ECoG can be formatted on- or off-line in any desired referential, bipolar, or mixed montage. Such a system would offer the clinical neurophysiologist the option of conducting the whole or part of the ECoG procedure from a location remote from the operating theater whenever desired. However, more important would be the acquired capability to supplement the visual appraisal of the ECoG with a variety of computer analyses. These could be designed to aid not only in the recognition and quantification of epileptiform discharges, but also in the assessment of their topographic and morphologic features and patterns of propagation and in the differentiation between primary and secondary

areas of epileptogenesis.[46,67,70] These analyses can increase the localizing power of the ECoG and improve the accuracy of estimation of the epileptogenic zone. We also view as desirable the inclusion in the recording system of stimulus artifact reduction capabilities making it possible to record the ECoG during stimulation, and the development of digital recording systems with sampling rates allowing the recording and storage of ECoG signals with a broader bandpass, such as DC to 300 Hz.[41] This last feature would facilitate the study of events having faster[41] or slower[49] frequencies than those recorded with current instrumentation.

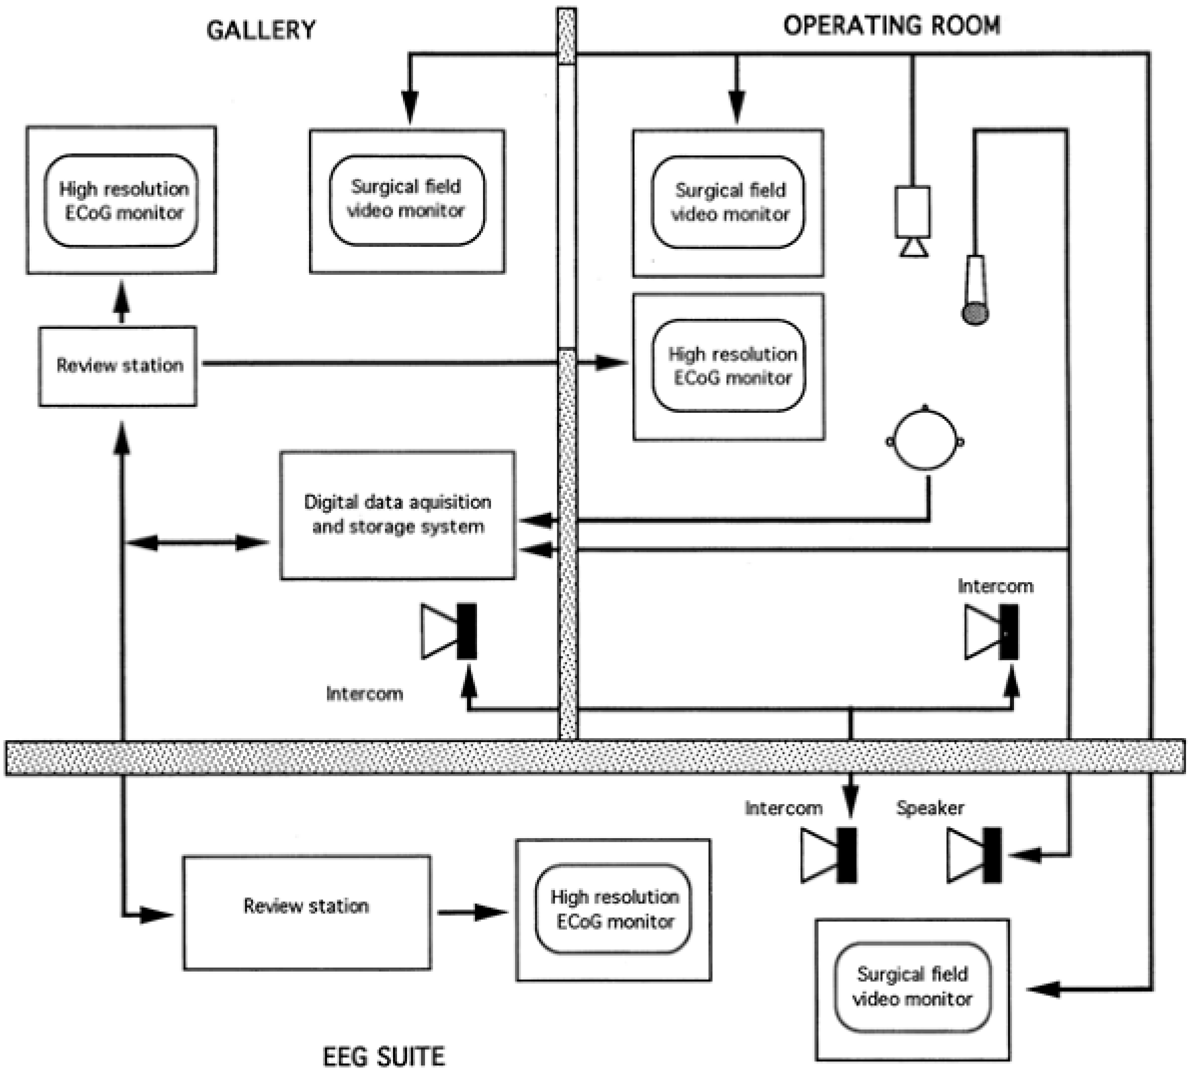

FIGURE 10. Diagram of suggested physical arrangement and computer-based instrumentation for ECoG recording and analysis.

An especially promising development is that the rapidly improving resolution of magnetic resonance imaging increasingly offers the opportunity to visualize the structural location of functional abnormalities of the brain by generating three-dimensional anatomic maps on which different functional images, such as those from functional MRI, PET, SPECT, magnetoencephalography, EEG, evoked potentials, and ECoG, can be superimposed. Frameless stereotactic systems interactively guided in the operating room by multimodal neuroimages, including the ECoG, are already in operation in several centers.[30,80] Their use is hoped to improve the precision of epilepsy surgery and provide novel insights into normal brain function and its aberrations in epilepsy.

Summary and Conclusions

No individual feature of the preoperative ECoG, as we presently assess it, is clearly indicative of the site of origin and pathophysiologic mechanisms of the patient's seizures, the site and nature of pathology, when any is demonstrable, or the extent of the epileptogenic zone Nevertheless, the method plays a major role in tailored temporal resections, which are based on the practice of excising only those regions of resectable hippocampus shown to demonstrate ECoG-identified interictally spiking tissue. In contrast, ECoGs serve no practical purpose in anatomically standardized temporal lobectomies. The method may be potentially misleading in selective amygdalohippocampectomies, which are typically followed intraoperatively by a marked increase of interictal spiking unrelated to seizure outcome, although preresection ECoG in these cases may relate to outcome. In frontal lobe and other extratemporal epilepsies without preoperatively identifiable structural pathology, the ECoG is of limited assistance in localizing the epileptogenic zone, although preresection spike distribution and post-resection spike presence or absence may have prognostic significance.

In the presence of a neuroimaging-demonstrated localized lesion, the utility of the method depends on factors that include

the nature and extent of pathology and the surgical approach chosen, among others. Removal of gross structural lesions and of extrinsic, dispensable epileptogenic tissue and excision of highly intrinsically epileptogenic, dysplastic cortex depend in large measure on clues provided intraoperatively by the ECoG. In contrast, the utility of this method is questionable in the resection of large hemispheric lesions by hemispherectomy, hemidecortication, or multilobar removals and is not clearly helpful in cortical disconnection surgeries such as multiple subpial transection and corpus callosotomy.

Changes in ECoG instrumentation, mostly based on available technology, are suggested. A major potential advantage of these modifications is the ability to apply powerful methods of computer analysis to the ECoGs with the hope of increasing the localizing power of this technique. In addition, especially promising is the recent introduction of image-guided neurosurgical systems that make it possible to determine interactively in the operative room the location of electrodes used to record the ECoG and other functional images relative to the underlying CT- and MRI-determined three-dimensional anatomy of the patient's brain.

Chapter 173

Intraarterial Amobarbital Procedures

Marilyn Jones-Gotman

Mary Lou Smith

Heinz Gregor Wieser

Introduction

Successive hemianesthesia of the two cerebral hemispheres elicited by injection of an anesthetic agent into the internal carotid artery has been practiced for >40 years. The technique is highly specialized and highly specific: It is performed in some patients who will undergo elective brain surgery. A simple rationale underlies this procedure: Temporary anesthetization of one hemisphere should allow the awake hemisphere to be tested alone, and the results of those tests should allow prediction of certain possible sequelae of the proposed surgery. It is an essential part of neuropsychological evaluation in most epilepsy centers and is carried out for two different purposes: (a) to determine cerebral dominance for language and (b) to evaluate memory function in each hemisphere independently.

This procedure was originally introduced in North America in the late 1950s by Juhn Wada,[118] and hence the frequently used nickname, “Wada test,” despite the now-formal appellation “intracarotid amobarbital procedure” or IAP. The basic procedure has undergone very little change over the years, with a few exceptions. One exception is the brain region targeted for anesthesia: Some centers use more selective procedures that target the medial temporal lobe (anterior choroidal artery) or language areas. Another exception is the use of other anesthetic agents in recent years; these are discussed later in a section about techniques. For simplicity, throughout most of this chapter we refer to these anesthetic procedures collectively as IAPs.

Indications

In some institutions, all surgical candidates receive an IAP as part of the presurgical workup. In others, only certain patients undergo this procedure. When only selected patients receive an IAP, it might be performed because cerebral dominance is uncertain, or it might be indicated for further assessment of memory. Whether the test is being performed for evaluation of language or of memory, the actual procedure is the same.

Language

An IAP to assess cerebral dominance is performed when there is reason to suspect an atypical cerebral organization for language, because this might interfere with the planned surgical intervention. Left-handed individuals, those with a strong family history of left-handedness, and people with evidence of early damage in or near speech areas of the left hemisphere fall into this category. Patients whose anatomical and functional (cognitive) lateralization is discordant are also candidates for an IAP because in such cases the mismatch can reflect right-hemisphere speech dominance. Dichotic-listening tasks are sometimes used as a screening test for atypical speech representation. In those tasks, competing verbal stimuli are delivered simultaneously to the two ears, with the expectation that the stimuli will be perceived best by the ear opposite the speaking hemisphere.[113,129] If there is little or no difference between the ears, or if best performance is observed from the left ear (right hemisphere) in the presence of normal hearing, then an IAP to determine cerebral speech dominance may be performed.

Memory

Patients are selected to undergo an IAP for memory evaluation based either on the presence of significant deficits on verbal and nonverbal memory tests uncovered during a basic neuropsychological assessment or on electroencephalogram (EEG), anatomic magnetic resonance imaging (MRI), or other evidence suggesting bitemporal damage. An IAP might also be performed in cases of mismatch between EEG and anatomic MRI findings such that an EEG focus is observed in one temporal lobe and a significantly small hippocampus is found on the opposite side.

Techniques

The basic technique involves injection of an anesthetic agent, usually sodium amobarbital, into one cerebral hemisphere, usually through the internal carotid artery. This anesthetizes the injected hemisphere and allows one to test the abilities of the awake hemisphere in isolation. With this agent and this technique, the effect is short and is usually dissipated after about 6 to 8 minutes,[10,102] depending on the dose[21,70] and individual differences[31] (a procedure with different timing is discussed later under "alternative drugs and techniques"). During the effect, simple speech and memory tests are administered. The tests are kept simple because the effect is short, patients must perform them with a single hemisphere, and the basic clinical questions asked by this procedure can be answered adequately with simple tasks.

Neuropsychologists usually administer the cognitive tests. An angiogram is obtained before the IAP to make sure that there is no serious vascular anomaly and to predict the distribution of the drug; this is done by a radiologist, who also performs the injection. The effect of the drug on the brain is monitored by EEG[92,107]; in some institutions this is done online during the test, and in others the EEG is recorded on a computer for playback and blind interpretation by an electroencephalographer afterward.[2,10,26] The patient's recovery from the hemiplegia that is induced by amobarbital injection is also monitored to estimate return of function, although this estimate is less satisfactory[10,17] (but see Bookheimer et al.[9]).

P.1834

Testing Paradigms

Before injection, basic speech and memory tests are performed to establish a baseline. On injection, more speech and memory tests are administered while only one hemisphere is functional. The same speech tests as used in baseline testing are performed after injection, but new memory material is shown. Memory for the new material is tested later, after the drug is no longer active and the injected hemisphere has returned to baseline functioning.

IAP speech tests sample different aspects of language, including serial or automatic speech (counting, reciting days of the week), naming, repetition, spelling, reading, and auditory comprehension (see, e.g., Fedio et al.[21] and Ravdin et al.[102]). Cerebral dominance should not be assessed with a single task because dissociations among types of speech functions are sometimes observed.[11,103,110] Tasks should be rotated throughout the crucial period of hemianesthesia so that all can be sampled.

Superimposed on the basic methodology of memory testing during the IAP are the many variations used by different institutions. The number of items introduced after injection to test the formation of new memories varies from only a few, such as five,[46] to continuous presentation for as long as the hemianesthesia is present.[67,100,101] The timing of memory item presentation can also vary.[72] Some centers[15,16] test memory using a mixture of materials that includes words, pictures, phrases, and commands, whereas others use all words or all pictures or all real objects. Real objects have the advantage of being perceived more easily by either hemisphere.[52] In most but not all centers the final interpretation of memory results is based on the patient's ability to recognize later the new material that had been shown during hemianesthesia, but free recall is taken into account in some institutions.[104] Despite this lack of uniformity in details of IAP memory-test methods, the essence of the procedure does not differ, and results from one institution can usually be interpreted by another.

Selective Studies

Although most centers carry out a "standard" intracarotid amobarbital test, some perform special procedures for selective temporary inactivation of temporal and extratemporal structures. The development of selective temporal lobe (TL) amobarbital tests was motivated by skepticism about the ability of "standard" IAP to predict postoperative memory performance in patients who would receive a TL resection,[69] especially a restricted resection such as selective amygdalohippocampectomy.[125] The main reasons for the skepticism were that the hippocampal formation may not be sufficiently anesthetized with the IAP[42] (but see refs. 26, 79, and 80) and that inactivation of large parts of one hemisphere does not allow examination of the functional role of the specific structures of interest. Furthermore, the sudden anesthesia of one hemisphere can produce an initial period of confusion, inattention, and disorientation, as well as aphasia if the speech-dominant hemisphere is involved. These side effects interfere with memory testing.

For anesthesia of medial TL structures, at least three selective procedures were developed—two anterior procedures and a posterior one. One *anterior* procedure[120,121,122,123,124] consists of a temporary balloon occlusion of the internal carotid artery distal to the origin of the anterior choroidal artery (acha), with subsequent injection of amobarbital into the territories of the acha, the posterior communicating artery, and the opthalmic artery. The second anterior procedure is a selective catheterization of, and injection of amobarbital into, the acha. Whether the selective inactivation of medial temporal-lobe structures by injection into the anterior choroidal artery has the advantages that are claimed for it should be verified by further studies.

The *posterior* TL amobarbital test[42,43,94,120,123] consists of selective catheterization and subsequent injection of amobarbital into the P2 segment of the posterior cerebral artery.

In the hands of an expert interventional neuroradiologist with appropriate sophisticated catheter techniques, *extratemporal* brain regions can be selectively approached and temporarily inactivated by amobarbital. Because of the inherent risks of such procedures, they are rarely performed. The need for extratemporal amobarbital testing arises if the function of the brain region under consideration involves potential essential cortex, such as classic speech or motor areas, or if the alternative approach of intraoperative functional mapping with the patient awake is not possible. Between October 1986 and December 2005 the Zürich group carried out selective amobarbital tests in 106 patients, only 6 of whom received an extratemporal procedure. One of these was a selective inactivation of Broca's region in a patient slated for resection of a tumor invading the left frontal operculum, 1 was a regional left frontal inactivation in a patient with a left anterior frontal epileptogenic lesion, 1 was a sequential Broca and Wernicke inactivation, 1 was a left posterior insula and Wernicke inactivation, and the remaining 2 underwent inactivation of selected branches of the middle cerebral artery.

Selective procedures are carried out far less frequently than the "standard" IAP; in a survey of epilepsy centers it was determined (among 68 respondents) that only 4% of all amobarbital procedures performed annually were selective.[101] Although no newer survey has been conducted, a PubMed search yielded only 13 articles about selective amobarbital procedures in the period from 1996 to 2006. This represents 5% of the approximately 250 articles that were published about the IAP in that same time period. Furthermore, judging by those publications, most selective procedures are being performed in Europe. The largest series of selective tests has been performed by the Zürich group; for details of their results, including angiographic, clinical, electroencephalographic, positron emission tomography (PET), and single photon emission computed tomography (SPECT) findings and memory performance, see Wieser et al.[123]

Alternative Drugs and Techniques

Owing to repeated shortages of amobarbital, within but especially outside of the United States, some centers have switched to other drugs. The most frequent alternative has been methohexital,[3,13,41] but propofol has also been used.[6,108,115] Clinicians who use methohexital are pleased with it as an alternative to amobarbital. It has an important limitation, however, in that it is so short-acting that it usually has to be reinjected within a test, leading to waxing and waning of the effect at least twice within critical testing time. This lack of control over the level of anesthesia is a problem for presentation of new memory items and consequently for interpretation of memory results. Propofol, which is used in the same way as amobarbital with a single injection and subsequent waning of the effect, is also problematic because it must be injected in a lipid carrier. It is a newer alternative, and has been used in only a few patients except for one series of 12[115]; the articles about propofol have also reported overall satisfaction with it. A third alternative, etomidate, has been used successfully in >42 patients (84 tests), and in this case the alternative also includes an important change in the procedure: In the etomidate Speech and Memory test (*e*SAM), the level of anesthesia is maintained with an infusion following the initial bolus injection.[52] This allows all critical speech and memory tests to be administered

during full hemianesthesia, eliminating the time pressure during test presentation, and consequently eliminating the incidence of uninterpretable memory tests that occur in the IAP owing to presentation of items when the drug is no longer active. The limitation for *e*SAM is that in about 45% of the first 26 tests performed, a side effect was observed that consisted of a shiver-like tremor. This was very mild or almost imperceptible in more than half of those incidents and was seldom noticed or remembered by the patients.

There were no serious adverse effects reported for any of these three alternatives to amobarbital.

Another agent is also used for a different but related purpose: Lidocaine has been used together with amobarbital for patients with cerebral arteriovenous malformations (AVM) who undergo superselective intraarterial injections and behavioral testing (language, memory, motor) before receiving embolization to treat the AVM.[23,98] According to Fitzsimmons et al.,[23] the reason for including lidocaine in those procedures is that amobarbital selectively inhibits gray matter structures, whereas lidocaine inhibits white matter tracts as well. They found that using both agents provided a fuller picture in predicting possible deficits following embolization of AVMs.

Interpretation

Speech and memory results from an IAP (or similar anesthetic procedure) can be interpreted only if the test is valid. Slow waves in the EEG and contralateral hemiplegia provide information that the drug is active, a necessary prerequisite to a valid test,[50] but it is also necessary to know that the test is indeed assessing what it aims to test. It is not valid if the patient is not attentive[40] or is not actively participating. Therefore many centers also monitor level of consciousness during the IAP.[76,82]

Given a valid test, interpretation of *speech* results is most often clear and simple. The results are unambiguous when a patient is aphasic while the drug is active after injection in one side and continues talking without significant errors after injection into the opposite side. This is the most common pattern. However, in cases of bilateral speech representation a range of different patterns can be observed. These include (a) disruption of all speech functions tested after injection in one hemisphere with minor but significant disruption after injection in the other; (b) dissociation of type of disruption (e.g., naming in one hemisphere and comprehension in the other); (c) equal and significant disruption in both hemispheres; and (d) no obvious disruption in either hemisphere. Interpretation of bilateral speech differs among institutions,[103] and as a consequence reports of the incidence of this type of atypical language organization varies widely.[101,109]

Underlying the interpretation of the *memory* application of the IAP is a basic assumption that the patient will have to rely on the awake hemisphere to remember material shown while the drug is active, and that the material will not be remembered if the awake, or noninjected, hemisphere is damaged.

The important test for memory is when the hemisphere of the planned surgery is injected because in that case one is testing the memory function of the hemisphere that will be left intact. It is expected that in that situation the test should predict how well the patient's memory will function after resection from a temporal lobe. In addition, ideally memory should be impaired when the hemisphere of planned surgery is tested (injection into the healthy hemisphere) because that result provides confirmation on dysfunction in memory structures that are to be resected.

A second assumption underlying IAP memory tests is that they are addressing the adequacy of hippocampal function specifically.[84] Therefore, in some centers a limited resection that spares hippocampus is performed in patients who fail amobarbital memory tests after injection into the hemisphere of a planned temporal lobe excision. In some other centers, surgery is denied altogether to such patients, whereas in still others operation with encroachment on the hippocampus has been offered. Thus, failing an IAP memory test can have important consequences for a patient's surgical management, but the consequences differ among centers.

Failure of an IAP memory test is also defined differently in different centers. Indeed, the way that the IAP memory-test results are interpreted is changing, and the concept of simply passing or failing is becoming infrequent. In many centers the test is used in a more general sense to predict postoperative memory performance, without specific reference to "failure" or to amnesia (see, e.g., Kneebone et al.[58]). It is also used as additional evidence in determining the side of epileptic focus when injection opposite the supposed focus results in substantially poorer memory performance than when injection was made on the side of suspected focus.[20,93,128]

Implications

One reason for carrying out an IAP is to screen for a risk of potential severe memory loss after resection from a temporal lobe, but it is very difficult to prove whether this test actually does predict amnesia. If patients who have failed amobarbital memory tests are denied surgery, or if they do undergo surgery but the hippocampus is spared, one cannot know whether they would have become amnesic if an extensive removal of hippocampus had been performed.

Some evidence does exist, however. There are two known cases of postoperative amnestic syndrome in patients who had been designated by IAP to be a risk and who still underwent resection from a temporal lobe.[68,99] Furthermore, in a survey of 71 epilepsy centers concerning IAP issues, an additional four such amnesic cases were reported,[101] and a later publication reported an additional patient who became globally amnesic for an extended period of time but who gradually recovered to a state of deficient memory but not amnesia.[28] Many other patients who have undergone temporal lobectomy after "failing" the memory test have not developed amnesia.[17,19,71]

Evidence that the IAP memory test does address hippocampal function can also be found. Sass et al.[106] counted hippocampal cells in resected temporal-lobe tissue and showed that patients with severe cell loss had shown deficient memory during the relevant amobarbital test when injection had been made opposite that damaged temporal lobe. Similarly, studies examining amobarbital memory performance as a function of hippocampal atrophy, as measured on magnetic resonance imaging (MRI), show significant memory failures after injection opposite the hemisphere harboring hippocampal atrophy and good memory after injection opposite a normal hippocampus.[51,75]

The foregoing results suggest that we are indeed testing hippocampal function with amobarbital memory tests. We infer further that doing so indeed allows us to predict postoperative memory loss, although this remains difficult or impossible to prove. Studies of later memory performance in patients who have passed versus those who have failed IAP memory tests suggest that the IAP is predictive.[19,48] Those studies show postoperative losses and long-term memory deficits in patients who had been determined to be at risk for serious global memory impairments. However, the patients in those studies were not amnesic. As we have just seen, postsurgical amnesia does occur, but rarely.

In many centers the IAP is used in a more general sense to predict postoperative memory performance without reference to global amnesia. Such prediction is based partly on the confirmation of side of epileptic focus when injection opposite it

results in memory failure.[97,128] In addition, *good* memory after injection opposite a temporal lobe targeted for surgery shows that that temporal lobe, and presumably that hippocampus, functions well and may be intact. Resection from a healthy hippocampus can result in a more marked postoperative memory loss than resection from a damaged one.[36,74,116] Thus IAP memory performance in both tests, ipsilateral and contralateral to proposed surgery, should be taken into account in decisions regarding hippocampal excision.

The question of seizure control is closely linked to questions of sparing hippocampus. Because at-risk patients who undergo surgery show poor memory but are not amnesic, and because most of them experience a significant postoperative reduction in their seizures,[89] they gain as well as lose from surgery. Thus, surgical decisions concerning hippocampal excision weigh the negative effect of possible memory dysfunction against the positive effect of seizure control, but this issue is complex and must add the presurgical efficiency of the patient's memory and hippocampus into the equation. Furthermore, memory efficiency itself can contribute to predicting outcome: IAP results that clearly lateralize dysfunction with a difference score comparing performance of the two hemispheres have been shown to be successful predictors of seizure control.[73,111]

Application to Children

Language

The intracarotid amobarbital procedure has been used with patients as young as 3 years of age, although it is usually used with children of school age or older. As is the case for adult patients, centers in North America differ in the selection of pediatric patients for the IAP, with all surgical candidates undergoing the procedure in some programs and only certain children receiving it in others. Confidence in the use of the procedure in children is evidenced by its acceptance as the “gold standard” for establishing the validity of other methods for language localization and lateralization in the pediatric age range.[5,7,12,22,37,38,53,56]

There is also general consistency in the procedures involved in testing for language.[25,105] Many of the protocols are adapted from those used with adults. There is reliance to a large degree on counting at the time of injection, followed by tests of naming of pictures or objects; reading is also widely assessed, although in young children or children with mental retardation, single letters or digits can be used instead of words. In some protocols, serial speech tasks such as spelling or reciting the days of the week or the alphabet can be used, and some include questions that vary in complexity, requiring gestures, yes/no responses, or more complicated answers. The language testing included in the protocol must be individualized to the child, which may require considerable pretest preparation. Chronological age, mental age, and delay in language development all factor into the choice of procedures and test items. Thus, there may be more variability across subjects in the items used than is typically the case with test protocols used with adults.

A major divergence from the procedures used with adults is seen in the preparation of the child for the amobarbital test. It is recognized that the setting and procedures are unfamiliar to children and therefore can be extremely stressful. To inform the child about the procedures, and thus to elicit maximum cooperation, a “dress rehearsal” is often performed. This practice might involve taking the child to the neuroradiology suite, providing information about who will be present during the test, and having someone familiar to the child, such as a nurse or child care worker, present in the rehearsal as well as during the catheterization and test.[47,114] Some children become fearful and anxious because of the unfamiliarity and stress involved in the catheterization. It has been reported, however, that the use of propofol (Diprivan), a short-acting sedative–hypnotic agent, during the catheterization succeeds in avoiding these problems and permits the test to be completed with quite young children.[8,37,77] With proper preparation, the test is feasible, even with young and intellectually delayed children.[44]

A review of the small number of studies conducted on language lateralization with the IAP revealed somewhat disparate estimates of left hemisphere language representation in children selected for epilepsy surgery. Several studies have demonstrated that approximately two thirds of their samples had speech represented exclusively on the left,[32,105,114] whereas others reported that 85% to 88% of their samples had left hemisphere speech.[37,119,126] Thus, the data show an approximate bimodal distribution in the estimates of language representation in the left hemisphere in children with epilepsy. The discrepancy in the estimates might reflect differences in testing procedures or criteria for classifying unilateral versus bilateral speech representation or actual differences in the patient populations studied at different surgical centers. For example, it appears that there was a higher percentage of younger children in the patient series that had the lower estimates of left language dominance than in those series with the higher estimates.

Memory

In children, the assessment of memory during the intracarotid amobarbital test is not always as successful as the assessment of speech.[30,47] The difficulty in arriving at a valid and reliable indicator of memory status can result from the fast-paced and stressful conditions, the inability of young children to comprehend the requirements of the task, or the failure of children to attend sufficiently well to the test items to ensure proper registration of the materials.[32,114] Szabo and Wyllie[114] also raised the possibility that children have less effective memory strategies than do adults, and these strategies are therefore more sensitive to disruption by the amobarbital than is the case for adults.

A number of patient characteristics have been examined for their contribution to the success of testing memory using the IAP and to the outcome of such testing. Sex of the child, dose of amobarbital, and order of hemispheres injected do not appear to influence the results of memory testing.[119,126] One of the major factors in determining whether the test yields any useful information may be age. Williams and Rausch[126] obtained the most reliable results in children >13 years of age but found that age interacted with language dominance; thus, younger children with epileptogenic regions in the nondominant hemisphere also performed the test well. Hempel et al.[32] found that memory testing was possible among 8- to 11-year-olds but met with considerably less success in children under <7 years of age. Obtundation and agitation, preventing successful memory testing, were found more frequently among younger children.[30] The effect of age may also interact with IQ; it has been reported that children who were brighter and older were more likely to have valid tests than younger children with low IQ.[47,119] Williams and Rausch[126] and Hempel et al.[32] found that IQ alone does not appear to bear on the outcome of memory testing, but others have described poorer performance in children with low IQ.[30,114]

Szabo and Wyllie[114] and Westerveld et al.[119] found that greater success on memory testing is associated with injection ipsilateral to the epileptogenic region, but, in fact, performance may be related not only to the site of epileptogenicity but also to whether speech is represented in that hemisphere.[30] Williams and Rausch[126] showed that memory performance was more likely to be impaired after injection of the language-dominant hemisphere (when the epileptogenic region was also within that

P.1837

hemisphere), although this effect again appeared to interact with age, being more pronounced in children <13 years old.

One difficulty in determining the predictive value of memory testing in children is the existence of wide differences across centers in the nature of the protocols and in the criteria used for determining whether a test has been passed or failed. In this respect, the issues are very similar to those encountered in the literature with adult patients.[18] For example, cutoff scores used for determining a pass range from 33% to 67% correct by either recall or recognition.[32,114,126] Szabo and Wyllie[114] found much lower overall retention scores in children than in adults, even with a modified pediatric memory protocol, and suggested that a lower passing score may be appropriate for children. Their finding was not confirmed by Westerveld et al.,[119] who showed that children <13 years of age did not obtain scores different from those of adolescents or those expected of adults. Patient characteristics other than age may have produced the differences in the former study. The materials used in the test may also be of importance. Real objects as stimuli during the IAP memory test are superior to mixed stimuli (a combination of verbal and nonverbal stimuli such as photographs, line drawings, printed words, geometric designs, arithmetic problems, and objects) for predicting side of seizure onset.[65] This differential sensitivity was most pronounced among younger children.

In comparison with the adult literature, the field is in a fledgling state with respect to using the IAP to predict laterality of seizure focus or the possibility of memory decline after surgery. Several studies have been conducted on the validity of the procedure with respect to identification of lateralized pathology identified with seizures. When the memory data are used in this way, the scores for the two hemispheres are compared to determine which is less efficient in the performance of the test. Westerveld et al.[119] demonstrated that the resulting laterality scores correctly predicted side of surgery in 91% of a group of children and adolescents with seizure foci in the temporal lobes. Szabo and Wyllie[114] found that, among children who failed memory testing after one injection and passed the other, the failed injection was always contralateral to the hemisphere with the predominant epileptogenic focus. In a much larger sample of children from a multicenter study, Lee et al.[63] found that asymmetries predicted side of seizure onset using group data, but prediction was less robust on an individual case level, particularly among children with left temporal-lobe epilepsy. In this group, prediction was better among children with older age of seizure onset. The memory asymmetry score correctly classified laterality of seizure onset in 69% of all cases (left and right hemispheres, temporal and extratemporal foci), a classification rate lower than is typically observed in adults, suggesting that IAP memory asymmetries should be interpreted cautiously for this purpose. It is interesting that another multicenter study showed that the memory asymmetry scores were predictive of seizure outcomes; 75% of children with asymmetries consistent with the seizure focus became seizure free after surgery, in contrast with 56% whose memory score asymmetries were inconsistent with the laterality of the seizure focus.[64]

The use of the IAP in children to predict memory decline after surgery has been addressed in only one study. Lee et al.[66] found that asymmetry scores were not related to change in performance on visual/figural memory tasks or to recall of a word list; however, more children with asymmetry scores showed improvement on story recall after surgery compared with those without memory asymmetries. This finding needs to be treated cautiously due to a small sample, but it suggests that further research should be done. Prediction of the possibility of memory change after surgery is clinically important for children, in whom new learning and school performance are of utmost significance.

Comparison to Other Approaches

Methodologic limitations to the predictive ability of IAP memory testing have led to the development of other techniques to determine the risk for postoperative global amnesia. One of these is electrical stimulation of the hippocampal region with memory testing.[29,124] However, this technique is only applicable in those few patients who require hippocampal depth electrode implantation for adequate identification of the seizure onset zone. The same limitation holds true for limbic TL evoked potentials.[27,81] Although noninvasive techniques like SPECT, PET, hippocampal MR-volumetry, MR-spectroscopy, and neuropsychologic testing have proven very useful in the prediction of the side of seizure onset, it has not been adequately tested or validated whether they can predict postsurgical amnesia or degree of postoperative material-specific memory loss.[14,39,61,62,81,112]

Functional MRI (fMRI) and, to a lesser extent, PET activation studies are also being developed as techniques that may serve this purpose. Several studies suggest that fMRI[1,45,59] and PET[33,34,35] have a good potential for taking on this role. These methods need to be validated in a larger number of patients with more variable pathology and should be compared with the IAP. The best prediction of memory outcome may require different tasks or batteries of tasks during fMRI with dominant and nondominant TLE patients. Thus the use of fMRI to predict postoperative memory outcome may eventually provide a satisfactory alternative to the IAP as part of the routine presurgical evaluation, but at this point it remains a future possibility.

Testing cerebral dominance with a number of other methodologies—prominent among them fMRI, PET, transmagnetic stimulation (TMS),[57] and magnetoencephalography (MEG)—has been attempted for a longer time and has reached a higher degree of success. In a study by Woermann et al.,[127] determination of language dominance using fMRI was compared with results of the IAP in 100 patients with different localization-related epilepsies. Those authors found 91% concordance between the two tests. The overall rate of false categorization by fMRI was 9%, ranging from 3% in left-sided temporal-lobe epilepsy to 25% in left-sided extratemporal epilepsy. Language mapping using MEG has also been compared with IAP. A study of 100 patients by Papanicolaou et al.[91] showed 87% concordance between MEG and IAP and a high sensitivity for MEG of 98%. However, selectivity was 83%, reflecting the tendency for MEG, as for fMRI,[117] to find some language on the nondominant side in cases in which IAP does not. A relative weakness of MEG is that most work has been on receptive language and thus posterior language areas (e.g., see Lee et al.[60]); more work is needed on expressive language to identify anterior language areas.

We conclude that language mapping with fMRI or MEG might reduce the necessity of performing an IAP to assess hemispheric dominance for language, especially in TLE and especially in straightforward cases in which language is all on the left or all on the right. In cases of discrepant findings, such as those reported for IAP and fMRI by Kho et al.,[54] disagreements might be solved by electrocortical stimulation mapping in the awake patient.[54,90] Finally, should fMRI become the standard for evaluation of language dominance, it is highly likely that there will still be certain patients for whom an IAP will be necessary. For example, some patients will not be testable by fMRI because they are too claustrophobic or too obese to go into the scanner, and some patients will have an uninterpretable or an unreliable result after being scanned successfully.

Thermal inactivation, or cooling, of brain[4] is another method for studying reversible brain dysfunction. Various groups examined the effects of localized brain cooling in

epileptic patients, mainly with a view toward the alteration of EEG activity and the effects on local spiking, whereas Flanigin et al. in Georgia used intraoperative thermal inactivation of the hippocampus in 33 patients to predict amnesia following temporal lobectomy.[24] Although they reported that their technique of hippocampal cooling with memory testing can be useful in selected cases, even at their center hippocampal cooling is no longer performed. Intraoperative functional mapping, especially speech mapping in the awake patient, is another approach used to tailor surgical resections according to the individual functional organization of the brain.[86,87,88]

Advantages

Intraarterial anesthetic procedures yield a nearly instantaneous result because an IAP can be interpreted immediately on completion of the second injection (both hemispheres tested). Conclusions about cerebral dominance can usually be made without ambiguity, and although memory results are less frequently unambiguous, solid conclusions about memory function can also be made in most cases. The brief reversible lesion provided by IAP gives a valuable preview to postoperative function that cannot be obtained by other means, including the techniques of intraoperative cooling and electrical stimulation, which affect very limited regions of brain compared to the gross hemispheric IAP effect. Because of its wide-ranging effect, one should expect the IAP to predict the maximum possible deficits that might result from surgery.

Limitations

The possible advantage of the IAP that it is likely to predict maximum possible deficits can be viewed also as a limitation because IAP memory testing might be an overly sensitive procedure that results in an excess of false-positive results[69,85] (but see McGlone and MacDonald[78]). In addition, the IAP yields a certain number of uninterpretable tests, especially for memory, because the sudden loss of function in one hemisphere sometimes results in confusion and obtundation that persists until too late to carry out valid behavioral testing. This latter problem does not exist in a new variant on the IAP (the etomidate Speech and Memory test discussed earlier) and to some extent in the selective amobarbital procedures. Furthermore, since about 1998 it has become evident that amobarbital injection sometimes has no effect or a reduced effect. Although the first hypothesis regarding the reason for this was that there had been a change in the drug itself, a source was found by Bookheimer et al.,[9] who showed that the anesthetization failures were occurring in patients who were taking antiepileptic drugs (AEDs) with carbonic anhydrase–inhibiting properties, in particular topiramate and zonisamide. The most frequent occurrence was in association with topiramate, and one patient showed reduced anesthetization when the IAP was performed 5 weeks after discontinuation of that drug. The authors therefore recommended that patients be tapered off these specific AEDs for at least 8 weeks prior to IAP. Given that it has been shown that patients who undergo IAP while taking topiramate show greater memory deficits than those who are not taking it,[55] discontinuing that AED before attempting an IAP is an important concern.

That there is no universally accepted and standardized IAP memory-test procedure may be considered a limitation, given that techniques of injection and scoring criteria differ among centers.[101,109] In addition, the fact that IAP lateralizes language but does not localize speech areas within a hemisphere is a limitation, and when one needs to know how the epileptogenic zone overlaps with language areas, language-mapping techniques have an advantage over IAP. Finally, the fact that the IAP is invasive must be taken into account, especially if alternative, noninvasive procedures become available.

Complications

In the hands of skilled specialists in experienced centers the complications of IAP and selective amobarbital tests are relatively low. However, by nature they carry an inherent risk. This risk must be weighed against the anticipated beneficial gains. Transfemoral carotid angiography is associated with complications that include thromboembolism and stroke (0.5%–1%), allergic contrast medium reactions (1/40,000), and local complications of femoral puncture.[96] In Rausch et al.'s survey of 68 epilepsy centers, the morbidity rates for the standard IAP were reported to range from 0% to 5%, with the majority of centers (61%) having experienced no complications.[101] Accidental injection of hypertonic saline during an IAP was associated with mortality in one case, and another mortality was associated with the angiography itself.[96] Because selective amobarbital procedures are relatively infrequent, less information is available about complications from those procedures. Petersen et al.[95] reported complications in 3 patients in a series of 59 who had undergone the posterior cerebral artery procedure, and, based on this relatively high rate, they and others have discontinued its use.[49] In Zürich, the center with the largest series of selective amobarbital tests, no complications have occurred (H.-G.Wieser, unpublished data, 2005).

Cost

In the context of the total cost of epilepsy surgery, the cost of an amobarbital test is minor. If the procedure is scheduled to be performed while implanted intracranial electrodes or attached scalp electrodes are already in place, there are no additional costs for an extra hospitalization or for EEG monitoring done during the IAP. Angiographic techniques that use several special catheters and the availability of a sophisticated angiography system can add to the costs. The main cost factor, however, is the availability of a well-trained team consisting of a neuroradiologist experienced in angiographic catheter procedures, neuropsychologists, an electroencephalographer or an EEG technician. and a nurse. A comprehensively monitored amobarbital study might therefore amount to $1,000 to $1,300 U.S. according to a detailed cost estimate published in 2004[83] or to as much as $1,500 to $2,000 U.S. according to calculations based on costs for 43 epilepsy surgery cases in Zürich, where selective procedures are used. IAP costs usually represent <5% of the total cost of a presurgical evaluation, however, and <3% of the total cost of a surgical case. Moreover, when the procedure is performed only in patients considered to be at risk, an IAP might not contribute more than 0.4% of the total cost incurred by an epilepsy surgery center.

Summary and Conclusions

The IAP is used to determine cerebral dominance for language before operation in patients who will undergo brain surgery. It is also used as a screening device to predict, and thus, it is hoped, to prevent, severe postoperative memory losses in patients who will undergo a unilateral resection from a temporal lobe. In addition, comparing the IAP memory results from the two hemispheres can indicate the dysfunctional side, providing confirmatory evidence (or not) for conclusions about the site of seizure focus.

The literature on the use of the IAP with children indicates that it provides valid information on language lateralization and will continue to be a valuable tool in identifying the variables that determine reorganization of function. Its usefulness in assessment of memory is less well established, with best results obtained in older and brighter children.

Although the IAP and its variants are invasive, complications are rare, and these procedures provide quick and reliable information about cerebral dominance for language and useful information about memory function. Despite the growth of other techniques such as PET, MEG, and functional MRI, the IAP—including the selective procedures in some centers and variations such as the *e*SAM—continues to play an important role in decisions about a patient's surgical management.

Chapter 174

Intraoperative Functional Mapping

George A. Ojemann

Susan Y. Bookheimer

Introduction

This chapter describes established intraoperative methods for identifying functionally important cortex during resective epilepsy surgery. Several other chapters are complementary. A promising new technique for intraoperative functional localization, optical imaging of the "intrinsic signal," is discussed in Chapter 86. Like extraoperative methods for functional localization discussed in Chapter 175, the established intraoperative methods rely on electrical stimulation mapping. Although the technical details of stimulation mapping differ in the different settings, several controversial issues concern both methods. How reliable is stimulation mapping in identifying areas that must be spared in a resection to avoid a functional deficit? When is stimulation mapping required for planning a cortical resection? Compared to intraoperative methods, extraoperative methods expose the patient to additional risks (including an extra craniotomy) and require a substantial additional investment of health care resources.[23] An additional area of controversy, then, is when the additional risk and cost of the extraoperative method are justified.

Application of an electric current to the cortical surface has a variety of effects, exciting both neurons and *en passage* fibers and also blocking their function, effects that can produce excitation and inhibition locally or at a distance.[37] Thus, the effects of stimulation cannot be easily predicted physiologically but rather must be determined empirically. In the quiet patient, responses are readily evoked from primary motor and somatosensory cortex (localized movements or dysesthesias), somewhat more rarely from primary visual cortex (localized phosphenes), and quite infrequently from primary auditory cortex. There are usually no responses from stimulation of other cortical areas at currents below the threshold for afterdischarges, although in patients with temporal lobe epilepsy, larger currents associated with afterdischarge will occasionally evoke the interpretive and experiential responses studied by Penfield et al.[8,20,34] However, if the patient engages in an ongoing measure of language, stimulation of some dominant hemisphere cortical areas outside primary cortices will disrupt language performance. Presumably the predominant effect of stimulation at those sites is a disruption of function, probably by depolarization blockade. This is the technique of intraoperative stimulation mapping of language developed initially by Penfield and Roberts.[35]

The choice of language measure to use with stimulation mapping is somewhat controversial. Penfield used object naming. This also has the advantage as a screening measure for language function that all aphasic syndromes include deficits in naming. This is the language measure most often used by the author.[31] However, reading has also been used as a screening test, particularly with extraoperative stimulation.[18]

The reliability of stimulation as a technique for identifying functionally important areas depends on how localized the effects are and how reliably those effects predict the effect of resecting that cortex. Intraoperative imaging of the changes in the "intrinsic signal" indicating where the stimulating current is altering neurons has shown that with bipolar cortical surface stimulation below the threshold for afterdischarge, as used by the author, the changes are confined to tissue between the electrodes in both man[11] and animals.[10] Behaviorally, both sensory-motor and language effects of intraoperative stimulation are usually localized on a scale of millimeters to a few centimeters. Threshold sensory-motor effects with intraoperative cortical stimulation are usually confined to a few millimeters on each side of the central sulcus, showing the classical homuncular pattern of localization. Sensory-motor changes with extraoperative stimulation are often evoked from a wider area.[17] Sites where intraoperative stimulation repeatedly evokes naming errors are often confined to several separate cortical sites, each 1 to 2 cm^2 in extent, often with sharp boundaries (Fig. 1).[31] Extraoperative stimulation mapping of language has often shown changes from somewhat wider areas.[16,32]

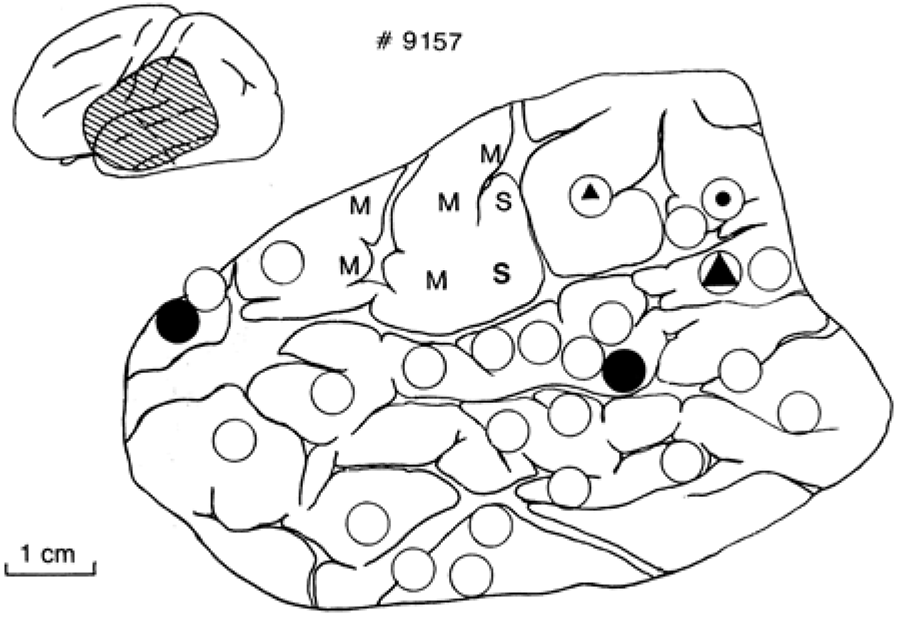

FIGURE 1. Location of areas essential for language in an individual, based on intraoperative electrical stimulation mapping during naming in two languages. *Circles* are sites of stimulation. *Filled circles* are sites of repeated errors in naming in English, this patient's primary language. *Small circle* is site with a single error out of three stimulations during English naming. No errors in naming the same pictures in Spanish were made at these sites. *Large triangle* is site with repeated errors in naming the same objects in Spanish. *Small triangle* is site with a single error out of three stimulations during Spanish naming. No errors in English naming were made at these sites. The patient was a teacher of English to Spanish-speaking students. He was fluent in both languages. Note that sites essential for each language occupy only a small portion of the classical language areas and that essential areas for the two languages are separate. (From Ojemann GA. Different approaches to resective surgery: standard and tailored. In: Theodore W, ed. *Surgical Treatment of Epilepsy*. Amsterdam: Elsvier; 1992:169–174, with permission.)

Evidence from several studies has shown that perisylvian sites identified as important to naming by intraoperative stimulation mapping can predict the language effects of a resection. In resections for epilepsy, Ojemann and Dodrill[27] found that when anterior temporal resections came within 2 cm along a continuous gyrus of a site where stimulation evoked repeated object-naming errors, testing with a sensitive aphasia battery 1 month after operation showed subtle language changes that were not present when the resection had not come within 2 cm and that were not related to the size of the resection, the degree of seizure control, or the patient's preoperative verbal abilities. In temporal lobe tumor resections, Haglund et al.[9] found that when the resection came within 5 mm of a site showing repeated naming errors with intraoperative stimulation, about one third of patients had a permanent postoperative clinically evident aphasia, whereas when these sites were 15 mm or more from the margin of the resection, no patient had even a temporary clinically evident aphasia. Very large resections in classical language cortex have not been followed by postoperative aphasias when stimulation mapping demonstrated all essential sites for naming elsewhere.[31]

Thus, stimulation and lesions seem to identify the same cortical sites as essential to language. Interestingly, surface cortical stimulation predicts effects of resections that include both surface and buried cortex, suggesting that essential language areas are rarely if ever located only in buried cortex.

On the other hand, stimulation in the dominant hemisphere outside of the perisylvian area evokes repeated changes in language measures in areas where resection does not lead to a permanent language deficit. These include the supplementary motor area in the superior frontal lobe,[7,24,35] where resection of sites with repeated naming or reading errors often results

in a dramatic initial deficit (patients may be mute), but with rapid resolution, so that there is little or no permanent language change.[39] Similarly, repeated language errors have been evoked by stimulation of basal temporal cortex,[18] but resection of this area rarely is associated with a persisting language deficit.

Indications

The location of eloquent areas is mainly a concern in planning cortical resections in central portions of the hemisphere and, in the language-dominant hemisphere, posterior frontal and posterior temporal-inferior parietal areas. Although language is usually lateralized to the left hemisphere, statistically independent of handedness,[48] when there is any question about unusual language lateralization, this should be established preoperatively with the intracarotid amobarbital perfusion test.[46] Eloquent areas can be identified either anatomically or functionally. However, the anatomic landmarks that identify rolandic cortex, vertically oriented gyri with a "U" shape at the sylvian fissure, are often hard to discern through the intact pia and may be displaced by tumors. Common anatomic landmarks for avoiding language areas in the dominant hemisphere are anterior to the pterion for frontal resections and, for temporal resections, the line of rolandic cortex or the vein of Labbe or 4 to 4.5 cm from the temporal tip, sparing superior gyrus.

Electrical stimulation mapping often localizes language to several quite focal perisylvian areas in an individual patient, but these sites are in somewhat different places in different patients (Fig. 2).[31] This variability in exact location of language areas is such that only the most posterior portion of inferior frontal gyrus, immediately in front of face motor cortex, is essential for language in a large proportion of patients. Elsewhere, including any portion of the entire Wernicke area, essential language areas are present in not much more than a third of patients. This substantial variability is one of the strongest arguments for mapping function in each patient rather than depending on anatomic landmarks derived from population studies. Use of anatomic landmarks rather than individual stimulation mapping to localize language unnecessarily restricts resections for many patients while not avoiding essential language areas in a few patients.[31] Thus, stimulation mapping is of value in safely maximizing resections in posterior frontal and posterior temporal lobes, whether the resection is for epilepsy or for a structural lesion including tumors and vascular malformations.[2]

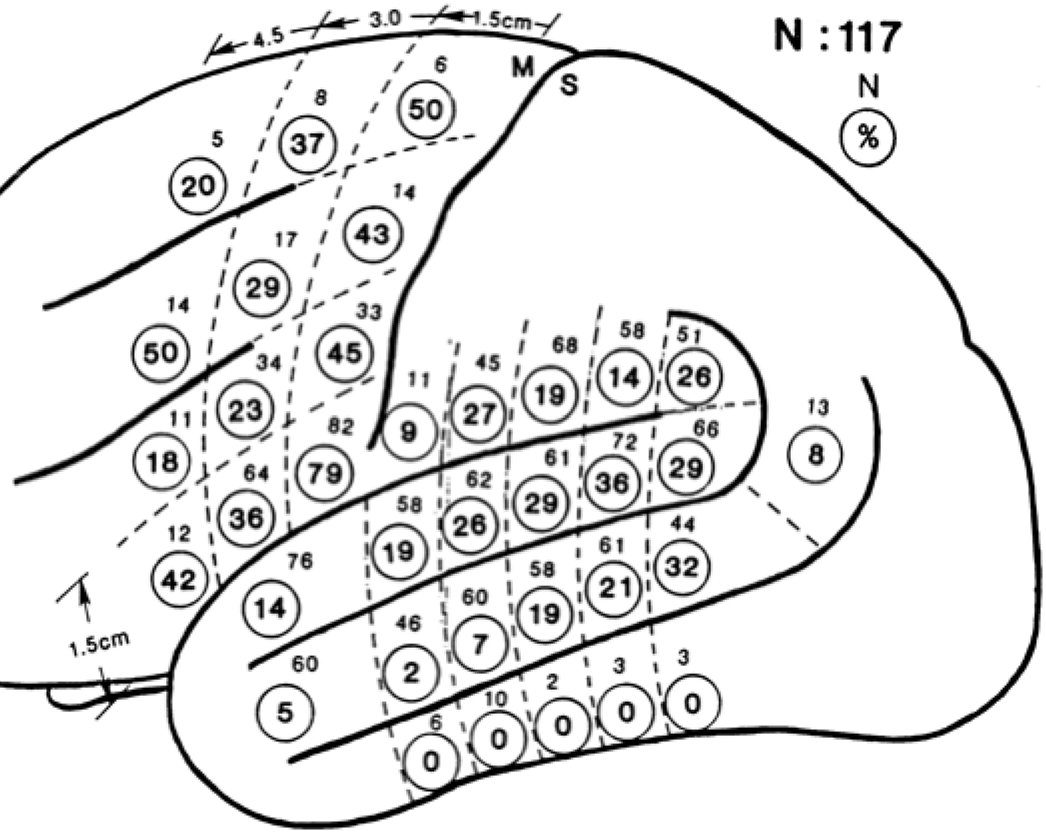

FIGURE 2. Variability in language localization in left hemispheres of 117 patients, all left dominant for language based on intraoperative electrical stimulation mapping. Maps of individual patients were aligned to common anatomic landmarks, and the cortex was divided into the arbitrary zones indicated by the *dashed lines.* The upper number in each zone is the number of patients with samples of stimulation effects on naming errors during stimulation. Substantial variability in location of essential language areas between individuals is evident. (From Ojemann GA, Dodrill C. Verbal memory deficits after left temporal lobectomy for epilepsy. *J Neurosurg.* 1985;62:101–107, with permission.)

Whether location of language areas is important to planning anterior temporal resections for epilepsy in the dominant hemisphere is controversial.[32] Stimulation mapping has occasionally identified sites related to language within 3 cm of the temporal tip, even in middle temporal gyrus. There are no randomized studies to resolve this issue, but a report of consecutive series of anterior temporal lobectomies with or without identification of language areas suggested that there was a slightly greater risk of a postoperative language deficit in the series done without identification of language areas, although the difference was small.[1,13]

Technique[1]

Motor cortex can be identified under either general or local anesthesia with intraoperative stimulation mapping, although motor mapping under general anesthesia requires a technique in which the patient is not paralyzed, and the resulting motor map is usually rather crude, with responses only at large currents; the extensive area devoted to tongue movement usually cannot be identified. An alternative method for intraoperative identification of rolandic cortex under general anesthesia is recording of somatosensory-evoked potentials (SSEPs).[47] However, with this technique, too, identification of face and tongue representation is difficult, and the author finds SSEP recording more time consuming than stimulation mapping. Detailed intraoperative mapping of rolandic cortex and intraoperative mapping of language require that the patient be awake, under local anesthesia, for that portion of the operation. Having the patient awake for part of the operation also allows recording of the electrocorticogram (ECoG) without alterations induced by general anesthetic agents. Thus, we discuss the technique of awake craniotomy with modern intravenous propofol anesthesia, followed by the technique of intraoperative stimulation mapping.

The advent of propofol intravenous anesthesia has made “awake” craniotomy much easier for both the patient and surgeon.[42] About the only demand now made on the patient is that he or she be able to hold still for 1 to 2 hours while awake. Thus, the technique can easily be used in children aged 12 or older and most adolescents and adults. It can also be safely used in the presence of an intracranial mass, although the brain will

be slightly “tighter” than is usually observed with modern endotracheal anesthesia, and it may be necessary to be slightly more aggressive with the use of intravenous osmotic agents in that setting compared to general anesthesia.

We now use only the lateral position with propofol. With that position we have not had difficulties maintaining an airway; those problems have occurred in patients in the supine position. The patient is positioned while awake, with particular attention to his or her comfort. The head rests on a foam “doughnut”; skeletal fixation is not used. Propofol anesthesia is then induced intravenously. Once the patient is asleep, a local anesthetic field block is placed, using a mixture of equal volumes of 0.5% lidocaine and 0.25% bupivacaine (Marcaine), both with 1:200,000 epinephrine. Propofol is not a particularly good analgesic, so the “asleep” patient will often show more reaction to the placement of this block than will an awake patient. Thus, we use the same technique, making the first injections slowly through a 30-gauge needle at sites near the major scalp nerves. Use of small amounts of intravenous fentanyl is of value in reducing responses to placement of the block. If the incision is to extend to the root of the zygoma, the insertions of the temporalis muscle are also infiltrated. The scalp incision and craniotomy then proceed in the usual manner. Once the dura is exposed, dural pain sensation is blocked by intradural injection of small quantities of the local anesthetic on each side of the middle meningeal artery, using the 30-gauge needle. A clamp is placed on the skull at the edge of the craniotomy, not only to provide a place to attach ECoG recording equipment, but also to provide a handle to control the head if the patient becomes restless.

At this point, all pain-sensitive structures have been blocked with local anesthetics, and the noisy bone removal has been completed, with the patient asleep. The lateral surface of the brain, of course, is insensitive to pain or touch. We usually awaken the patient before opening the dura, unless that opening is expected to be very tedious, for example, when extensive pial–dural adhesions are anticipated. Patients are usually able to converse within 7 to 12 minutes of stopping the propofol. At that time, they are reminded that they are in the operating room and should not move their head without first asking. The longest period before awakening in our experience has been 30 minutes. The patient usually awakens abruptly without a period of confusion, a major advantage of propofol. Propofol is also not a particularly good antiepileptic agent. We have very occasionally observed clinical signs of spontaneous seizures in severe epileptics asleep with propofol. Short-acting benzodiazepines or barbiturates may be needed to control those seizures but will interfere with subsequent recording and stimulation.

Several technical factors are important to successful stimulation mapping: (a) mapping is difficult beyond the edges of the craniotomy. The exposure should therefore be generous, to include likely locations of functionally important areas. (b) Sites where language is located must be identified, for only then does the absence of language changes indicate cortex that can be resected with a low risk of aphasia. This also requires that the exposure include areas that are likely sites for language. (c) The stimulating current must be sufficiently large to alter function in cortex but not so large as to evoke a seizure. (d) The patient must make few errors on the language measure in

the absence of stimulation. Only a few samples of stimulation effect at any one site can be obtained. If there are many errors in the absence of stimulation, errors during stimulation may be random events and not related to stimulation effects at that site. The author regularly obtains three samples of stimulation effect at each site. For errors on all samples to have less than a 5% probability of being random events, the error rate in the absence of stimulation must not exceed 40%. Thus, stimulation mapping is of limited value in severely aphasic patients. Patients with mild aphasias may not be able to name with a low enough “control” error rate but may be able to read single words or can be continuously engaged in conversation during stimulation, although neither technique seems to be as satisfactory as naming for localizing language.

The only parameters of stimulation varied in the author's technique are the current level and train duration. All stimulations use 60-Hz trains of biphasic pulses, each phase 1 msec in duration, delivered from a constant-current stimulator across 1-mm stainless steel bipolar ball electrodes 5 mm apart. Most other contemporary stimulation techniques use somewhat shorter pulses, often 0.3 msec for each phase, and some use 30-Hz frequency but are otherwise similar. Levels of electrical charge that produce histologic changes in tissue have been extensively studied in animals (see reference 32 for review). Histologic examination of stimulation sites in resected human cortex does not show any changes in the author's patients (unpublished data). Moreover, patient performance in the absence of stimulation does not deteriorate after repeated stimulations. These findings both indicate that stimulation at the indicated parameters does not permanently alter cortex.

After the patient is awakened and the dura opened, ECoG recording is undertaken. At the completion of this recording, the afterdischarge threshold is established for the area of cortex to be sampled with language mapping. A small current, commonly 2 mA between pulse peaks, is applied for 4 seconds to cortex adjacent to an ECoG electrode; in the case of temporal exposures, thresholds are first determined for more posterior electrodes. This stimulation is repeated at increasing currents until afterdischarges are evoked, the patient reports a response, or an arbitrary upper limit on current is reached, usually 10 mA between pulse peaks for direct cortical stimulation. The current is then reduced 2 mA below that afterdischarge threshold, and the threshold at the next most anterior electrode is determined. After all electrodes are sampled, a process that requires 5 to 10 minutes, a current is selected for mapping that is at the lowest threshold. The main reason for establishing the afterdischarge threshold is to avoid evoking a seizure. A brief train of afterdischarge after a stimulus train is usually not a problem, but afterdischarge thresholds are occasionally <2 mA. Using larger currents in such patients is likely to evoke a seizure. However, using that small a current in other patients with higher thresholds may not alter cortical function and so may not provide a reliable mapping.

Sensory-motor cortex is then identified. The author uses stimulus trains beginning at 2 mA and asks the patient for any evoked sensory responses while an assistant looks for any overt movements. Current is increased in 1-mA intervals until responses are obtained. The site of each positive response is identified with a sterile numbered ticket. Electromyographic responses to single pulses have also been used to identify motor areas. Following identification of rolandic cortex, sterile numbered tickets are placed across the remaining cortex that is to be sampled during naming. The patient then begins the naming task. The author uses slide pictures of common objects to elicit naming, showing slides at 4-second intervals on a back-projecting slide projector. Stimulation is applied to one of the sites identified by a ticket at the appearance of the second or third slide. An assistant records the patient's responses and the number of the site stimulated. Another site is stimulated two or three slides later, until all sites have been sampled once. The process is then repeated in a different order two more times, so that stimulation effects on naming have been determined three times for each site. Sites with repeated naming errors are considered essential for language. With this technique, stimulation effects on naming can be determined for 20 sites in 20 minutes. Stimulation mapping with other language measures follows this same general plan, although the relation of applying the current to the behavioral measures may vary, especially in assessing memory. Our specialized and rather time-consuming protocol for assessing cortical stimulation effects on the input, storage, or retrieval phases of recent verbal memory has been published.[27]

Comparison to Other Approaches

For some patients, extraoperative methods are the only option for stimulation mapping. These include patients requiring language mapping who cannot cooperate with an awake craniotomy, such as young children, or when recording of seizure onsets is needed to plan the resection, as when there are widespread or multifocal interictal spikes on scalp electroencephalogram (EEG), and particularly if these overlap eloquent areas. Then it is often of value to establish the relationship between the site of seizure onset and the eloquent areas. However, use of chronic electrode techniques exposes the patient to two operations, one to place the electrodes and one to remove them and undertake any indicated resection. Both the risk, particularly that of infection, and the total investment of health care resources are increased when larger arrays of chronic electrodes are used, as is required for detailed mapping. Extraoperative stimulation mapping involves an additional investment of 1.5-fold or more over the amount required for a resection including electrocorticography, intraoperative stimulation mapping, and postoperative care.[23] In addition, although there is more time for extraoperative stimulation mapping, the anatomic resolution of that technique seems to be less than that with intraoperative stimulation because of both uncertainties about the relationship of the electrodes to the cortical surface with the extraoperative technique and the inflexibility of the electrode array, preventing mapping beyond its edges.

If chronic electrodes are to be used in patients who could alternatively be managed with awake craniotomies, an improved outcome must be present to justify these increased risks and costs. That is *not* the case for adolescents and adults who require only mapping (as in lesions near eloquent areas) or who do not require intracranial ictal recording (as with patients with epilepsy and a focus clearly established by noninvasive preoperative evaluation). In the author's view, these patients are best managed with awake craniotomy.

Functional Magnetic Resonance Imaging and Electrical Stimulation Mapping

Preoperative functional magnetic resonance imaging (fMRI) mapping of language is an emerging approach that may augment and in some cases substitute for cortical stimulation mapping (Chapter 83). Numerous studies at the group level (i.e., representing averaged language maps across a cohort of volunteers or patients) have proven effective in identifying the organization of language functions in the brain and in elucidating the nature of this organization. In patients with epilepsy, such studies have been few in number and most have emphasized

hemispheric laterality. Rarely, however, is hemispheric dominance the critical question in subjects undergoing electrocorticography; rather, the goal here is to locate eloquent areas *within* the hemisphere. Few studies to date have attempted to demonstrate the accuracy of fMRI in localizing critical language areas within the hemisphere in comparison to the “gold standard” of electrocorticography, at the single-subject level. If fMRI is ever to substitute for cortical stimulation, a very high degree of reliability within subjects must be demonstrated, particularly in those with anomalous language laterality. Patients with epilepsy are more likely to have atypical language organization; thus, to be useful, fMRI studies will have to include sufficient numbers of language-reorganized subjects, with electrical stimulation mapping confirmation, in order to prove its worth as an alternative to direct cortical stimulation. Furthermore, the studies must be reliable for each individual, confirmed with appropriate sensitivity and specificity measures. An additional complication with developing fMRI for intrahemispheric language mapping is that different techniques, including image acquisition parameters (field strength, pulse sequences), activation tasks chosen, and analysis approaches, can yield strikingly different results. Thus, a validated fMRI approach in one center may not support the utility of fMRI in another center that uses different experimental paradigms or technical procedures. To date, only a few studies have attempted to meet high standards of fMRI sensitivity and specificity profiles using electrical stimulation mapping as a validation tool.

One study examining fMRI in arteriovenous malformations reported sensitivity and specificity of a standardized fMRI approach with electrical stimulation mapping validation. Pouratian et al.[36] used three activation tasks, deriving “conjunction maps” showing brain regions activated across tasks with an expressive component (object naming and reading comprehension with naming) and a comprehension component (reading comprehension and auditory comprehension). Conjunction maps show regions of the brain that are significantly activated for each task included in the analysis (a logical “AND” operation rather than an average). Optimal results for frontal regions were found using expression maps, while temporal and parietal regions correlated best with comprehension maps. Activation maps for each subject were projected onto MRI-derived brain surfaces, which were in turn registered to intraoperative photographs of brains labeled with tags following electrocorticography. For each subject, the authors calculated the distance between the external boundary of the fMRI activation and a radius around the center of the electrical stimulation mapping tag. Both positive and negative areas were compared with radii of 2.5, 5, and 10 mm. In 17 patients, the sensitivity of finding frontal and temporal or parietal regions with expression and comprehension maps, respectively, were 100% (frontal-expression) and 90% (temporal/parietal-comprehension) at a 5-mm diameter; given a 10-mm radius, sensitivity of both regions was 100%. fMRI was less specific, however, with 66% frontal-expression specificity and 81% temporal/parietal-comprehension specificity at a 0.5-mm radius. This result is characteristic of fMRI, which effectively measures all brain regions involved in, though not necessarily essential to, task performance. The margin of error—0.5 to 1 cm—is relatively large and likely reflects the additive errors across the various transformations, including functional to structural MRI misregistration, errors in matching fMRI to intraoperative photographs, distortions due to the local magnetic fields in MRI, and displacement of the brain during surgery, to name a few. One report indicates that intraoperative brain displacement may vary by more than a centimeter relative to the skull,[14] though much of this error may be accounted for by adjusting the simple offset from skull to brain surface. While more sophisticated nonlinear image registration techniques can reduce these errors, such as those using extensive manual tracing of cerebral sulci,[45] these are very time consuming and require special training, perhaps impractical for a clinical setting. Nonetheless, by sacrificing specificity, fMRI appeared to be extremely sensitive in revealing significant language areas that correlated with electrostimulation mapping results in the Pouratian et al.[36] series of arteriovenous malformation (AVM) patients.

While the majority of fMRI electrical stimulation mapping comparison studies have focused on AVM or tumor cases, a few have included a large percentage of patients with epilepsy. For instance, Yetkin et al.[49] compared electrocorticography with preoperative fMRI using a range of functions from finger, lip, and tongue movements to counting and word generation in 28 patients with lesions near motor cortex; of these 22 had epilepsy and 13 of the subjects were mapped for language using a word generation task (12 left, one right hemisphere). Of these patients, only one had activation further than 10 mm from the lesion; however, results for smaller diameters were not specified for the language regions. Sensitivity was 100% given a 20-mm diameter, and 87% within 10 mm overall across all tasks (including motor tasks). It should be noted, however, that the slice thickness (10 mm) would be considered unacceptably large by today's standards, and the 2-cm distance required for 100% sensitivity is probably too large for surgical decision making in the absence of correlated electrical stimulation mapping measures (specificity was not reported in this study). Another limitation of this study was the absence of patients with temporal lesions; Pouratian et al.[36] found posterior language regions less reliably identified by fMRI than the frontal regions targeted by Yetkin et al.[49] A more recent study of 13 patients with epilepsy used four different language tasks during fMRI in comparison with electrical stimulation mapping[41]; 11 patients successfully completed electrical stimulation mapping, which identified language cortex in eight of these patients. fMRI sensitivity was 100% in seven of eight patients and 38% in the remaining patient, while specificity was 51%. Overall, the level of predictive validity given these sensitivity and specificity figures of fMRI was too poor to be considered useful (51%). Nonetheless, the authors argue that fMRI may have accelerated the electrical stimulation mapping procedure by guiding the surgery toward likely candidate regions. The small number of subjects, especially those with anomalous language organization by electrical stimulation mapping (n = 1), limit the generalizability of these results to a broader sample of patients with epilepsy. Larger series comparing fMRI with electrical stimulation mapping have been conducted on tumor cases in the motor system,[15] but without sensitivity and specificity measures.

In the largest fMRI electrical stimulation mapping series to date, Duffau et al.[5] combined clinical information from both procedures and reported on the long-term outcome of 103 surgical patients receiving both procedures; they found 94% had no deficits (motor or language 3 months postoperatively (10% had actually improved). However, without randomized trials it remains unclear whether the addition of fMRI changed the clinical outcome. In summary, though fMRI is increasingly performed in presurgical patients and has become more widely available to treatment centers, there remains far too little data to consider fMRI as an alternative to direct cortical stimulation in most cases.

Aside from the dearth of data supporting the exclusive use of fMRI for surgical planning, fMRI has an additional disadvantage in epilepsy cases in that one cannot determine the relationship between defined eloquent cortex and abnormal electrical activity determined intraoperatively. Nonetheless, there are several instances in which fMRI may have a clear advantage. One is when subject cooperation during an awake procedure is simply impossible, such as in many children and in patients with excessive apprehension of the procedure. Another is in those patients for whom stimulation at low thresholds

P.1848

produces significant afterdischarges, particularly when they evolve into seizures during electrocorticography. In cases where functional tissue may be buried deep within a sulcus, electrical stimulation mapping may not show disruption on the brain surface, leading to false-negative results and potential patient harm. One such case was reported recently[40] where fMRI demonstrated an area of activity buried deeply beneath the surface, which electrical stimulation mapping found negative on traditional surface stimulation; however, when the lesion (a tumor) was resected leaving the fMRI-identified area exposed, stimulation produced significant language disruption. fMRI frequently reveals areas of activation that do not reach the brain surface[36]; no studies to date have examined these regions with regard to electrical stimulation mapping, and their significance and frequency are unknown.

Ultimately, fMRI may prove most useful as an adjunct to, rather than a replacement for, electrical stimulation mapping. Rutten et al.[41] argue that a high-quality fMRI may be useful in focusing in on likely language areas, potentially reducing the length of the stimulation procedure. Methods and applications of fMRI for surgical planning and in seizure focus localization are discussed in detail in Chapter 83 of this volume.

Future Directions

Stimulation mapping has been a useful technique for investigation of human cortical organization, particularly for language and memory.[22] Some of those findings also have implications for planning resections very close to eloquent areas. Patterns of localization of perisylvian sites essential for naming differed between men and women, with a subset of women tending to have fewer temporal-parietal naming sites, including a small group who seemed to have only frontal sites.[31] Patients who were verbally brighter tended to have naming sites in middle temporal gyrus; those with poorer verbal skills had sites in superior temporal gyrus. Highly localized perisylvian essential sites for naming have been identified in children as young as age 4.[31]

When perisylvian stimulation effects on different language measures are examined intraoperatively, the general rule seems to be that slightly different cortical areas are essential for different language dimensions. Different sites seem to be essential for naming the same objects in two different languages,[3,21,33,38] including sign and oral languages.[12,19] Different sites are often essential for naming or reading[21,25] and for naming or reading compared to recent verbal memory,[27] generating verbs from nouns, and different semantic categories.[30] In a few special settings, it may be useful to map localization of some of these other functions (e.g., in a patient heavily dependent on a second language or on reading skill). Avoiding cortical sites related by stimulation to recent verbal memory has been shown to be of value in decreasing the likelihood of a postoperative memory deficit in epilepsy patients who “fail” intracarotid amobarbital assessment of memory function.[27,28]

In this context of frequent separation of sites where intraoperative stimulation affects different dimensions of language, the finding of several different dimensions altered at a common site takes on added significance. A particularly striking combination of effects was observed in an intraoperative investigation of the effects of stimulating the same site during identification of phonemes and mimicry of orofacial speech gestures, singly or in sequence.[21,29] Single orofacial speech gestures were altered by stimulation at posterior frontal sites, whereas sequences were altered by stimulation in superior temporal and inferior parietal gyri. Thus, “motor speech” representation extends well beyond the frontal lobe in the perisylvian cortex. At 85% of these same sites, stimulation at the time a phoneme was presented interfered with later identification (in the absence of stimulation), suggesting that stimulation at the site altered some mechanism common to language perception and production. Several possible common mechanisms have been suggested.[17,21,44] Based on the sites where stimulation altered these two functions, as well as effects at these and other sites on naming, reading, and recent verbal memory, a model of the organization of language in perisylvian cortex has been proposed that differs from the classical one derived from lesion aphasiology.[21,22]

In addition, stimulation mapping has been used to investigate localization of visuospatial functions in the nondominant hemisphere, including the identification of sites in posterior middle temporal gyrus that were related to identification of facial emotional expressions.[6] However, to date, nondominant hemisphere stimulation mapping has not been used to plan resections.

Summary and Conclusions

Human cortex has localized areas that are crucial for different functions, including language and motor systems. These areas are often quite localized in any individual, sometimes to locations not predicted on purely anatomic localization criteria. These locations also vary between subjects. Intraoperative electrical stimulation mapping provides a technique for identification of these crucial areas in an individual patient, so that any resection can be planned to spare them, reducing the chances of postoperative functional deficits. Compared to extraoperative techniques for stimulation mapping, the intraoperative method provides somewhat greater localization, less risk, and considerably less resource utilization. Thus, for patients who could be managed with either technique, the intraoperative approach is preferable. Intraoperative identification of crucial language sites requires an awake patient, under local anesthesia. With the use of intravenous propofol anesthesia for craniotomy and placement of local anesthetic blocks, most adolescents and adults can cooperate with intraoperative language mapping. Language mapping also involves careful selection of stimulation current levels to avoid evoking seizures while using a current large enough to alter cortical function. Recent investigations suggest that separate cortical areas may be crucial for many different dimensions of language, including different languages, different linguistic and semantic functions, and recent verbal memory. These studies suggest that under some circumstances, intraoperative mapping of multiple language dimensions may be advisable to reduce the risk of functional deficits after cortical resections.

Chapter 175

Extraoperative Functional Mapping

Prasanna Jayakar

Ronald P. Lesser

Introduction

Focal cortical resections are now frequently performed in patients with partial seizures or hemispheric tumors. During resection, it is important to spare "essential" cortical regions whose removal would lead to an unacceptable neurologic deficit. Essential areas generally can be spared by limiting the resections to certain anatomic landmarks. For example, a left anterior temporal lobectomy restricted to approximately 4 to 5 cm from the temporal tip will usually spare language cortex.[10,22] There is considerable variability, however, in both the location and the extent of essential cortex in different subjects. The anatomic approach thus does not allow the maximal removal of abnormal tissue, nor does it provide complete security that eloquent cortex is not resected.[24,44]

Electrical stimulation has been used for greater than half a century to accurately map essential cortex intraoperatively. With development of the subdural electrode technology, extraoperative functional mapping became an option, especially in patients in whom invasive ictal recordings are necessary for planning resection. Responses to electrical stimulation have also been used by some epileptologists to confirm the location of epileptogenic tissue. This chapter reviews the role and technique of extraoperative mapping in patients undergoing cortical resections.

Effects of Electrical Stimulation

Electrical stimulation can produce a variety of effects. It may evoke "positive" responses such as localized movements from the primary or supplementary motor cortex, dysesthesia from the somatosensory cortex, phosphenes from visual cortex, or, rarely, "buzzing" from auditory cortex. Formed visual responses may be elicited from secondary visual cortex. Alternatively, stimulation may block function, presumably by sustained depolarization or activation of inhibitory systems. This effect cannot be appreciated in a quiet, resting patient and can only be demonstrated by having the patient engage in specific tasks during the stimulation. For example, stimulation of specific regions of the cortex can interrupt higher cortical functions such as those involved in receptive or expressive language. In areas such as the primary or supplementary motor cortex, both "positive" responses in the form of motor movements and "negative" responses such as arrest of movement or speech can be demonstrated.

In addition to clinical responses, stimulation also can provoke sustained electrographic afterdischarges, which generally last from seconds to minutes after cessation of the stimulus. Because afterdischarges are known to propagate to remote regions, functional localization is often felt to be more reliable when clinical responses are elicited without provoking afterdischarges. It is also generally assumed that the observed clinical response arises from cortex below the stimulated electrode or from the region between two closely spaced bipolar electrodes, an assumption that is supported by evidence from experimental models, although remote effects may occasionally occur.[35,42]

The thresholds for evoking both clinical responses and afterdischarges are usually higher in children than in adults.[2,26,35] This difference is particularly striking in the first 2 years of life. Young children also differ from adults in that they rarely demonstrate clinical responses in the absence of an electrical afterdischarge.[11,26] As illustrated in FIGURE 1, clinical response threshold usually exceeds the afterdischarge threshold in children younger than age 4 to 6 years, although this trend may occasionally be seen in older children and adults as well. This finding has important practical implications because the lack of a clinical response during an afterdischarge does not guarantee the absence of underlying eloquent cortex.[26]

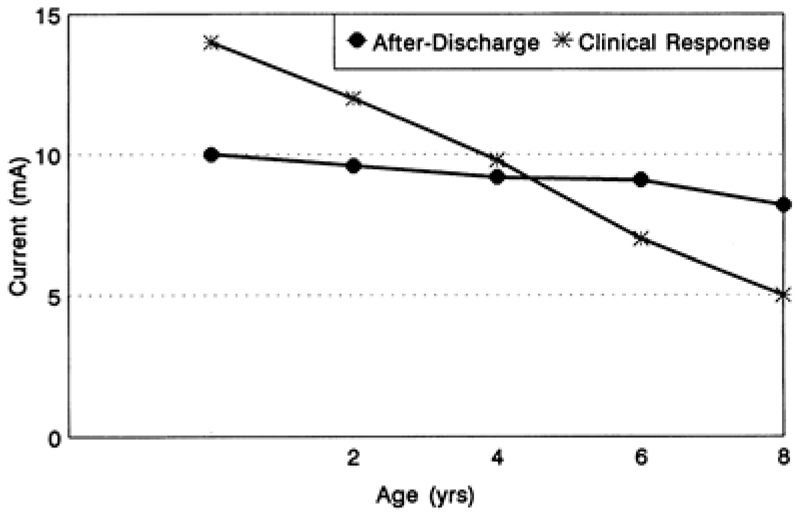

FIGURE 1. Graphic representation of the mean thresholds (mA) for clinical responses and afterdischarges obtained during functional mapping in 20 children (160 electrodes). Note that clinical responses in the very young are obtained only above afterdischarge thresholds.

Indications

Functional mapping is used primarily to define essential cortex during surgeries for epilepsy or removal of structural lesions such as tumors or arteriovenous malformations (AVMs). Once eloquent cortex is precisely defined, the surgical resection can be accomplished to within 0.5 to 1.0 cm from it. In specific cases such as the one illustrated in FIGURE 2, one can assess the risk–benefit relationship and decide to resect a part of the motor cortex involved in the epileptogenic process. Functional mapping thus allows the removal of the most tumoral or epileptogenic tissue possible without incurring significant postoperative deficits.

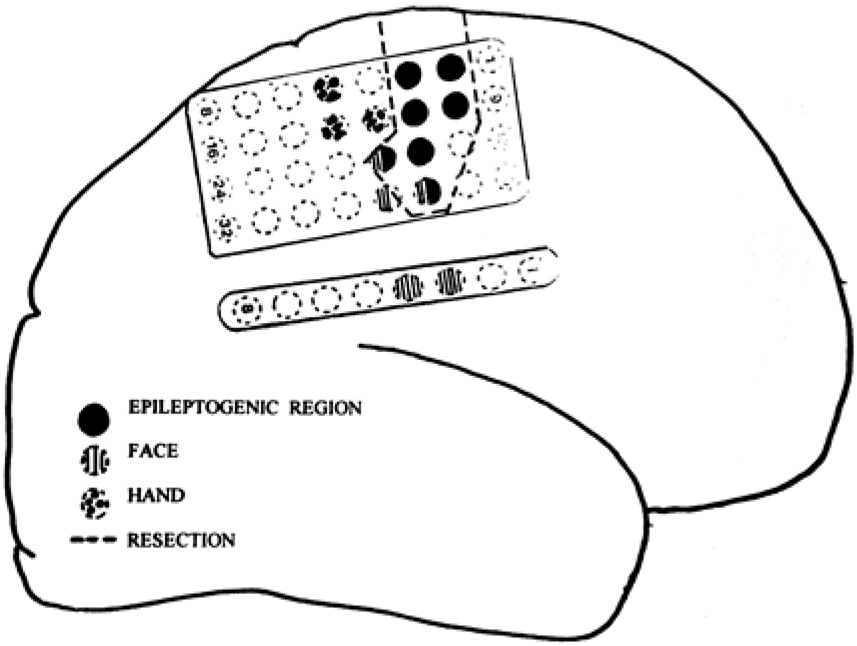

FIGURE 2. Functional mapping of the motor cortex revealed a rather extensive face area. Resection included a part of the face region that was significantly involved in the epileptogenic region defined by ictal onset and prominent interictal spiking. There were no significant postoperative deficits.

Identification of Normal Cortical Function

Mapping is most frequently indicated to define critical cortical regions subserving primary sensorimotor and language functions, which are often very localized in a patient but show considerable intersubject variability. This variability may be even more pronounced in patients in whom underlying lesions such as tumors cause considerable displacement of critical cortex. It is not unusual to find functional responses occurring over wide regions in a patchy distribution (Fig. 3), especially when a mass lesion is present. The thresholds for eliciting responses may also vary surrounding the tumor sites.

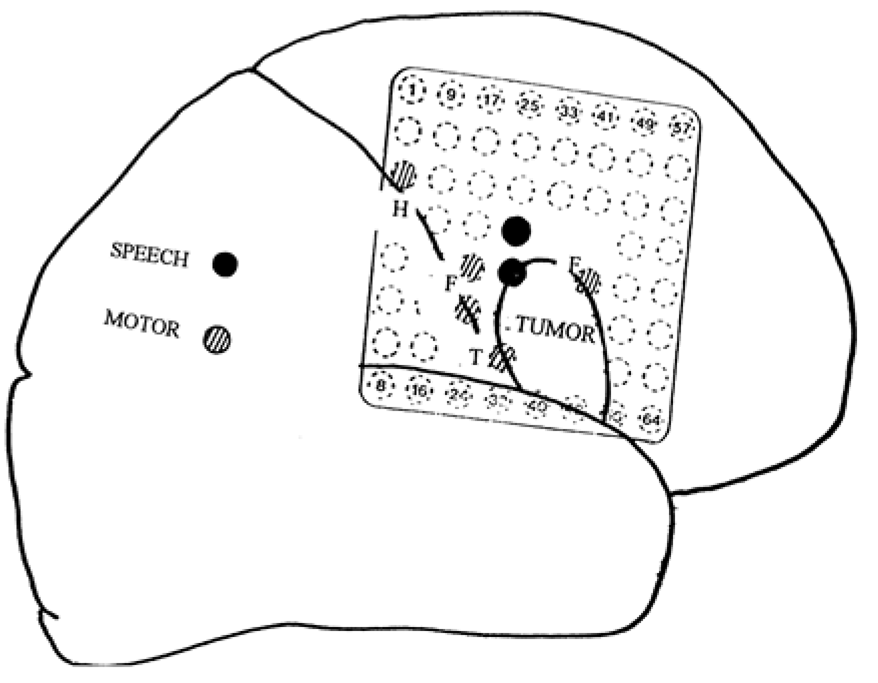

FIGURE 3. Functional mapping in a right-handed patient with a frontal lobe tumor. Language cortex is pushed upward, and motor area for the face (F) is splayed over both the anterior and posterior aspects of the tumor.

Language Cortex

Cortical stimulation of specific areas will block comprehension or other language-related activities such as spoken speech and writing abilities. Although language is most frequently represented in the left hemisphere, right hemispheric language dominance can occur even in patients who are motorically right

P.1852

P.1853

handed (Fig. 3). The majority of patients will demonstrate language cortex over both frontal and temporoparietal sites. However, in a few patients, essential language cortex is found only over the frontal or temporoparietal regions but not over both.[46]

Localized regions of language cortex can be identified in children even as young as 2 1/2 years old (unpublished observation). Ojemann et al.[46] reported both frontal and temporal language sites in children 4 to 10 years of age, including sites within 3 cm of the temporal tip. These findings indicate that a high degree of language localization occurs very early in childhood and suggest that mapping may have a role in planning resections even while the brain is still plastic.

Frontal Lobe.

In general, the frontal language area is anterior to but contiguous with the bulk of the motor and sensory area, although considerable overlap between these regions can occur.[34,44] It is most frequently located at the posterior aspect of the inferior frontal gyrus or middle frontal gyri or both. However, language functions may occasionally be disrupted on stimulation of inferior frontal regions as far anterior as the pterion or even posterior to the rolandic sulcus. Writing capability is generally represented at sites overlapping those representing verbal speech, but in some patients they may be separate and involve the posterior part of the middle frontal gyrus.[34,37]

Temporal Lobe.

Stimulation of the posterior aspects of the superior or middle temporal gyrus in the dominant hemisphere can interrupt reading, naming, comprehension, and other language-related functions.[36,44] Either single functions or groups of functions may be affected at single sites. Critical language cortex is usually located >4 cm from the temporal tip, although more-anterior locations are occasionally observed.

Stimulation in the adjacent temporo-parieto-occipital junction can affect nonverbal capabilities. For example, Morris et al.[41] demonstrated all of the features of Gerstmann's syndrome in this region, including right–left confusion and finger agnosia. Hart et al.[21] reported an area where stimulation selectively interfered with the representation of size. These observations appear to support the idea that many types of information may be organized in a categoric fashion by the brain.

In addition to the temporo-parieto-occipital junction, language function may also be subserved by the temporal base.[8,39] A variety of language functions can be altered at sites throughout the dominant temporal base, but unlike the convexity sites, resection of basal sites generally does not lead to significant permanent deficit.

Stimulation of some sites in the left lateral temporal cortex reportedly disrupts pathways involved in recent verbal memory. These sites cannot be consistently demonstrated in all patients, even after detailed testing extraoperatively, and the role of mapping memory cortex is yet to be fully defined.

Sensorimotor Cortex

Motor or sensory responses can be elicited by stimulating not only the primary sensorimotor cortex but also adjacent regions, which are not as critical and are termed the supplementary sensorimotor areas.

Primary Sensorimotor Cortex.

The primary motor and sensory homunculi do not necessarily conform to specific gyri on either side of the rolandic sulcus. Although the motor cortex is in general located anterior to sensory cortex, there is often an overlap, with some electrodes revealing both motor and sensory responses. Motor responses are usually elicited from a thin, strip-like region that varies in width between 1 and 2 cm. Wider motor representation of >3 cm also can be demonstrated, especially during extraoperative stimulation.[53] Such wide representation may be attributable to atypical gyral orientation or technical factors such as current spread.

Motor responses in children show a developmental trend and become increasingly complex and well defined with age.[2,11] Although hand and face regions can be defined, movements of an individual finger or the tongue are rare below age 2 years and become reliably elicited only after age 4 to 6 years. One could speculate that these findings may somehow reflect immaturity of cortical systems subserving fine finger movements or oroglossal coordination necessary for speech.

Stimulation of the lower rolandic region in children <1 to 2 years of age elicits bilateral rather than unilateral responses from the lower half of the face, suggesting that lower as well as upper facial muscles are likely to be innervated bilaterally in fetal and early postnatal life. Maturation would therefore lead to a loss of ipsilateral lower representation, probably through synaptic or axonal elimination. Such a hypothesis is consistent with the observation that the lower face is completely spared in prenatally acquired hemiplegia but is invariably involved when insults are acquired postnatally.[32] On occasion, there can be ipsilateral as well as contralateral responses in adults as well, especially when stimulation is used to inhibit movement.

Supplementary Sensorimotor Area.

The supplementary sensorimotor area (SSMA) occupies mainly the superior frontal gyrus within the interhemispheric fissure, anterior to the primary motor cortex with variable extension onto the premotor convexity.[38] Regions over the paracentral lobule, the precuneus, and even the adjacent cingulate gyrus, however, may reveal similar responses (Fig. 4). Stimulation of the SSMA can elicit unilateral or bilateral movements from both upper and lower extremities and the face. Stimulation at specific sites may interrupt ongoing motor activities, for example, those that produce alternating movements in the extremities or speech or writing. In general, the face and upper extremities are represented anteriorly and the feet toward the paracentral lobule.[14,38]

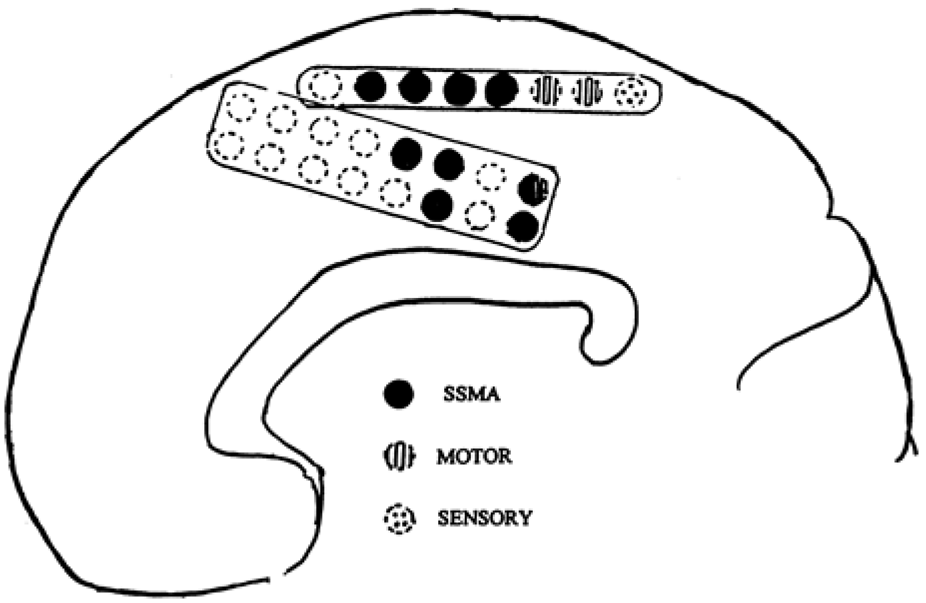

FIGURE 4. Functional map of the right interhemispheric cortex. The supplementary sensorimotor area (SSMA) is located anterior to but encroaches on primary motor and sensory regions.

The SSMA is presumably involved in the planning and initiation of motor movements. Resection of this region on one side usually produces only transient alteration of movement or speech. From a practical standpoint, it is therefore important to differentiate the SSMA from the primary motor leg area located just posterior to it. Besides eliciting ipsilateral limb movements, SSMA response thresholds can be higher than those in the primary motor cortex. Time-locked responses to single-pulse stimuli reportedly occur only from the primary cortex and may help to further differentiate it from premotor areas.

Premotor Cortex.

Stimulation of the frontal premotor convexity produces head and eye movements. This region is usually very discrete and located anterior and contiguous to the primary face and hand cortex. Head version is almost always contralateral to the hemisphere stimulated. The eyes may be deviated tonically or exhibit saccadic movements.

Visual Cortex

Like other sensory areas, the visual cortex is also represented as primary and secondary regions. The primary visual or striate cortex is located around the calcarine sulcus on the mesial aspect of the occipital lobes. The macula is represented at the pole, whereas the peripheral retina is represented along the calcarine fissure, forming concentric circles away from the pole. In general, the upper halves of the retina are represented superior, and the lower halves inferior, to the calcarine fissure. The secondary or association visual cortex is located around the primary cortex and occupies the base and posterior convexity of the occipital lobe.

Stimulation of primary visual cortex over the occipital pole or in the region of the calcarine cortex produces phosphenes

or flashes in the corresponding visual fields. Association visual areas are generally associated with formed visual responses.

Other Critical Functions

Many functions can be defined by stimulating specific regions in either hemisphere, but few have been systematically studied. "Buzzing" can be elicited from primary auditory cortex, whereas more complex auditory experiences occur from auditory association areas located over the posterior perisylvian region. Stimulation at sites in the right middle temporal gyrus may affect ability to label facial expression.[15]

Identification of Dysfunctional or Displaced Cortex

Epileptogenic Cortex

In patients being assessed for seizure surgery, functional mapping serves the additional role of defining dysfunctional cortex. Several features of the stimulus response may be of relevance in defining the epileptogenic region. The most widely studied is the threshold for eliciting afterdischarges. Unfortunately, afterdischarge thresholds vary considerably and can be either below or above those of the surrounding normal cortex. Thresholds may also change from one trial to the next.

In some patients, stimulation may elicit extremely prolonged afterdischarges lasting up to several hours. Occasionally, prolonged afterdischarges are provoked not at the stimulated electrodes but at remote sites. Although these findings suggest that the underlying cortex is hyperexcitable, the various patterns and features of the provoked afterdischarge generally fail to reveal a consistent correlation to the epileptogenic region.[7]

Stimulation may also elicit auras or activate clinical seizures and assist in defining the spontaneous ictal focus. Bernier et al.[6] found that the side from which seizures were provoked generally corresponded to the side of spontaneous seizures, both for temporal and extratemporal seizure foci. However, in our experience, seizures are often provoked on stimulating regions remote from the spontaneous ictal focus and are thus less reliable for defining the exact location of the seizure focus within the same hemisphere. The reliability of defining the ictal focus sometimes is increased if the provoked seizure shows the same clinical semiology as the patient's habitual seizures.

Displaced or Atypical Representation

When lesions involve the dominant hemisphere early in life, while the brain is still plastic, language reorganization is often complex and tends to vary with the nature of the underlying pathology. Language tends to move away from destructive lesions, and when damage of the dominant hemisphere is widespread, there can be an almost complete transfer to the opposite hemisphere. In patients with epileptogenic lesions, however, language cortex is often observed to overlap and scatter around the epileptogenic cortex rather than shift to remote sites.[8,11] Even some right-handed patients may reveal language cortex surrounding a focal epileptogenic lesion over the right hemisphere. These findings indicate that most epileptogenic lesions do not cause relocation of critical language cortex and stress the importance of accurate functional mapping.

Children with developmental pathology may also reveal atypical distribution of motor cortex in which there may be inversion or duplicate representation of some body parts.[11] For example, we have observed a child with double shoulder regions above and below the hand and finger areas, the lower atypical shoulder region being the site of ictal onset (Fig. 5). Aberrant and secondary motor representation of the face has been demonstrated in the infrasylvian region over the middle temporal gyrus[27,29]; in the case reported by Jayakar et al.,[27] ipsilateral facial contractions were elicited by stimulating an area of left temporal cortical dysplasia. Resection of such aberrant duplicated representation sites generally does not result in clinical deficits.

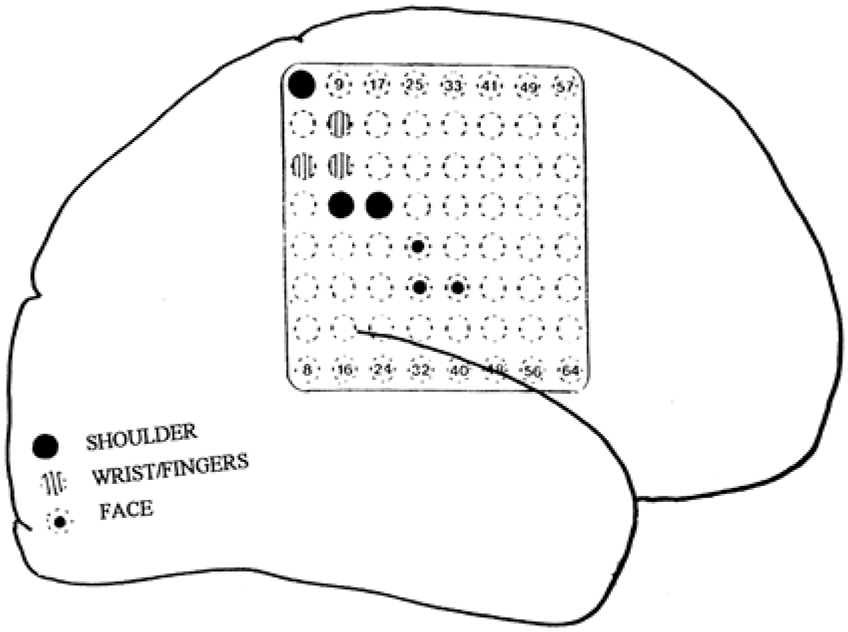

FIGURE 5. Functional mapping in a child with cortical dysplasia. Note the "atypical" double representation for the shoulder; the lower of the two is also the seizure focus.

Although it could be argued that these findings merely represent extreme variations of the normal, the developmental nature of pathology in these patients leads one to speculate that disturbed neuronal migration and other factors operating during fetal life may be responsible for the anomaly. This hypothesis would be in keeping with experimental observations that prenatally acquired lesions can produce both anomalous sulci and functional reorganization of cortex.[18,19]

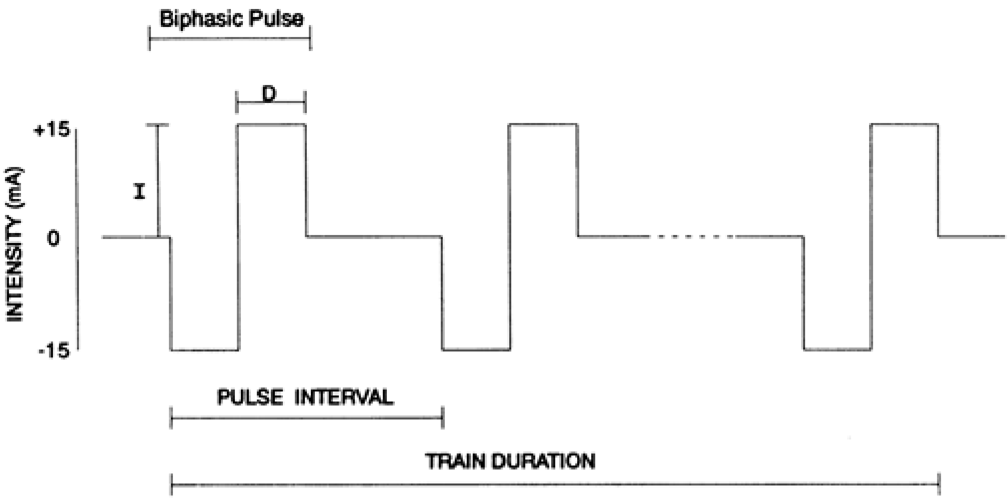

FIGURE 6. Graphic illustration of stimulus parameters using a rectangular biphasic pulse.

Technique

Electrodes

The subdural electrodes used in standard clinical settings usually are thin metal disks with exposure ranging from 2.3 to 4.0 mm in diameter and electrode centers typically spaced 0.5 to

1 cm apart. The size and configuration of subdural electrodes can be tailored to the area of interest. Strips of four to eight electrodes can be used for sampling basal or mesial structures and allow the option of insertion via a burr hole. Larger rectangular arrays ranging from two by four, to two by eight, to eight by eight are suited for monitoring the hemispheric convexity, and these arrays can be tailored to fit the configuration of the cortex found in the operating room. A combination of grids and strips can be used for adequate cortical coverage. Arrays of somewhat different configurations have also been used; for example, in interhemispheric regions, a curvilinear array can be placed mesially over the corpus callosum to record from supplementary motor or cingulate cortex.

Electrodes available for extraoperative mapping are composed of either platinum–iridium or stainless steel. Platinum is less prone to ionic deposition than stainless steel when current is passed and is thus, in theory, safer than the latter. However, the risk of injury related to ionic diffusion becomes significant only when stimulation is carried out continually over several weeks.[1] Because stimulation in the clinical setting occurs only in brief sessions daily for at most a few days, the practical differences between the two metals in terms of safety should be relatively minor. Platinum electrodes, by virtue of being less ferromagnetic than stainless steel, are also presumably more suitable for magnetic resonance imaging (MRI) scans, which help to document the relationships of electrodes to the underlying cortex.[31]

Stimulation Parameters

Cortical mapping is generally performed by delivering biphasic pulse stimuli at a rate of 50/s in trains lasting 3 to 8 seconds (Fig. 6). Faster rates of 100 to 300 pulses/s and slower rates of 5 to10 pulses/s have been used for transcranial elicitation of motor responses, but their efficacy and safety for direct cortical stimulation are yet to be established.

Pulses also can vary with respect to intensity, duration, the charge and energy applied, and the corresponding densities. The smaller the diameter of the electrodes used, the higher are the charge and energy densities.

The limits of stimulus strength used clinically are guided primarily by safety considerations. Stimulation-induced tissue injury can occur by several mechanisms, which include accumulation of ions (polarization), hydrolysis of water, and heat generation.[1,50,54] Use of a biphasic stimulus pulse minimizes effects of polarization but does not protect against other mechanisms of tissue injury. It is thus critical to try to use the minimal stimulus strengths necessary to elicit a response.[25]

In the clinical setting, stimulus intensity is maintained between 1 mA and a maximum of 15 to 17.5 mA. Gordon et al.[20] reviewed the charge densities from a variety of techniques and concluded that intraoperative testing with hemispheric ball electrodes would result in charge densities from 159 to 796 mC/cm^2 per phase for peak currents of 2 to 5 mA. By comparison, the estimated charge densities for the grid electrodes in clinical use were 52 to 57 mC/cm^2 per phase for peak currents of 13.6 to 15 mA.

These charge densities are larger than the “safe” limit derived from animal studies, which was approximately 40 mC/cm^2 per phase.[1] However, animal studies typically have used continuous stimulation over more prolonged periods of time.[3,4,50] In humans, mapping is performed by stimulating intermittently for relatively brief periods, and the total length of stimulation time at any given site is far less than was utilized in the animal studies. In addition, humans have a thicker pia–arachnoid and a larger volume of subarachnoid cerebrospinal fluid, so that greater current shunting should occur in humans than in animals.

Gordon et al.[20] studied the microscopic characteristics of cortical tissue samples that had undergone a large number of subdural electrode stimulation trials and found no evidence that electrical stimulation had caused cortical changes. Gervin[17] reported on a patient who had received occipital cortical stimulation via subdural electrodes for a period of 10 years for the purposes of artificial vision production. There were no reported pathologic changes when the electrodes were removed.

Yet another safety consideration relates to the possibility of kindling the brain because of recurrent electrical stimulation. However, there is no evidence that stimulation thresholds progressively decrease on repeated trials, as might be expected were a kindling phenomenon present. Furthermore, kindling of the neocortex is difficult, especially in higher primates.

Testing Parameters

Cortical mapping is generally performed by delivering biphasic pulse stimuli at a rate of 50/s to adjacent pairs of electrodes. Responses at individual electrode sites can be confirmed by monopolar stimulation using a reference electrode located over a remote noncritical site—a procedure that reduces the likelihood of false detections. Stimulation is begun at a low intensity, generally 1 mA, and increased in 0.5- to 1.0-mA increments until a functional change occurs, afterdischarges are elicited, or the ceiling on the stimulation device is reached. Maximum intensity is that of the stimulator utilized, for example, 15 mA for the Grass S88 stimulator and 17.5 mA for the Grass S12 stimulator. Pulse durations are maintained constant at 0.3 msec. Stimulation is continued for 3 to 5 seconds, but longer-duration trains may be required to test more complex functions such as language and praxis.

When afterdischarges occur, one can test again at the same or slightly lower intensity and in many cases avoid the occurrence of additional afterdischarges. It often is possible, using this method, to gradually increase the intensity of stimulation to a current setting much higher than that at which afterdischarges originally occurred, without continued afterdischarges, so that functional changes can be documented. In patients who have unusually large numbers of afterdischarges, small doses of benzodiazepines, generally lorazepam or diazepam, may be needed at the time of stimulation testing. To avoid the occurrence of afterdischarges or seizures, at each testing session the stimulation threshold should be reassessed by beginning at a low stimulation intensity and gradually increasing.

Special considerations are pertinent to stimulation in children.[26] Stimulation paradigms that work well for adults do not necessarily work in children,[51] probably because immature cortex and nonmyelinated nerve fibers require different pulse characteristics to be activated. Immature neural tissues typically have longer chronaxies with their strength–duration curves shifted to the right and thus require stimuli with longer pulse duration to elicit responses. A stimulation paradigm based on stepwise increments of both stimulus intensity and pulse duration converges to the tissue chronaxie and is usually effective for mapping children.[26] This paradigm also keeps the energy and charge requirements to a minimum,[16] a feature that is especially welcome because there are no firm guidelines for electrical safety in this setting. During stimulation, the patient can be subjected to specific tasks designed to test language and memory functions or identify supplementary motor areas.[36,43,45,46,49] In general, the testing paradigms are modified according to age and neurodevelopmental status of the patient. The tasks used most commonly for defining language cortex include naming of common objects and colors, reading of age-appropriate materials, spontaneous speech, and basic mathematics skills. Auditory or visual cues can be administered separately to test receptive or expressive functions. The patient can be asked to respond either verbally or through writing or gestures. Intraoperative testing can be accomplished by showing materials to the patient under the surgical drapes, or even via small computer monitors or television screens. More complex standardized testing of specific functions such as word frequency, grammatic form, or semantics can also be performed.[33,45] Bilingual subjects need to be tested in both languages.

Comparison to Other Approaches

Intraoperative Versus Extraoperative Mapping

Intraoperative functional mapping can be an option when intracranial ictal recording is not needed to plan resection. Motor and sensory homunculi can be easily defined intraoperatively in awake, cooperative adults who describe their subjective sensations. However, in patients under general anesthesia, responses are crude and are usually obtained only at high stimulus strengths. It thus becomes difficult to obtain a fine spatial definition of motor cortex. The effects of anesthesia are even more profound in young children, and motor mapping may occasionally fail despite the use of maximum stimulus strengths (unpublished observation). In some children higher current intensities of 18 to 30 mA may be needed, but their safety is yet to be documented.

There is a general consensus that extraoperative language mapping is indicated in patients who cannot be expected to cooperate during surgery under local anesthesia. Extraoperative mapping is thus clearly the only means to define language cortex in children. There are differing opinions regarding the relative value of intraoperative and extraoperative language testing.[47] Some authors believe that language can be adequately mapped using local and ultrashort anesthetic agents and argue that the cost and risks of extraoperative mapping cannot be justified in these patients. Most authors believe, however, that, given the time restriction, language cannot be mapped with adequate precision in the intraoperative setting. It is not possible to determine thresholds at each tested site, and stimulation may occur at intensities that are not optimal for producing minimal functional alterations. Furthermore, they believe that the much greater time spent in the operating room for intraoperative mapping offsets much of the cost benefits. Extraoperative functional testing occurs during a time when extraoperative localization of epileptogenic cortex is occurring in any case.

There are some technical differences in the two methods of mapping. The electrodes used for intraoperative stimulation are generally much smaller than those employed extraoperatively.[13,43,44,46,48] The smaller electrodes have the advantage that they allow one precisely to define the functions in very small areas of cortex. In addition, they are placed by hand, with direct visualization of the cortex. However, smaller size could potentially be a disadvantage if one wants to screen functional capacities of larger neuronal networks. The smaller electrodes also lead to higher charge densities, but safety is less likely to be an issue because intraoperative testing lasts for only short periods.

Subdural electrodes bear a fixed relationship to one another, and so some electrodes might be over vessels or otherwise suboptimally placed in the extraoperative setting. In comparison, one can ensure adequate electrode contact with the brain during intraoperative mapping. Intraoperative mapping has the added advantage of monitoring critical function during the course of surgical resection. Periodic stimulation of cortex or the exposed white matter pathways enhances the security of motor or language integrity; the latter can be tested only with the patient awake.[5,12,28] Many centers now use a combination of extraoperative and intraoperative mapping techniques.

Somatosensory-evoked-response Topography

The sensory cortex can alternatively be defined by mapping the topography of the somatosensory-evoked responses from the cortex. Typically, the evoked response reveals a phase reversal in the region of the central sulcus. In some patients, however, the phase reversal may be difficult to define or may be 1 to 2 cm anterior or posterior to the central sulcus and thus could potentially mislead the localization of motor cortex. Furthermore, this technique does not help to delineate the anterior extent of the motor cortex and thus serves mainly as an adjunct to stimulation mapping.

Future Directions

Although cortical stimulation has been a very successful technique for mapping eloquent functions, there are complementary electrophysiologic methods that are likely to be helpful in the future, such as event-related potential or gamma frequency recordings and frequency analysis–based techniques.[9,23,30,40,52]

Magnetoencephalography and functional imaging using positron emission tomography, functional MR, or optical techniques also promise to be valuable tools for demonstrating eloquent cortex. These newer methods of functional assessment define the network involved in a particular task and not necessarily the critical sites alone. By contrast, electrical stimulation produces a transient reversible lesion and may thus more accurately identify the tissue that is critical for the function being tested, a factor of importance when considering the potential effects of surgical resection.

Finally, the use of three-dimensional imaging modalities should make it possible to determine more precisely the location of the electrodes and define their relationship to the underlying cortex. This will make it easier to establish anatomic–physiologic correlations during electrical stimulation and thus help us to understand better the overall organization of cortical functions in humans.

Summary and Conclusions

Electrical stimulation provides a safe and effective method for functionally mapping critical cortex. Although testing of various functions can be carried out intraoperatively, extraoperative mapping allows a more detailed analysis that can be reliably reproduced on sequential trials and is particularly suited to mapping in children.

Chapter 176

Anterior Temporal Resection

Kenneth Vives

Dennis D. Spencer

Introduction

Temporal lobectomy is the most common surgical procedure performed for medically refractory symptomatic epilepsy. This operation has evolved with our understanding of the pathophysiology of medial temporal epileptogenesis. The neurosurgical approaches presented in this chapter reflect this evolution and, undoubtedly, will continue to change as we refine our knowledge of the responsible epileptogenic substrates in the temporal lobe and other lobar regions. In fact, defining the symptomatic epilepsies by substrate adds the needed specific pathologic diagnosis to the traditional lobar localization classification to further characterize the various diseases that are expressed as temporal lobe epilepsy (TLE).[73] Temporal lobectomy continues to play an important role not only in the treatment of epilepsy, but also as a bridge between laboratory and clinical research because the resected tissue is assumed to be epileptogenic and a variety of neurobiologic tools can be used to examine this hypothesis. The modern neurosurgical rationale for the more selective medial temporal resections depends on our contemporary knowledge of temporal lobe function and the pathophysiology of the epileptogenic substrates. This has continued to evolve over time as our knowledge about patient selection and outcomes has expanded and accumulated.

Historical Perspective

Bouchet and Cazauvieilh, in 1825, described grossly visible and palpable abnormalities of hippocampal autopsy specimens obtained from nine patients with "alienation epilepsy."[7] This was the first evidence linking the most common form of partial epilepsy to a pathologic substrate. In another autopsy study, Sommer, in 1880, described gliosis and pyramidal cell loss within the hippocampus of epileptic patients and hypothesized that this finding was responsible for their epilepsy.[71] In 1872, Hughlings Jackson suggested that hyperexcitable brain adjacent to temporal lobe lesions was responsible for epilepsy, and in 1888 he pointed out the association of the "dreamy state" and the classic auras of taste, smell, and epigastric sensations with temporal lobe lesions.[30] Therefore, well over 100 years ago, a variety of temporal lobe epileptogenic substrates were recognized.

Surgical resection provided the link between medial temporal pathology and seizures by permitting the correlation of seizure control and electrophysiologic evidence of epileptogenicity with the resected tissue's histopathology. The first operations were pioneered by Horsley[18] in 1886, who performed surgery for epilepsy by excising visible cortical scars. Bailey and Gibbs, in 1951, popularized the resection of the temporal lobe using electrographic data, limiting their resection to the lateral temporal cortex.[5] Penfield[20] also adopted intraoperative electrocorticography (ECoG) to determine the extent of his temporal lobectomy, but, with Baldwin, he noted an increase in successful outcome with more complete resection of the medial structures (amygdala and anterior hippocampus).[60]

Early Role of Pathology

Surgical experience continued to verify the significance of the medial abnormalities. Earle et al.,[12] in 1953, described diffuse atrophic changes in the inferior medial portion of the temporal lobe in the majority of their patients with epilepsy who underwent temporal lobectomy. Margerison and Corsellis[43] found hippocampal sclerosis (neuron loss and gliosis) in patients diagnosed with TLE. Morris, in 1956, described intraoperative abnormal electrographic discharges originating from the amygdala and anterior hippocampus and pointed out that pathologic changes were most noticeable in these structures.[48] He proposed that the "standard temporal lobectomy" should include 6.5 cm of the lateral cortex, the uncus, the amygdala, and 2 to 4 cm of the anterior hippocampus. This was similar to Walker's description of the standard temporal lobectomy.[97] Falconer then described detailed pathology in the en bloc temporal lobe resections he performed. The atrophy and gliosis he found included and extended beyond the hippocampus, leading him to call the abnormality mesial temporal sclerosis (MTS).[15] He noted that patients exhibited a better prognosis if either MTS or a lesion was discovered within the specimen.[16,17] Falconer also directed his resection to the lateral temporal neocortex, but the emphasis on medial pathology served to help model most technical modifications that followed.

Impact of Early Electrophysiology Studies

Stereotactic depth recordings, introduced by Bancaud and Talairach,[6,88] further altered patient selection. This technique of using acute interictal recordings with depth electrodes provided better intracranial electrophysiologic localization of some partial epilepsies. Crandall also used depth electrodes, but extended the use to chronic recordings of both medial and lateral temporal lobe during seizure events. He also adopted a standardized en bloc resection, which preserved the tissue anatomically, and this was, therefore, well suited for the correlation of ictal electrophysiology with tissue histopathology.[9,38] These intracranial studies demonstrated the frequent hippocampal origin of ictal events in TLE, stimulating further surgical interest in medial resection and setting the stage for more selective surgical intervention and more sophisticated tissue studies.[75,101]

Impact of Neuroimaging

During the decade between 1975 and 1985, computerized tomography (CT) revolutionized neurology's and neurosurgery's diagnostic acumen, particularly regarding intracranial hemorrhage, stroke, and some brain tumors. The impact on the surgery of medically refractory epilepsy was limited, but a great

deal of progress was made by coupling video electroencephalographic (EEG) monitoring and intracranial electrode technology. Positron emission tomography (PET) began to confirm unilateral temporal lobe metabolic dysfunction in a majority of patients who were concordantly localized to the same medial temporal lobe.[14] In the late 1980s, magnetic resonance imaging (MRI) confirmed that the neuronal loss and gliosis that had been demonstrated pathologically for decades could be visualized as hippocampal atrophy and signal change. This stimulated a number of clinical investigations that correlated these MRI changes with both quantitative hippocampal cell counts and qualitative visualization and surgical outcome. Because these were retrospective studies, it is not surprising that there is a strong correlation of hippocampal pathology and MRI hippocampal atrophy discovered in patients coming to partial temporal lobe resection. In most studies, an imaging abnormality was a major criterion for selection of surgical candidates. On the other hand, even in series in which both MRI and invasive monitoring were used to select patients with presumed TLE, a high incidence of hippocampal neuronal loss and gliosis was identified in the resected tissue and was highly correlated with preoperative MRI quantitative atrophy and hippocampal signal change.[35,36,81]

A meta-analysis of the literature was performed to determine whether any one imaging method was more sensitive to the detection of TLE and how these methods correlated with each other.[80] The techniques available for analysis included MRI, single-photon emission computed tomography (SPECT), and PET. Both MRI and PET were highly intercorrelative and quite sensitive and specific to mesial temporal sclerosis the most common substrate of medial temporal lobe epilepsy (MTLE), but they did not delineate other forms of pathology that might be more subtle and more regional, such as cortical dysgenesis. There is evidence that the extent of resection of areas identified as hypometabolic by PET is related to short-term outcome.[94] Thus, imaging, invasive electrophysiology, and light microscopic pathologic studies directed the surgeon's attention to the medial temporal structures as the primary generator or amplifier in TLE. What has become increasingly clear is that the medial temporal structures participate in a much larger, complex network. The individual variations in both the location and extent of damage of this network lead to the clinical phenomena that we associate with temporal lobe epilepsy. Magnetic resonance spectroscopic imaging has also corroborated evidence based on anatomic MRI that frequently there are *bilateral* medial temporal abnormalities.[58] These abnormalities may actually improve following resection of the lobe responsible for seizure generation.[92] It is likely that variations in both of these network-related findings contribute to variations in outcomes as well.

Frequency of Use

Temporal lobe resection in some form continues to be the most commonly performed operation for the medically intractable symptomatic epilepsies. Almost all temporal lobectomies performed before the late 1970s involved a generous lateral temporal neocortical resection, which was either standard or determined by intraoperative ECOG spikes and limited by essential cortex such as language and visual fields. The volume of medial hippocampus, parahippocampus, and amygdala removed was extremely variable and surgeon dependent.

In the late 1970s, based on invasive electrophysiology and pathology, Spencer modified the standard resection for those patients with medial temporal ictal onset, such that all of the medial structures (amygdala, hippocampus, and parahippocampus) were removed via a limited temporal pole resection.[75] At the same time, Wieser and Yasargil independently devised the more restricted amygdalohippocampectomy for presumptive medial basal epilepsy with or without an associated amygdalohippocampal mass (usually tumor).[100] Although some centers still perform generous lateral resections often based on ECOG, modifications of these more selective medial approaches have been used increasingly over the last decade. The increased use of selective medial resection has been based on the aforementioned convergence of medial electropathophysiology and on additional literature demonstrating more failures of temporal lobe resection when the medial structures are incompletely resected.[51,56,63]

Recently, a number of centers have looked at the seizure and neuropsychological outcomes of patients that have undergone transsylvian selective amygdalohippocampectomy.[57] These results seem to indicate that seizure control is equivalent to that with resections that involve limited resection of the lateral structures.[57] The neuropsychological results show either equivalence[41] or some trends toward decreased morbidity for functions involving the temporal lobe but increased morbidity for frontal lobe functions, especially when associated with subarachnoid hemorrhage from the sylvian dissection.[25]

Indications

Principal Candidates

The following discussion is concerned with patients undergoing evaluation for surgical candidacy for treatment of *intractable epilepsy*. Typically, patients with new-onset seizures and significant MRI findings are treated with paradigms that address their underlying pathology first but may be considered for epilepsy surgery should their epilepsy prove to be intractable despite optimal treatment of their underlying pathology.

Patients With Pathogenesis Acquired Younger Than the Age of 4 to 5 Years

Three groups of MRI-analyzed substrates are commonly recognized as epileptogenic and when found in the temporal lobe are presumed to be responsible for the ictal events and the typical behavior of TLE. The first is classical MTLE associated with the pathology of MTS (neuronal cell loss, gliosis, and synaptic reorganization). The other imaged substrates are responsible for lesion-related TLE (LRTLE) and are not restricted to the temporal lobe but may interact uniquely with this portion of the limbic system and require special attention, particularly when they are situated medially. These are primarily vascular cavernous angiomas (CAs), arteriovenous malformations (AVMs), focal developmental abnormalities (DAs), and low-grade neoplasms. The last group, cryptogenic TLE (CTLE), has no imaged lesion or atrophy, and the temporal lobe is identified as the presumed epileptogenic source based primarily on electrophysiology.

MTLE represents 60% to 70% of all localization-related epilepsies and constitutes a syndrome because it has been defined by a common etiology (early injury, particularly febrile seizure at age <4 years), diagnostic evaluation, unilateral ictal EEG and MRI hippocampal atrophy, resistance to medical therapy, and responsiveness to selective resection. The pathogenesis of this syndrome represents a special substrate (MTS), even if the etiology and maintenance of epileptogenicity are not fully understood.

The patients with LRTLE do not have a significant history of early injury, are older when their seizures begin, most frequently have unilateral temporal scalp EEG ictal onset, and, with the exception of some DAs, respond well to resection of the mass and a surrounding margin of tissue.[77] It is not clear whether any of the medial temporal lobe structures other than

the immediate surround need to be included in the resection for seizure control. The resected hippocampi of this group generally have the characteristics of relatively normal tissue, with only some neuronal loss and no reorganization.[33] A variable percentage of hippocampi associated with lesions may demonstrate atrophy on MRI. This does not necessarily indicate that the atrophic hippocampus is nonfunctional and epileptogenic and should be removed.[21] Although this dual pathology has been increasingly characterized by hippocampal atrophy with neocortical DAs (mostly neuronal dysgenesis), the concurrence of a mass and hippocampal atrophy has stirred a debate regarding whether the hippocampus has been only passively injured or is epileptogenic and needs to be removed for best seizure control.[37] There are insufficient data to answer this question, but it is particularly relevant when dominant, temporal lobe–specific, short-term memory is normal or only mildly impaired and a medial dominant mass has been targeted for resection. Is the atrophic hippocampus or its more normal adjacent parahippocampus capable of normal function, and is there a risk of cognitive deficits if it is included in the resection?[66] The LRTLE group shares this feature of a usually preserved hippocampus with patients in the CTLE group. Patients with CTLE have presumptive electrophysiologic localization but do not have the consistent history of developmental injury or medial temporal lobe atrophy visualized on MRI.

Patients With Pathogenesis Acquired Older Than the Age of 4 or 5 Years

Trauma and infection after the age of 4 or 5 years may cause isolated injury and consequent excitability in one temporal lobe, but frequently there is more diffuse neocortical involvement requiring invasive electrophysiology for localization.

Thus, patients who have medically intractable complex partial seizures with regional temporal lobe scalp EEG localization may be candidates for some form of temporal lobe resection. The form this resection takes, however, varies considerably with a given substrate. Patients with CTLE or TLE acquired after age 4 or 5 years should be evaluated for resection based on invasive recordings, and such resection should exclude the reorganized essential brain, such as those areas governing language and verbal memory.

Evaluation Criteria

Selecting patients with TLE for the appropriate operation begins by first using MRI to classify them into the three anatomic substrate categories noted earlier: (a) hippocampal atrophy (MTLE with presumed MTS), (b) lesions (LRTLE), and (c) normal anatomy (CTLE). Noninvasive tests are then applied to search for either concordance to an anatomic abnormality or a well-delineated temporal lobe EEG localization when the MRI is normal. For example, in a patient with a history of febrile seizures or early injury at age <4 years and unilateral hippocampal atrophy, a selective medial temporal resection might be indicated if the MTLE syndrome was confirmed by video-EEG–recorded appropriate ictal pattern, temporal lobe–specific short-term memory deficit, and unilateral hypometabolic PET scan when available. Finally, although the method and interpretation vary considerably, the intracarotid Amytal procedure (IAP) will usually demonstrate a more specific memory deficit in the suspicious temporal lobe.

A patient with a temporal lobe lesion also requires EEG concordance. Neuropsychological, PET, and IAP testing can range considerably from normal to various degrees of abnormality. These latter three tests are not well categorized regarding usefulness in deciding about a resection or its volume. Nonetheless, the concordance of scalp EEG and anatomic substrate directs the surgeon to a specific region. The variability of other tests can result from lesion location, extent and age of an injury or lesion, and the central nervous system response to the same. The IAP's major role has been to assure the physician that memory is adequate in the temporal lobe opposite to the one to be surgically addressed. Outcome studies with substantial numbers of patients are needed to clarify how cognitive testing, IAP, PET, and ictal and interictal SPECT can be used in modifying decisions based on the major criteria of MRI substrate and EEG localization.

In cases in the third category (CTLE), in which hippocampal atrophy or T2 signal change does not clearly predict MTS and the MRI appears normal, all EEG criteria must be typical of MTLE and the PET scan likewise positive for selective medial temporal resection to be performed in some centers. Patients in this group with a normal MRI often undergo chronic invasive electrophysiologic recording of seizures. Almost all centers agree that some form of invasive recording must be used if the preoperative evaluation criteria are discordant with one another; particularly when any imaging abnormality (MRI, PET, or SPECT) conflicts with the EEG. The temporal lobe resection region will then be tailored to the invasive ictal findings.

Chronic invasive electrophysiologic monitoring shows that the majority of ictal events observed in TLE originate in the medial temporal lobe, often within the hippocampus.[78,79,82,83] Electrographic ictal localization with invasive studies, such as depth and subdural electrodes, is accepted as the most accurate method for identifying the region of seizure onset.[14,23,79] Use of interictal spikes was advocated historically and is still advocated by some to define the cortical resection.[55] However, the location of interictal spikes has only been weakly correlated with the site of ictal onset or any pathology within the resected tissue.[23,72]

Considering that interictal spikes may represent synaptically mediated events propagated from distant abnormal sites, this finding is not unexpected.[103] Epileptiform spiking can be nonspecific because it has been described in nonepileptic individuals.[8] Ictal electrophysiologic data remain the standard for resective procedures for TLE. The disconnection of afferent and efferent networks also helps to explain how varied temporal lobectomy approaches across the spectrum from standardized to tailored resections can have similar outcome efficacy.

Discordant electrophysiology and imaging also may be seen in patients with LRTLE and may lead to invasive recordings to clarify ictal onset. When an MRI lesion is present, the necessity for invasive EEG is substrate dependent. It is infrequently necessary when the lesion is a neoplasm, circumscribed DA, or CA, unless there is ictal scalp onset clearly from another lobe or the opposite hemisphere. Other MRI lesions may not be associated so robustly with just perilesional epileptogenicity because a microscopic substrate may extend beyond the imaged abnormality. These patients with LRTLE require invasive recording to define the necessary and sufficient temporal lobe volume that must be removed. Common lesions in this category are most of the DAs, such as cortical dysplasia and gyration defects, and the indeterminate substrates, including traumatic and infectious gliosis and neuronal loss. Separate consideration for invasive monitoring may be necessary to stimulate and localize certain essential cortical regions such as language and sensorimotor areas when awake craniotomies are not possible, such as in children or adults with limited ability to undergo awake procedures.[23]

Goals of Surgery

In MTLE that meets evaluation criteria, neuropathologic, neuroanatomic, and neurophysiologic[10,33,102] findings all identify abnormalities in the medial temporal structures, particularly

the hippocampus. Therefore, an extensive medial resection removes the majority of this epileptogenic substrate. Accumulated evidence suggests that the medial structures should be resected extensively in this syndrome. Depth electrodes placed parallel and through the long axis of the hippocampus have shown that electrical abnormalities are usually found throughout the body of the hippocampus, and less often is there a distinct segment of the hippocampus that initiates the seizure. In approximately 20% of patients with unilateral TLE studied with depth electrodes, abnormal electrical foci in the posterior portions of the hippocampus were not routinely resected by traditional standard lobectomies.[78,83] MRI most frequently shows atrophy of the entire hippocampus.[44] And although investigators have described a decreasing gradient of neuronal cell loss from anterior to posterior hippocampus, pathology is generally seen throughout.[4] The need to include the posterior portions of the hippocampus in the medial resection was addressed by designing a more radical hippocampus and parahippocampectomy that preserved the lateral temporal cortex—the anterior medial temporal resection (AMTR). Finally, Wyler et al. reported a prospective, randomized study of patients undergoing surgery for MTLE, with ictal onset verified in each case by subdural recordings.[105] They compared the AMTR to a more limited medial resection in this group. Complete seizure control was seen in 69% of the AMTR patients and in only 38% of the patients with a partial hippocampectomy. Other surgical options are also reviewed in what follows, representing variations of opinion of the extent of medial resection necessary and sufficient for success, and representing different approaches to minimizing the functional disruption of overlying cortex. They all share the common goal of medial temporal resection, specifically of the hippocampus.

Surgical Approaches

Reliance on Presurgical Evaluation Emphasizing the Substrate

Medial Temporal Lobe Epilepsy

Most temporal lobectomies today are subtotal temporal resections for MTLE where MTS is the presumed pathology based on MRI showing unilateral atrophy and/or increased T2 signal change in one hippocampus. Dysfunction of this temporal lobe, particularly the medial region, is expected in this syndrome and corroborated by specific cognitive deficits, particularly temporal lobe–specific memory loss and PET hypometabolism. Temporal lobe ictal onset recorded by scalp electrodes may be sufficient to assume relatively isolated medial temporal lobe epileptogenesis when imaging and cognitive deficits are concordant. Invasive medial electrical onset using depth electrodes and/or subdural strips may otherwise be required. With either of these approaches, that is, concordant noninvasive studies or invasive recordings, the medial temporal lobe has become increasingly the targeted region of resection. Resection strategies in this syndrome still include intraoperative ECoG in some centers, but most involve removing a preoperatively determined volume of temporal lobe, emphasizing substantial parts of the hippocampus, parahippocampus, and amygdala and preserving the lateral temporal neocortex.

Anterior Medial Temporal Resection.

The extent of lateral temporal resection in the AMTR developed at Yale is limited to the temporal pole to provide access for a generous resection of the medial structures (Fig. 1).[72,74,75] Because cognitive function is not at risk in the majority of patients with MTLE, this complete removal of amygdala, hippocampus, and parahippocampus is logical because maximal efficacy is assured with one definitive safe surgical procedure.

This method's advantages are similar to those of the other approaches described later. They all preclude intraoperative ECoG, and the limited anterior temporal resection makes language mapping unnecessary in the dominant hemisphere. Operations can then be performed under general anesthesia. With this approach, visual field cuts often can be avoided or, if present, not exceed a partial contralateral superior quadrantanopia.

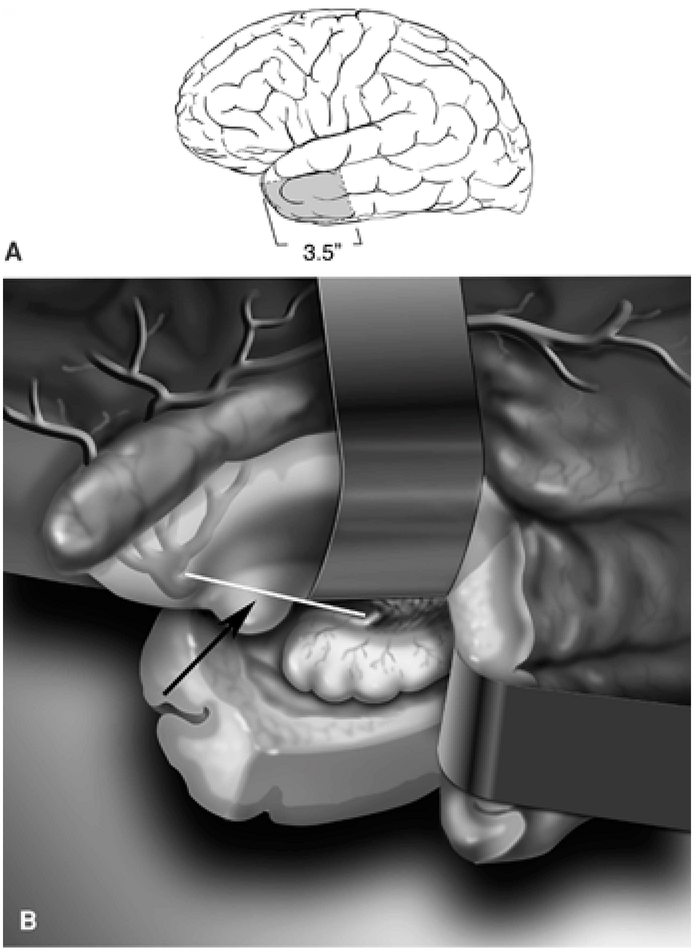

FIGURE 1. Anteromedial temporal resection. **A:** The lateral resection is invariant from dominant to nondominant side and consists of the anterior 2.5 to 3 cm of the middle and inferior temporal gyri. **B:** Diagram illustrating retractor placement and exposure of the medial temporal lobe structures as viewed from anterior to posterior. Arrow points to a line connecting the "knee" of the middle cerebral artery in the sylvian fissure to the velum terminale or anterior choroidal point in the temporal horn of the lateral ventricle. This line is used as a guideline to the extent of the resection of the amygdala.

Standardized AMTR permits assessment of intact tissue from the en bloc removal and allows evaluation of surgical outcome without the confounding variations inherent to varied tailored resections. Standardized procedures permit studies of induced changes in neuropsychological and psychosocial function, validation of presurgical criteria, and correlation of the pathology in the resected tissue with new assessment criteria and modalities.

Transsylvian Amygdalohippocampectomy.

Wieser and Yasargil reported a series of patients who underwent selective unilateral amygdala-hippocampectomy for drug-resistant TLE.[100,101] Their operation was very selective, including only the amygdala, uncus, and hippocampus posteriorly to the level of the superior colliculus. With their transsylvian approach, lateral temporal cortex was not resected. Detailed neuropsychological testing was not reported for these patients, but the investigators thought in general that there were fewer

functional deficits than in a comparable group that they treated with larger temporal lobectomies.

The transsylvian approach is technically demanding.[101] In addition to limitations associated with the very restrictive exposure, there is a risk of morbidity related to dissection through the sylvian fissure. This involves possible damage to the sylvian veins, branches of the middle cerebral arteries, the anterior choroidal artery, and the branches of the posterior cerebral artery.[34] The vessels need not be damaged, because vasospasm alone can result in hemiparesis or hemianopsia. Both vasospasm and blood flow are significantly different in patients undergoing transsylvian versus transcortical approaches.[67]

Transcortical Transventricular Amygdalohippocampectomy.

Niemeyer, in 1958, presented a small series of histologic abnormalities mostly within the hippocampus of temporal lobes removed by standard temporal lobectomy[52,100] and provided the rationale for the procedure he went on to describe. He developed a transventricular amygdalectomy and a 3-cm hippocampectomy performed through a 2-cm middle temporal gyrus incision. The disadvantages of this technique include its limited field of exposure and its preclusion of en bloc excisions. A variation of this approach is used by Olivier at the Montreal Neurological Institute for selective resections.

Subtemporal Amygdalohippocampectomy.

The subtemporal approach is also technically complex because it entails zygomatic process removal for exposure of the inferior middle fossa. For rare cases of tumor or cavernoma in the dominant hemisphere, this can be considered, but alternative approaches, notably awake temporal lobectomy with functional mapping, is usually preferred.[107]

Stereotactic Frame, and Frameless Amygdalohippocampectomy.

Open stereotactic selective amygdalohippo-campec-tomy[34] is also described as a method for minimizing neocortical resection. Although the technique was developed for removal of neoplastic lesions, it has been used in selective resections of the amygdala–hippocampal complex in patients with TLE.[32] The lateral transcortical temporal approach uses a stereotactic, computer-based, image-directed system. According to its advocates, this method offers selective resection with very limited superficial cortical resection, avoiding the functional cortex and not exposing important vascular elements. A large series using this technique is not available for comparing efficacy of seizure control and neurologic outcome.

There are also isolated reports of closed stereotactic ablations of medial structures in the literature.[50,85,89] However, they are limited to relatively small areas of anatomy and usually have poor results. No formal modern series comparable with open craniotomies is available.

Lesional Temporal Lobe Epilepsy: Developmental Abnormalities, Neoplasms, and Vascular Anomalies

A complete preoperative evaluation is just as critical when an MRI lesion in the temporal lobe is discovered in a patient with chronic epilepsy.

To direct surgical attention to the lesion, the scalp EEG should be concordant, and video-EEG is recommended to confirm appropriate temporal ictal onset and verify the behavior of a complex partial seizure. In general, discrete MRI lesions of all three substrates—developmental, neoplasms, and vascular anomalies—can then be approached and the operation designed to remove the pathology and its surround until one is assured that only normal cytoarchitectural brain remains. Lesions in the lateral dominant temporal lobe require either intra- or extraoperative language mapping. More controversial is the handling of medial lesions adjacent to the amygdala and hippocampus, sometimes called the parahippocampus complex.

Three surgical solutions to this problem are possible. First, only the lesion may be removed; second, the lesion and some portion of the medial structures may be removed to assure a margin of resection; and, finally, a formal AMTR may be performed in addition to removal of the lesion. The larger, more complete resection may sound more attractive; however, often cognitive testing shows normal specific short-term memory. A medial resection in the nondominant hemisphere may be functionally inconsequential; however, the same resection in a normally functioning dominant hemisphere may drop verbal memory scores by more than two standard deviations and significantly affect the patient's learning ability and quality of life.

Some still advocate a medial resection in these circumstances when the hippocampus is atrophic on MRI, feeling that this represents the dual pathology of lesion plus MTS. However, hippocampal atrophy may be seen accompanying a variety of lesions at variable distance from the medial temporal lobe where lesion resection alone has been sufficient to stop seizures. As a corollary, dominant temporal lobe–specific memory may be normal in the setting of hippocampal atrophy, and resection of that hippocampus may still be harmful. There are clearly not enough data in this regard to solidly support one or another approach. Therefore, it may be most prudent to approach this problem with a conservative resection when faced with normal cognitive examination results. This issue again emphasizes the importance of the preoperative evaluation in the surgical decision.

Another controversial problem regarding MRI lesions is the DA and gliosis of trauma. Although there are no outcome data to support this approach, it is not unreasonable to handle discrete DAs (hamartomas) like neoplasms and vascular anomalies. On the other hand, when MRI depicts a more diffuse DA, such as pachygyria or schizencephaly, and the gliosis of trauma, invasive recording is recommended to define what broader epileptogenic region is most likely. A resection based on these ictal recordings is again tempered by the cognitive evaluation, particularly in the dominant temporal lobe.

Cryptogenic Temporal Lobe Epilepsy: No Image Substrate

This group constitutes the most difficult management problem. They most frequently do not have the history or cognitive findings of MTLE, although the scalp electrophysiology and seizure semiology may demonstrate probable temporal lobe ictal onset. These patients require one and sometimes two chronic invasive recording sessions to define the resection volume. They may undergo an initial bilateral depth or subdural analysis to define the suspicious temporal lobe, and then they may require a more regional grid-and-strip study to define a more focal volume and its relationship to structures essential brain.

These resections are all totally electrophysiologically guided by a combination of ictal and interictal activity. In some instances, the seizure source is determined to be outside the temporal lobe such as the occipital or temporooccipital region and projected into the temporal lobe. Nonetheless, good surgical outcome is less well assured in this group, and the resected tissue is either normal or, increasingly, the DA of neuronal microdysgenesis is appreciated. This is clearly a group of patients that needs further intense scrutiny before they can be appropriately classified and treated.

Alternatives to Resection

For some patients, neuropsychological morbidity or patient preference leads to considerations for alternatives to resection to ameliorate seizure activity. For patients in whom the morbidity or resection is too high, for instance, in patients with well-preserved verbal or visual-spatial memory ipsilateral to the intended resection or demonstrated poor memory contralateral to resection by IAP, nondestructive means of altering the pathologic network can be entertained. Either programmatic[90] or

P.1864

responsive electrical stimulation[47] directly to the hippocampus or parahippocampus has shown limited success in early studies. Other groups are attempting multiple subpial transections of the hippocampus, but superior neuropsychological outcomes and seizure efficacy have yet to be substantiated.[70] For patients wishing to avoid open surgery for health or other considerations, several groups have attempted stereotactic radiosurgery, again, with limited[65] to no success.[86]

Outcome and Predictors of Success

Success

Comparing success rates among different surgical techniques or among different epilepsy centers is difficult because a uniform criterion of success has not been established. Typically, outcome of surgery for TLE is reported with respect to seizure frequency, usually independent of whether patients remain on anticonvulsant medications.[64] Efforts recently have been made to include quality-of-life indicators such as social and personal factors in outcome classification schemes because social, familial, psychiatric, and employment issues are recognized as equally important in describing the overall outcome and success when treating this functional disease. Outcome can be considered quite individualized. For example, a rare seizure in one individual may represent a dramatic improvement in this patient's life, whereas in another patient even one rare seizure could have a serious negative effect. Because reports of various centers often depend on the variables that reflect the center's surgical philosophy, outcome for a particular procedure may be directly related to the patient selection process. Therefore, direct comparisons between published series cannot be readily made.

The binary classification scheme of being either seizure free or not seizure free offers the most valuable information because it is the seizure-free category that has the most potential impact on a patient's life. Neuropsychological improvement and the quality of life show the most improvement when the patient is seizure free[27,39,93,96]; however, subjects do report a meaningful positive change in health-related quality of life with either Engel grade I or II outcomes.[95]

One-year outcome statistics show that with AMTR, 78% of the patients with MTLE have complete seizure control. As a comparison, patients with temporal lobe tumors with TLE had an 85% seizure-free outcome.[74,77] In the short term, patients experience benefits in quality of life regardless of seizure outcome, but by 1 year the two groups significantly diverge.[84] At 2.5 to 5 years, patients who undergo surgery report better quality of life than matched nonsurgical controls.[45] Patients' outcome groups do not remain static over time; even at 10 years, patients who initially have enjoyed seizure freedom may relapse.[106]

Surgical Failures and Their Pathoetiology

In the majority of surgical failures, seizures recur within the first year after surgery, often as early as in the first weeks and months after surgery.[13,40,87] Seizure recurrence increases progressively with the length of follow-up; however, being seizure free 1 year after surgery is an excellent predictor of continued seizure-free outcome.[40] Engel reported that 79% of patients seizure free at 1 year remained seizure free at 5 years, and 63% remained so at 10 years.[13] In a large multicenter evaluation of outcomes, similar numbers were found: 83% of patients at 1 year, 72% at 5 years, and 56% at 10 years, although about half of these patients experience one or fewer seizures a year.[106] Realizing that the original insult that these patients suffer can sometimes be linked to a remote childhood event, such as febrile seizures, that does not manifest itself until adulthood, one can hypothesize that a slow “neurodegenerative” process might be responsible for some of these late failures.

There are several reasons for surgical failure. Epileptogenic scarring at the resection edge is uncommon and perhaps just theoretical; proving this is difficult. However, there may be a predisposition to epileptogenicity in these patients, either genetic or acquired. Therefore, these patients are more prone for either recurrence or for developing new extra-resection epileptogenic areas.[1] A satisfactory resection of one epileptogenic region may still result in failure when another site such as the opposite medial temporal area begins or continues to cause seizures.[2,42] This probably is the etiology for many recurrences observed after years of seizure-free status. Outcome studies have correlated poor outcome with the duration of preoperative illness and the presence of normal pathology of the resected specimen.[106] An error in localizing the epileptogenic area during the preoperative evaluation will direct the wrong surgical removal and could be another cause of failure and thus lead to the findings of normal pathology. Localization error in presumed TLE cases may occur when seizure onset in the lateral temporal neocortex or in an extratemporal location was not recognized. This represents a failure of patient selection rather than a surgical technical failure. Often, repeat evaluation shows that both temporal lobes harbor dependent or independent epileptogenic potential. Finally, the association of lengthy preoperative illness with poor outcome raises the question of whether the phenomenon of secondary epileptogenesis within the network responsible for the patient's original seizures may play a role.

The most important reason for technical surgical failure is probably insufficient excision of epileptogenic tissue or, in the setting of a lesion, incomplete resection of the epileptogenic surround. This accounts for the majority of patients with recurrent refractory epilepsy. In patients with TLE, Olivier et al. recognized the role of retained mesial structures in patients with failed temporal lobectomy.[56] Wyler et al. also reported on a large series of reoperations, also concluding that primarily insufficient resection of medial structures at the first operation was the etiology for failure.[104] Awad et al. reported similar results. The majority of their cases had persistent epileptogenicity related to inadequate resection, retained mesiotemporal structures, or retained epileptogenic structural lesions. Other cases had more remote areas of epileptogenicity or diffuse epileptogenicity in the residual temporal lobe.[2,3]

Surgical failures should be managed aggressively. They require repeat evaluation with anatomic and metabolic imaging and video-EEG monitoring and careful review of their surgical pathologic profile (substrate classification).[73] The AMTR surgical approach results in a uniform aggressive hippocampal removal during the first operation. Therefore, failures of this resection are usually due to an epileptogenic contralateral medial temporal lobe or extensive ipsilateral regional disease, often of developmental origin in either the temporal or extratemporal cortex. Simply removing more lateral temporal lobe often is not successful in converting these failures to successes. In the setting of tumors, seizure recurrence often precedes radiographic tumor recurrence by about 6 months.[77]

In failed amygdalohippocampectomy patients, Wieser and Yasargil reoperated using a standard anterior temporal lobectomy with a 50% success rate.[99] Short- and medium-term seizure control has been accomplished in most of the reported cases of reoperation.[42,56,104] Nearly half the reported patients in another series[3] remained seizure free for periods of up to 72 months, and another one third showed worthwhile improvement in seizure frequency despite severe intractable seizures before reoperation.[2]

Neuropsychological and Neurologic Sequelae

With resective surgery involving the hippocampus and lateral temporal lobe, one would expect possible sequelae of visual field defects, deterioration in memory function, and fluent dysphasia. The visual field defect in a patient who has an anterior temporal lobectomy is usually a superior quadrantanopia contralateral to the surgery.[91] The visual loss becomes more hemianopic as the lateral incision is extended more posteriorly.[19,31] The posterior location of the optic radiation fibers is variable among individual patients, and, as a rule, patients will acquire more than an upper quadrant visual field cut. By limiting the lateral cortical resection to only that sufficient to allow entry into the temporal ventricular horn (3–3.5 cm from the temporal tip), typically one observes only a partial superior quadrantanopia or often no field defect at all. A homonymous hemianopsia has never resulted.

Dysnomia and other fluent speech errors elicited by stimulation are found in variable locations on the lateral temporal cortex of the dominant hemisphere.[54] Resecting these positive stimulation areas is thought to result in some degree of permanent fluent dysphasia. Preserving one gyrus between the cortical incision and the most anteriorly located site of the speech error most often avoids a permanent speech deficit. With stimulation in awake patients, only one occasion of fluent speech was represented in the Yale series more anteriorly than 4.5 cm on the middle temporal gyrus and 3 cm on the superior temporal gyrus, as measured from the anterior temporal tip.[54,75] This is well beyond the posterior resection margin. Wyler studied language function in patients with medial temporal epilepsy who underwent anterior temporal lobe resection modeled after the AMTR description.[29] He found that AMTR of the dominant hemisphere can be accomplished without intra- or extraoperative language mapping with no measurable compromise of language function.[29] He also demonstrated that patients rendered seizure free by any surgical procedure demonstrated significant gains in several language areas, whereas patients who continued to experience even some seizures showed no improvements in language function.[26]

Historically, the hippocampal model of human memory was elaborated by Scoville, Penfield, and Milner, who observed that bilateral hippocampal ablation produced permanent complete amnesia.[46] They also found that the dominant hippocampus served verbal memory function, whereas the nondominant hippocampus served nonverbal (i.e., visual-spatial) memory function, and that the extent of unilateral hippocampal ablation seemed to relate to the severity of the memory deficit.[46,62] This is contrary to the Yale group's findings that patients who underwent extensive unilateral hippocampectomy did not demonstrate either amnesia for specific material or memory impairment greater than that occurring with traditional partial hippocampectomy.[75] This is probably a result of selection because AMTR is not typically indicated in patients demonstrating intact material-specific memory on the presumed affected side. Typical patients with MTLE have had an early injury to the medial structures that are not generally functional.

This also may support the concept that temporal lobe memory mechanisms are not exclusively confined to medial temporal structures.[75,101] Ojemann reviewed the occurrence of verbal memory deficits after dominant hemisphere temporal lobectomies and found that they correlate with the extent of lateral, but not medial, resection.[55] All of these findings suggest that it is the lateral cortex rather than medial structures that must be preserved to avoid memory deficits in this particular epileptic population but not in the group that retains modality-specific memory.[69,76]

It is known that seizure activity and many anticonvulsants depress cognitive functions,[11,68] and following surgical control of seizures, selected cognitive functions improve. The improvements are due to the elimination of ictal disturbances and from reduction in medications. The most likely improvements to occur are those related to general measures of cognition such as IQ and learning or to selective functions associated with brain regions outside the resected area.[28,49,53,64,98] Therefore, there is growing evidence that a limited anterior temporal resection in either hemisphere does not produce significant long-term adverse neurologic or neuropsychological sequelae, and the result of a seizure-free status may even improve the patient's neuropsychological baseline.

Surgical Complications

Complications are not frequent. There are general complications of neurosurgical procedures that are common to all intracranial operations, and there are specific neurologic complications associated with AMTR. General complications include acute postoperative hemorrhage, retraction injury, wound infection, and the usual perioperative sequelae such as anesthetic and medication intolerance, deep vein thrombosis and infections of the bladder, lung, and intravascular lines.

Transient Deficits

Complications associated with AMTR and other temporal lobectomy procedures for TLE are considered separate from the transient deficits that are seen. Penfield described “neuro-paralytic edema,” which contributed to the transient deficits he observed.[59] Whether it is retraction injury or functional damage from temporary ischemic conditions, if functional cortex is involved, then transient neurologic dysfunction will result. Such deficits include memory impairment, decreased spontaneous speech, and anomias. Transient diplopia, ptosis, and pupillary dilation result from manipulation of the third and fourth cranial nerves just under the arachnoid of the perimesencephalic cisterns and the tentorial edge. These transient deficits invariably clear within several days but sometimes may last longer.[96]

Permanent Deficits

Anything less than a contralateral upper quadrant defect should not be considered a complication. In 1961, Penfield et al. presented eight patients who developed a postoperative hemiplegia,[61] which Penfield called “manipulation hemiplegia.” He believed this to be a consequence of traction on the middle cerebral artery perforators, resulting in vasospasm and infarction of their vascular territory.[24,61] In >300 temporal lobe procedures, Girvin had only 1 postoperative hemiplegia that was due to infarction within the internal capsule.[22] This was attributed to injury of the anterior choroidal artery. Early in the Yale experience, a patient was encountered who experienced a dense contralateral hemiparesis but who, fortunately, subsequently recovered. MRI showed that this was clearly a result of coagulating the choroid plexus lying on the hippocampal body with inadvertent coagulation of a branch of the anterior choroidal artery. Anterior choroidal artery injury probably accounts for the majority of manipulation hemiplegia cases. The choroid in the choroidal fissure should be gently retracted and never coagulated.

Summary and Conclusions

Evaluation of the MRI and study of the resected hippocampus show that there are different forms of TLE characterized by history and image, as well as by the degree of neuronal cell loss, gliosis, and neuronal reorganization within the hippocampus. LRTLE is associated with a structural mass, usually a low-grade tumor or cavernoma. In general, the hippocampus is removed

in these patients only if a margin is required for complete tumor extirpation. Conservative hippocampal resection in these patients is always the rule in the dominant temporal lobe with intact short-term verbal memory. AMTR was designed for the treatment of MTLE that involves the medial structures, and by offering en bloc resection of these structures, this operation is ideal for clinical studies in which the anatomically intact pathologic substrate is required.

Patients who undergo AMTR require careful preoperative evaluation and, if selected properly, have had excellent seizure control, small visual field defects, and fewer and shorter-lived speech deficits. Neuropsychological testing shows no additional deficits resulting from modified temporal lobectomy compared with the deficits seen after the standard operation. Most patients have had less impairment in visual-spatial perception than was common with the more standard lobectomy. Because of these encouraging results, some form of limited medial resection has gained popularity as a standard operation for MTLE.[75]

Introduction

The histories of extratemporal epilepsy, epilepsy surgery, and neurosurgery are intimately related. The intractability of posttraumatic epilepsy led to the early use of trephination as a treatment modality. In the eighteenth century, Percivall Pott, a British neurosurgeon, established that the brain rather than the skull was responsible for the seizures. Posttraumatic scars were often focal and offered guidance for early neurosurgeons into the functional anatomy of the brain. The era of modern neurosurgery was ushered in by Sir Victor Horsley,[46] who introduced asepsis, anesthesia, and the new science of cerebral localization. He also described the technique of subpial cortical dissection and resection, a standard technique used by epilepsy surgeons today.

The seizure outcome after surgical management of patients with temporal lobe epilepsy is excellent in most of the recently reported series,[73] and a recent randomized, controlled trial comparing surgical to medical treatment showed a significantly better outcome in the surgical group.[136] However, the results of surgery in extratemporal epilepsy are less encouraging. Many factors seem to account for this difference: Whereas mesial temporal sclerosis constitutes the majority of temporal lobe epilepsies, extratemporal epilepsy is a more heterogeneous group and lacks a common pathologic substrate. Furthermore, the difficulty in interpreting the semiology, the uncertainty of the localizing value of the different studies performed, and the vicinity of eloquent areas to the epileptogenic focus in many of these cases appear to decrease the chances of obtaining an excellent outcome.

In spite of the difficulties previously mentioned, recent radiologic and neurosurgical advances undoubtedly revolutionized this field: Modern anatomic and functional imaging are able to detect more-discrete lesions, and neurosurgical techniques help to optimize resections while minimizing morbidity.

Historical Perspectives

Impact of Neuroimaging

The advent of magnetic resonance imaging (MRI) and its ever-improving sensitivity in detecting cerebral abnormalities had its greatest impact on the surgical management of neocortical epilepsy. With the improvement in the anatomic details provided, more-subtle variations are being observed and a larger number of patients are being diagnosed as harboring neoplastic or developmental lesions. Nevertheless, even with these advances, MRI was unrevealing in 39% of histologically verified focal cortical dysplasia in a recent study,[22] and it has been estimated that ~25% of cases with refractory epilepsies have normal MRI.[67,120]

Overall, MRI is more sensitive in detecting tumors than neuronal migration disorders,[47] and in general, the detection of abnormalities by MRI is known to be associated with good surgical outcome.[47,69,147]

New MRI techniques such as diffusion-weighted MRI[29,80] and quantitative MRI[11] appear to be promising and may further help to localize the epileptic focus.

Impact of Pathology and Electrophysiology

Whereas most temporal lobe epilepsy (TLE) is characterized by hippocampal pathology,[12,61,62] neocortical epilepsy lacks a common pathologic substrate. A wide range of structural anomalies has been associated with chronic partial neocortical epilepsy. These anomalies can be classified into five large categories: (a) malformative, (b) tumoral, (c) ischemic, (d) traumatic, and (e) infectious. In a small number of patients, the nonspecific substrate of gliosis is found. Most of these lesions are not believed to be epileptogenic per se; rather, the epileptogenicity is due to excitability of the surrounding cortex. Numerous mechanisms have been implicated.[104,105] These include neurochemical changes, pressure effect, and ischemia. In the congenital malformative diseases, intrinsic epileptogenicity has been established with recording of continuous ictal epileptogenic discharges on electrocorticography.[86] Dual or multiple pathologic substrates are increasingly detected owing to advances in imaging techniques and careful pathologic studies from large surgical series. The occurrence of hippocampal volume loss in association with pathologies outside of the archipallium are examples of distant but coexistent disease.[17,66,72,101] Furthermore, the coexistence of dysplastic and neoplastic disease has been established in developmental tumors, for example, gangliogliomas and dysembryoplastic neuroepithelial tumors (DNETs).[50] This has important consequences for the surgical strategies, which are generally designed to resect all identified pathology for best results. In fact, the identification and resection of all focal pathology is considered a predictor of good outcome following neocortical resection.

Indications

Principal Candidates

The indications for surgery are discussed in the chapters referring to the surgically remediable syndromes (see Chapters 167,168,169). Briefly summarized, three major groups are identified.

The first group consists of lesional, nondevelopmental pathology causing partial epilepsy. A majority of these patients continue to have intractable epilepsy despite antiepileptic drugs

P.1870

(AEDs). A favorable outcome following resective surgery is expected, often with lesionectomy alone. The second group consists of developmental abnormalities causing partial epilepsy and is characterized by a more diffuse pathology and difficulty in precisely localizing the ictal onset zone (Table 1). Patients in this category are considered for surgical treatment only following failure of AEDs. The third group has partial epilepsy without evidence of a lesion on MRI or metabolic imaging. This is the most difficult subgroup of patients who have less favorable results following resective surgery. These patients should be investigated in an experienced epilepsy surgery center.

Table 1 Developmental abnormalities associated with epilepsy

Abnormalities of gyration	Megaloencephaly
Agria	Heterotopias
Macrogyria, focal, diffuse	Tuberous sclerosis

Polymicroggyria, focal, diffuse	Focal cortical dysplasia, microdysgenesis
Polymicrogyria, or macrogyria with cleft	Cortical dysgenesis associated with neoplasia

Evaluation Criteria

The goal of the evaluation criteria is to identify the epileptogenic zone, or the area of abnormal brain tissue responsible for genesis of the seizures, and its relationship to essentially normal brain. In this respect, the stages or steps in the presurgical evaluation are essentially similar to the evaluation of temporal lobe epilepsy. These steps include neuroimaging, interictal and ictal recordings with video-electroencephalography (EEG), neuropsychological testing, and the Wada test for speech lateralization. The value of the sodium Amytal test for memory localization in neocortical epilepsy is unclear[57] because in a significant number of patients a decreased memory reserve is noted without evidence of limbic disease.

Careful anatomic imaging is essential and should be performed early in the presurgical evaluation so as to guide the electrophysiology evaluation and correlate it with the lesional pathology using magnetic resonance imaging protocols. The specific sequences are evolving and at present include (a) a coronal, high-resolution volumetric acquisition (e.g., three-dimensional [3D] spoiled gradient-echo [SPGR]) in the coronal plane to produce 2-mm contiguous slices of the entire brain (flip angle 10/TR 11/TE 4.4/TI 300/250 mm Fov/192 × 256 matrix); (b) a conventional double-echo T2-weighted sequence in the coronal or axial plane (TR 2000/TE 20, 80/230 mm Fov/192 × 256/5 mm slice/2 mm gap); and (c) a two-dimensional fast fluid-attenuated inversion recovery (FLAIR) sequence in the coronal or axial plane (TR 2000/TE 80/TI 2400/230 mm Fov/192 × 256/5 mm slice/2 mm gap). The combination of the conventional pulse sequences is used to characterize a structural abnormality using morphology, signal intensity characteristics, and, if appropriate, the degree of enhancement with gadolinium. The fast FLAIR sequence has been particularly useful in localizing structural abnormalities of the neocortex and archicortex because it is essentially a heavily T2-weighted sequence with dark cerebrospinal fluid (CSF). This contrast results in increased conspicuousness of peripheral cortical lesions or subtle underlying white matter abnormalities that may be identifiable on the conventional pulse sequences only in retrospect. The volumetric acquisition is then used to further characterize morphology, accurately localize the lesion within the brain, and precisely define its 3D spatial relationships relative to adjacent normal brain. The 3D study is also specifically designed so that the data can be reformatted along any orthogonal or oblique plane without significantly compromising image quality or subjected to alternative postprocessing algorithms (surface reconstruction, volumetric analysis). This has been proven to be especially helpful in the identification of subtle neocortical developmental anomalies[121] (e.g., small focus of polymicrogyria or more subtle cortical disorganization) (Fig. 1) or very mild volume loss in the archicortex. Hippocampal volumetric data are obtained when a dual pathology is suspected.[17]

The role of positron emission tomography (PET) scanning in neocortical epilepsy is controversial.[1,128] In patients in whom a lesion is identified on MR, the PET scanning role is superfluous because the relationship between the ictal onset zone and the hypometabolic zone, when identified, has not yet been determined. Interictal PET has been carried out mainly with fluorodeoxyglucose and flumazenil. In temporal lobe epilepsy it demonstrates hypometabolism in 60% to 90% of patients; however it is less sensitive in extratemporal epilepsy (45%–60%).[42,118] Flumazenil-PET may have a higher sensitivity than fluorodeoxyglucose-PET in delineating the epileptogenic zone in extratemporal cases,[75] but these findings need further study for confirmation.

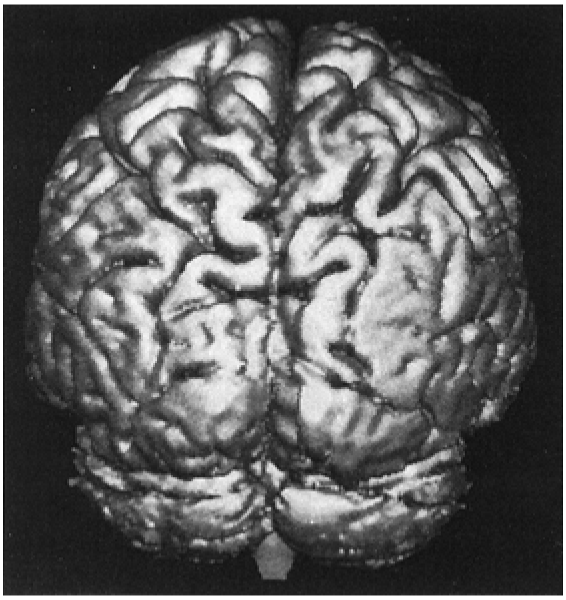

FIGURE 1. Posterior hemispheric three-dimensional volumetric re-cord rendering: A cortical dysplastic area is noted posterior parietal. This abnormality was not seen on standard magnetic resonance imaging studies.

Single photon emission computed tomography (SPECT) scanning performed interictally, and particularly ictally, can be of help in the localization of neocortical epilepsy. Ictal SPECT is complicated by the need to deliver the radiopharmaceutical early in the ictal phase and poor resolution leading to variable interpretation. The SPECT information should be used judiciously and carefully correlated with the electroclinical syndrome. Recent studies tried to establish its sensitivity and specificity. The following results were obtained when SPECT was compared to intracranial EEG recordings (considered as gold standard): Interictal SPECT was consistent with intracranial EEG localization in 33% of patients and was normal in 52% of

patients in whom seizures were localized by intracranial EEG. On the other hand, ictal SPECT was consistent with the intracranial localization in 74% of patients and was normal in 7% of cases in which seizures were localized by intracranial EEG. The presence or absence of a structural lesion did not appear to affect the reliability of ictal SPECT in this study.[126]

SISCOM (subtraction SPECT coregistered to MRI) refers to the subtraction of ictal and interictal SPECT scans with subsequent coregistration to MRI. This technique is clearly superior to conventional visual analysis and appears to be a better predictor of surgical outcome.[78,111]

Several centers have reported the use of proton MR spectroscopy in nonlesional epilepsy.[76,77] The high-resolution metabolic imaging is combined with precise delineation of anatomic structures. Decreased *N*-acetylaspartate (NAA) and increased choline are seen interictally. Postictally, a focal increase in lactate[36] appears to correlate with the ictal onset zone.

Goals of Surgery in the Ideal Candidate

The goal of the surgery is to render the patient seizure free without disturbances in cognitive function and off or with decreased antiepileptic medications. This goal can be reasonably achieved in patients with localized pathology and concordant with the electroclinical syndrome. In the less-than-ideal candidate, when a seizure-free outcome is less likely, surgery is undertaken when there are significant chances of seizure improvement and psychosocial gain.

Surgical Approaches

Reliance on the Presurgical Evaluation

History, Neurologic, and Cognitive Examination

In establishing the electroclinical syndrome, the history and physical examination are paramount, and family and friends can provide important information. The familial and prenatal histories yield clues to genetic susceptibility or early insults. Information concerning the natural evolution of the seizure pattern is gathered, particularly the presence of an aura, as well as findings of the various seizure types and response to medication for each type. The semiology of the ictal phenomenon can yield important clues to locate the generator. In some patients, subtle neurologic deficits are noted, which helps in the localization process. The cognitive deficits should be interpreted in relation to dominance established by the Wada test.[133] It is essential to establish the lateralization of speech in neocortical epilepsy because there is a high incidence of unusual speech lateralization in this patient population, particularly with an early age of seizure onset.

Scalp and Invasive Electroencephalography

Scalp EEG with interictal and ictal recordings are essential in the localization process of focal epilepsy. The distribution of interictal discharges correlates better with the extent and location of the epileptogenic zone than ictal recordings. Because in neocortical epilepsy the epileptogenic zone is larger than in temporal lobe epilepsy, the interictal discharges tend to be widely distributed. In addition, the availability of several pathways of propagation results in a poor localization of the ictal discharges. False localization–lateralization occurs in 28% of occipital and 16% of parietal lobe epilepsies. Generalized ictal onsets are noted in mesial frontal and occipital lobe epilepsies. Lateral frontal and parietal lobe seizures frequently have a localized onset.

To further define the ictal onset area, several classes of invasive electrodes have been introduced.[70] These consist of electrodes of intermediate invasiveness such as epidural pegs, foramen ovale, and more invasive electrodes such as depth, subdural grid, and strip electrodes. Each type offers specific advantages and disadvantages, and these are reviewed in Chapters 170 and 171. Recently, with the introduction of advanced MR techniques, there has been less reliance on invasive electrodes in the preoperative workup.

Functional Mapping

When the lesion or the epileptogenic zone involves or is adjacent to eloquent cortex, functional mapping should be performed so that a safe and complete resection is possible. Mapping is usually performed when resections are contemplated in the central area, dominant inferior frontal cortex, dominant temporal lobe posterior to the precentral sulcus, and the dominant parietal lobe and occipital lobe. A variety of mapping methods is available (see Chapters 173,174,175), and newer, noninvasive methodologies are being assessed, for example, functional MR techniques[10,24,63,79] and magnetoencephalography.

Awake Craniotomy

This technique has been facilitated with the introduction of propofol anesthesia[71] (refer to Chapter 174 for complete description of the method). Patient cooperation and an anesthesiologist familiar with the technique are essential.[4] This technique provides continuous feedback while the patient is maintained awake during resections adjacent to language areas. An awake craniotomy is difficult to perform in children, who, therefore, may require an implanted grid and extraoperative language mapping.[2]

Acute Mapping Using General Anesthesia and Intubation

Cortical stimulation can be performed in the primary motor cortex with judicious use of short-acting muscular blockade agents, low concentrations of inhalation agents, and the substitution or addition of propofol, with adequate responses. This may be supplemented by somatosensory-evoked potentials to map the postcentral gyrus.[143]

Chronic Mapping Using Subdural Electrodes

This method offers several advantages because it allows repeated stimulation under variable intensities and with full patient cooperation. Cortical areas that are difficult to stimulate acutely, such as the dominant posterior basal temporal lobe and occipital and medial frontal lobe, can be carefully investigated using this method. The area to be stimulated and potentially resected can be thoroughly discussed with the patient preoperatively. There are several disadvantages to this technique. The functional areas seem to be wider than on acute studies,[41] which would indicate that this may be due to the larger grid electrode size, the method of stimulation, and simultaneous responses from adjacent gyri and current spread. The cost of this investigation is high. Infections are a rare but serious complication.

Functional Magnetic Resonance Imaging

Functional MRI (fMRI) allows noninvasive functional mapping. The combination of echo-planar imaging (EPI), which is a fast magnetic resonance imaging technique, with the blood oxygenation level–dependent (BOLD) method allowed functional brain imaging. fMRI studies have used successfully in

identification of the primary motor and sensory cortex.[40,54,97] Cortical simulation and fMRI activation were found to lie within 3 to 5 mm of each other.[35] On the other hand, fMRI of language processing has focused on language lateralization and, to a lesser extent, on localization. Numerous studies showed excellent agreement of the fMRI lateralization with the intracarotid amobarbital test or electrocorticography.[28,44] The value of speech localization by fMRI remains unclear.[14,32]

Reliance on Preoperative Substrate

Developmental Substrate

Malformations of cortical development are frequently associated with intractable epilepsy. From 8% to 12% of patients with partial epilepsy are found to have cortical dysplasia. It is expected that, with the improvement in MRI technology, this incidence will increase as a significant number of patients with negative MRI show cortical dysplasia on surgical specimen. Recently reported surgical series show that cortical dysplasia is the leading etiology in patients subjected to epilepsy surgery.[34,134,142,147]

The term focal cortical dysplasia was initially used by Taylor et al. in 1971.[125] Subsequently this term has been used for a wide range of abnormalities. There is a general agreement that classifications based on pathologic findings are the most useful. These have adopted a three- or four-tier classification with minor, moderate, and severe disruption of cortical structure. The Taylor type represents the most extensive disruption.

The mild dysplasia, classified also as type 1a or architectural dysplasia, consists of cortical dyslamination with or without poorly differentiated cells and occurs mostly in the temporal lobe in association with hippocampal sclerosis. MRI is frequently negative or shows focal hypoplasia and gray–white matter blurring. The moderate dysplasia, or type 1b or cytoarchitectural dysplasia, consists of disruption of cortical layering with giant neurons. MRI, when positive, shows focal hypoplasia but no significant signal alterations. PET and SPECT are important imaging methodologies in the localization of the epileptogenic zone.

The Taylor-type dysplasia, or types 2a and 2b, is characterized by the absence of cortical layering and the presence of giant dysmorphic neurons with or without balloon cells. MRI often detects these lesions as focal thickening of the cortex and blurring of the gray–white matter junction. A funnel-shaped increased signal intensity on T2 with its summit reaching the ventricle is characteristic of the Taylor-type dysplasia with balloon cells.

In general, postoperative seizure control is less favorable than with other lesions, such as tumors or vascular lesions. A seizure freedom rate ranging between 35% and 55% was reported in many series.[45,85,95,144] A number of studies suggest an influence of the histopathology on the seizure outcome, with the presence of milder histologic abnormalities being a predictor of a better outcome.[31] Nevertheless, the presence of balloon cells (even though a sign of a more severe abnormality) was also associated with a favorable outcome.[21,124,132]

Tumors

Brain tumors are found in 15% to 30% of patients undergoing surgical resection for neocortical epilepsy.[34,134,142,147] These tumors can be classified into two main categories: (a) glial (mainly astrocytomas, oligodendrogliomas, and oligoastrocytomas) and (b) neuronoglial (mainly gangliogliomas and dysembryoplastic neuroepithelial tumors [DNETs]). In the published experience at Cleveland Clinic Foundation over a 17-year period,[34] 133 patients underwent extratemporal resections for epilepsy: tumors were found in 27.8% of cases; of these, 27% were low-grade astrocytomas, 18.9% gangliogliomas, 16.2% DNETs, 16.2% glioneuronal hamartomas, 10.8% oligodendrogliomas, 8.1% anaplastic astrocytomas, and 2.7% mixed oligoastrocytomas.

Seizures are more frequently associated with low-grade than with high-grade tumors, and their occurrence appears to be a favorable prognostic factor.[9] The pathogenesis underlying these seizures remains poorly understood; multiple mechanisms have been proposed: Traditional explanations included impaired vascularization and ischemic changes in the surrounding cortex[90] and local peritumoral ischemia induced by the mass effect.[39] More recent studies invoke peritumoral disturbance of compounds that alter the membrane potential of neurons,[9] mainly amino acid neurotransmitters (gamma-aminobutyric acid [GABA], taurine, aspartate, and glutamate)[38,55,115,116] and magnesium[6] and iron ions.[119] Furthermore, the pH, which modulates neuronal excitability, is significantly more alkaline in the peritumoral cortex.[68,81]

On the other hand, glioneuronal tumors (gangliogliomas and DNETs) may have intrinsic epileptogenic activity. The histopathologic hallmark of these tumors is a combination of neuronal and glial cell elements.[140] The neuronal component of the tumor itself may contribute to epileptic activity.[13]

Compared to other lesions, tumors were found to have a higher rate of seizure control after surgery.[130] Several authors have reported a seizure-free rate ranging between 66% and 82%.[15,37,147] Laoprasert et al.[64] reported a better seizure outcome with total compared to partial resection (89% seizure-free with total vs. 63% with partial resection).

Given their developmental nature, neuronoglial tumors are frequently associated with cortical dysplasia.[96] This could explain the persistent seizures following some lesionectomies. The role of electrocorticography has not been established because the interictal discharges are frequently diffuse or not prominent at all. In dealing with this pathology, wide resection of the gyrus involved is recommended rather than a pure lesionectomy. If seizures persist, an invasive electrode study is indicated.

Gliotic Substrates

Trauma.

Hippocrates first reported seizures as a complication of head injury. Subsequent landmarks in understanding the pathophysiology of epilepsy and cerebral localization resulted from the careful studies of meningocerebral scars by pioneers of epilepsy surgery.[88,89] Recent data show that posttraumatic epilepsy can complicate 25% to 30% of cases of severe head injury and 5% to 10% of cases of mild to moderate injury.[51] It is a common cause of epilepsy, accounting for approximately 4% of focal epilepsy in the general population, and it is the leading cause of epilepsy with onset in young adults (15–24 years of age).[3]

Two types of head injury are distinguished—penetrating and nonpenetrating. A variety of pathologic changes are noted following blunt or nonpenetrating injury to the brain. These include axonal damage, intracerebral hematomas, ischemic parenchymal changes, and contusion frequently involving the orbitofrontal cortex and the basal and anterior temporal lobes. The incidence of seizures following blunt injury is variable.[18,19] Due to the diffuse nature of closed-head injury, localization of the epileptogenic cortex is frequently difficult. Dual pathologies can occur with the presence of orbitofrontal and associated mesial temporal epilepsy.[72] Patients are considered for surgery when there is a good correlation between the electroclinical syndrome and pathologic changes on MRI. Wide cortical resections are recommended to ensure a good surgical outcome. Invasive electrodes should be used when focal resections are contemplated or dual pathologies are suspected.

Missile injuries to the brain are frequently complicated by seizures.[18,19] Focal and diffuse pathologic changes are noted. The focal damage results in the classically described meningocerebral scar. The management of meningocerebral scars has been described in the classical papers of Penfield. Seizure outcome following cortical resection is excellent if the pathologic changes are focal and correlate well with the semiology and electrophysiology of the seizures.

Strokes

The surgical treatment of intractable epilepsy following ischemic vascular events has not received much attention,[52,58] likely because the incidence of strokes is highest in the elderly, who would not qualify for surgical management. In this pathology, it is paramount to consider the pathophysiologic mechanism leading to ischemia. The epileptogenic zone can overlap the ischemic area or can occur at some distance from it. As an illustrative case, a 16-year-old, right-handed girl suffered from transposition of the great vessels, which was repaired at the age of 2 years. Postoperatively, she suffered a cardiac arrest and was resuscitated. Subsequently, she developed seizures characterized by an aura of a scary feeling and complex visual phenomenon. The MRI showed a watershed, right parietal infarct. Interictal and ictal data were suggestive of a posterior temporoparietal epileptogenic zone. The visual field examination was normal. Subdural electrodes were placed over the parietooccipital area and basal temporal lobe. Typical seizures were recorded with a right amygdala and anterior parahippocampal onset. No seizures were noted from the vicinity of the ischemic area. She underwent an anteromedial temporal resection and has been seizure free for 2 years.

Vascular Malformations

Vascular malformations are increasingly being detected in patients with localization-related epilepsy. These usually fall into three categories: (a) cavernous angiomas, (b) arteriovenous malformations (AVMs), and (c) venous angiomas. The surgical management of intractable epilepsy associated with these lesions is controversial, and different pathophysiologic mechanisms leading to epileptogenicity are likely in each.

Cavernous angiomas can be considered as one of the more focal models of epilepsy in humans. Seizures are their most common presenting symptom, observed in 38% to 100% of cases in different reported series,[26,53,56,103] and they probably result from the toxic effects of iron deposition in the form of hemosiderin.[119,135] Although the pathophysiologic mechanism appears to be very focal, several series have recorded suboptimal seizure outcome following lesionectomies. This could be due to incomplete resection of the hemosiderin-impregnated area or the existence of dual pathology, specifically when located in the mesial temporal lobe. An accepted management strategy is to resect the surrounding damaged cortex until normal cortex is identified. In primary cortex or speech areas, surgery can be performed under local anesthesia.

The role of radiosurgery remains questionable and its results regarding seizure control are inferior to those of surgery: Regis et al.[102] reported a seizure-free rate of 53%, and Shih et al.,[117] in a comparative study between craniotomy and radiosurgery, found better results with craniotomy (79% seizure free with craniotomy vs. 25% with radiosurgery). Furthermore, many authors reported no effect of radiosurgery on the bleeding risk associated with cavernous malformations.[49,114]

In the case of AVMs, several mechanisms for the pathogenesis of epilepsy have been advanced, including previous hemorrhage resulting in gliosis or hemosiderin, perilesional neurochemical changes, and focal cerebral ischemia due to a steal phenomenon.[59,141,145] A number of earlier studies showed a poor seizure outcome following surgery, with some even reporting an increase in seizure frequency.[25,33,74,87] More recent series, however, documented postoperative seizures in <40% of patients with a history of preoperative seizures and <10% in those without a history preoperative seizures.[94,146] A recently published large series[129] found that there was >50% reduction in seizure frequency from the preoperative incidence. Furthermore, 75% and 83% of patients were seizure-free postoperatively in two recent surgical series.[30,94] On the other hand, seizure-free rates ranging between 51% and 80% are reported in recent series of gamma knife radiosurgery,[51,60,112] the antiepileptic effect of radiosurgery being unknown.

Venous angiomas are rarely associated with epilepsy. They are at times discovered during the surgical workup and are frequently unrelated to the seizures. Resection of these lesions can yield to hemorrhagic infarcts; thus, surgical excision is not recommended.

Technique

Cortical Resections

Defining the Boundaries of the Epileptogenic Zone

Resection of the epileptogenic cortex is an established treatment modality for neocortical intractable epilepsy. If the epileptogenic zone is circumscribed, focal cortical resection is recommended. When the ictal area is wide, a lobectomy might be considered. The resection strategy should take into consideration the peculiar gyral and sulcal organization of the brain and its arterial supply and venous drainage. Frequently, anatomic considerations have a significant effect on the geometry of the resected area. The subpial dissection is a preferred technique. Penfield noted long ago the absence of a meningocerebral scar and distal ischemic insult when this technique was used. When a focal cortical resection is performed, the subcortical white matter pathways should be preserved.

Role of Pre- and Postresection Electrocorticography

Despite the very early introduction of this technique as an effort to improve outcome following surgical treatment, the value of intraoperative electrocorticography (ECoG) is questionable. Interictal discharges are variable in location, intraoperative time constraints lead to sampling errors, and resective strategy is more influenced by ictal recordings from invasive electrodes. In the absence of invasive ictal recordings, the geometry of the epileptogenic zone is inferred from the converging evidence of the nature, location, and symptomatology of the structural abnormality and its concordance with the scalp electrophysiology. In some cases, the surgeon may apply a two-staged procedure using a minimalist approach at the first stage, reserving a more aggressive resection if the first procedure fails to produce a desired effect.

Frontal Lobe Resections

The frontal lobe encompasses one third of the cerebral cortex volume, yet, despite its large size and its high epileptogenicity, the frequency of surgically treated frontal lobe epilepsy is small as compared with temporal lobe epilepsy. This varies between 18%[65,83] and 5.5% in large reported series.

The manifestations of frontal lobe epilepsy are protean[8,137] and can be divided into three major groups[109]: (a) supplementary motor type, (b) complex partial seizures, and (c) focal motor seizures. Five electroclinical syndromes[27,65] are distinguished: (a) frontopolar, (b) orbitofrontal, (c) dorsolateral,

P.1874

(d) supplementary motor area, and (e) cingulate. The localization of an ictal onset area is difficult in frontal lobe epilepsy and is facilitated when a lesion is present on imaging.[65] In nonlesional cases, chronic recordings are recommended using subdural electrodes.

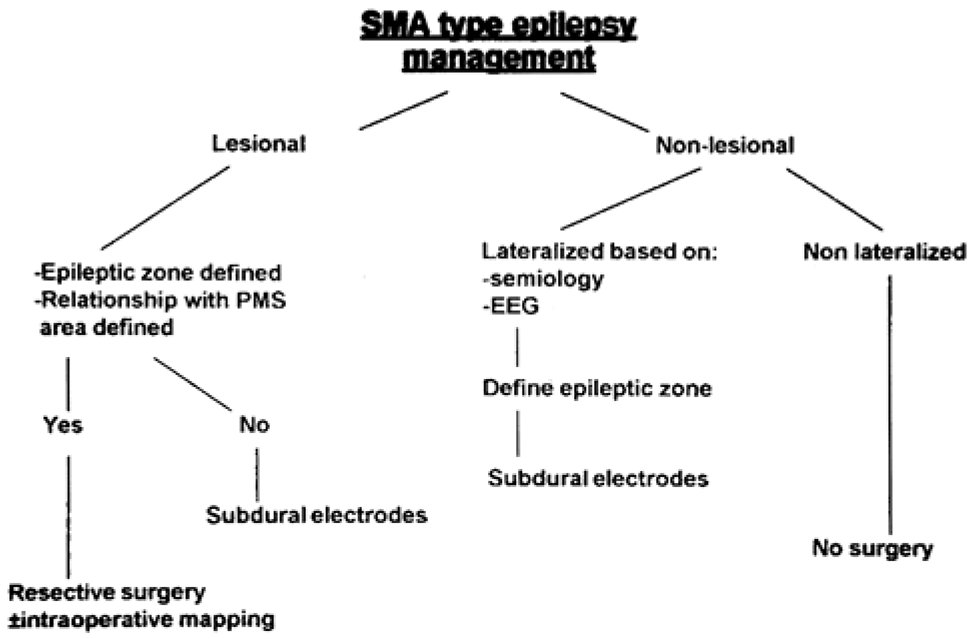

FIGURE 2. Management of epilepsy of the supplementary motor area (SMA) type. EEG, electroencephalogram.

Frontal Lobectomy

When the epileptogenic zone is diffuse, a complete frontal lobectomy anterior to the precentral sulcus can be performed under general anesthesia. The patient is positioned supine, with the head slightly rotated to the contralateral side. A large, C-shaped skin incision is fashioned, followed by a large craniotomy extending to the midline. The location of the central sulcus is determined using somatosensory-evoked potentials or cortical stimulation.[82,84] The resection initially is carried one gyrus anterior to the precentral sulcus. This is subsequently removed in a subpial fashion, taking care not to undercut the white matter tracts coursing from the precentral gyrus; the ascending venous system draining the central area is spared. On the dominant hemisphere, the Broca area should be identified and preserved.[82,83,93] This is best performed under local anesthesia or with the use of a subdural grid. The complications of a complete frontal lobectomy are rare. Hemiplegia occurs in 0.5% of reported cases. There are no significant neurophysiologic deficits.

In the Montreal Neurological Institute series reported in 1975,[99] 55% of patients benefited from a frontal lobe resection, with 23% becoming completely seizure free. In a more recent series,[65] 68% became seizure free following frontal lobe resection. In this series, chronic EEG recordings were found to be helpful in planning surgery but had limited sensitivity and specificity.

Supplementary Motor Area

The supplementary motor area (SMA), as defined by Penfield and Welch,[92,93] is located in the mesial superior frontal cortex anterior to the primary motor cortex of the lower extremity and superior to the cingulate gyrus. Functional studies have shown that this area is activated during initiation of movement and vocalization. Stimulation of this area leads to a fencing posture with bilateral motor movement. Unilateral responses are rare. Resection of this area leads to transient contralateral weakness and apraxia. The SMA is extensively and somatotopically connected through the corpus callosum; this results in quick spread of the ictal discharges to the contralateral side, making lateralization of the ictal onset zone difficult.[130] An algorithm for investigation of SMA-type seizures is shown in FIGURE 2. When the ictal onset area is not clearly defined, bilateral subdural electrodes are placed within the interhemispheric fissure. These are also used to delineate the primary motor cortex. There is considerable anatomic variation in the precentral sulcus and its relationship with the marginal ramus. On long-term follow-up, no gross motor deficits are noted with this resection.

Orbitofrontal Resections

The orbitofrontal area is limited laterally by the orbitofrontal sulcus, medially by the olfactory sulcus, anteriorly and superiorly by the frontomarginal sulcus, and posteriorly by the anterior perforated area. The orbitofrontal cortex is extensively connected with the anterior and mesial temporal lobe, cingulum, and opercular area. For this reason, orbitofrontal seizures are frequently misdiagnosed as anterior temporal.[126] Adequate sampling of these structures using invasive electrodes is recommended. On the nondominant side, extensive resection of the orbitofrontal cortex can be performed. The intersection of the optic nerve and olfactory nerve is used as the posterior limit of the resection. On the dominant side, mapping of the Broca area should be performed.

Resections in the Primary Motor and Sensory Cortex

Central-type epilepsies are rare, and their surgical management remains a challenge because of the risk of a permanent neurologic deficit. However, we recently reported our series of 24 patients operated at the American University of Beirut between 1997 and 2003, in which we showed that selective resection in the primary sensorimotor cortex (PSMC) can be performed,

P.1875

and the neurologic deficit observed in the immediate postoperative status is transient.[20]

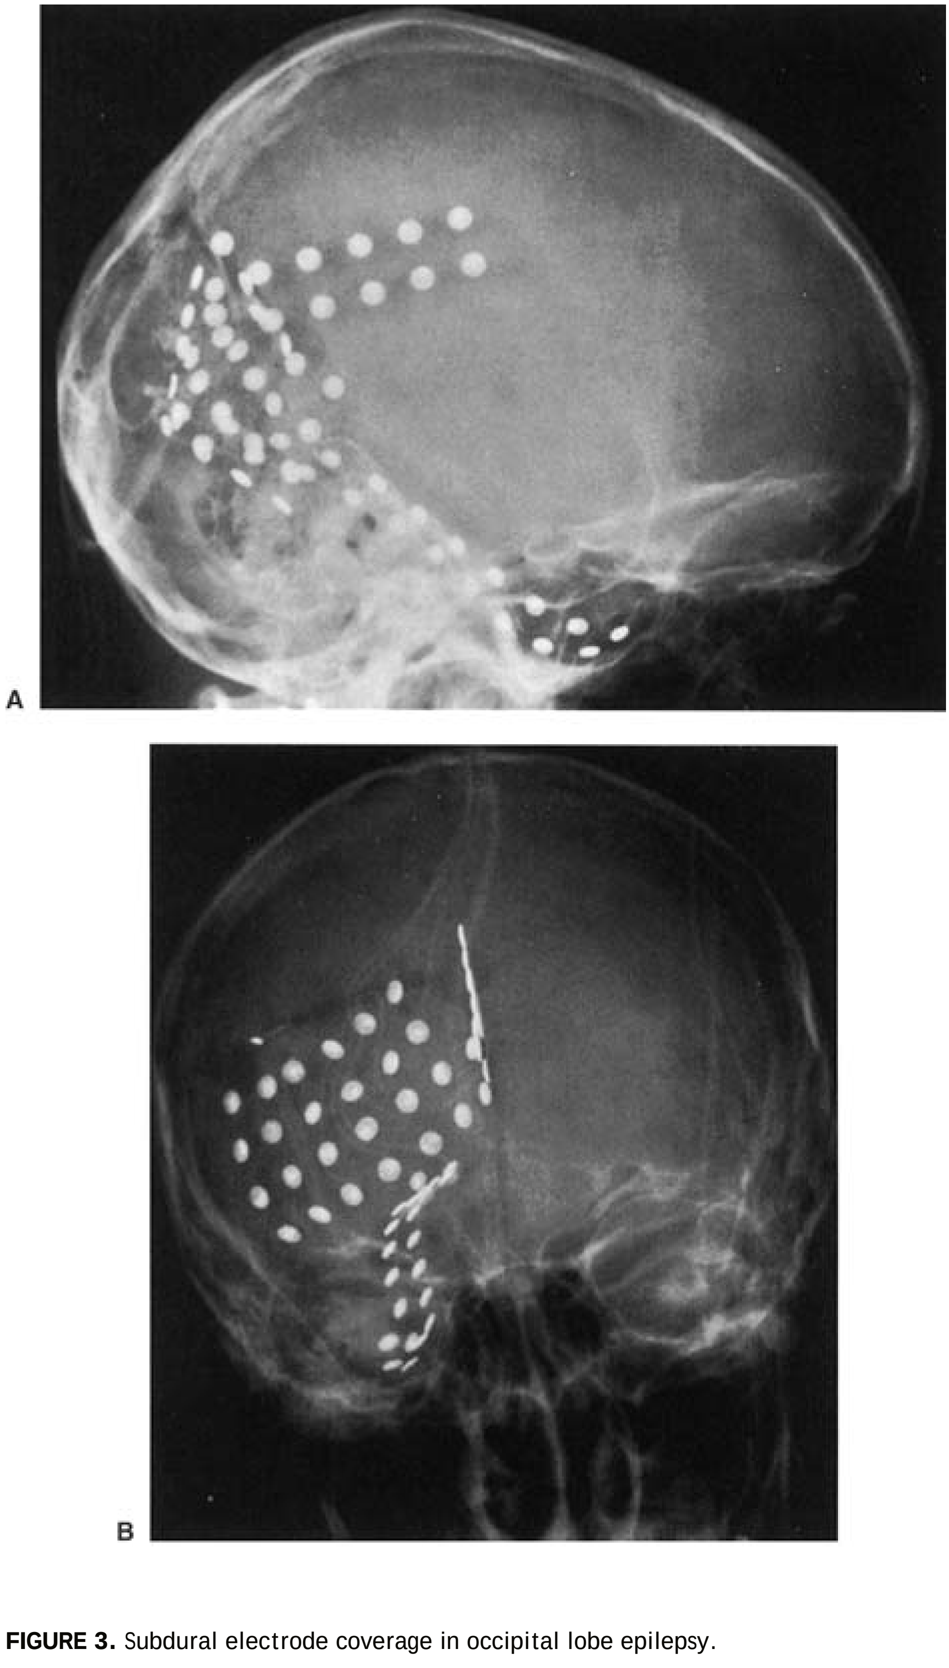

FIGURE 3. Subdural electrode coverage in occipital lobe epilepsy.

Following selective motor resections, severe motor deficit occurred in the immediate postoperative period, gradual improvement started 1 month postoperatively on average, and substantial improvement was found at 6 months of follow-up. Long-term sequelae included impaired fine hand movements after motor hand area resection, and no recovery of toe movements after motor leg area resection.

Following sensory resections, severe sensory deficit occurred in the immediate postoperative period but progressively improved over 2 to 3 months. Long-term sequelae included impaired position sense after sensory hand area resection.

The average period of follow-up was 4.6 years, and 18 of 24 patients remained seizure free at last follow-up.

Functional recovery following injury to the PSMC has been studied in experimental animal studies[105] and in humans following strokes (mainly using fMRI[48] and PET[112]). The main proposed mechanisms for recovery involve reorganization within the PSMC,[48,105] recruitment of nonprimary motor areas,[105,112] and possibly recruitment of the contralateral PSMC.[16,73]

Parietal Lobe Resections

Seizures originating in the parietal lobe account for up to 6% of reported series. A large proportion of patients exhibit an aura, most commonly somatosensory.[108] Pain, vertiginous sensations, aphasia, or disturbance of body image suggest parietal origin. The ictal manifestations are varied and reflect the quick spread to the frontal lobe in superior parietal epilepsies and to the temporal lobe in inferior parietal cases.[136] Interictal and ictal scalp EEG recordings were not reliable markers for parietal lobe epilepsy. In two recent series, lesions were noted on imaging in all cases, and surgical resections yielded an excellent result. Salanova et al. recently reported the Montreal Neurological Institute (MNI) experience of 79 patients with nontumoral parietal lobe epilepsy. Of these, 45.5% were seizure free, 19% had rare seizures, and 21.5% had worthwhile improvement. Persistent dysphasia was noted in 2 patients, a Gerstmann syndrome in 1, and contralateral weakness in 3.

Occipital Lobe Epilepsy

Occipital lobe seizures are rare, representing 1% of the MNI series.[107] Early clinical manifestations of elementary visual hallucinations, ictal amaurosis, eye movement sensations, and blinking are highly suggestive of an occipital origin.[138] In infracalcarine cases, quick spread to the temporal lobe can produce symptomatology typical of mesial temporal lobe epilepsy. Various spread patterns have been described and can make diagnosis difficult. The presence of a superior quadranopsia or posterior temporal interictal and ictal discharges should suggest occipital lobe epilepsy. An imaging abnormality is found in a large proportion of cases.[138] In patients with hemianopsia, resective surgery carries little risk. On the dominant hemisphere, the speech-related cortex should be identified and spared. The management of patients with intact vision is challenging. When a circumscribed lesion is found, lesionectomy can yield satisfactory results. In nonlesional cases, the ictal onset area should be precisely localized using invasive electrodes. These are used in addition to mapping of the calcarine cortex and speech-related cortex. With this strategy, visual deficits can be minimized (Fig. 3). Resections of the dominant basal temporal lobe should be carefully planned because this can yield an alexia without agraphia deficit.

Good results have been reported in 65% to 80% of patients with occipital lobe epilepsy in recent series. In the MNI series of 37 patients, 46% became seizure free, 21% had rare seizures, and 10% had a worthwhile improvement.

Summary and Conclusions

The management of neocortical epilepsy relies on the identification of a pathologic substrate, which will guide the electrophysiologic evaluation. Circumscribed cortical resections are performed when the pathologic substrate is focal and concurs with an electroclinical syndrome. When the pathologic substrate is diffuse or nonconcordant, electrophysiologic invasive electrodes should be used to determine the volume of resection. The outcome following neocortical resections has significantly improved with the introduction of high-resolution MRI. However, it is still not optimal. Advances in metabolic imaging could yield a more precise definition of the epileptogenic cortex.

Chapter 178
Multilobar Resections and Hemispherectomy

Devin K. Binder

Johannes Schramm

Introduction

Multilobar resection and hemispherectomy are surgical options available for the treatment of medically intractable seizures arising from a diffuse area of epileptogenicity that remains unilateral but extends beyond one lobe. The nature and extent of the underlying pathologic process, the patient's neurologic status, and the results of preoperative neurophysiologic and neuroimaging studies together determine which surgical procedure should be recommended.

For clarity, hemispherectomy and multilobar resections are presented separately in this chapter.

Hemispherectomy

Historical Perspectives

The term hemispherectomy refers to a variety of operations that functionally isolate the cerebral cortex of one hemisphere from the rest of the nervous system. In 1928, Dandy[24] and L'Hermite[59] originally described hemispherectomy for diffuse infiltrative glioma, but in the next decade few other reports of hemispherectomy for tumor were published.[40] Ten years later, McKenzie performed the first hemispherectomy for epilepsy.[69] In 1950, Krynauw reported on hemispherectomies in 12 children with infantile hemiplegia and intractable epilepsy.[58] In this report, he noted excellent seizure control as well as marked and long-lasting behavioral improvement.

Because of the success of the operation for improving seizure control and behavior, hemispherectomy became widely used in the treatment of seizures associated with infantile hemiplegia. In addition, it came into use for the treatment of other unihemispheric syndromes associated with intractable epilepsy, such as Sturge-Weber disease, Rasmussen encephalitis, and cerebral infarct. By 1961, White reviewed 267 cases from many neurosurgical centers.[113] However, enthusiasm for hemispherectomy waned in the 1960s as more effective anticonvulsants became available and as significant long-term complications became apparent. Many patients developed delayed neurologic and intellectual deterioration postoperatively, and ultimately it became clear that hemorrhage, superficial cerebral hemosiderosis (SCH), and resultant mass effect and hydrocephalus were responsible, and even caused significant mortality.[33,42,74,83]

Over the next two decades, modifications to anatomic hemispherectomy were proposed, aimed at eliminating the late complications of SCH and hydrocephalus. The Oxford-Adams modification involved occlusion of the foramen of Monro with a muscle plug and stripping down the dura to reduce the subdural space.[1,7] Peacock et al. routinely implanted a shunt system into the subdural cavity.[78] Rasmussen developed a new technique termed *functional hemispherectomy* that involved a large central resection, temporal lobectomy, callosotomy, and fronto- and parieto-occipital disconnection.[82] This procedure improved seizure control while maintaining a low incidence of SCH. Other approaches removed only the cortex, termed *hemidecortication* or *hemicorticectomy.*[48,52,115]

Over the past 10 to 15 years, there have been further development and modification of functional hemispherectomy techniques, including hemispheric deafferentation,[89,90] peri-insular hemispherotomy,[107] dorsal transcortical subinsular central hemispherotomy,[26,109] Shimizu and Maehara's variation,[94] and the transsylvian keyhole functional hemispherectomy[88,91] (Table 1). All of these procedures are aimed at less resection and more disconnection, increasing the safety of the procedure and reducing postoperative complications. The improved safety of these modifications and the improvements in neuroimaging and neurophysiologic monitoring have made hemispherectomy a more attractive option for patients with intractable unihemispheric epilepsy.

Role of Pathology

Typical pathologies leading to diffuse unihemispheric disease and intractable epilepsy include neonatal injury, vascular insults, hemimegalencephaly, hemispheric cortical dysplasia and other neuronal migration disorders, Sturge-Weber syndrome, and Rasmussen encephalitis.[34,100] One group of patients has experienced the acute onset of a massive insult resulting in a fixed neurologic deficit. These include those with infantile hemiplegia resulting either from posttraumatic brain injury or vascular insults.[12,58] A second group of patients has malformations of cortical development (MCD), which vary in severity from focal cortical dysplasias to hemispheric cortical dysplasia and hemimegalencephaly.[16,53,102,108,110] In these patients, neurologic manifestations are often delayed or progressive. Another group of patients has Sturge-Weber syndrome (encephalotrigeminal angiomatosis).[32,45,72] Characterized by a facial port wine stain (*nevus flammeus*) and pial angiomatosis, patients develop intractable epilepsy associated with impaired cognitive development and hemiparesis. A final group has acquired progressive neurologic deterioration with intractable epilepsy. The prototype for this is Rasmussen encephalitis. In 1958, Rasmussen et al. first described this chronic childhood encephalitis that leads to intractable epilepsy and neurocognitive deficits.[84] In this disease, the presentation may be delayed but the disease course, once established, is inexorably progressive.

Table 1 Hemispherectomy Techniques

Role of Functional Localization

Because no portion of the hemisphere is to be spared functionally, preoperative or functional localization has no specific

P.1880

role. However, as discussed below, the presence or absence of residual language, motor, and visual function in the affected hemisphere will affect risks of surgery.

Impact of Electrophysiologic Studies

The primary goal of electrophysiologic studies is to lateralize the disease to the radiographically and clinically abnormal hemisphere. Typically, a detailed investigation with both ictal and interictal recordings is performed. Most often, interictal surface electroencephalograms (EEG) show a clearly asymmetric tracing with abnormal slowing, low background voltage, and multifocal independent sharp waves and spikes over the affected hemisphere.[96] In specific disorders, there may be characteristic EEG abnormalities; for example, in hemimegalencephaly, the EEG may demonstrate hemihypsarrhythmia.[75,99]

The other important goal is to determine whether there are abnormalities in the “good” hemisphere. Bilateral independent epileptogenic foci are associated with a poor prognosis for seizure control.[14,96,118] In a study of 12 patients, Carmant et al. demonstrated that a good outcome from hemispherectomy was associated with interictal EEG suppression over the abnormal hemisphere, absence of contralateral slowing, absence of generalized discharges, and absence of bilateral independent spiking.[14] In a study of 28 patients, Doring et al. found that 75% had bilateral EEG abnormalities preoperatively, which was more common in patients with MCD than with acquired lesions.[29] Notably, 77% of patients with acquired lesions became seizure free, compared with only 47% of patients with MCD. Thus, the presence of bilateral EEG abnormalities alone does not preclude consideration for hemispherectomy.

In general, the EEG will lateralize well with structural imaging abnormalities. For hemispherectomy, accurate lateralization and not intrahemispheric localization is most important. In cases without radiographic lateralization, of course, both surface EEG and, when necessary, invasive EEG monitoring play a critical role in both lateralization and localization.

Impact of Neuroimaging

Structural neuroimaging plays an integral role in the preoperative evaluation of the hemispherectomy candidate. The advent of computed tomography (CT) imaging in the 1970s permitted direct visualization of the “good” and “abnormal” hemispheres. While CT can still provide important information (e.g., calcification in Sturge-Weber syndrome), magnetic resonance imaging (MRI) has become the study of choice, as it provides excellent visualization of structural abnormalities in the cerebral cortex and subcortical white matter. It also provides a high-resolution assessment of the “good” hemisphere.

Structural imaging may reveal the severity of disease in vascular or posttraumatic hemispheric injury, from atrophy to porencephalic cysts. Atrophy, characterized by loss of gray and white matter and the presence of an enlarged ventricle, is encountered in most conditions and may be of varying degree, depending on the severity or chronicity of the underlying disease process. In Sturge-Weber syndrome, CT and plain films may show “tram-track” hemispheric calcification, and gadolinium-enhanced MRI demonstrates pial angiomatosis.[67,68] In hemimegalencephaly, structural imaging shows marked enlargement of the affected hemisphere with abnormal thickening of the cortical mantle.[35,50,116] High-resolution structural MRI showing both large and subtle cortical abnormalities has also revolutionized the diagnosis of MCD.[4,63] Early MRI may be useful in the diagnosis of Rasmussen encephalitis,[17,61] but definitive diagnosis requires the appropriate clinical picture together with biopsy demonstrating perivascular lymphocytic cuffing and gliosis.[8,9,36,43,84]

Functional imaging may also be incorporated into the evaluation of the hemispherectomy candidate. For example, positron emission tomography (^{15}O-PET) can be useful to follow disease progression, either with hemimegalencephaly,[85] Sturge-Weber syndrome,[19,60,79] or Rasmussen encephalitis.[17,61] Diffuse unilateral interictal hypometabolism of the affected hemisphere is most commonly found. Single photon emission computed tomography (SPECT) scanning, which provides information regarding cerebral blood flow, may show hypoperfusion in the affected hemisphere.[15,17,18] In one study of seven patients undergoing hemispherectomy, the six patients with unilateral preoperative SPECT findings all had a favorable outcome regardless of the surface EEG.[15] Functional studies are most important in cases without lateralizing findings on structural imaging studies.

Frequency of Use

Hemispherectomy is primarily a pediatric operation, as perinatal, congenital, and early developmental pathologies account for the majority of conditions leading to intractable unihemispheric epilepsy. In 1993, of 47 surveyed epilepsy surgery centers, 29 were performing hemispherectomies; hemidecortication was advocated in three, the anatomic technique in four, and functional hemispherectomy in 22.[97] In an extensive multicenter study of 333 hemispherectomies from 11 centers published by Holthausen et al. in 1994, distribution of etiologies was as follows: 31% hemispheric dysplasia, 25% Rasmussen encephalitis, 14% vascular, 13% hemiatrophy, 8% Sturge-Weber, and 8% other.[47] Surgical techniques included functional hemispherectomy (33%), “Adams modification” (18%), hemidecortication (18%), hemispherotomy (17%), and anatomic hemispherectomy (13%). With the introduction of modern functional hemispherectomy techniques with reduced risk and postoperative complications,[88] and as patients are offered the benefit of the operation earlier in life, it is expected that the number of centers and hemispherectomy cases will increase.

P.1881

Indications

The indications for hemispherectomy include damage to one hemisphere accompanied by medically intractable epilepsy and accompanying neurologic deficits. As described above, etiologies include extensive hemispheric dysplasia, hemimegalencephaly, Sturge-Weber disease, Rasmussen encephalitis, and perinatal infarction. One group of patients presents with a maximal hemispheric deficit, with contralateral hemiplegia and hemianopsia, usually due to a fixed perinatal insult. The other group presents with intractable epilepsy associated with progressive neurologic deterioration, most often due to a pathology that will evolve ultimately into a maximal hemispheric deficit (e.g., Rasmussen encephalitis).

Hemispherectomy is contraindicated if preoperative evaluation fails to demonstrate that ictal activity arises from the affected hemisphere. Usually, the history of medically intractable epilepsy often with lateralizing semiology is combined with evidence of extensive hemispheric involvement on high-quality MRI and further lateralization and localization with inpatient video-EEG seizure monitoring. Furthermore, hemispherectomy is not employed if less extensive surgical therapy (callosotomy or focal or multilobar resection) may potentially be effective.

Evaluation Criteria

Evaluation of whether and when to recommend hemispherectomy relies on seizure characteristics, neurologic examination, language evaluation, EEG and imaging findings, and the natural history of the associated pathologic process.

Seizure Characteristics

Hemispherectomy candidates may have a variety of seizure types and severity, including drop attacks, focal motor seizures, complex partial seizures, epilepsia partialis continua, and generalized seizures. The seizures are frequent and severe enough to be incapacitating in daily activities; typically, patients will have 10 to 200 seizures per day. In around 80% of patients, a partial motor seizure pattern appears to predominate as a clinical manifestation. Epilepsia partialis continua is characteristic of chronic encephalitis, whereas infantile spasms appear related to a variety of etiologies.

The seizures must truly be medically intractable for a patient to be considered for hemispherectomy. Therapeutic trials of different antiepileptic drugs (AEDs), alone or in combination, should be attempted by a neurologist expert in AED management strategies. However, continued unsuccessful trials of many different

AEDs must be balanced against the potential benefits of early surgery in individual cases.

Neurologic Examination

In addition to intractable epilepsy, these patients typically present with other findings of unilateral hemispheric damage, including impairment of cortical sensory modalities, hemianopsia, hemiplegia, and spasticity. Often they are able to walk and movement of the arm is often more impaired than that of the leg. Fine motor control (pincer grasp) is often absent, but gross motor control (e.g., handgrip) may be preserved. In these cases, no new motor deficit is created by hemispherectomy; occasionally, there may be immediate postoperative hypotonia and loss of voluntary movements that may last a few days to a few weeks. Postoperative completion of hemianopsia is unavoidable and should be part of informed consent, but is not considered an absolute contraindication to hemi-spherectomy.

Language Evaluation

Preoperative language function depends on whether the dominant hemisphere is affected and the severity of disease progression. The younger the age of injury, the more likely language transfer to the healthy hemisphere will occur. Thus, the potential for postoperative language deficits depends on the timing of transfer of language function, and incomplete transfer of language function is a relative contraindication to hemispherectomy. Older children with dominant hemisphere disease and some language function should undergo assessment of lateralization of language (e.g., with the intracarotid amobarbital [Wada] test). The "worst-case scenario" is late appearance of progressive disease (e.g., Rasmussen encephalitis) in the dominant hemisphere; these patients may have severe language deficits following dominant hemispherectomy.

Electroencephalography and Imaging Findings

As described above, there is usually a concordance between EEG abnormalities and a structurally abnormal hemisphere as seen on preoperative imaging studies. In a significant number of cases, however, EEG abnormalities may be recorded from the good hemisphere, either secondary to or independent of the abnormalities of the diseased hemisphere.[47] Bilateral abnormal EEG findings do not represent an absolute contraindication to hemispherectomy, as they may reflect secondary epileptogenesis and disappear after surgery. An explanation for the presence of independent epileptic activity recorded from the good hemisphere should be taken into account during the decision-making process for hemispherectomy.

Etiology, Natural History, and Timing of Surgery

Three aspects of the etiology and natural history of the condition may affect timing of surgery: Whether the condition is congenital or acquired, whether it is strictly unilateral or possibly bilateral, and whether it is static or progressive. Congenital pathologies such as large porencephaly resulting from in utero or perinatal insult or the Sturge-Weber syndrome, which are usually strictly unilateral, have a better prognosis with surgery than a congenital lesion such as hemimegalencephaly or hemispheric dysplasia, which may be associated with some degree of contralateral involvement. Acquired unilateral pathology, such as Rasmussen encephalitis, has a better prognosis than infectious processes, which usually have bilateral involvement.

Timing of surgery is determined by the severity of epilepsy, the age of the patient, the natural history of the disease, and the adequacy of therapeutic trials of anticonvulsant medications. Hemispherectomy before the second or third year of life carries no risk of increasing deficit and is therefore ideal in those cases that present early for diagnosis and evaluation. In later-onset cases (e.g., Rasmussen encephalitis in older children), timing is controversial; while complete transfer of language and motor function to the healthy hemisphere is less likely to occur in older children, nevertheless, the intractable seizures can produce neuropsychological deterioration and may prompt earlier surgery. Evidence is accumulating that seizures themselves as opposed to the pathologic substrate may significantly delay cognitive and psychosocial development.[49,64,87] In certain conditions (e.g., inborn brain malformations) leading to catastrophic infantile epilepsy, very early surgery may be optimal; in our experience, hemispherectomy can be performed safely at 4 months of age.

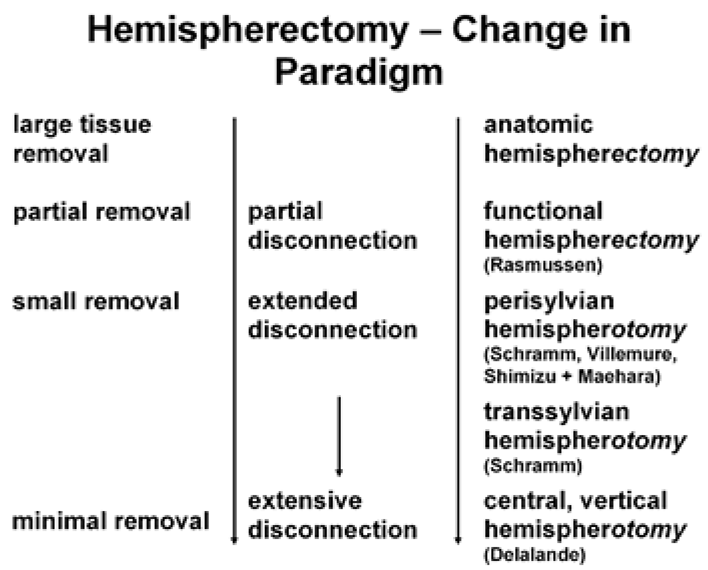

FIGURE 1. Hemispherectomy techniques. Over time, there has been a change in paradigm to more minimal resections combined with more extensive disconnection.

Goals of Surgery

The primary goal of hemispherectomy is to achieve seizure control via complete disconnection of the epileptogenic abnormal

P.1882

hemisphere from the "good" hemisphere. In anatomic hemispherectomies, this was accomplished by extirpation of the affected hemisphere. In functional hemispherectomies, the emphasis is on complete disconnection rather than resection, although some tissue is resected in each of the current variations of functional hemispherectomy.

The second major goal is to improve psychosocial and cognitive development. Adequate seizure control can be expected to lead to better psychosocial and cognitive development and improved quality of life.[30,49,58]

Surgical Approaches **(Table 1, Fig. 1)**

The classic *anatomic hemispherectomy* involved a large T-shaped skin incision along the midline down to the temporal base; hemicraniotomy; occlusion of the anterior and middle cerebral artery and parasagittal veins; interhemispheric callosotomy and frontobasal disconnection; disconnection of insular cortex and temporal stem; and removal of the hemisphere en bloc or in lobes. Total anatomic hemispherectomy was associated with severe intraoperative hemorrhage, hypotension, early and late hydrocephalus, and SCH.[25,33,42,44,74,83,88,104] Development of hydrocephalus necessitated shunting in ~50% of patients. SCH typically developed after 8 to 15 years and led to progressive neurologic deterioration, increased intracranial pressure, and death in many cases.[33,42,74,83]

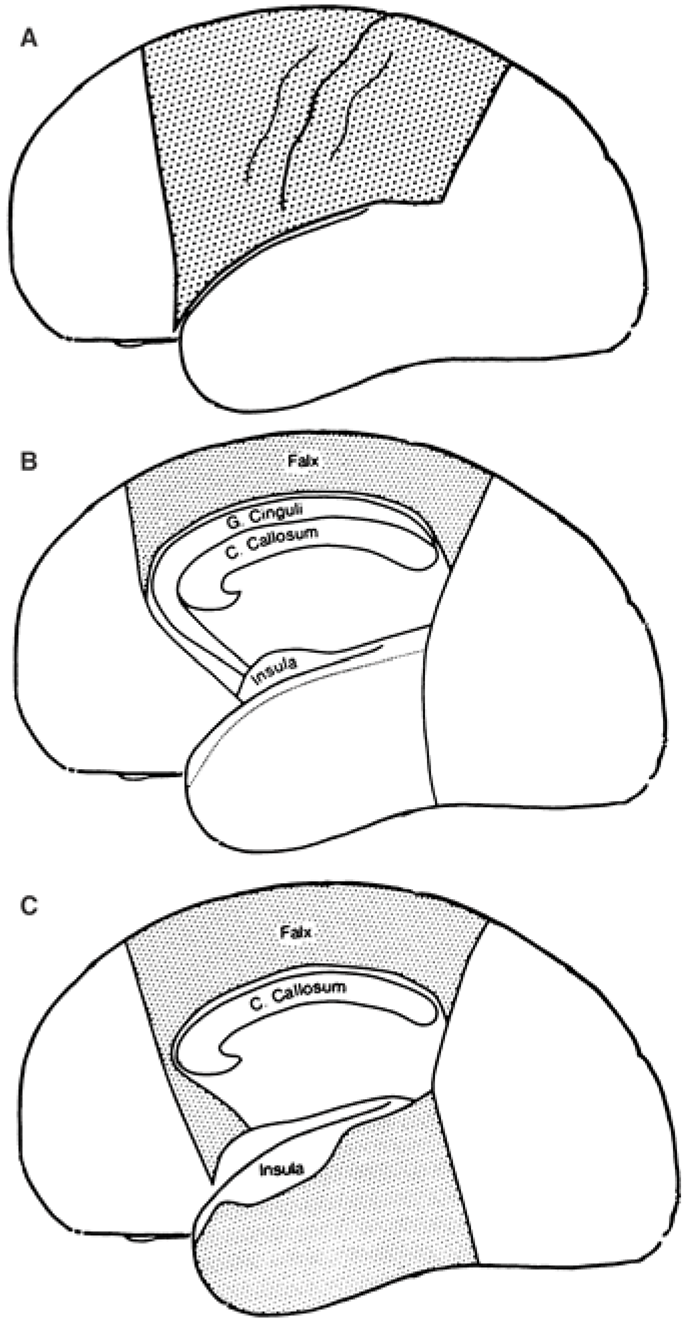

FIGURE 2. The Rasmussen functional hemispherectomy. Diagrammatic representation of left functional hemispherectomy. **A:** Excision of central suprasylvian region, lateral aspect. **B:** Medial aspect. **C:** Removal of cingulate and subcallosal gyri, frontal and parieto-occipital disconnection, and temporal lobectomy. (Reproduced from Rasmussen T. Commentary: extratemporal cortical excisions and hemispherectomy. In: Engel J, ed. *Surgical Treatment of the Epilepsies.* New York: Raven Press; 1987:417–424, with permission.)

The *Oxford-Adams modification* was an attempt to avoid the complications of SCH and hydrocephalus by reducing the subdural space and insulating the subdural cavity from the ventricular system. In this technique, the classic anatomic hemispherectomy is supplemented by occlusion of the foramen of Monro with a muscle plug and occlusion of the subdural space by folding down the convexity dura onto the tentorium, falx, and floor of the middle fossa, thus creating a large extradural space.[1,7] The *shunted hemispherectomy* used by

Peacock at UCLA supplemented the classic anatomic hemispherectomy with routine subdural drainage for 5 days postoperatively to evacuate the debris resulting from the operation followed by placement of a shunt in all cases.[78]

Hemidecortication or *hemicorticectomy* was developed based on the principle that only the ictogenic cortex needs to be removed. This procedure, developed by Ignelzi and Bucy in 1968,[48] involves a large craniotomy; removal of all cortical gray matter while the white matter is left intact, without callosotomy; and no opening into the lateral ventricle except at the temporal tip required to remove the hippocampus. Several modifications of hemidecortication have been proposed.[44,52,115]

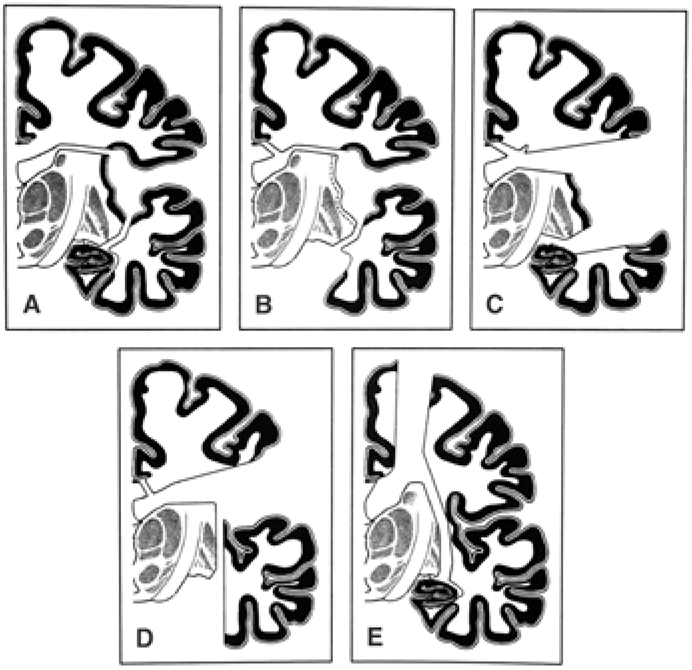

FIGURE 3. Modified functional hemispherectomy techniques. **A:** Transsylvian transsulcal keyhole approach to ventricle (Schramm J, Kral T, Clusmann H. Transsylvian keyhole functional hemispherectomy. *Neurosurgery.* 2001;49[4]:891–900). **B:** Second part in transsylvian keyhole approach: Temporomesial resection, mesial disconnection, and insular cortex removal. **C:** Peri-insular window technique (Villemure JG, Mascott CR. Peri-insular hemispherotomy: surgical principles and anatomy. *Neurosurgery.* 1995;37[5]:975–981; Villemure JG, Vernet O, Delalande O. Hemispheric disconnection: callosotomy and hemispherotomy. *Adv Tech Stand Neurosurg.* 2000;26:25–78). **D:** Variant of peri-insular window technique (Shimizu H, Maehara T. Modification of peri-insular hemispherotomy and surgical results. *Neurosurgery.* 2000;47[2]:367–372). **E:** Dorsal transcortical subinsular hemispherotomy (Delalande O, Pinard JM, Basevant C, et al. Hemispherotomy: a new procedure for central disconnection [Abstract]. *Epilepsia.* 1992;33[Suppl 3]:99–100 [abst]; Villemure JG, Vernet O, Delalande O. Hemispheric disconnection: callosotomy and hemispherotomy. *Adv Tech Stand Neurosurg.* 2000;26:25–78). (Reproduced from Schramm J. Hemispherectomy techniques. *Neurosurg Clin N Am.* 2002;13[1]:113–134, with permission.)

In response to the problems associated with classic anatomic hemispherectomy, Rasmussen introduced the *functional hemispherectomy*, which involved a slightly smaller craniotomy, temporal lobectomy, large central hemispheric resection, callosotomy, and fronto- and parieto-occipital disconnection[82] (Fig. 2). This procedure improved seizure control while maintaining a low incidence of SCH.

P.1883

Over the past 10 to 15 years, there have been further development and modification of functional hemispherectomy techniques, including hemispheric deafferentation,[38,89,90] peri-insular hemispherotomy,[107] transcortical subinsular hemi-spherotomy,[26,109] the Japanese peri-insular modification,[94] and the transsylvian keyhole functional hemipherectomy[88,91] (Fig. 3). While in the literature these are sometimes called "hemispherotomies," there is a degree of brain resection in each case in addition to the disconnection from the contralateral hemisphere and long tracts, and consequently it is logical to refer to all these procedures as "functional hemispherectomies." All of these procedures have the common anatomic goal of complete hemispheric disconnection[70,111] and involve smaller brain resections with disconnections and callosotomy that are essentially variations of the Rasmussen functional hemispherectomy. The goal of these procedures is to maintain efficacy while increasing safety and reducing postoperative complications.

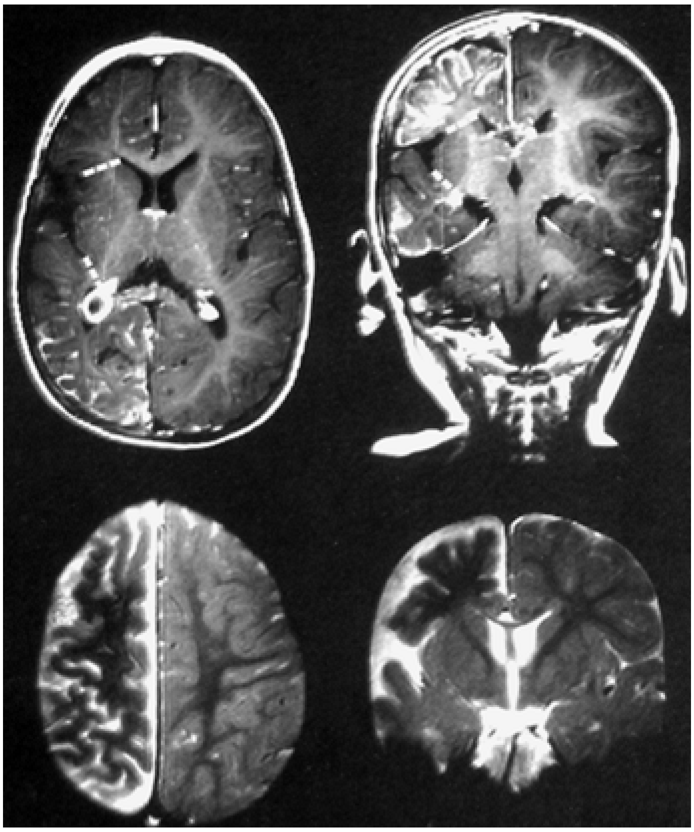

FIGURE 4. Sturge-Weber disease in a 16-month-old male. Axial **(left)** and coronal **(right)** magnetic resonance images with contrast **(upper)** show the pathologic vascularization and the enlarged insular cistern and atrophy of single gyri and the whole hemisphere. White lines indicate the short distances between circular sulcus and ventricle. This case was done with the transsylvian keyhole functional hemispherectomy technique. (Reproduced from Schramm J. Hemispherectomy techniques. *Neurosurg Clin N Am.* 2002;13[1]:113–134, with permission.)

For example, the transsylvian-transventricular keyhole functional hemispherectomy developed at our center[88,91] entails four main features: (a) linear incision and small craniotomy; (b) a transsylvian exposure and resection of the mesial temporal structures (uncoamygdalohippocampectomy); (c) transventricular callosotomy; and (d) transsylvian frontobasal disconnection and transsylvian-transventricular occipitoparietal mesial disconnection (Fig. 4). It is ideal for atrophic hemispheres with enlarged ventricles and is especially suitable for cases of perinatal infarction and cystic encephalomalacia. A key important advantage over the "classic" Rasmussen functional hemispherectomy is in the smaller exposure, shorter operative time, and lower blood loss.[91] However, it is not ideal for hemimegalencephaly, in which there is an enlarged and dysplastic hemisphere. Instead, for hemimegalencephaly, a hemispherectomy technique with sufficient exposure and tissue resection is preferred to allow space for postoperative swelling (Fig. 5).[21,28,41]

One specific question that arises in these functional hemispherectomy modifications is whether insular cortex should be removed. The concern is that residual insular cortex may be a generator of persistent postoperative seizures. Villemure et al. report using intraoperative electrocorticography from the insular cortex following hemispherectomy and proceed to remove the structure if abnormal spiking is recorded.[105,106,112] This question has also been addressed by other investigators.[2,37] However, in a large multicenter study and in a recently reported series, the presence of residual insular cortex was not statistically associated with poor seizure control.[41,47] Perhaps the most prudent approach is to always opt for removal of insular cortex during the initial surgery to exclude this possible cause of persistent seizures.[88,92]

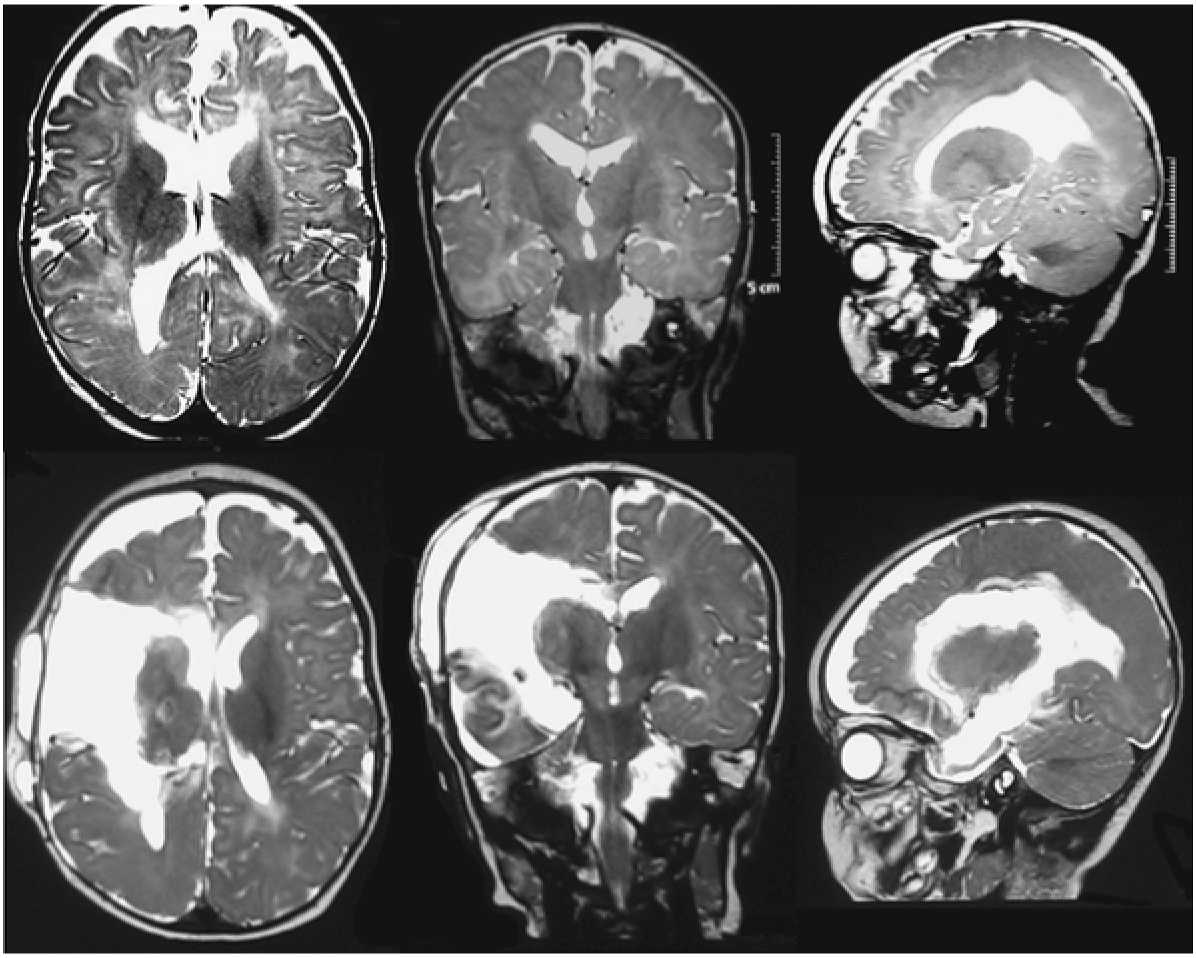

FIGURE 5. Right-sided hemimegalencephaly in a 7-month-old male. Preoperative T2-weighted magnetic resonance images **(top)** demonstrate an enlarged right hemisphere with impaired sulcation, especially posteriorly. Corresponding axial, coronal, and sagittal postoperative images **(bottom)** demonstrate functional hemispheric disconnection. This case was done with a perisylvian window technique.

Results and Complications

Potential operative and postoperative complications include hemorrhage, infection, hydrocephalus, SCH, and cerebral

edema.[103,104] In early series, these problems led to unacceptably high perioperative mortality (6% to 8%). Modern series are associated with lower mortality: In the recent multicenter series reported by Holthausen et al. mortality was 1.5%.[47] The original Montreal series of anatomic hemispherectomy had a 52% hydrocephalus rate and a 30% SCH rate.[33,114] Fortunately, there have been few reports of SCH since the 1970s,[51] and the hydrocephalus rate is much lower in modern procedures. The Oxford-Adams modification was associated with a reduced rate of hydrocephalus (<10%).[100,105] However, modern hemispherectomy approaches are still associated with an appreciable rate of hydrocephalus requiring shunting: 10 of 53 patients with the Delalande technique,[109] 5 of 32 cases with Shimizu and Maehara's technique,[94] 5 of 63 cases with Villemure's perisylvian window technique,[109] and 2 of 49 cases with Schramm's transsylvian keyhole technique.[10,91]

Important perioperative advantages of newer techniques include reduction in operative time and blood loss. In Schramm's series, operative time (mean 6.3 hours) and transfusion requirement (100% of patients) was higher for the classic Rasmussen technique than for the transsylvian keyhole hemispherectomy (3.6 hours and 15%, respectively).[91] In a recently published UCLA study, lateral hemispherotomy was associated with lower operative blood loss and intensive care unit (ICU) stay compared with anatomic and Rasmussen functional hemispherectomy.[21] In addition, operative blood loss and other perioperative complications differed by pathologic subgroup, highest in hemimegalencephaly cases.[21]

All of the modern hemispherectomy techniques have as their primary goal the elimination of seizures via total hemispheric disconnection. Approximately 70% of patients will be seizure free following surgery, with anticonvulsant requirement either eliminated or simplified. Comparisons of seizure outcome between series are limited by lack of standardized outcome measures in some studies. Most useful is the extensive review of 333 patients from 11 centers reported by Holthausen et al.[47] In that study, overall 70.4% of patients became seizure free (Engel class I). Interestingly, there appeared to be significant differences between operative techniques, with better results from modern functional hemispherectomy techniques (85.7% class I) compared with the Rasmussen technique (66.1% class I) or the hemidecortication techniques (60.7% class I).[47] In Schramm's series of 49 patients, with a median follow-up of 52 months (range 12 to 146 months), 44 patients were seizure free (Engel class I, 90%), three patients experienced seizure reduction of more than 75% (Engel class III, 6%), and two patients had no seizure relief (Engel class IV, 4%).[10] In the Holthausen et al. series, there was also a difference in outcome by pathology, with the best results in Sturge-Weber syndrome (Engel class I, 82.1%) and the worst with dysplastic lesions (Engel class I, 56.6%). No significant relationship was found between seizure outcome and preoperative EEG, seizure characteristics, or age at surgery.

Clearly, longer follow-up is necessary in all modern series,[27,39,41,49,56,78,91,98,109,110,117] both with respect to late development of complications and whether the seizure

control is persistent. For example, in a large recently reported series from UCLA, 78.6% of patients were seizure free at 6 months, 76.3% at 1 year, 70.4% at 2 years, but only 58.0% at 5 years.[49] In addition, longitudinal studies of these patient populations will be critical to determine long-term postoperative cognitive,[5,7,27,80] language,[11,22,23,87,101] and developmental[3,13,25,49,65,100] outcomes.

Multilobar Resections

Indications and Role of Pathology

Multilobar resections are indicated for the control of pharmacologically refractory seizures in the presence of epileptogenic zones that affect more than one lobe of the brain in patients with some preserved neurologic function.[73,81] As for hemispherectomy, multilobar resections are considered with pathologies that lead to unihemispheric disease and intractable epilepsy, including neonatal injury, vascular insults, tumors, gliosis, hemispheric cortical dysplasia and other neuronal migration disorders, and Sturge-Weber syndrome.[34] The extent of the pathologic process responsible for the seizures or the wish to spare some function guides the extent of the resection and the decision between multilobar resection and hemispherectomy. Seizures related to large porencephalic cysts resulting from prenatal vascular occlusion of either the anterior or posterior main branch of the middle cerebral artery may be successfully treated by bilobar or trilobar resection. A significant percentage of patients with Sturge-Weber syndrome do not have complete hemispheric involvement, and if the sensorimotor cortex is not involved, a lobar or multilobar resection can be performed. Extensive dysplastic lesions may also be associated with multilobar epileptogenicity. In general, if the degree of cortical dysplasia is less than that seen in hemimegalencephaly and the patient has no evidence of a hemiplegia, multilobar resection can be considered instead of hemispherectomy. In contrast, in Rasmussen encephalitis, epileptogenicity may appear partial at the onset but the disease is known to be progressive and ultimately involve the whole hemisphere; in this disease, early multilobar resection is unlikely to provide permanent seizure control.

Role of Functional Localization

In multilobar resections, surgery aims at excising the epileptogenic zone as completely as possible while sparing function and avoiding the creation of a new deficit or the exacerbation of an existing one. Preoperative or intraoperative functional localization may be obtained to map out the anatomic region responsible for speech as well as sensorimotor cortical areas. Functional mapping before resection is obtained either through depth electrodes or subdural grids for localization of epileptogenic sites and motor, sensory, or speech areas. Intraoperative mapping by cortical electrical stimulation or the use of sensory-evoked potentials may help to indicate the exact location of motor and sensory functional areas, so that damage to them during resection can be avoided and the extent of removal of the epileptogenic zone optimized. The widespread extent of brain pathology in these patients (e.g., large atrophic lesions or extensive dysplasia) may distort the normal anatomy and therefore functional mapping may be helpful.

Impact of Electrophysiologic Studies

Electrophysiologic investigations follow the usual approach of interictal surface EEG recordings, including sleep recordings, drug tapering, and long-term video-EEG monitoring of ictal and interictal states. Typical findings with multilobar epileptogenic regions are widespread interictal abnormalities with independent multifocal features. It may be difficult to determine the exact lobar zone of seizure onset. As usual, electrophysiologic findings must be correlated with seizure semiology and imaging findings.

In some patients, there is also a role for invasive intracranial monitoring (9% in our series in Bonn). Placement of depth electrodes, subdural strips, or grids can help to delineate the predominant epileptogenic zone[73] and also to map functional areas. However, Rasmussen observed that in these patients even the full battery of recording techniques frequently failed to demonstrate a focal seizure onset in the damaged hemisphere.[81] In cases in which the imaging studies demonstrate a widespread lesion corresponding anatomically to diffuse electrophysiologic abnormalities, there is probably no need for invasive recording, and it can be assumed that the epileptogenic zone corresponds with the zone of anatomic abnormality. In some cases (34% of the Bonn series), after an intermediate degree of resection and/or disconnection, intraoperative electrocorticography may help to determine the final extent of resection, sparing certain areas if no spikes can be recorded there following the nearby resection.

Impact of Neuroimaging

Imaging studies are important to localize the hemispheric pathology. However, it is important to keep in mind that the epileptogenic zone may extend outside the range of the obvious anatomic lesion. CT is useful, especially in processes of atrophy, showing enlarged sulci and ventricles. MRI is superior in defining the anatomy and adds higher resolution in delineating the gyral pattern and in demonstrating parenchymal lesions or signal abnormalities. Recent improvements in MRI have led to much greater recognition and delineation of varieties of cortical dysplasia.[4]

If the pathology on imaging is focal and the epileptic activity widespread, metabolic imaging studies may help in the localization of the epileptogenic zone. For example, Chugani et al. demonstrated the value of PET when combined with intraoperative electrocorticography in defining the boundaries for multilobar resections.[20] Hypometabolism on interictal fluorodeoxyglucose-positron emission tomography (FDG-PET) was found in the parieto-occipitotemporal cortices of patients who eventually underwent multilobar resections with successful control of their seizures.[18]

Frequency of Use

Multilobar resections constitute a small proportion of epilepsy surgery procedures. In the Bonn series of 2,000 epilepsy procedures, there were 32 multilobar resections (1.6%). However, the increased diagnosis of hemispheric or subhemispheric pathologies (such as multilobar cortical dysplasia) with modern MRI techniques may lead to identification of more patients who would benefit from multilobar resections, especially in those with preserved functions that are not good candidates for hemispherectomy.

Evaluation Criteria

The most important decision with this group of patients is whether to perform a hemispherectomy or a multilobar resection. The presence of only a minimal or moderate hemiparesis, the presence of useful vision in the contralateral

visual field, or the preservation of speech functions in the damaged hemisphere often precludes consideration of hemispherectomy despite the presence of extensive damage and widespread epileptogenicity in the involved hemisphere.[81] In particular, patients with nonprogressive disorders (e.g., atrophy, gliosis, dysplasia) with good contralateral extremity function (e.g., fine finger movements and foot tapping) are potential candidates for multilobar resections instead of hemispherectomy. However, if a hemiplegia is present with loss of digital dexterity, the EEG shows diffuse abnormalities throughout the affected hemisphere, and the MRI reveals widespread hemispheric pathology, hemispherectomy is indicated. If the history is suggestive of Rasmussen encephalitis, and surgery has been decided upon, it is wisest to perform a hemispherectomy as the primary procedure, because any lesser procedure is unlikely to control seizures and the inevitable subsequent surgery is rendered more difficult. In young children with infantile spasms, the clinical appearance of the seizures and the hypsarrhythmic pattern on EEG would suggest a generalized seizure disorder, rendering the patient unsuitable for surgery.

During the preoperative evaluation for multilobar resections, attempts are made to tailor the surgical excision for maximal benefit. To eradicate the epileptogenic tissue, the epileptogenic zone must be defined. Clues are obtained from analysis of the patient's history, which helps determine the possible etiologic factors. These may be congenital (dysplastic) or acquired (infection, head injury), static (vascular), or progressive (Rasmussen encephalitis). The clinical seizure pattern often helps to indicate laterality and localization of onset. Noninvasive and invasive electrophysiologic studies further pinpoint the epileptogenic zone. These observations should be closely correlated with findings from anatomic (CT and MRI) and functional (PET, ictal SPECT) imaging investigations.

In cases in which the imaging abnormalities are minor, invasive monitoring may be indicated or a multistage surgical approach may be considered. In staged multilobar resections, the obvious focal, lobar, or multilobar epileptogenic zone may first be excised, with the plan to proceed to further excision at a later date if seizures are not satisfactorily controlled. Recently, this “multistage” approach has been successfully applied by the NYU group.[6,86] Olivier as well has taken the approach of proceeding in successive stages, limiting the initial resection to the most active or most damaged lobe and proceeding, 1 or 2 years later, with resection of another area if the seizures persist.[73]

When an obvious anatomic abnormality is demonstrated by imaging that correlates with the clinical and electrophysiologic definition of the epileptogenic zone, there is no need for invasive monitoring. Examples include porencephaly reflecting atrophy of more than one lobe; extensive but subhemispheric Sturge-Weber syndrome; and hemi-hemimegalencephaly.

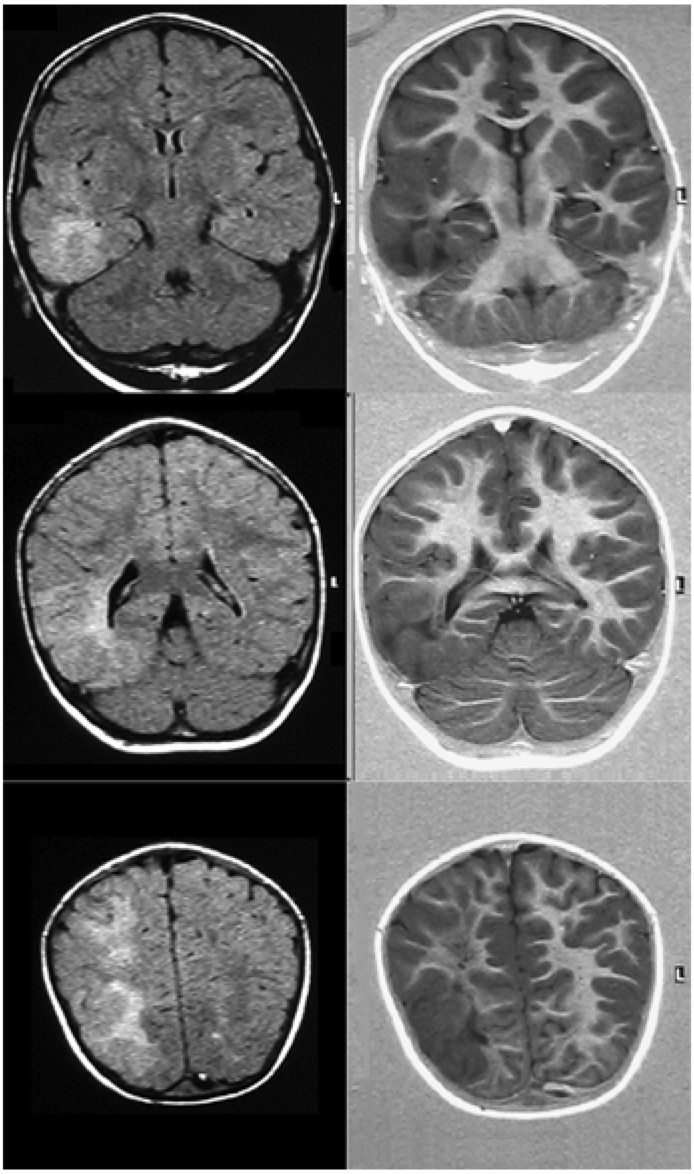

FIGURE 6. Multilobar resection for hemispheric cortical dysplasia in a 4-year-old male who presented with intractable seizures. Fluid-attenuated inversion recovery **(left)** and spoiled gradient-echo **(right)** magnetic resonance images demonstrate a right temporal-parietal-occipital lesion consistent with hemispheric cortical dysplasia at three different coronal levels. An extended right temporal-parietal-occipital lesionectomy was done with electrocorticography. Pathology demonstrated focal cortical dysplasia type IIb.

Goals of Surgery

Multilobar resection aims at achieving complete cessation of seizures or significant improvement in seizure frequency without producing neurologic deficits. Most widespread lesions responsible for seizure disorders are static and thus do not require surgery to alter their natural course. Atrophic, porencephalic, and dysplastic lesions are not by definition progressive disorders. However, these static lesions may indirectly interfere with brain function through mechanisms of secondary epileptogenesis.[71] On the basis of these mechanisms, another goal of multilobar resections may be to prevent further brain damage. It is thus important to identify candidates, localize the lesion, and then proceed to surgery early in the evolution of the seizures. Good seizure control in these patients is accompanied by improved psychological performance and social integration, which are often listed as secondary benefits.[64] The ultimate goal of the surgery should be to improve psychosocial functioning and thereby promote a better quality of life.

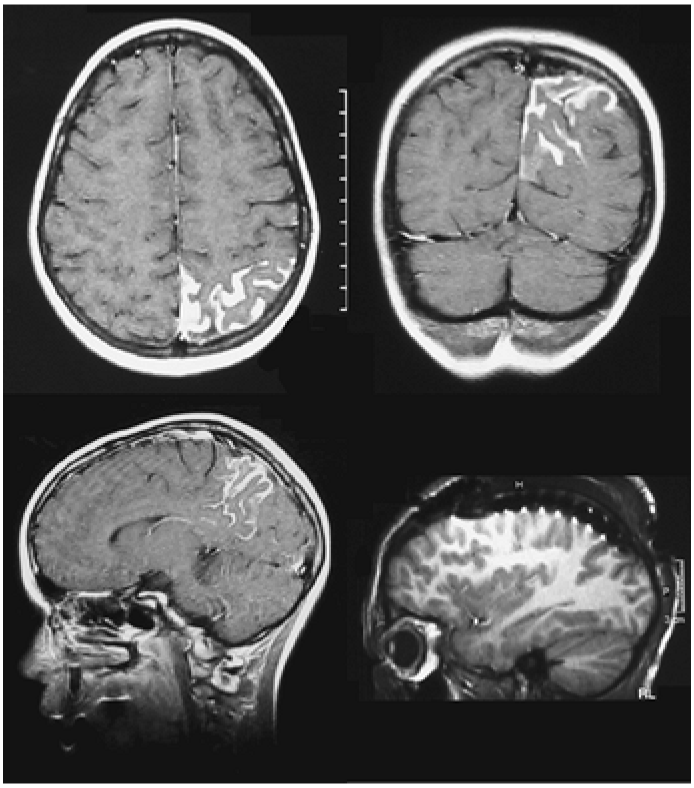

FIGURE 7. Multilobar resection for Sturge-Weber disease in a 10-year-old female. Axial **(top left),** coronal **(top right),** and sagittal **(bottom left)** magnetic resonance images demonstrate a left parieto-occipital lesion consistent with vascular malformation. Invasive diagnostic monitoring was performed with grid and strip electrodes **(bottom right)**. Subsequently, a left parieto-occipital extended lesionectomy with multiple subpial transections was performed. Pathology demonstrated Sturge-Weber disease.

Surgical Approaches

Multilobar resections may involve the frontotemporal, frontoparietal, parieto-occipitotemporal, or parieto-occipital lobes (Figs. 6 and 7). The techniques utilized vary from extensive corticectomy, lobar excision, or lobe disconnection to a combination of these. The corticectomy technique involves excision by aspiration of the cortical gray matter felt to correspond to the epileptogenic zone. Lobar excision consists of the anatomic removal of gray and white matter corresponding to the epileptogenic zone, the brain structural abnormalities responsible for the seizures, or both. Disconnection of a lobe

or its isolation from the rest of the brain has been utilized by some authors, thereby avoiding removal of the lobe (frontal or parieto-occipital) but eliminating, by disconnection, the epileptic manifestation. Removal of the epileptogenic tissue by en bloc resection appears to be the preferred technique in multilobar resections. Rasmussen stressed two important technical aspects of the resection strategy: (a) subpial removal along sulci to leave the removal cavity lined by untraumatized pial-covered gyri and (b) avoidance of movement of the underlying white matter during the cortical excision to minimize risk of injury.[81]

Unlike the case of hemispherectomy, intraoperative attention to preservation of function is essential. When a less than maximal hemiparesis is present, the arm and leg area of the sensorimotor gyri should be preserved. If a useful visual field is present, the posterior parietotemporal and occipital regions should also be preserved. During surgery, somatosensory-evoked potentials and motor-evoked potentials can be used to delineate the sensorimotor cortex, which can then be left intact. Preoperative investigations localizing the epileptogenic area should be available in the operating room, so that the intraoperative findings can be correlated with those obtained preoperatively. Some surgeons have also used intraoperative electrocorticography to further define the margins of the multilobar resection.

Results and Complications

There have been relatively few studies of outcome in children undergoing extratemporal and multilobar epilepsy surgery.[31,46,54,57,62,77,95,117] One problem is that this is a very heterogeneous group of patients, both in clinical and pathologic characteristics. In general, seizure-free outcome in patients with multilobar resections is poorer than those with unilobar resections or hemispherectomy,[57,62,77,117] which is not surprising since most unilobar resections are temporal lobectomies, and hemispherectomy provides a complete disconnection of the affected hemisphere. Outcome for hemispheric cortical dysplasia is clearly related to the extent of resection of the dysplastic tissue.[31,46,54,76,77] For the subset of patients with malformations of cortical development in particular, approximately 50% of patients become seizure free postoperatively.[31,57] One recent study indicates that the presence of acute postoperative seizures is an independent predictor of poor postoperative seizure outcome at 2 years.[66]

Complications are not usually separately reported for multilobar resections. Clearly, neurologic outcome depends on preoperative neurologic status as well as location and extent of multilobar resection. Patients undergoing multilobar resections as a repeat resection for initially failed epilepsy surgery have increased potential for neurologic deficits after the second operation.[93] Long-term follow-up of cognitive outcomes, as for hemispherectomy, will be an important component of future research.[55]

Summary and Conclusions

In multilobar resections and hemispherectomy, intractable seizures are secondary to widespread, usually unilateral, hemispheric damage resulting from multiple possible etiologies—some static, others progressive. Surgery has to be extensive and should aim at eliminating the influence of the abnormal tissue responsible for epileptogenicity. Seizure characteristics, neurologic status, EEG and imaging findings, and judgment regarding medical intractability all guide the decision regarding timing of surgery and the most appropriate surgical procedure. In the presence of some degree of preserved neurologic function, multilobar resection should aim at eliminating the epileptogenic zone without creating new deficits. In similar pathologies in which the underlying condition has created a complete hemispheric syndrome, the need to preserve function does not limit the surgery and hemispherectomy can be considered. Hemispherectomy under these circumstances is most likely to bring about complete seizure control. With the use of modern functional hemispherectomy techniques, operative morbidity and mortality can be minimized, and seizure control is usually good. The improved safety of these modifications together with improvements in neuroimaging and neurophysiologic monitoring has made hemispherectomy a more attractive option for patients with intractable unihemispheric epilepsy.

Chapter 179

Lesionectomy: Management of Substrate-directed Epilepsies

Kurupath Radhakrishnan

Itzhak Fried

Gregory D. Cascino

Introduction

Nearly one third of patients with newly diagnosed epilepsy on long-term follow-up will have their seizures unsatisfactorily controlled by treatment with antiepileptic drugs.[125] A majority of these patients with difficult-to-control seizures have focal epilepsies.[20] Nearly half of the patients with medically refractory focal epilepsies are potential candidates for epilepsy surgery.[44] The remarkable advances in neuroimaging technologies during the past two or three decades has allowed detection of a variety of brain lesions responsible for refractory focal epilepsies such as hippocampal sclerosis, malformations of cortical development, neoplasms, vascular malformations, and focal gliotic lesions that are amenable to surgical treatment. Table 1 summarizes the frequently encountered surgically remediable lesional epilepsy syndromes. The understanding that a majority of patients with substrate-directed intracranial lesion–associated chronic focal epilepsies can be selected for surgery based on a noninvasive presurgical evaluation has resulted in recent years in both an increase in the number of epilepsy surgeries being performed in developed countries and in the creation of epilepsy surgery programs in developing countries. A recent survey revealed that in 26 of 142 (18.3%) economically disadvantaged nations, at least one center regularly conducted epilepsy surgery, compared to 18 of 24 (75%) developed countries.[149]

In this chapter, we willc review the etiologies and pathogenesis of refractory lesional epilepsies and discuss the surgically remediable lesional syndromes including the presurgical evaluation strategies, surgical management, and postsurgery outcomes. The syndrome of mesial temporal lobe epilepsy with hippocampal sclerosis, which is the prototype of medically refractory lesional human epilepsy syndromes, is discussed in Chapter 247. Therefore, we will confine our discussion to the remaining lesional epilepsy syndromes listed in Table 1.

Historical Perspectives

Lesionectomy was introduced as one of the earliest surgical treatments for patients with partial or localization-related epilepsy. The modern era of epilepsy surgery began on May 25, 1886, when Victor Horsley operated, at the National Hospital for Paralysed and Epileptic at Queen Square in London, on a 22-year-old male referred to him by John Hughlings Jackson with focal motor seizures due to a focal cortical scar left behind by a depressed skull fracture he sustained 15 years before.[65] A month later, on June 22, 1886, Horsley operated on a second patient of Jackson's, a 22-year-old male who for 2 years suffered from recurrent focal motor seizures with onset in the left thumb and forefinger progressing on to involve the rest of the left upper extremity and left half of the body, the so-called jacksonian seizures.[65] At exploratory operation, Horsley found a tumor at the site of brain predicted by Jackson based on the seizure semiology that turned out to be a tuberculoma. This second operation is truly the first substrate-directed surgical treatment of epilepsy, not only because it was guided by the meticulous analysis of the seizure semiology, but also because it involved resection of the lesion and the surrounding brain tissue responsible for the seizures.

The introduction of electroencephalography (EEG) by Hans Berger in the 1930s permitted identification of epileptiform discharges.[12] Herbert Jasper, in collaboration with Wilder Penfield, effectively utilized EEG in the neurosurgical treatment of focal epilepsies at the Montreal Neurological Institute, not only in preoperative localization of the epileptogenic focus, but also during surgery to tailor the extent of resection—intraoperative electrocorticography.[69] The development of inpatient video-EEG recordings and digitalization of the EEG data in the 1980s and 1990s permitted precise electroclinical correlation of focal seizures.[22]

Although the introduction of computed tomography (CT) in the 1970s facilitated detection of some overt lesions,[53] the most important advance in the surgical treatment of focal epilepsies is the introduction of magnetic resonance imaging (MRI) in the 1980s.[83] A high-resolution MRI has become the integral part of presurgical evaluation of focal epilepsies, as it is the only investigation that can distinguish between substrate-related and substrate-unrelated epilepsies. Several studies, both in temporal and extratemporal epilepsies, have shown that an MRI-identified lesion is a strong predictor of favorable seizure outcome following surgery.[23,93] Newer MRI techniques like MR spectroscopy, MR volumetry, MR T2 relaxometry, and diffusion-weighted MRI have further improved the yield of detection of the epileptogenic focus.[41] A wide array of additional investigations such as positron emission tomography (PET), single photon emission tomography (SPECT), functional MRI (fMRI), MR tractography, and magnetoencephalography (MEG) and the coregistration of data from multiple sources have helped not only in detecting areas of altered electrical activity, blood flow, and metabolism, but also in defining the relationship of the lesion to adjacent cortical areas and white matter tracts with critical neurologic function.[43,87,113,136]

Table 1 Surgically Remediable Lesional Epilepsy Syndromes

Hippocampal sclerosis

Neoplastic lesions

- Neuronal and glial neoplasms
  - Ganglioglioma
  - Dysembryoplastic neuroepithelial tumor
- Glial neoplasms
  - Pilocytic astrocytoma
  - Low-grade astrocytomas
  - Pleomorphic xanthoastrocytoma

Oligodendroglioma

Oligoastrocytoma

Developmental lesions

Malformations of cortical development

Focal malformations of cortical development

Periventricular heterotopia

Polymicrogyria and schizencephaly

Tuberous sclerosis complex

Hypothalamic hamartoma

Vascular lesions

Arteriovenous malformations

Cavernous angioma

Chronic inflammatory focal lesions

Tuberculoma

Cysticercosis

Focal encephalomalacias

Large hemispheric lesions

Rasmussen encephalitis

Hemimegalencephaly/hemi-hemimegalencephaly

Hemiconvulsion-hemiplegia-epilepsy syndrome
Sturge-Weber syndrome

New surgical techniques such as microneurosurgery and image-guided surgery have made lesionectomy safer and more effective.[30] The role of radiosurgical techniques in selected substrate-related focal epilepsies such as those due to vascular

malformations[129] and hypothalamic hamartomas[117] are currently undergoing evaluation.

Pathophysiology of Substrate-directed Epilepsies

The underlying pathophysiologic mechanisms of lesion-related epilepsies are multifactorial and poorly understood. While focal malformations of cortical development[17,108] and hypothalamic hamartomas[72] are intrinsically epileptogenic, in brain tumors and focal gliotic lesions, it is often the alterations in the perilesional cerebral cortex that incite epileptogenesis. Occasionally, long-standing lesions within or adjacent to the temporal lobe can result in hippocampal sclerosis. In these patients with dual pathology, either the primary lesion or the secondary hippocampal sclerosis or both may initiate epileptic seizures.[25,27,46,49]

Several histologic changes have been observed in the brain tissue immediately surrounding a brain tumor, but it remains unclear how these factors relate to epileptogenesis.[127] Comparison of peritumoral cortex from patients with and without seizures have demonstrated significant differences in the number and organization of the synapses with an increase of excitatory synapses[94] and a decrease of inhibitory synapses.[59] Wolf et al.[151] investigated perilesional changes in pharmacoresistent tumoral epilepsies by using the immunoreactivity of the γ-aminobutyric acid $(GABA)_A$ receptor, NR1-*N*-methyl-D-aspartate (NMDA) receptor subunits, and glutamate decarboxylase activity and concluded that not only alterations of concentrations of neurotransmitters in peritumoral cortex occur, but also that these changes involve heterogeneously the number of receptors and the concentration of enzymes that synthesize and degrade neurotransmitters. Additionally, the multidrug resistance (MDR) protein-1 and the MDR-associated proteins may play a role in contributing to pharmacoresistance.[88,135] Recently, the CC genotype at the C3435 T polymorphism of the MDR-1 gene was shown to be associated with resistance to antiepileptic drugs.[131]

Glioneural tumors like ganglioglioma and dysembryoplastic neuroepithelia tumor are frequently associated with dysplasia in the adjacent cortex. In a recent study, in 20 of 24 (83%) surgically treated cases of dysembryoplastic neuroepithelial tumor (DNET), associated cortical dysplasia was found on pathologic examination.[141] To achieve favorable postoperative seizure outcome, presurgical evaluation and surgical treatment in these lesions should be aimed at defining and radically resecting the pathologic areas, both the tumor and associated dysplasia. Similarly, in an analysis of the seizure outcome of a group of patients with refractory focal epilepsies associated with cavernous malformations, complete removal of surrounding hemosiderin-stained brain tissue along with the vascular lesion was shown to result in a better seizure outcome when compared to removal of the lesion alone.[9]

Substrate-directed Epilepsy Syndromes

Tumoral Epilepsies

Brain neoplasms comprise 10% to 30% of the pathologic substrate in surgically treated patients with medically refractory focal epilepsies.[21,138,150] The histopathologic profile of tumor-related chronic epilepsy is quite different from the usual pattern of primary brain neoplasms. Although low-grade tumors such as ganglioglioma and DNET account for only a very small proportion of primary brain neoplasms, they are more frequently associated with tumoral refractory epilepsies.[74,91,98,109]

Ganglioglioma

The recent World Health Organization classification on brain tumors defines ganglioglioma as a neoplasm composed of neoplastic neural and neoplastic glial cells (Fig. 1).[75] Ganglioglioma may occur in any part of the neuraxis, but the most frequent site is the temporal lobe. Ganglioglioma is a common cause of tumor-related refractory epilepsies and in some series account for nearly half of the tumoral substrates,[54,91,98,109] though in others it is lower.[18,50] In one series of 38 patients with ganglioglioma (28 temporal and 10 extratemporal), the mean age at surgery and mean duration of epilepsy prior to surgery was 19.3 years and 9.7 years, respectively.[99] In another series of 23 patients with surgically treated ganglioglioma, the median age at surgery was 20 years and the median duration of epilepsy prior to surgery was 9 years.[116]

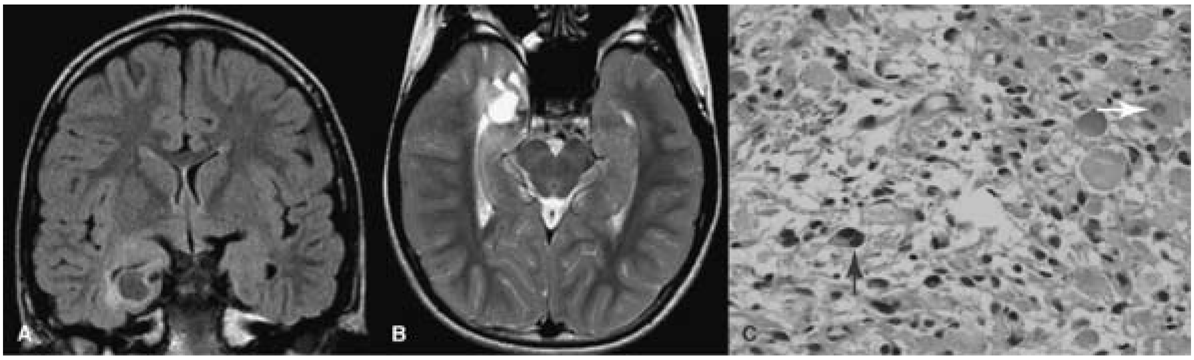

FIGURE 1. Imaging and histopathologic data of an 11-year-old boy with complex partial seizures since age 1½ years. **A:** Coronal fluid attenuated inversion recovery magnetic resonance imaging sequence shows a cystic space-occupying lesion involving the right hippocampus and parahippocampal gyrus with surrounding areas of hyperintensity. **B:** T2-weighted spin echo sequence shows extension of the lesion to the amygdala and head of hippocampus. **C:** Photomicrograph shows admixture of neoplastic neurons (*white arrow*) and astrocytes (*black arrow*) characteristic of ganglioglioma (hematoxylin and eosin ×200). The patient was seizure free for 18 months following anterior temporal lobectomy with amygdalohippocampectomy.

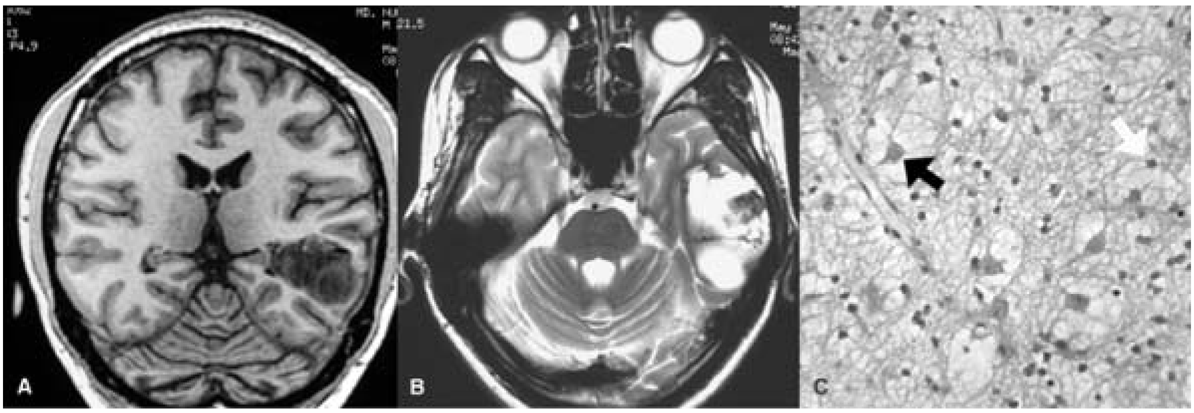

FIGURE 2. Imaging pathologic correlation in a 20-year-old male with complex partial seizures with behavioral arrest, oral and bilateral upper automatisms, head and eye deviation to the right, and frequent secondary generalization. A multicystic mass lesion involves the left inferior temporal gyrus with remodeling of the overlying skull, which is hypointense on T1 coronal sequence **(A)** and hyperintense on axial T2 sequence **(B)** with hypointensity within suggestive of calcification. **C:** Photomicrograph shows microcystic spaces with floating neurons (*black arrow*) and oligodendrocyte-like cells (*white arrow*), characteristic of a dysembryoplastic neuroepithelial tumor (hematoxylin and eosin ×200). Patient was seizure free for the last year following lesionectomy.

The typical CT appearance of gangliogliomas is a well-circumscribed hypodense or isodense lesion, with focal calcification in one third of tumors and enhancement in nearly half.[52] With MRI, they appear as a heterogenous mass, hypointense on T1-weighted and hyperintense on T2-weighted sequences (Fig. 1). Cystic changes and slight enhancement are frequently observed.[52]

Dysembryoplastic Neuroepithelial Tumor

The DNET accounts for 10% to 20% of chronic tumoral epilepsy syndromes.[35,91,109] Its typical pathologic features include disorganized arrangement of neural and glial elements

P.1893

without significant cytological atypia[35] (Fig. 2). The frequent association of DNET with cortical dysplasia is being increasingly recognized.[114,141] From these features, DNET might be regarded even as an atypical hamartomatous lesion.[35] The histologic diagnosis of DNET may be challenging in the absence of a sizeable specimen preserving the peculiar disarray of the neural and glial elements. In a group of 39 patients with DNET, age at onset of seizures ranged from 1 to 19 years (mean 9 years), and the duration of epilepsy prior to surgery averaged 9 years (range 2 to 18 years).[35] In a recent Japanese series of 20 patients, the mean age at seizure onset was 16.8 years (range 1 to 38 years) and the mean age at surgery was 24 years (range 4 to 46 years).[141]

The CT demonstrates a well-circumscribed hypodense lesion, but may be normal in 10% of cases.[52] The MR appearance of DNET may be indistinguishable from that of ganglioglioma, astrocytoma, and oligodendroglioma. Absence of calcification, the cortical location and associated gyral thickening, and frequent cystic changes may be helpful in differentiation[52] (Fig. 2).

Low-grade Glial Neoplasms

Pilocytic astrocytoma, low-grade gliomas, pleomorphic xanthoastrocytoma, and oligodendroglioma comprise a substantial part of the pathologic substrates of tumoral chronic epilepsies.[18,50,91,109] Seizures occur in 70% of those with astrocytomas and in 92% of those with oligodendrogliomas.[16,138] Nearly 75% of glial neoplastic lesions associated with chronic epilepsy involve the temporal lobe.[16,98,138] Fried et al.[50] have

P.1894

proposed that limbic and neocortical gliomas associated with chronic seizures constitute a unique group of glial tumors that involve the gray matter, arise in a young host, and exhibit stable biologic behavior over many years. Yet the possibility of malignant transformation cannot be ruled out. This is an added consideration in the treatment of these lesions, as their total re-moval addresses the issues of both seizure and tumor control.

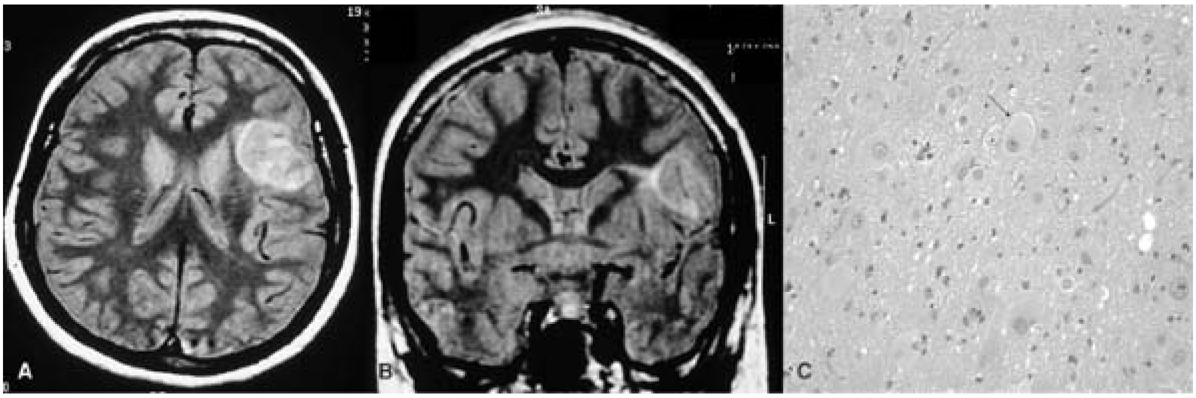

FIGURE 3. The data of a 19-year-old female with frequent complex partial seizures characterized by cephalic sensation, bilateral upper limb clonic jerks, and falls. **A:** Axial proton density (PD) magnetic resonance imaging sequence shows thickened left inferior frontal gyrus forming a globular hyperintense lesion. **B:** Coronal PD sequence depicts a radial band extending transmantally up to the frontal horn of left lateral ventricle. **C:** Photomicrograph shows dysplastic neurons with variation in size and shape and balloon cells (*arrow*). There were no postoperative neurologic deficits and no disabling seizures for the last 4 years following lesion resection under awake craniotomy and cortical stimulation and mapping.

Malformations of Cortical Development

Malformations of cortical development are second only to hippocampal sclerosis as a frequent pathologic substrate detected in 20% to 40% of pediatric and adult surgically treated patients with pharmacoresistent epilepsies.[115,152] Developmental malformations are fully discussed in Chapter 259. The main pathologic hallmark of malformations of cortical development is the presence of columnar and laminar disorganization that can be intermixed with various cellular abnormalities that include dysmorphic neurons, giant neurons, and balloon cells.[115] The classification scheme of Barkovich et al.[7] is centered on three processes of cerebral development: Neuronal proliferation and eventual apoptosis of selected cells; neuronal migration; and cortical organization. In relation to resective surgery, the following malformations of cortical development are relevant: Focal cortical dysplasia or more appropriately focal malformations of cortical development, periventricular heterotopia, polymicrogyria, and schizencephaly.[100,134] In addition, malformations of cortical development associated with DNET and tuberous sclerosis significantly contribute to the pathogenesis of refractory focal epilepsies.

Focal Malformations of Cortical Development

The focal malformations of cortical development are important substrates for focal motor status epilepticus or epilepsia partialis continua. Preoperative detection of focal malformations of cortical development depends on high-resolution MRI. The following MRI features suggest focal malformations of cortical development: Local cortical thickening, blurring of gray–white matter interphase, increased signal in the underlying white matter, and sometimes a wedge-shaped tail extending radially to the ventricle ("transmantle dysplasia") (Fig. 3).[6] Distinction from tuberous sclerosis–associated lesions may not be possible and may not even be rationale.[10,92] Focal malformations of cortical development are most frequently encountered in the frontal or temporal lobes, though may occur anywhere.

Periventricular Heterotopia

This is a form of focal malformations of cortical development in which neurons generated in the periventricular region have failed to migrate, resulting in nodules abutting the ventricular ependymal lining. Isointensity of periventricular nodules with normal gray matter on all sequences of MRI helps to distinguish periventricular nodular heterotopia from the subependymal nodules of tuberous sclerosis.[5] The pathophysiologic basis of epilepsy in periventricular nodular heterotopia may be related to their intrinsic epileptogenicity and connection to other nodules and to the cortex.[80]

Polymicrogyria and Schizencephaly

Polymicrogyria is the presence of an excess number of abnormal small gyri resulting in an irregular cortical surface. Polymicrogyria is not invariably associated with epilepsy. Patients may present with developmental delay, learning disabilities, or congenital hemiparesis.[134] The mechanism of epileptogenesis in polymicrogyria is unknown; surrounding cortex is implicated in epileptogenesis. Perhaps because of this reason, surgical resection of the microgyric area alone seldom results in favorable seizure outcome. Schizencephaly is currently grouped with polymicrogyria, which is defined by the presence of transcortical cleft, open or closed, lined by gray matter, and often with microgyria along the cleft borders.[7] Schizencephaly may be associated with a wide range of other malformations involving the septum, optic nerve, and hippocampus.[61]

Tuberous Sclerosis Complex

Tuberous sclerosis complex is an autosomal dominantly inherited multisystem genetic disorder characterized by variable phenotypic expression, resulting from mutations in one of two genes, TSC1 on chromosome 9q34 encoding hamartin, and TSC2 on chromosome 16p13 encoding tuberin.[33] The brain lesions in tuberous sclerosis complex are due to disordered

P.1895

neurogenesis and neuronal migration, resulting in very different neurologic phenotypes including seizures, mental retardation, learning disabilities, and autism. Pathologically, tubers are characterized by disorganized cortical laminations, aberrant dendritic and axonal projections and arborizations, astrocytic proliferation, dysplastic neurons, and giant cells.[32] Giant cells are the pathognomonic histologic feature of tuberous sclerosis complex.[33]

FIGURE 4. A 17-year-old male referred to the Comprehensive Epilepsy Program of the Sree Chitra Tirunal

Institute for Medical Sciences and Technology, Trivandrum, India, from an endemic area for cysticercosis in southern India for refractory complex partial seizures since the age of 14 years. **A:** Noncontrast axial computed tomography shows a calcified lesion in the left posterior temporal region. **B:** T2 axial magnetic resonance imaging sequence shows hypointense calcification with surrounding hyperintensity representing gliosis. The patient was seizure free for nearly 2 years following lesionectomy.

Epilepsy is the most common presenting symptom of tuberous sclerosis complex. The seizures are focal or multifocal in origin and are often resistant to antiepileptic drugs.[105] Immunohistochemical evidence and electrophysiologic evidence have indicated that the neurons within cortical tubers are intrinsically epileptogenic.[33] Surgical management of epilepsy is challenging in patients with tuberous sclerosis complex because the epileptogenic tubers are often multiple, bilateral, and extratemporal, overlapping with eloquent cortex.[57,68,82]

Hypothalamic Hamartomas

With improved detection of the lesion by MRI, the wide clinical spectrum of epilepsy syndromes associated with hypothalamic hamartoma is being increasingly understood. In addition to gelastic seizures, hypothalamic hamartoma can manifest with partial seizures of temporal or frontal semiology and with a catastrophic pediatric epileptic encephalopathy with polymorphic seizures, intellectual deterioration, and marked behavioral disturbances.[8,72,139] The seizures in individuals with hypothalamic hamartoma are often refractory to antiepileptic drugs, but in most cases are reversed by surgical excision,[48,103] radiofrequency thermocoagulation, or Gamma Knife surgery (Chapter 250).[117]

Vascular Malformations

Seizures occur in about one third of patients with arteriovenous malformations and the response to antiepileptic drug therapy is variable.[64] Among those with medically refractory focal seizures, nearly three fourths of patients benefit either from lesion resection[111] or from radiosurgery.[129] Seizures represent the most common symptomatic presentation of supratentorial cerebral cavernous malformations.[31,73] In a comparative analysis of the seizure propensity of patients harboring arteriovenous and cavernous malformations, Awad et al.[4] found a prevalence of 50% to 70% in cavernomas and 20% to 40% in arteriovenous malformations. Recurrent microhemorrhages and the resultant hemosiderin deposition may contribute to the epileptogenic potential of cavernomas.[9]

Cerebral Cysticercosis

Neurocysticercosis currently represents a major public health problem in developing countries of Latin America, Asia, and Africa, as well as in industrialized nations with a high immigration rate from endemic areas.[37,133] As the number of immigrants entering the United States from Latin America has increased, so has the incidence of neurocysticercosis. More than 1,000 new cases are being diagnosed in the United States annually, and large neurocysticercosis case series have been reported from California, Texas, Oregon, Chicago, and New York.[38,119,128,137,144] Seizures are the most common neurologic symptoms associated with neurocysticercosis, occurring in up to 70% of symptomatic patients. Neurocysticercosis might lead to chronic epilepsy either due to calcified lesions or by triggering epileptogenesis at distant sites (Fig. 4). In a recent study, out

P.1896

of 512 patients evaluated for intractable epilepsy in an endemic area in Brazil, isolated cysticercosis was found as the cause only in eight patients (1.6%). However, the authors observed calcified cysticercus lesions more frequently in patients with hippocampal sclerosis, raising suspicions of dual pathology.[146]

Focal Encephalomalacia

Encephalomalacia resulting from destructive brain injury accounted for as much as 17% of all focal structural lesions in a recent large MRI series of patients with refractory focal epilepsies.[85] Encephalomalacia can result from perinatal insults, head injuries, or previous surgical procedures. Similar to patients with other types of structural lesions, patients with encephalomalacia may benefit from resection of the lesion and the adjacent electrophysiologically abnormal brain tissue.[71] Accompanying porencephalic cyst may necessitate modification of the surgical procedure.[58]

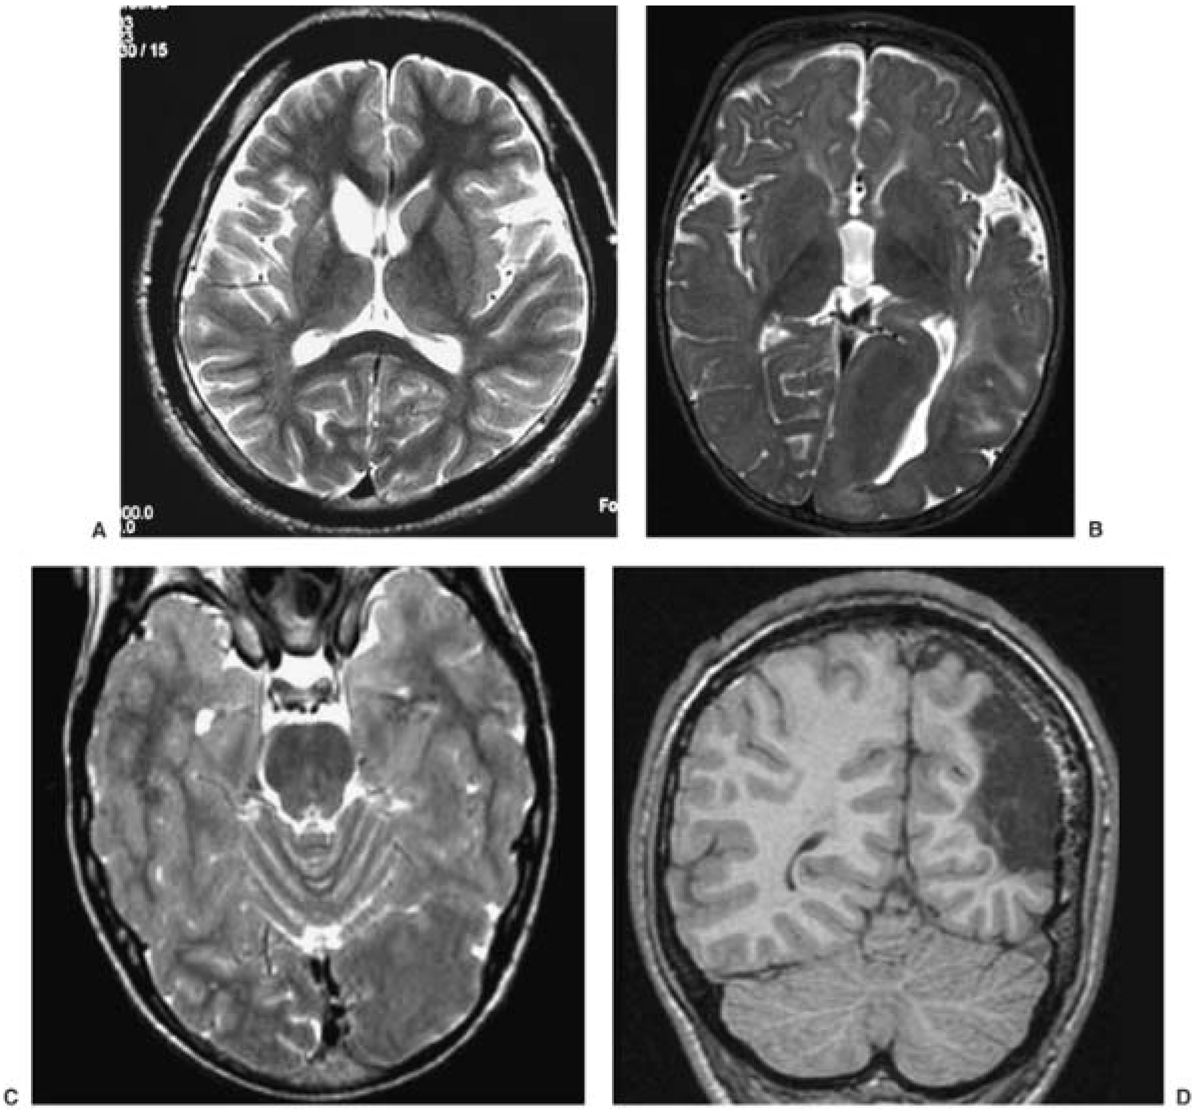

FIGURE 5. Major hemispheric lesional substrates from patients who had undergone hemispherectomy or multilobar resections. **A:** Right hemispheric predominant perisylvian and right caudate head atrophy characteristic of Rasmussen encephalitis. **B:** Left hemimegalencephaly. **C:** Left posterior quadratic dysplasia. **D:** Profound left hemispheric atrophy in hemiconvulsion-hemiplegia-epilepsy syndrome.

Multilobar and Widespread Hemispheric Lesions

Patients with major lesions involving one hemisphere such as Rasmussen encephalitis, Sturge-Weber syndrome, hemimegalencephaly, and hemiconvulsion-hemiplegia-epilepsy (HHE) syndrome are potential candidates for hemispherectomy or multilobar resections.[55,79] These are only briefly discussed here and are presented in more details in other chapters.

Rasmussen Encephalitis

Rasmussen encephalitis is a chronic inflammatory disease of uncertain etiology, usually affecting one cerebral hemisphere (Chapter 243).[15] The disease evolves from an initial prodromal phase with infrequent focal seizures to epilepsia partials continua and progressive hemiparesis lasting several months or years, and subsequently passes into a residual stage with marked decrease in the frequency and distribution of focal seizures.[14,56] The MRI after transient focal swelling and hyperintensity involving the cortex, especially over the insular and preinsular regions, shows progressive atrophy of the involved hemisphere.[14,15] Disproportionate atrophy of the head of the caudate nucleus of the involved side is a characteristic MRI appearance of Rasmussen encephalitis (Fig. 5A). The pathologic changes are multifocal in distribution within the hemisphere, characterized by a variable combination of neuronal damage, astrogliosis, and lymphocyte infiltration.[110] Although in some patients the progression may be arrested by immunotherapy with corticosteroids, intravenous immunoglobulin, or plasma exchange, a majority would require hemispherectomy to control their severely disabling epilepsia partialis continua and secondary generalized seizures.[14,145] An occasional patient presenting in the residual stage of the disease with epilepsia partials continua of a restricted distribution may benefit from focal cortical resection.[102]

Sturge-Weber Syndrome

Sturge-Weber syndrome is a rare, sporadic neurocutaneous syndrome characterized by unilateral facial nevi, leptomeningeal angiomatosis, and congenital glaucoma.[39,143] Epilepsy occurs in 75% to 90% of the cases and is often refractory to medical treatment. Although controversies still exist regarding the advantages of early (prophylactic) versus later surgical interventions, excision of the angiomatous cortex or hemispherectomy in those with extensive unihemispheric involvement should be considered once the seizures become refractory to antiepileptic drugs and disabling.[78]

Hemimegalencephaly

Hemimegalencephaly is a malformation of cortical development arising from an abnormal proliferation of anomalous neuronal and glial cells leading to hypertrophy of the whole affected cerebral hemisphere (Fig. 5B). Hemimegalencephaly can occur alone or may be associated with neurocutaneous disorders, such as neurofibromatosis, epidermal nevus syndrome, hypomelanosis of Ito, and Klippel-Trenaunay-Weber syndrome.[40] Severe drug-resistant epilepsy is a dominant clinical picture of hemimegalencephaly, and hemispherectomy is the most effective treatment to control seizures.[55,79] Posterior quadrantic dysplasia (hemi-hemimegalencephaly) involves the occipital, parietal, and posterior temporal lobes (Fig. 5C).[34]

Hemiconvulsion-Hemiplegia-Epilepsy Syndrome

HHE syndrome is characterized by prolonged unilateral convulsions during fever in children under 4 years of age, who subsequently develop a permanent hemiparesis.[124] Focal seizures, poorly responsive to antiepileptic drugs, ensue later. An extensive atrophy of the involved hemisphere is evident on neuroimaging (Fig. 5D). In developing countries, HHE syndrome still forms a significant proportion of patients selected for hemispherectomy.[36]

Indications for Surgery

Because of the widespread availability and increasing use of MRI, today patients presenting with epileptic seizures are likely to be imaged quite early for a structural lesion than in the years past. The identified lesion may require resective surgery either because of the epileptic seizures that are refractory to antiepileptic drugs, for pathologic verification of the lesion before additional treatments such as radiotherapy or chemotherapy can be administered, or because of the risks other than seizures associated with the lesion, such as potential for malignant transformation from a suspected benign neoplasm or hemorrhage from a vascular malformation. All patients with medically refractory epilepsies and an MRI-identified lesion should be referred for presurgical evaluation. Several years of polytherapy with antiepileptic drugs is not required to define medical refractoriness. Although a period of 2 years of observation on adequate antiepileptic drug therapy is advocated prior to consideration for epilepsy surgery, infrequent seizures that are potentially injurious and socially disabling, even of 1 year or shorter duration, may necessitate referral for surgery. In patients harboring a suspected low-grade neoplasm, whose seizures are well controlled with antiepileptic drug therapy, it remains controversial whether resection of the tumor either improves long-term survival or the control of epilepsy. The controversies surrounding the management of low-grade intracranial neoplasms[20] are beyond the scope of this chapter, but it has been proposed that low-grade astrocytomas associated with chronic seizures in a young host represent a distinct clinicopathologic entity with a unique biologic behavior.[50]

Presurgical Evaluation

Basic Principles

The objective of epilepsy surgery is to make the patient seizure free without producing any unacceptable neurologic sequelae (Chapters 167,168,169). Finding an intracranial lesion in a patient with recurrent focal seizures does not necessarily mean

that the lesion is responsible for the seizures. It is necessary not only to confirm the relationship between the lesion and the seizures, but also to delineate the relationship of the lesion to adjacent functional networks. The relationship between the lesion and seizures is much more complex than what may be envisaged. First, in a majority of patients, the seizure-generating focus may be contiguous with but may extend beyond the lesion itself. Second, in patients with malformations of cortical development, the MRI-identified lesion may be “the tip of the iceberg,” and there may be additional MRI occult areas contributing to epileptogenesis. Third, in patients with multiple lesions, such as in tuberous sclerosis complex, it is necessary to identify which of the lesions is primarily responsible for the patient's habitual seizures. Fourth, the lesion may have resulted in a second epileptogenic focus, such as hippocampal sclerosis (dual pathology), which may be responsible for perpetuation of seizures. Last, the lesion occasionally may be incidental and bear no causal relationship to epileptogenesis. For example, in a recent study from an endemic area for neurocysticercosis, although a significant proportion of patients with medically refractory epilepsies had calcified brain cysticercus lesions, a majority of them had additional lesions like hippocampal sclerosis classically associated with refractory epilepsies.[146]

Failure of epilepsy surgery to control the seizures means that the epileptogenic zone has not been adequately resected. The *epileptogenic zone* by definition is the area of brain that is necessary and sufficient for initiating seizures, whose resection or disconnection is necessary for abolition of seizures.[89] Since the epileptogenic zone is a theoretical concept and there is currently no way of defining it prior to surgery, information

is obtained during the presurgical evaluation about identifiable zones as listed in Table 2 and are utilized to reliably predict the epileptogenic zone.[45] As the lesional zone is already evident at referral in patients with substrate-related epilepsies, the objective of presurgical evaluation is aimed at identifying other zones and establishing their relationship to the lesion.

Table 2 Definition of Abnormal Brain Areas Involved in Focal Epileptogenesis

Area	Definition	Mode of definition
Epileptogenic lesion	Structural brain abnormality that is the direct cause of seizures	Structural imaging, tissue pathology

Irritative (spiking) zone	Area that generates interictal spikes	EEG and MEG
Ictal onset zone	Area of cortex that generates seizures	EEG and MEG
Symptomatogenic zone	Area that produces the initial clinical symptomatology	History, observation during video-EEG monitoring
Functional deficit zone	Cortical area with functional abnormalities	Neurologic examination, neuropsychological testing, EEG, MEG, PET, SPECT
Epileptogenic zone	Area of brain that is necessary for generating seizures and whose removal or disconnection abolishes seizures	Theoretical concept

EEG, electroencephalography; MEG, magnetoencephalography; PET, positron emission tomography; SPECT, single photon emission tomography.
Modified from Liégeois F, Cross JH, Gadian DG, et al. Role of fMRI in the decision-making process: epilepsy surgery for children. *J Magn Reson Imaging.* 2006;23:933–940.

Patients with medically refractory lesional epilepsies belong to different categories depending on the degree of complexity involved in presurgical evaluation. The decision making for epilepsy surgery requires a multidisciplinary approach in which the epileptologist, neurosurgeon, neuroradiologist, and neuropsychologist work in conjunction to understand the integrated picture of epileptogenesis. Understanding when not to operate because of the need for further evaluation is as important as knowing which patients may benefit from surgery with the investigative facilities available in a particular epilepsy surgery center.

Generally, the presurgical evaluation follows the steps listed in FIGURE 6. Information obtained by noninvasive means such as history, neurologic examination, MRI, and scalp and video-scalp EEG monitoring are discussed in the patient management conference to decide about surgical candidacy or the need for further investigation. To minimize the requirement of intracranial EEG monitoring, multiple noninvasive investigative strategies such as PET, ictal SPECT, MEG, fMRI, and peri-ictal diffusion-weighted MRI are currently available that can provide information to localize the epileptogenic zone.[41,76] Furthermore, information obtained from these sources can be combined with MRI, as in subtraction ictal SPECT coregistered to MRI (SISCOM)[136] and MEG coregistered to MRI (magnetic source imaging)[43,77] to provide structural and functional data correlation. The relative sensitivity of these new technologies in predicting the localization of the epileptogenic zone and therefore their relative role in presurgical evaluation are uncertain. The local availability and expertise in a particular technique dictates the preferential usage of one technology over the other by individual epilepsy surgery centers. For example, despite lacking these new technologies, in the last decade, several epilepsy centers in economically disadvantaged countries have successfully implemented epilepsy surgery programs and have produced results comparable to those from industrialized countries by selecting for surgery patients in whom the epileptogenic zone can be localized by using locally available, relatively inexpensive, and noninvasive strategies.[140] The availability of newer technologies has helped in selecting more and more patients for surgery, in whom the initial evaluation data have remained inconclusive.

History and Examination

A thorough neurologic examination may detect subtle motor or sensory neurologic signs or visual field defects that may assist in clinically lateralizing the functional deficit zone. Emotional facial weakness (mimic facial paresis) may occur in nearly two thirds of patients contralateral to a temporal lobe lesion.[26,67] Age at onset of seizures and duration of epilepsy prior to seeking medical attention are seldom helpful in predicting the nature of the lesion.

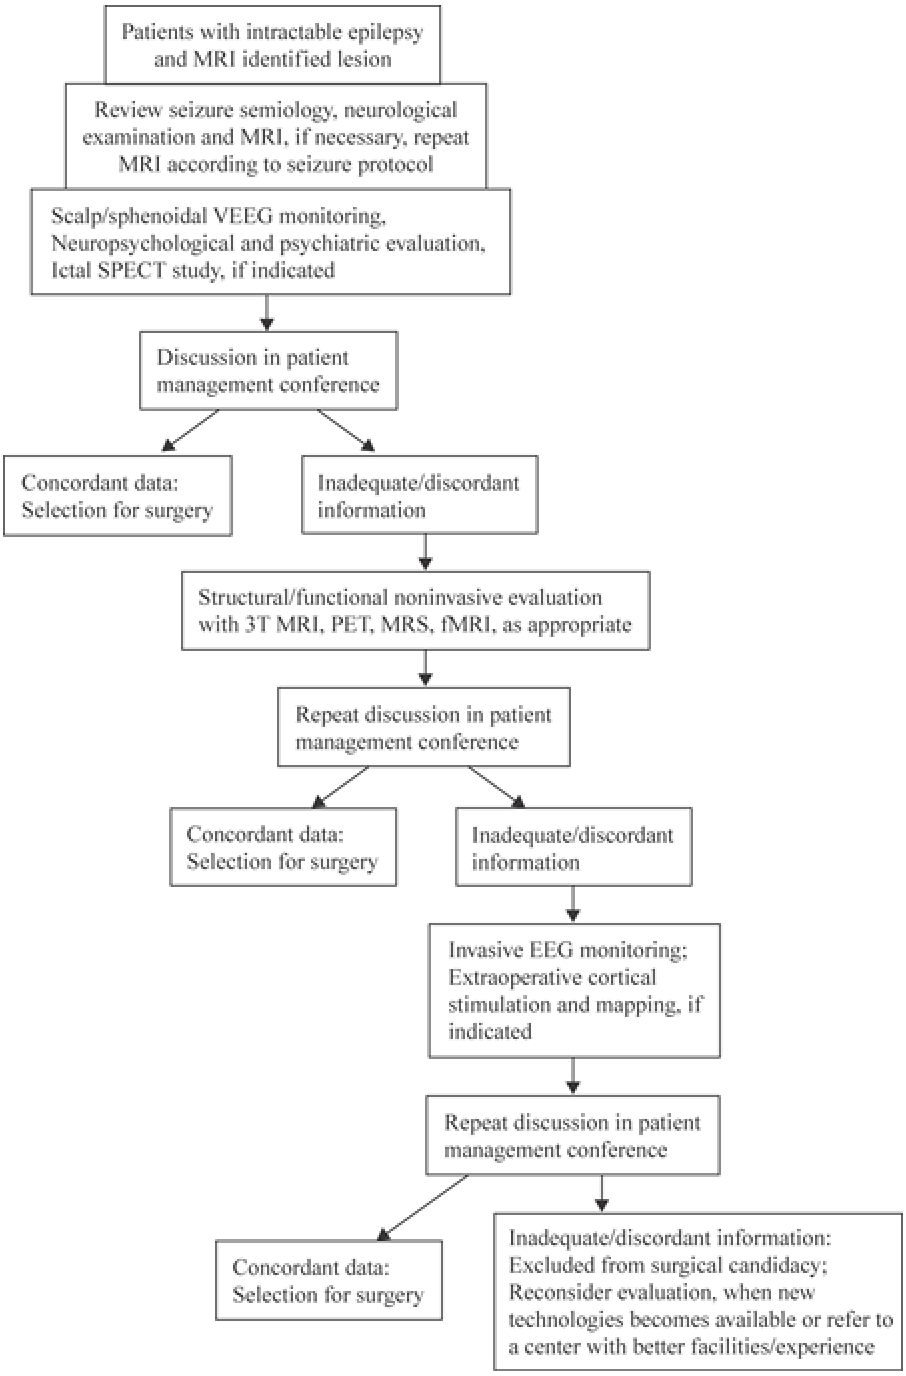

FIGURE 6. Steps in the presurgical evaluation of a patient with substrate-directed refractory epilepsy syndrome.

Clinical Seizure Characteristics

Lesional epilepsy may be associated with simple partial, complex partial, or secondarily generalized tonic–clonic seizures. There is an established association between gelastic seizures and hypothalamic hamartomas; however, children with these lesions can also present with complex partial seizures simulating temporal lobe seizures, and with polymorphic seizures, intellect deterioration, and behavioral problems simulating Lennox-Gastaut syndrome.[8,139] In a patient presenting with chronic epilepsia partialis continua, the differential diagnosis includes Rasmussen encephalitis and focal malformations of cortical development; associated progressive hemiparesis points to the former. The most frequent seizure type associated with tumoral epilepsy is complex partial seizures. The semiology of auras may have localizing value.[51] While the majority of the patients with temporal, frontal, and occipital lesions present with complex partial seizures conforming to the

P.1899

semiologic features well known to be associated with their respective location, seizures originating in the parietal lobe can mimic temporal, occipital, or frontal seizures.[24,122] A simple partial seizure as a manifestation of a lesional syndrome, either alone or with complex partial seizures or secondarily generalized seizures, was found to be nearly always associated with a neoplasm by some investigators.[16,138]

Structural Imaging

MRI is the structural imaging of choice in patients with refractory focal epilepsies. When reviewing the MRI, in addition to identifying the lesion, close attention should be paid to not only the lesion, but also its relationship to neurologic function in adjacent areas and any secondary changes such as hippocampal sclerosis associated with the lesion. The MRI done outside a comprehensive epilepsy program may not provide all of this required information and often needs to be repeated according to dedicated MRI imaging protocols as performed at the epilepsy surgery centers. Von Oertzen et al.[147] compared the sensitivity of identifying focal lesions between standard MRI reported by "nonexpert radiologists," standard MRI evaluated by "expert radiologists," and epilepsy-dedicated MRI read by "expert radiologists" among 123 consecutive patients undergoing epilepsy surgery evaluation. While the sensitivity of "nonexpert" reports of standard MRI for focal lesions was 39% and "expert" reports of standard MRI 50%, the yield of epilepsy-dedicated MRI was 91%.[147] Neoplastic, vascular, and inflammatory mass lesions are almost always evident in routine sequences of MRI. The diagnostic yield of MRI is variable in patients with malformations of cortical development. With improvements in MRI techniques such as 3.0 Tesla MRI, the use of special sequences such as fluid attenuated inversion recovery, and diffusion tensor imaging, it is now possible to better define malformations of cortical development and its relationship

P.1900

to white matter tracts.[41,62] CT is much more sensitive than MRI in detecting calcifications within lesions such as ganglioglioma, oligodendroglioma, neurocysticercosis, and vascular malformation.

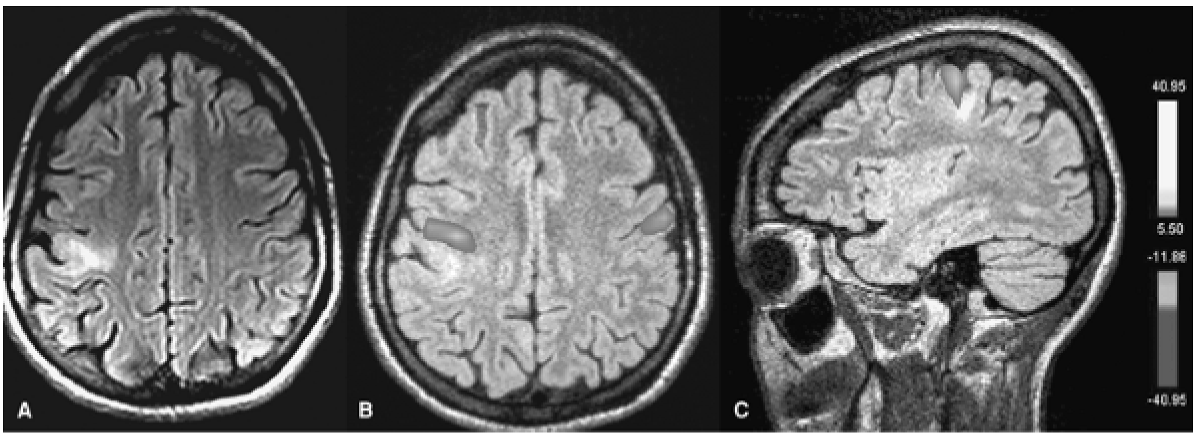

FIGURE 7. A 25-year-old female with daily refractory focal seizures characterized by paresthesia and tonic posturing of left upper extremity, occasionally progressing on to the left lower extremity since the age of 10 years. **A:** Axial fluid attenuated inversion recovery magnetic resonance imaging (MRI) sequence shows a focal cortical malformation in the right sensorimotor cortex. Inline blood oxygenation level–dependent functional MRI axial **(B)** and sagittal **(C)** during left finger tapping versus rest show right motor activation very close and within the lesion. Surgery was deferred in view of the high likelihood of postoperative left upper extremity weakness.

Video-electroencephalographic Monitoring

Although digitalization has enhanced clarification of the EEG by allowing reformatting of the recorded data by changing montage and filter settings, the yield of scalp EEG in substrate-related epilepsy syndromes in general is unsatisfactory. In a comparative analysis of the distribution of scalp-recorded interictal epileptiform abnormalities in temporal lobe epilepsy due to hippocampal sclerosis versus temporal lobe tumors, Hamer et al.[60] observed more widespread distribution of interictal epileptiform abnormalities in tumor patients compared to the restricted spiking zone at the anterior temporal region in patients with hippocampal sclerosis. In patients with frontal, parietal, and occipital epilepsies, scalp EEG may provide misleading information in one third to one half of patients.[126] In view of the poor predictive value of the interictal and ictal EEG abnormalities in patients with tumoral focal epilepsies, the need for long-term video-EEG monitoring in such patients has been questioned.[99] Ictal monitoring, however, is the only method to document the patient's habitual seizures and to exclude associated nonepileptic behavioral events. Moreover, video-EEG monitoring is mandatory for timing the ictal SPECT injection. The information gathered from surface video-EEG recording can be improved by additional electrode placements as indicated by relevant clinical and EEG data, such as sphenoidal electrodes in detecting temporal activity and supraorbital electrodes in detecting orbital-frontal activity.[70,126]

Noninvasive Functional Mapping

2-[^{18}F] Fluoro-2-deoxy-D-glucose PET (FDG-PET), ictal SPECT, and MEG are currently established functional imaging tests that can provide information toward localization of the epileptogenic zone.[76] The data from these tests can be coregistered to high-resolution MRI to offer epilepsy-related structural and functional disturbances with a degree of confidence, comparable to that obtained with intracranial monitoring. Recently, the use of fMRI correlated with interictal discharges to delineate epileptogenic networks has been investigated.[123] In addition, fMRI and MEG are being increasingly used to map functional cortical areas and provide information about whether the lesion itself is functionally active (as in malformations of cortical development) and whether any functional reorganization has occurred (Fig. 7). The fMRI in recent years has significantly contributed to the decision-making process about surgical candidacy and to surgical planning.[3,87] However, additional studies are needed to compare these newer mapping techniques with electrical stimulation map-ping.

Invasive Monitoring

A small proportion of patients whose noninvasive presurgical evaluation data are inconclusive would require invasive EEG monitoring by placing strip or grid electrodes over the surface of the brain or depth electrodes intracerebrally. Such monitoring is much less common in lesional epilepsy compared to nonlesional epilepsy. Still, it provides an opportunity for gathering ictal and interictal data as well as performance of detailed electrical stimulation mapping of the nearby cortical functional zone. Invasive monitoring should always be hypothesis driven. The noninvasive presurgical evaluation data should be subjected to a detailed discussion in the patient management conference to generate a hypothesis about the probable localization and extent of the epileptogenic zone and its resectability without acceptable neurologic sequelae before making decision about the feasibility of invasive monitoring and the monitoring strategy (Fig. 5). Although MRI-detected structural substrate may guide the electrode placement, more often the epileptogenic zone may extend well beyond the MRI-identified lesion location and extent.

Surgical Strategies

Lesionectomy

Strict lesionectomy entails resection of the MRI-apparent lesion. Modern neurosurgical techniques now use navigational frameless stereotactic tools enabling resection of the imaged lesion. The particular MRI sequence best delineating the lesion should be used. For instance, fluid-attenuated inversion recovery (FLAIR) imaging may be useful in delineating the full extent of many low-grade glial tumors, which commonly do not enhance with MR contrast agents. Strict lesionectomy does not involve the use of electrophysiologic tools such as intraoperative electrocorticography to guide resection, and the resection is anatomically guided. See Chapter 179 for a more complete discussion.

Extended Lesionectomy

The most common resection strategy involves excision of the lesion with a "margin" around the lesion.[20] The margins may be structural, such as removal of all hemosiderin-laden tissue around a cavernous angioma or tumor margins around a low-grade glioma that may exceed the boundaries of the MR-apparent image. The seizure outcome has been shown to be better after resection of vascular malformations, when the hemosiderin-stained brain tissue is included within the resection.[9]

The use of intraoperative electrocorticography (ECoG) to guide extended lesionectomy has been controversial. The role of ECoG in tailoring resection in tumoral focal epilepsies is uncertain. Some studies have found better seizure outcome in patients who underwent resection of the neoplasm under electrocorticographic guidance,[13,112] while others have achie-ved the same results without assistance of electrocorticogra-phy.[106,116] Mikuni et al.[95] recently analyzed the outcome of 25 patients with refractory epilepsy associated with benign neoplasm. Removal of the tumor and additional irritative zone as demonstrated by electrocorticography was associated with seizure-free outcome in over 90% of patients. Especially in patients with DNET, because of the frequent association with malformations of cortical development, extended resection guided by electrocorticography may achieve better postoperative seizure control.[141] There are reports that better seizure outcome in cases with focal malformations of cortical development is achieved when resection of both the MRI-identified lesion and the cortical areas displaying continuous rhythmic spiking (ictal-like pattern) can be performed.[107]

Extended lesionectomy is subject to functional considerations delineated by functional mapping, usually electrical stimulation mapping, which can be performed intraoperatively when the lesion is in the vicinity of functionally critical cortex, such as language or rolandic cortices. fMRI has been increasingly applied as an aid for surgical planning in this setting. Delineation of cerebral white matter using MR tractography and integrating this information with intraoperative neuronavigation may be helpful in resecting lesions adjacent to fibers of these cortices.[30,63] This strategy may be especially useful in malformations of cortical development, which often extend deeply through the white matter to the periventricular region (transmantle dysplasia).[6,28]

In cases where extended lesionectomy is limited by adjacent functional cortex, multiple subpial transactions[97] can be used as an adjunct to the resection of the lesion.[11] In this setting, lesionectomy plus multiple subpial transactions has been shown to provide good seizure control with less neurologic morbidity.[66,101]

Dual Pathology and Secondary Epileptogenesis

Two concepts form the basis for significantly wider resections beyond lesionectomy in cases of lesional epilepsy: Secondary epileptogenesis and dual pathology. According to the model of secondary epileptogenesis, irreversible lesions develop in patients who experience frequent seizures over a long period of time. Such a lesion may develop as a second, independent epileptogenic zone.[96] In theory, then, resection of the primary lesion in these patients may not be sufficient to control seizures. In a report by Awad et al.,[4] 18 of 47 patients with intractable seizures and lesions had an epileptogenic region (defined by intracranial EEG) that was not contiguous with the lesion. It is not clear to what extent the resection of the epileptogenic zone contributed to seizure control. However, when complete resection of the lesion was achieved in these patients, the extent of the epileptogenic region resected did not affect outcome.

The concept of dual pathology implies additional or concomitant pathology beyond the primary pathology (i.e., the lesion). This concept is often invoked to explain involvement of the hippocampus in cases of structural lesions outside the hippocampus. There is evidence that epilepsy patients with mass lesions in the temporal lobe have some degree of cell loss in the hippocampus. The extent of cell loss is related to several variables, including the type of lesion, the distance of the lesion from the hippocampus, the age at seizure onset, and the occurrence of a prolonged first seizure.[49,84] Patients with gliomas or cavernous hemangiomas, patients with lesions distant from the hippocampus, and patients with a late age of seizure onset are less likely to have hippocampal cell loss. On the other hand, patients with arteriovenous malformations or heterotopias, patients with lesions close to the hippocampus, and patients with early onset of seizures are likely to exhibit significant cell loss in the hippocampus.

High-resolution MRI has been shown to detect extrahippocampal lesions plus hippocampal atrophy in about 5% to 20% of patients referred for refractory focal epilepsies.[85] Some structural substrates, such as malformations of cortical development and porencephalic cysts, are more likely to be associated with hippocampal atrophy, independent of the distance of the lesion from the hippocampal formation.[27] In an analysis of 41 surgical interventions in patients with dual pathology, lesionectomy plus mesial temporal resection resulted in complete freedom from seizures in 73% patients, while only 20% who had mesial temporal resection alone and 12.5% who had lesionectomy alone were seizure free.[85] Therefore, whenever possible, in patients with dual pathology, removal of both the lesion and the atrophic hippocampus should be considered as a surgical option.[25,85] However, the decision to remove the mesial temporal structures including the hippocampus in a patient with an extrahippocampal lesion is very complex and depends on multiple considerations, including not only the type of the lesion, but also the neuropsychological profile of the patient and the potential for cognitive sequelae, specifically memory dysfunction, following resection of the hippocampus. For instance, for a patient with epilepsy and a small cavernous angioma in dominant middle temporal gyrus, who has good verbal memory function, a resection of the lesion with the mesial temporal lobe structures may entail significant morbidity in mnemonic function.

Special Cases

The variety of lesions associated with epilepsy include special cases requiring varying surgical strategies. Two strikingly different examples include hypothalamic hamartoma, a highly

P.1902

focal lesion outside the traditional cortical boundaries, and wide hemispheric lesions such as Rasmussen encephalitis requiring hemispheric resection and disconnection procedures. The discussion of hemispherectomy and hemispherotomy is beyond the scope of this review and is discussed in Chapter 178.

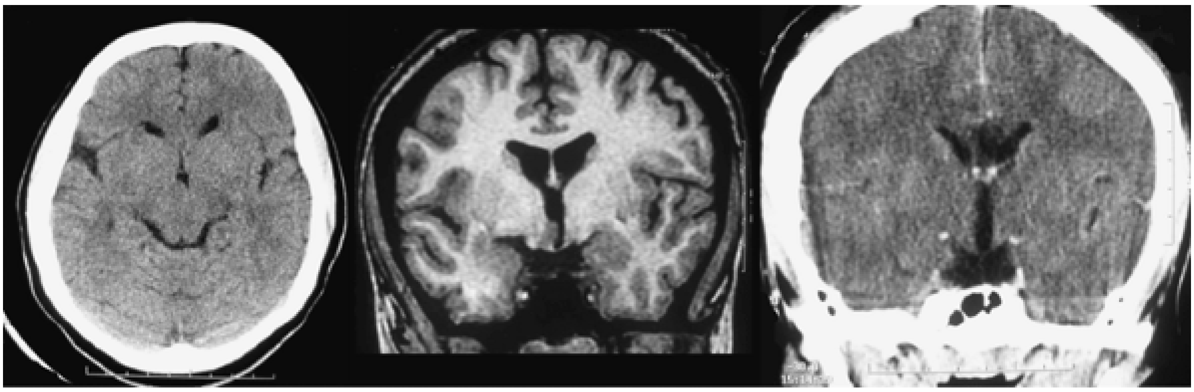

FIGURE 8. A 16-year-old girl with seizures since the tenth day of birth characterized by behavioral arrest, oral and upper limb extremity automatisms, ictal speech and incessant cry or laughter for 2 minutes, and urinary incontinence occurring approximately ten times per day. Electroencephalography (EEG) revealed bitemporal epileptiform discharges, and video-EEG monitoring could not localize seizure onset. The patient underwent hypothalamic hamartoma resection by the transcallosal anterior forniceal approach at the Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum, India, in November 2003, and has been seizure free since then except for a few auras of fear. Axial and coronal magnetic resonance imaging sequences show the lesion abutting the right lateral wall of the third ventricle; postoperative computed tomography shows complete lesion resection.

Hypothalamic Hamartoma

The surgical management of hypothalamic hamartoma has generally met with limited success and a high complication rate. In 2001, Rosenfeld et al.[120] described the use of a transcallosal, anterior forniceal approach for microsurgical resection of hypothalamic hamartoma in patients with refractory epilepsy with good results. Alternate surgical approaches such as lateral pterional and midline frontal through the lamina terminalis and endoscopic treatment through foramen of Monro; radiofrequency ablation; and Gamma Knife surgery are currently available to treat hypothalamic hamartoma.[8,117] The specific approach should be tailored according to the surgical anatomy of the lesion and the experience of the surgeon. While small lesions may be amenable to Gamma Knife, larger lesions will require surgical excision or disconnection. The transcallosal approach is best suited for intraventricular lesions, while the pterional approach is useful for interpeduncular lesions (Fig. 8).[8,103,117]

Postoperative Outcome

The beneficial effects of epilepsy surgery in patients with MRI-identified lesions in general are far superior to those with normal or nonspecific MRI findings.[24,93]

Tumoral Substrates

Over three fourths of patients become seizure free following resection of neoplastic lesions associated with refractory focal epilepsies.[42,50] In a recent analysis of 207 patients with tumor-associated chronic epilepsies such as ganglioglioma, DNET, pleomorphic xanthoastrocytoma, and pilocytic astrocytoma, during a median follow-up of 8 years, 82% of patients were seizure free,[91] remarkably consistent with earlier series.[50] Even among patients with astrocytomas, tumor recurrence at 10-year follow-up was only 25% and the 10-year survival was 90%.[91] While patients with ganglioglioma and low-grade gliomas do uniformly well,[54,109,116] because of its frequent association with peritumoral malformations of cortical development, DNET carries a less favorable outcome.[141] In a retrospective analysis of 18 patients who underwent removal of DNET, during a median follow-up of 10 years, two thirds of the patients were seizure free.[29] Although patients with temporal lobe lesions or patients with dual pathology have a better seizure outcome with resection of the mesial temporal structures, the decision to remove the latter is a complex one and should only be undertaken in carefully selected cases, taking into consideration the type of lesion (e.g., DNET and cortical dysplasia) and the neuropsychological evaluation. Neuropsychiatric considerations may sometime be relevant. For instance, an increased occurrence of psychosis with predominant depressive and paranoid features following surgical treatment for temporal lobe ganglioglioma has been observed.[2,142]

Malformations of Cortical Development

The postoperative seizure outcome of patients with malformations of cortical development has improved in recent years because of better definition of the lesion due to advances in structural and functional imaging, careful selection of ideal surgical candidates, and more radical resection of the lesion guided by electrocorticography and functional mapping.[90] A significant proportion of patients with malformations of cortical development still require invasive EEG monitoring to localize the ictal onset zone. In a recent series of 41 patients (22 adults and 19 children) with MRI-defined malformations of cortical development, after a minimum follow-up of 1 year, 63.4% of patients were seizure free.[1] Better seizure outcome was observed following temporal resection. In another study involving 53 patients with histopathologically confirmed malformations of cortical development (24 temporal and 29 extratemporal), after a mean

follow-up of 50 months, 38 (72%) patients were seizure free.[81] The patients with widespread cortical dysplasia who required multilobar resection had the poorest outcome. In a multicenter series, out of 21 patients with focal cortical dysplasia of Taylor type with adult-onset seizures, after surgery, 16 (76%) were rendered seizure free.[132]

Vascular Malformations

Nearly three fourths of patients with refractory seizures who underwent resection of arteriovenous malformations had significant reduction in seizures.[111] Schäuble et al.[129] analyzed the seizure outcome of 65 patients with cerebral arteriovenous malformations who underwent radiosurgery. During the median follow-up of 4 years, 51% were seizure free and 78% had an excellent outcome (either seizure free or auras only). Noto et al.[104] recently compared the outcome of 15 patients with cavernous angiomas who were continued on medical treatment without surgery to 16 patients who were treated surgically. During the mean follow-up period of 5.3 years, the seizure-free outcome was significantly higher in the surgical group than the medical group (80% vs. 19%). In addition, the number of antiepileptic drugs required was also significantly less in the surgical group. Considering the epileptogenic effect of the hemosiderin-stained brain tissue immediately surrounding the cavernoma, resection only of the cavernoma may not be sufficient for optimal seizure control. In an analysis of 31 patients with refractory epilepsy, patients in whom hemosiderin-stained brain tissue had been removed completely had a better chance of seizure outcome compared to those in whom only the cavernoma was resected.[9] However, in another study involving 163 patients with cavernous angiomas who underwent "pure" lesionectomy without removal of hemosiderin-stained gliotic parenchyma, 68.7% were seizure free.[47] If feasible, attempts should be made to remove the hemosiderin-stained tissue in addition to the cavernoma to optimize postoperative seizure outcome.

Hypothalamic Hamartoma

The previous dismal outlook for children with severe seizures and encephalopathy with hypothalamic hamartoma has now changed. Following transcallosal removal, more than three fourths of patients reportedly become essentially free of all seizures.[48,103,121] Gelastic seizures respond immediately, while other seizure types may take a few weeks or months to run down. In children with epileptic encephalopathy, cognitive decline stops and marked improvement in behavior has been reported.[8] Both transventricular resection and Gamma Knife surgery are associated with similar success rates and less morbidity.[8,117]

Tuberous Sclerosis

Most of the studies that have evaluated the postsurgical outcome of patients with tuberous sclerosis have concluded that good seizure outcome correlated with focal seizures and concordant imaging and EEG findings.[33,68,118,148] Resection of epileptogenic tuber(s) can result in seizure freedom in nearly three fourths patients.[33] In a recent analysis of 25 consecutive children (13 had invasive monitoring), at 6-month or more follow-up, 84% were practically seizure free.[148] Even children with multifocal seizures who required initial bilateral intracranial electrode study achieved excellent seizure outcome. Reduction in seizures and medication is associated with improvement in quality of life in nearly 95% of the operated children.[118] There is a concern that the nonresected tubers could become epileptogenic and could result in seizure recurrence during follow-up. However, in a recent study, only a quarter of patients who achieved an initial excellent outcome had recurrence of seizures when followed for more than 5 years.[68]

Summary and Conclusions

Patients with substrate-related epilepsies with suboptimal seizure control should be identified early and referred for presurgical evaluation before irreversible deterioration in their quality of life ensues due to long-standing disabling seizures and chronic antiepileptic drug–related side effects. In addition, the consideration of the natural history of the lesion and its potential risk to the host regardless of the seizures should always be considered. Although most of the tumors associated with chronic seizures have an indolent biologic course, the potential for malignant transformation should not be overlooked. The potential for spontaneous bleeding of a vascular lesion should also be considered. The best treatment should be based on both lesional and epileptogenic considerations. Success of epilepsy surgery depends on accurate preoperative localization of the epileptogenic zone and its complete resection. Patients with medically refractory lesional epilepsies belong to different categories depending on the degree of complexity involved in presurgical evaluation to define their epileptogenic zone. While some patients, such as those with tumoral epilepsy syndrome, can be selected for surgery by simple noninvasive presurgical evaluation strategy, others with malformations of cortical development and those with multiple lesions often require complex and invasive means to define their epileptogenic zone. Recent advances in structural and functional imaging have obviated the need for invasive monitoring in the majority. These advances along with improvement in surgical techniques have made lesionectomy safer and more effective. The role of radiosurgical techniques in the treatment of selected substrate-related epilepsy syndromes such as those associated with vascular malformations and hypothalamic hamartomas are currently undergoing evaluation.

Chapter 180

Corpus Callosotomy

David W. Roberts

Introduction

A number of newer procedures—most notably, multiple subpial transection, vagal nerve stimulation, and deep brain stimulation—have become available in the treatment of seizure disorders, and these have legitimate roles either as alternatives to resective procedures or as strategies when a resective procedure is not an option. [15,35,49,89,139] The role of the corpus callosotomy in this setting warrants reevaluation.

Surgical division of the corpus callosum for the treatment of certain medically intractable seizure disorders, at one time about the only alternative to resective surgery, was first undertaken >60 years ago on the basis of two lines of evidence. The first was the observation of Van Wagenen that epileptic patients who subsequently suffered strokes or tumors involving the corpus callosum often had concurrent improvement in their seizure disorders.[128] The second was a growing experimental literature demonstrating, most notably in the work of Erickson in monkeys, [25] that the corpus callosum was the major route of seizure propagation from epileptogenic focus to generalization. [25,52,53,70,71] Van Wagenen went on to perform callosal section in a small number of patients with some success,[128] and similar clinical experiences were reported by Bogen and coworkers[11,12,13] and Luessenhop.[64,65] It was not until the series of Wilson and coworkers[136] that a sustained clinical experience developed, and over the last three decades, there has been widespread adoption of the surgical procedure.

Removing an epileptogenic region with the goal of surgical cure has always been preferred, but in those patients with generalized seizures in whom a discrete epileptogenic region could not be identified or resected, surgical disruption of secondary generalization was logical. Consequently, the earliest patients for this surgery were those who were not candidates for resective surgery but who demonstrated secondary generalization.

It was quickly appreciated that of the types of seizures most likely to be helped—drop attacks (variously classified as atonic and akinetic seizures)—are among the most responsive, often being eliminated altogether; tonic and tonic–clonic generalized seizures also have been shown in multiple series to be similarly affected.[3,4,7,10,14,17,18,20,26,29,31,33,34,35,41,43,45,46,47,48,50,51,55,56,57,59,66,67,68,69,72,73,76,77,78,79,80,81,82,83,87,88,90,93,94,95,96,97,98,99,102,103,104,106,108,111,112,114,115,116,117,118,119,122,123,124,125,130,131,132,133,134,135,] Whereas corpus callosotomy had been performed in fewer patients than had most other epilepsy operations, and in many respects the procedure was not as well understood as other surgeries, it was reasonable that many patients underwent callosal section largely on the basis of their seizure semiology.

From a historical perspective, the role of pathology, as well as that of electrophysiologic studies, has been secondary. A spectrum of disease has been encompassed in clinical series. Williamson [131]) looked at surgical outcomes in terms of clinical diagnoses and classified patients into groups of infantile hemiplegia, forme-fruste infantile hemiplegia, Rasmussen syndrome, Lennox-Gastaut syndrome, frontal lobe epilepsy, and other secondarily generalized epileptics. Slightly better outcomes were found in the first two groups, but there was sufficient improvement in all categories to justify surgical intervention.

The electrophysiologic role has been an indirect one, by demonstrating the absence of a resectable epileptic region. In addition, however, electroencephalogram (EEG) findings in patients selected for callosotomy have been analyzed by a number of investigators. [44,54,58,62,74,84,92] Correlating EEG with surgical results, Geoffroy et al.,[41] Spencer et al.,[124] and Matsuzaka et al.[75] all reported better results in patients with lateralized EEG abnormalities. The majority of patients have evidence of bilaterally synchronous epileptiform activity, and this does not necessarily represent a bad prognostic sign. The significance of bilateral, independent foci is undetermined.

The impact of neuroimaging on the callosotomy experience has been limited. Lateralized structural lesions have been believed to be associated with a better surgical outcome, [124,136] but in the selection process their presence or absence has always been secondary to clinical and electrophysiologic information. As imaging technologies continue to evolve with increasing sensitivity and specificity, they are directing such aspects of the seizure evaluation as intracranial recording electrode placement. This increased sophistication of seizure investigation affects both patient selection and perhaps the surgery itself.

From the isolated clinical experiences of Van Wagenen,[128] Bogen and coworkers,[11,12,13] Luessenhop,[64,65] and Wilson and coworkers,[132,133,134,135,136] callosum section has seen a cautious but marked increase in application over the last several decades. Less than a dozen centers were performing callosal section in 1982 when the first Dartmouth workshop on the corpus callosum was held; nearly every surgical epilepsy center performs this surgery today. A survey of epilepsy centers in 1986 found 197 patients who had undergone corpus callosum section [23]; a follow-up survey 5 years later reported 563 patients so treated.[24]

Indications

The principal candidates for callosal section are those medically intractable epileptic patients in whom a resectable seizure focus cannot be identified and whose generalized seizures are believed likely to be ameliorated by disruption of seizure propagation. Patients in whom seizure semiology, electrophysiologic studies, neuroimaging, and neuropsychologic testing have shown localized disease amenable to resection are excluded. The remaining candidate pool is heterogeneous, including patients with infantile hemiplegia, forme-fruste infantile hemiplegia, Rasmussen syndrome, Lennox-Gastaut syndrome, frontal lobe epilepsy, and other secondarily generalized epilepsies.

Selection criteria at our institution, in addition to the principal exclusion of resectable disease, include (a) medical intractability of at least 2 and usually 4 years' duration, with exhaustive anticonvulsant regimens and documented adequate serum anticonvulsant levels, (b) generalized seizures, usually but not necessarily major motor or akinetic in type, and

(c) potential functional benefit if improvement in the seizure disorder is achieved. We have not automatically excluded patients from surgery because of retardation, age, mixed hemisphere dominance,[69,108] lack of demonstrable partial seizure onset, or bilaterally independent EEG abnormalities, although the likelihood of success may be less in certain instances.

The goal of surgery with callosal section is distinguished from that of other epilepsy surgeries in usually being palliation rather than cure. Although a seizure-free patient is always hoped for, such an outcome is achieved in only 5% to 10% of patients.[23,24] More likely, callosal section will achieve a significant reduction and perhaps elimination of certain seizure types, such as drop attacks or secondarily generalized seizures, but often with persistence of attenuated partial seizure activity. The positive impact of such an outcome on these patients is often dramatic and greatly appreciated.

Surgical Approaches

The greatest variable in callosal surgery is that of extent of section. Early clinical series often included division of the corpus callosum, the underlying hippocampal commissure, and additional structures, including the anterior commissure and, in some instances, one fornix. [11,13,64,65,128,132,134,135] Nearly all series today restrict division to the corpus callosum and, in posterior or complete callosal section, the hippocampal commissure that is immediately apposed to the ventral aspect of the posterior portion of the callosum. There remains variation, however, with regard to which part or how much of the structure is divided. Seizure outcome appears to have some correlation with extent of section, [104,122] and because neuropsychologic consequences of callosal section are encountered primarily with complete section,[126,129] most centers today usually divide the anterior three fourths and spare the splenium at initial surgery. Completion of the section can then be performed in those patients who fail to obtain an adequate response to such surgery. Exceptions to this approach are division of a smaller, select portion of the callosum, division of the posterior half as an initial procedure, and division of the entire callosum in one operation. The presurgical evaluation and preoperative substrate may influence the consideration of these alternatives.

The history, neurologic exam, and cognitive evaluation are useful in suggesting diffuse or bilateral disease for which commissurotomy may be an appropriate strategy; these factors contribute in the consideration of the risk-benefit ratio for partial or complete section. The sensory dissociation whereby visual, auditory, or tactile information received by the nondominant hemisphere may not be accessible to the speech-dominant hemisphere is of diminished consequence in the severely impaired individual, and in such a setting complete section may be a reasonable surgical approach. This is especially true if drop attacks, which usually respond to anterior section, are not the predominant seizure pattern. If presurgical evaluation, including electrophysiologic studies, demonstrates predominantly parietal-occipital disease, it may be appropriate to consider posterior partial section as the first stage.

The preoperative epileptogenic substrate is important for reasons similar to those for the preoperative evaluation. A more discrete pathology may direct one toward an appropriate partial section, [119] and diffuse disease may render any partial section futile. The correlation between extent of disease and successful section, however, is insufficient to place great reliance on these factors. Lateralized pathology does have a modest but worthwhile role in determining the side of the interhemispheric approach; this is usually on the nondominant right side, but in the setting of an atrophic left-hemisphere or right-hemisphere language dominance, surgery from the left side of the falx may be indicated.

Surgery is usually performed under general anesthesia, and intraoperative electroencephalographic recording, when performed, has been primarily for investigative purposes. Tailoring of the length of resection based on intraoperative EEG information has been advocated by at least one center, [73] but given the reality of often insufficient abnormal interictal EEG findings intraoperatively, as well as the observation that subsequent seizure propagation may occur across remaining, adjacent callosal fibers, most have not adopted this practice. The patient is placed supine on the operating table, with the head unturned and secured in three-point pin fixation. For the anterior division, the neck is kept in neutral position; for the posterior division, flexion of approximately 20° facilitates exposure. Spencer has favored placing the patient's head such that the hemisphere to be retracted is dependent, thereby allowing gravity to help provide the exposure (Spencer D. D., personal communication, 1986).[29,68] This has the appeal of minimizing any retracting force placed interhemispherically, although other surgeons have not considered this retraction significant enough to warrant the perhaps less comfortable and differently oriented horizontal positioning.

Linear incisions and 2-inch trephinations[100,133] have been easy and reliable in our series, but the actual type and extent of craniotomy is relatively unimportant. A 9-cm transverse incision with one third of its length across the midline and placed 2 cm in front of the coronal suture is used for the anterior procedure. A similar incision and trephination at the level of the parietal eminence is used for the posterior procedure. The placement of the craniotomy across the sagittal sinus requires caution but facilitates exposure down the interhemispheric fissure with minimal retraction.

Localization of parasagittal draining veins by angiography prior to transcallosal procedures has been advocated, but this has not been a routine step in our series. It has always been possible to work on either or both sides of such a vein using microsurgical technique without requiring its sacrifice. Nevertheless, Apuzzo et al.'s observation that in 42 of 100 angiographic studies, significant veins were noted to enter the sagittal sinus within 2 cm of the coronal suture, with 70% of these posterior to that suture, is of interest. [5] Such angiographic information may be available in those patients who have previously undergone Amytal testing or in whom magnetic resonance angiography (MRA) techniques have delineated parasagittal venous structures.

Dural opening follows standard practice, with a curvilinear incision and reflection on the sagittal sinus. Dissection is begun down the interhemispheric fissure under loupe magnification, and retraction is aided by the earlier administration of mannitol (1 g/kg). Pressed Gelfoam (Upjohn, Kalamazoo, MI) is used to protect the exposed cortex, and a Greenberg self-retaining retractor is placed prior to employment of the operating microscope. Gentle retraction is accomplished with a single retractor blade on the ipsilateral hemisphere, and, when occasionally needed, an additional blade retracts the inferior aspect of the falx or contralateral cingulate gyrus.

The exposure can be rendered difficult by adhesions between the hemispheres, which is especially common in the setting of previous infection or trauma. With patient microsurgical technique, these are usually surmountable, although approaching the callosum more posteriorly and using the deeper extension of the falx can help in this situation. The corpus callosum is distinguished from the more superficial cingulate gyrus by its glistening white appearance, and exposure along the length of callosum to be divided is obtained prior to entering the commissure. The pericallosal arteries are easily identified overlying the callosum, and care is taken to avoid their injury. Actual sectioning of callosal fibers is usually carried out between these arteries, although division lateral to these vessels can be performed if this is more convenient.

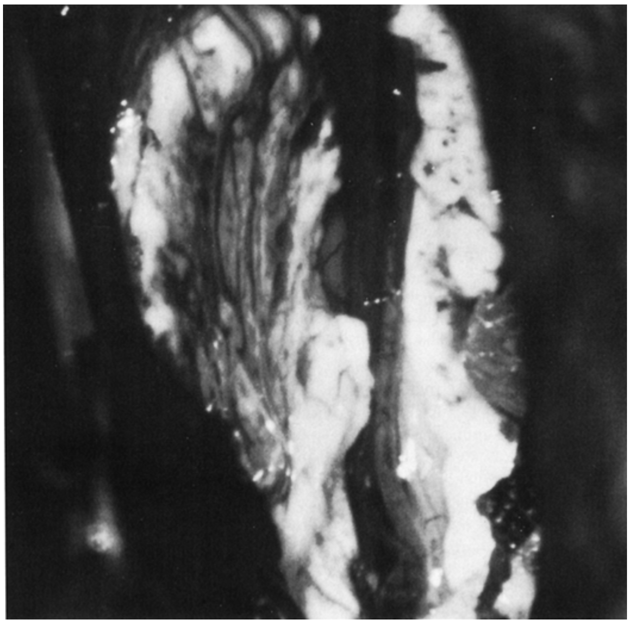

FIGURE 1. Division of the genu, whose cut surfaces appear glistening white, reveals the underlying paired anterior cerebral arteries, which course anteriorly, superiorly, and then posteriorly around the commissure. (From Roberts DW. Corpus callosum section. In: Spencer SS, Spencer DD, eds. *Surgery for Epilepsy*. Boston: Blackwell Scientific; 1991:168–178, with permission.)

The operating microscope with its superb magnification and illumination has proven invaluable during the final exposure and actual sectioning (Fig. 1). Bipolar cautery is used for coagulation of small vessels supplying only the callosum itself. The actual division of callosal fibers is carried out with a microseptal or microsuction tip. The ultrasonic aspirator may prove to be of greater utility in this step as it becomes more refined and thinner.

The bluish appearance of the underlying ventricular ependymal surface is described in early reports of callosal section that recommend using this landmark as the limit of division. [134] The alternative of identifying the midline, however, offers numerous advantages that have become increasingly evident over the course of our series. These include unequivocal assurance of completeness of fiber division, elimination of possible lateral deviation (especially in the frontal region), decreased likelihood of entering the lateral ventricle, and less operative time. A blunt microinstrument is gently swept from side to side as the callosum is nearly traversed, and this will usually expose the midline cleft between lateral ventricles. Once this cleft has been identified, the remainder of the section is easily accomplished.

Localization of the midline during the anterior division is easiest at the posteriormost portion of the genu or the anterior portion of the body. The actual direction of subsequent section is not particularly important. Division around the genu and down the rostrum is performed extraventricularly as far as possible. The rostrum at this point is nearly paper thin, and any remaining fibers are insignificant. No attempt is made blindly to divide the anterior commissure.

The posterior extent of the division is readily performed following the midline cleft (Fig. 2). If an attempt is being made to achieve success with a partial division, it is reasonable to carry the division through approximately the anterior three fourths. A number of methods have been employed to ensure accomplishment of the desired length of section. These include physical measurement of the exposed callosum to be sectioned, identification of structural features (such as the thinning of commissure generally seen in the posterior body or the appearance of the fornices), intraoperative radiographs,[8] and, more recently, the image guidance of frameless stereotactic navigational systems. When assurance of section and hemostasis is complete, a metal clip attached to a small piece of Gelfoam is placed at the posterior extent of the divided callosum; at subsequent surgery, such a marker has often been greatly appreciated when gliosis may obscure the extent of previous resection. It has not created an undesirable, excessive magnetic resonance imaging (MRI) artifact.

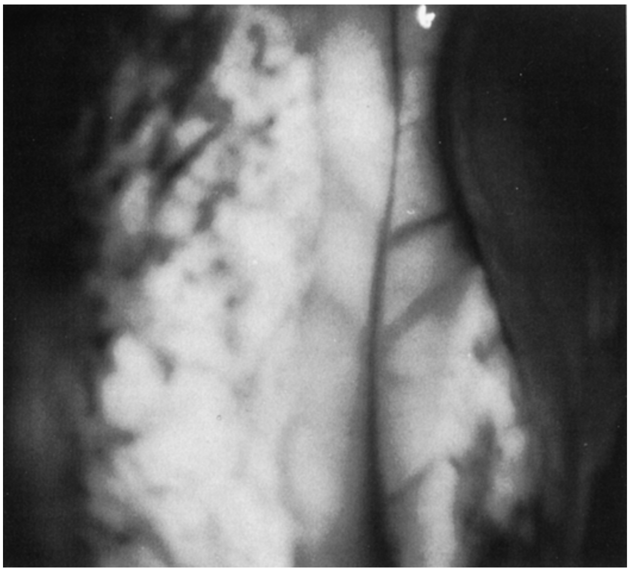

FIGURE 2. Continuing callosal section posterior to the genu is greatly facilitated by following the midline cleft formed by the ependyma of the lateral ventricles. (From Roberts DW. Corpus callosum section. In: Spencer SS, Spencer DD, eds. *Surgery for Epilepsy*. Boston: Blackwell Scientific, 1991:168–178; with permission.)

Section of the posterior corpus callosum, either as a second or initial procedure, is accomplished in a similar manner. The more extensive falx cerebri greatly facilitates this exposure. The fibers of the splenium are divided with similar instrumentation, and under magnification the completeness of the

section is certain. The underlying arachnoid, beneath which lie the pineal and quadrigeminal cistern, is preserved. The posterior hippocampal commissure may be difficult to distinguish from the overlying callosal fibers, but this is of no practical significance because it is divided as well. If an anterior section has already been performed, the previously placed clip is retrieved. If the posterior section is the initial commissurotomy procedure, a clip is left as a marker at the anteriormost extent of the section.

Closure follows standard surgical practice. The dura is closed over Gelfilm (Upjohn, Kalamazoo, MI) using 4-0 Vicryl (Ethicon, Inc., Johnson & Johnson, Somerville, NJ) after confirmation of hemostasis. The bone flap is secured with a bone-plating system; the galea aponeurosis is reapproximated using 3-0 Vicryl; and the skin is closed with either 4-0 Prolene (Ethicon, Inc., Johnson & Johnson, Somerville, NJ) or staples. The patient is observed in the neurosurgical observation unit overnight and transferred to the neurosurgical ward the following morning. Mobilization begins immediately, and the patient is typically discharged 4 to 5 days following surgery; in anterior section alone or in children, hospitalization may be shorter. Anticonvulsant medication is generally left unaltered until at least subsequent follow-up. A decision regarding completion of the callosotomy is made a minimum of 2 months after the first procedure.

Alternative techniques have been occasionally proposed. Stereotactic lesioning, radiosurgery, [85] and endoscopic strategies[127] can certainly be used, but experience with these techniques for this specific purpose is very limited. Any such technique must be ensured to not inadvertently spare commissural fibers, because suboptimal seizure outcomes have been attributed to such sparing during open procedures. Such techniques must also match the low morbidity and mortality of today's microsurgical procedure.

Image-guided surgical techniques (neuronavigation) have been incorporated into the majority of neurosurgical operating room environments. They are routinely used in microsurgery, particularly in epilepsy, and, as alluded to earlier, can be a useful aid in callosal section as well. With respect to intraoperative MRI, computed tomography (CT) or other updated imaging, the role for these more resource-intensive techniques has not been demonstrated for this procedure. Intraoperative brain shift or deformation is less an issue in either such a central location or in a nonresective procedure.

Complications of corpus callosotomy can be considered as surgical or functional in nature. [86] Frontal lobe swelling or infarction with resultant hemiparesis or plegia can result from excessive retraction or sacrifice of bridging veins, and hydrocephalus requiring shunting has been seen with larger surgeries in which there may have been soiling of the ventricular system with surgical debris and blood.[134,136] Current microsurgical technique, with reduced retraction and extraventricular callosal sectioning, has greatly reduced the incidence of these sequelae. The risk of infection at this time is similar to that of standard neurosurgical procedures.

A syndrome of usually transient mutism or decreased spontaneity of speech, with or without mild hemiparesis, has sometimes been noted following anterior callosal section and is

presumed to result from either medial frontal retraction or perhaps disconnection. [91,105,133] When it does occur, it almost always resolves within days and is rarely problematic. Posterior section, on the other hand, disrupts interhemispheric transfer of visual, tactile, and auditory information and is responsible for the long-term disconnection syndromes associated with this operation.[36,37,38,39,126] Objects presented solely to the hemisphere that is not dominant for language may not be verbally reported by the patient, but because isolation of such stimuli to one hemisphere usually requires a fairly constrained, laboratory environment (e.g., tachistoscopic hemifield visual presentation), it is unusual for this to cause disability. Most patients, as well as many early investigators, have been unaware of the deficit.

Complete callosal section can be associated with independent and sometimes conflicting behaviors generated by the two hemispheres. [119] Anecdotal reports of uncooperative or antagonistic action of the two hands while the person is getting dressed or repeated hesitation about whether or not to enter a room are certainly true, but over time such behaviors generally abate.

Of greater concern has been the deficit that can arise when an interhemispheric compensatory mechanism that has developed after an earlier hemispheric insult is disrupted by callosal surgery. Mixed dominance, in which language resides in the hemisphere ipsilateral to the dominant hand, may predispose to postoperative language difficulty, [107] but this has not been a consistent finding. By a similar mechanism, a preexistent hemiparesis might worsen following commissurotomy. Fortunately, such deficits are relatively uncommon. The nature of an occasionally observed postoperative memory disturbance remains incompletely understood.[126,138]

Summary and Conclusions

For certain patients who have failed medical management, who are not eligible for resective seizure surgery, and who have either preferred not to undergo vagal nerve stimulation or failed to respond to that procedure, commissurotomy may successfully reduce seizure frequency and severity. Atonic seizures (drop attacks) and secondarily generalized major motor seizures are most likely to be improved, but other seizure types may also respond.

Division of the corpus callosum alone achieves the aforementioned success. Complete callosotomy may not be required in all patients, and anterior three-fourths section, followed by completion of the section if needed, remains a reasonable approach in most patients. As a microsurgical procedure, extraventricular division of the corpus callosum can be safely and assuredly performed. Although there are always numerous variations in surgical technique, the procedure of corpus callosum section is probably less variable than that of most other, longer-established surgical interventions for the treatment of epilepsy.

The behavioral sequelae of commissurotomy have received extraordinary attention in the past for their neuropsychologic interest,[1,2,6,9,14,16,19,21,22,27,28,30,36,37,38,39,40,42,60,61,63,105,107,108,109,110,113,126,129,138] but it is uncommon to encounter permanent disabilities. For the great majority of patients, the benefits resulting from the procedure outweigh any such effects.

Chapter 181

Reoperation for Medically Refractory Epilepsy

Robert R. Goodman

Introduction

Medically refractory epilepsy (MRE) has been widely recognized as a medical problem that significantly impairs quality of life[3] and significantly decreases life expectancy.[8] The surgical treatment of epilepsy was developed more than 50 years ago[2] and has expanded greatly since the early 1980s.[4] Epilepsy surgery generally involves a resective surgery with the goal of rendering a patient free of disabling seizures.[4] Surgical candidates are generally patients who have undergone an extensive evaluation and are thought to have seizures originating from a single brain region. In the majority of patients, this "seizure focus" is felt to be confined to one of the temporal lobes. Resective surgery is pursued if it is thought that there will either be no noticeable neurologic deficit or that any deficit will be "acceptable" (i.e., some verbal function and/or verbal memory impairment with dominant temporal resections). Many medical centers[4] and a multicenter National Institutes of Health (NIH)-sponsored study[22] have reported a high percentage of patients to be seizure free following resective surgery. It is presumed that this result indicates that all (i.e., in patients ultimately able to discontinue antiepileptic medication) or an adequate amount (i.e., in patients rendered seizure free with well-tolerated antiepileptic medication) of epileptogenic tissue has been resected. Many patients continue to have rare seizures or a much lower frequency or severity of seizures and have a difficult-to-assess degree of improvement or benefit.[5] A significant percentage of patients continue to have medically refractory seizures that are frequent enough and/or of a severity that prompts consideration for a reoperation with the goal of accomplishing the original surgical goal. This was reported by Penfield and Jasper in the 1950s[14] and subsequently further explored by Rasmussen, operating on patients from Penfield's series.[15] A number of more recent reports[1,6,7,10,12,16,17,18,19,20,23] have provided much more knowledge regarding the subject of reoperation for MRE. A significant percentage of patients were reported to be seizure free following reoperation, often indicating that the full extent of the epileptogenic tissue had not been appreciated at the initial surgery or (in a minority of patients) that the "seizure focus" had been misidentified. Patients without improvement after a reoperation have often been felt to harbor multiple or widespread epileptogenic brain areas and it is often concluded that these patients are not able to be rendered seizure free by resective surgery. The analysis of patients who failed to achieve the desired result with a first, or subsequent, resective surgery may be one of the keys to improving resective surgery for MRE, both by improving our ability to select patients who can be rendered seizure free by resective surgery and by improving our understanding of the tissue that must be resected to achieve this goal. For the purposes of this chapter, reoperation will refer to a resective surgery intended to achieve the elimination of seizures in a patient who has previously undergone a similar surgery. It is often helpful to subdivide patients having resective surgery for MRE into three subgroups: Medial temporal lobe resection, resection of a structural/pathologic lesion with associated epileptogenic cortex, and resection of a neocortical nonlesional epileptogenic region. Reoperations can be similarly categorized. In this chapter, the published experience of a number of epilepsy centers with such reoperations will be considered by, wherever possible, subdividing the reoperations into these same three subgroups. This may be the most useful way to gain from the reported experience and to use this knowledge in approaching patients undergoing either an initial or a repeat resective surgery for MRE. Glial neoplasms are being excluded from the structural lesion subgroup, because these lesions often progress over time and should be considered a distinct entity with regard to the management of associated medically refractory seizures. This subject is not addressed in this chapter. Reoperation sometimes is a hemispherectomy. This surgery does not have the same goal as the initial surgery (i.e., focal resection with preservation of hemispheric function) and falls outside of the scope of reoperation defined above. Callosotomy is a distinct type of epilepsy surgery that typically aims to eliminate a specific seizure type and will not be addressed here. Palliative surgery following resective surgery, having the goal of reducing seizure frequency and/or severity (not seizure elimination), such as vagal nerve stimulation, similarly will not be considered reoperation. Also, such surgery as an initial operation will not be considered a “first” operation for MRE.

Incomplete Medial Temporal Resection

Many of the reports of reoperation for epilepsy have included patients whose reoperation involved resection of medial temporal structures, often the posterior hippocampus. The series reported by Rasmussen in 1975[15] included 129 nontumor patients who had a reoperation between 1928 and 1971. Of the 115 patients with at least a 2-year follow-up (2 to 39 years), 29 (25%) were seizure free and 31 (27%) were categorized as having significant improvement of seizure frequency. It is probable that the majority (possibly all) of the benefited patients had an extension of their original temporal resection and that this included an extension of the medial temporal resection, although the publication does not provide enough detail to confirm this. By 1984, Spencer et al.[21] had reported that depth electrode evaluations indicated that about 20% of hippocampal seizures had a posterior onset and they described a surgical technique to accomplish a complete hippocampal resection. The importance of this recommendation for complete hippocampal resection is supported by subsequent experience. A large percentage of patients who have been reported to be seizure free after reoperation have had a posterior hippocampal resection at the second surgery. The abstract by Olivier et al. in 1988[13] reported that 20 of 425 anterior temporal resections for epilepsy were

P.1915

reoperations. Of these, 13 (65%) had not had any hippocampal resection at the initial surgery and seven (35%) had only an anterior/partial resection. The seizure outcome for this group was six (30%) seizure free, three (15%) with a marked reduction, and seven (35%) with worthwhile improvement. Another series reported in 1989[23] included 28 nontumor patients who had a second focal resection for medically refractory epilepsy. Although not specifically stated, it seems that in 16 of these patients the second surgery was an extension of the temporal lobe resection that included additional hippocampus and that 10 of the 16 (62.5%) were reported seizure free at follow-up (duration not reported). It is important to note that one patient had a permanent hemiparesis after reoperation. Three other patients in this series were seizure free after reoperation (frontal lobe structural lesions) and will be discussed later. Subsequently, Wyler et al.[24] reported on a study to compare seizure outcome with anterior versus complete hippocampectomy that showed a significantly greater seizure-free outcome with the complete resection.

The Cleveland Clinic in 1991[1] reported on 15 reoperated patients from an overall series of 154 resections for medically refractory seizures. Ten of these patients had their initial operation at their center. The 15 patients were selected from 23 patients who were felt to have “truly intractable seizures” following a resective surgery. In this group, seizure recurrences occurred within 7 months of surgery and reoperation occurred 3 months to 12 years after the first surgery (mean = 38 months). Eleven of the 14 focal resection patients (one patient had a functional hemispherectomy as the second surgery) had invasive electrode investigation before the second resection. Seven of these 14 were seizure free at the last follow-up (range of 8 to 82 months), but four of the 12 had <12 months and only one had >15 months follow-up (82 months). Reoperation in 6 of the 14 involved resection of residual medial temporal structures in patients without structural lesions, and these accounted for three of the seven seizure-free patients and two of the four patients with a >90% seizure frequency reduction. The other eight patients are discussed later. The series had no mortality or serious morbidity.

The Montreal Neurological Institute reported an experience with reoperation on the temporal lobe (for refractory epilepsy) in 1994.[7] This included 40 of the approximately 260 temporal lobe surgeries performed by the senior author (A. O.) over a 9-year period. The senior author performed the first surgery in 31 of the 40 (nine had been done at other institutions). The original surgery was based primarily on scalp/sphenoidal interictal and ictal evaluation, with 6 of the 40 having depth electrode evaluations due to inadequate lateralization or localization. Recurrent seizures were similar to preoperative seizures and occurred within 6 months in 60% and by 2 years in 90% of the patients. The mean time to reoperation was 5.5 years. Reoperation was based on scalp electroencephalogram (EEG) in 36 patients (31 with temporal and five with mostly temporal, but multifocal, onsets) and depth electrodes in four patients (three with multifocal and one with temporal onsets). At follow-up (range 2 to 11 years; mean of 4.8 years), 21 patients were seizure free and four had rare seizures (one to two per year). All of these patients had resection of residual medial temporal tissue, with some having resection of neocortex as well. Three of the other 15 patients were rendered seizure free by a third operation, one by resection of a missed cavernous malformation, one by resection of additional neocortex, and one by resection of further mesial tissue. Lack of seizure improvement was associated with multifocal EEG abnormalities and seizure recurrence within 1 month of the first surgery. There was no significant permanent neurologic morbidity in the series.

Experience with reoperation at the University of Washington was reported in 1999.[10] This involved 21 patients who had their reoperation between 1991 and 1996 and represented <5% of the epilepsy surgeries performed over that period at that center. At follow-up (1 to 5 years, mean of 3 years), nine (43%) were seizure free and two (9%) had a >95% seizure reduction. There was no surgical morbidity. Only 17 of the patients had focal resections, with two having multiple subpial transections of motor cortex and two (children) having hemispherectomies. The results of the various types of surgery were not reported. Thus, it is not possible to determine how many patients were rendered seizure free by resection of medial temporal structures or residual structural lesions. Eleven of the 17 focal resections were of temporal tissue only, and seven of these included resection of mesial structures. Also, two patients had calcified lesions in the temporal lobe and one had an intraventricular calcified lesion (the pathologies of the series included one ganglioglioma, one cortical dysplasia, and 19 with gliosis). Resections were described as tailored and 11 of the patients had intracranial electrode evaluations. It is possible that all seizure-free outcomes occurred in patients who had either a resection of medial temporal structures or a structural lesion. The study did find two factors that significantly correlated with outcome: (a) that four of the patients had a central nervous system (CNS) infection before the onset of epilepsy and that none of these patients became seizure free, and (b) that the seven patients with a focal magnetic resonance imaging (MRI) abnormality concordant with the ictal EEG onsets before and after the first surgery had a better seizure outcome than the other 14 patients.

In 2000, a group of patients with persistent or recurrent seizures after temporal lobe resection for MRE at the Kings College Hospital of London was analyzed,[9] in an attempt to identify the apparent cause for failure to achieve seizure freedom and to possibly identify appropriate candidates for reoperation. This study has limited usefulness for the assessment of the role of, or optimal approach for, reoperation, but does seem to provide some insight into the population of patients who have been subjected to reoperation. From a series of 282 consecutive temporal lobe resections for MRE between 1976 and 1995, 56 patients (20%) were known to postoperatively have at least one seizure per month and 44 of these patients were assessed in detail. Of these 44 patients, 20 were diagnosed with mesial temporal sclerosis (MTS), ten with a structural/mass lesion (dysembryoplastic neuroepithelial tumor [DNET], discussed below), and 14 with nonspecific pathology (discussed below). Of the 20 patients with MTS, the postoperative electroclinical diagnosis was of ipsilateral temporal seizures in 12 patients (although one was felt to have independent ipsilateral frontal seizures and two were felt to have contralateral seizures), ipsilateral nonlocalized seizures in one patient, ipsilateral frontal seizures in one patient, generalized seizures in one patient, and contralateral temporal seizures in five patients. None of the patients had evidence of contralateral seizure onsets preoperatively. Five patients had residual hippocampus, but only two were felt to have seizures from this area. One also had a new major seizure type with apparent contralateral frontal onset and one had a reoperation for resection of the residual hippocampus and was seizure free at last follow-up (6 months after surgery). Reoperation was not performed in any other of these patients, although 11 were felt to have strictly ipsilateral neocortical onset seizures.

A more recent study, from the Yale University Epilepsy Center,[18] contrasted itself from prior studies by including only patients who had had their initial surgery at their own center (and thus had undergone a thorough and fairly uniform preoperative evaluation), had a preoperative MRI, and had a minimum 1-year follow-up after reoperation. Importantly, no patient had partially retained medial temporal structures, since any patient who had a medial temporal resection had had a complete one. This series reported on a total of 27 patients, 17 of whom had two successive resective surgeries with the goal of seizure elimination, while the others had a palliative surgery (corpus callosotomy or vagal nerve stimulator) as either the first or second operation. Of the 17 patients, five had glial tumors (oligodendrogliomas) and one became seizure free with a functional hemispherectomy as the reoperation (for a presumed hemispheric syndrome that had been suspected before the initial surgery), leaving 11 patients without a glial tumor or hemispheric syndrome who had two resective surgeries. Interestingly, all 11 of these patients had a focal MRI abnormality prior to their initial operation. One of these was a patient with temporal neocortical changes and hippocampal atrophy who had only a neocortical resection, without preliminary invasive electrode evaluation. A subsequent medial temporal resection rendered this patient seizure free. The three patients with a medial temporal resection for presumed MTS at their initial surgery had invasive electrode evaluation beforehand, due to a discordant evaluation. Ten of the 11 patients, accumulated over 11 years at an active epilepsy surgery program, had resections involving structural lesions or neocortex, with only one becoming seizure free (see later sections). No mortality or significant morbidity was reported.

A recent publication reviewed the Mayo Clinic experience with reoperation.[20] This represented 64 of 1,486 operations (4.4%) from 1985 to 2000, with 18 of the 64 not having had their first operation at Mayo Clinic. Fifty-one of the 64 had an MRI before the first surgery. No patient had a malignant tumor, but 18 had low-grade tumors and two had tuberous sclerosis lesions. Information is not provided that would allow a breakdown of results based on reoperation for mesial temporal structure resection without lesionectomy versus structural lesionectomy versus neocortical resection alone. Temporal surgeries were performed in 44 of the patients, with 16 involving lesionectomies. Resection of mesial temporal structures was involved in 31 of these patients, but it is not clear how many of these also had a structural lesion. Fourteen of these 31 were rendered seizure free. Twenty-eight of the temporal surgeries did not involve a structural lesion and eight were rendered seizure free. It is not stated, but from the available data it is possible that all of these included resection of mesial temporal structures. Of the 20 nontemporal resections, 17 involved lesionectomies (six became seizure free) and three were nonlesional (one becoming seizure free). With regard to EEG, surgeries were largely guided by scalp ictal findings, with intraoperative corticography in a large percentage (56% at the first and 77% at the second surgery) and rare invasive ictal data (three patients at the first and six patients at the second surgery). Seizures recurred within 1 year of surgery in 56 patients, but 2 to 11 years after surgery in the other eight patients. Following reoperation (three surgeries in nine patients and four in two patients), with a follow-up of at least 1 year, 25 (39%) of the 64 patients were seizure free and six (9%) had rare seizures postoperatively. Predictors of seizure freedom, using a logistic regression model, included seizure onset after 15 years old, seizure duration ≤5 years, and focal spikes on scalp EEG. Also, reoperations that included resection of residual medial temporal structures were more commonly associated with seizure freedom than the other reoperations. Interestingly, prognostic factors for a first surgery did not predict seizure outcome with reoperation and seizure freedom was similar for the temporal and extratemporal reoperations. The morbidity in this series was very low, with one permanent mild hemiparesis, two wound infections, and one subdural hematoma. Five patients had a new quadrantic visual field deficit and four had an increase of a prior field deficit (the extent was not reported).

A recent publication reviewed the experience of a single neurosurgeon, at Indiana University, with reoperation after failed surgery for temporal lobe epilepsy.[16] Initial surgery involved 262 patients operated on from 1984 to 2002. All patients had an MRI, with volumetric MRIs since 1994, but the findings were not described. Most patients had ictal single photon emission tomography (SPECT) and 2-[^{18}F] fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) scans were done since 1993. Intracranial electrodes were used in 24 patients, 18 with bilateral temporal grids/strips and six with bilateral temporal depth electrodes. Unilateral onsets were recorded in 259 patients, bitemporal onsets with over 80% from one side were recorded in two patients, and one patient (with a cavernous malformation) had no seizures recorded. Electrocorticography (EGoG)-guided en bloc temporal resections or lesionectomies including the presumed epileptogenic zone were performed. Complications were rare, with one mild hemiparesis, one transient hemiparesis, and one homonymous hemianopsia. There was no mortality. With follow-up of 1 to 18 years, 65% were seizure free, 19% had rare seizures, and 16% (41 patients) were Engel class III or IV. Compared to the seizure-free patients, the class III and IV patients were significantly less likely to have a history of febrile seizures or to have abnormal MRI, and more likely to have a history of head injury and to have had an invasive electrode evaluation. Among the 41 patients with significant persisting seizures were 9 of the 24 patients who had undergone an invasive electrode evaluation preoperatively. Thirty of these 41 patients had postoperative MRI, with 28 having residual posterior medial temporal structures (two also had posterior temporal lesions) and two having posterior temporal lesions. The 41 were considered for reoperation. Twelve were not recommended for reoperation: Six who had invasive electrode evaluation preoperatively, five who had frequent bilateral temporal interictal epileptiform discharges (IEDs), and one who had frequent right frontotemporal IEDs and was felt to have an extensive epileptogenic zone. Twenty-nine of the patients were recommended for reoperation and 21 elected to proceed. All 21 patients had resection of residual posterior medial temporal tissue, under general anesthesia and with electrocorticography, with two also having resection of a posterior temporal glioma. ECoG guided additional posterior basal temporal resection in five patients. At follow-up (1 to 16 years), 12 patients (57%) were seizure free (one with a glioma) and five (24%) had rare seizures. Of the four patients with significant persisting seizures, one had a posterior temporal glioma. There was no surgical mortality or significant morbidity. Importantly, during long-term follow-up the mortality rate (excluding one patient who died due to cancer) was 1.1% for seizure-free patients (none of those seizure free after reoperation) and 15% for patients with persisting seizures (including two following reoperation). These results suggest that if the initial surgery had included a complete resection of the medial temporal structures, then the rate of seizure freedom might have been increased from 65% to 69% and for rare seizures from 19% to 21%.

A recent report summarized the Montreal Neurological Institute experience with surgery for temporal lobe epilepsy in 109 children (up to 19 years old) from 1985 to 2000.[12] Invasive electrode evaluation was performed in six of these patients. Ten patients had gliomas. Resections were tailored by ECoG. Twenty-three patients had a reoperation, with 14 (61%) becoming seizure free (including all three with resection of residual medial temporal structures) and three (13%) having a >90% seizure reduction. Reoperations included 15 patients with neocortical resections and five with recurrent gliomas. The seizure outcomes for these subgroups were not detailed. Overall, reoperation increased the good seizure control rate from 71% to 86% of patients. In the entire experience, there was no surgical mortality or permanent neurologic deficit.

A recent case report[6] emphasizes the importance of complete mesial temporal resection for patients with hippocampal sclerosis. The report involved a 30-year-old patient with recurrent seizures after two temporal lobe resections. Residual hippocampus was seen on MRI and invasive recording

identified seizure onsets from this tissue. Resection yielded long-term seizure freedom.

To summarize the published experience reviewed in this section, of the 249 reoperations that included resection of medial temporal structures (the vast majority having had a partial resection at the first operation), without a structural lesion, 94 (38%) were reported seizure free. The reported surgical morbidity was very low. This suggests that when an initial surgery for MRE is to include a mesial temporal resection, a complete resection of the medial temporal structures is preferable to a partial resection. Such an approach will of course eliminate the consideration for a reoperation to complete the resection of medial temporal structures for patients with persistent or recurrent seizures after a first resective surgery for MRE.

Reoperation for Structural Lesions

Medically refractory seizures associated with a structural or “MRI visible” lesion represent a distinct subgroup of patients with regard to initial operation and reoperation with the goal of achieving seizure freedom by a focal resection. Reported experience strongly suggests that complete lesion resection is the single most important factor for these patients with regard to achieving the desired outcome. As noted above, glial neoplasms complicate the analysis of reoperation for MRE, since they often are not static, and an attempt will be made to exclude them from consideration here. The lesions being considered primarily include malformations of cortical development, dysembryoplastic neuroepithelial tumors, cavernous malformations, and other vascular malformations. Some reports of reoperation for MRE have not distinguished glial neoplasms from other structural lesions, and these will be included in this section.

In the Wyler series,[23] three of six frontal resections were reported to be seizure free. Two of these were extensions of cortical dysplasia resections in pediatric patients (the details of the third were not clear). Also, four temporal resections had had frontal resection at the first operation and had no seizure improvement, suggesting that they had a widespread or multifocal epileptogenic zone.

In the Awad series,[1] 4 of the 14 resection patients had an excision of a residual structural lesion (three vascular malformations and one hamartoma) and these accounted for three of their seven seizure-free patients. The Montreal Neurological Institute series reported in 1994 (see above) included two patients rendered seizure free by resection of cavernous malformations that had not been resected at the first surgery.

As noted above, the University of Washington series reported in 1999[10] apparently included only one resection of a structural lesion (a patient with a ganglioglioma), although two patients were noted to have calcified temporal masses on MRI. The seizure outcome was not reported. One patient had hemispheric dysplasia (presumably one of the children who had a hemispherectomy).

The failed patients analyzed by the Kings College Hospital of London[9] included ten patients with temporal DNETs and three patients with temporal resections despite the presence of known extratemporal structural lesions. Postoperative electroclinical diagnosis in the ten temporal tumor patients included four with temporal seizures, three with frontal seizures (two with incomplete resections), and three with a generalized or multifocal seizure disorder. Of the four with temporal seizures, two had residual lesion on MRI and one had a reoperation for resection and was seizure free at last follow-up (4 months after surgery). None of the other patients had a reoperation. The three patients with extratemporal structural lesions included two occipital lesions and one hypothalamic hamartoma, and none had a reoperation.

In the Spencer series,[18] 6 of the 11 relevant reoperations involved MRI-visible structural lesions (two DNETs, one cavernous malformation, one angioma, two focal cortical dysplasias). Although not explicitly stated, it seems likely that most (possibly all) of these patients had an invasive electrode evaluation for the second resection. One of the DNET patients was rendered seizure free by intentional resection of the foot primary motor area, with an expected residual deficit. Two of the other five patients were reported to have a >75% reduction of seizure frequency (the angioma was found to have an unsuspected developmental abnormality in the resected tissue). Interestingly, without detailed explanation, the authors reported that the cavernous malformation was incompletely resected. The focal cortical dysplasia patients were postulated to have widespread epileptogenic tissue that limits the reliability of even widespread invasive electrode evaluations, even when localized onsets are felt to be well defined. The DNET patient who did not have significant seizure reduction was felt to have widespread undetected focal cortical dysplasia. The authors discouraged reoperation for failed surgery in patients with developmental abnormalities.

In the Mayo Clinic series,[20] 33 of the 64 patients had structural lesions at the initial surgery, although the lesion was “missed” in three of them. These three were seizure free after lesionectomy at reoperation. Of the nine who had partial lesionectomies at the initial surgery, reoperation for further lesionectomy yielded seizure freedom in five (56%) and rare seizures in two (22%). “Complete” lesionectomy was reported for the initial surgery for 21 of the 33 patients and, although not explicitly stated, reoperation was presumably guided by non-MRI data (EEG, ECoG, interictal PET, ictal SPECT, etc.). The 30 pathologies reported included nine low-grade glial tumors, three gangliogliomas, three pilocytic astrocytomas, three nonspecified lesions, two tuberous sclerosis lesions, six focal cortical dysplasias, and four “gliosis.” As a group, seizure outcome for the 33 reoperations was quite good, with 16 (48%) seizure free, five (15%) having rare seizures, and five (15%) with significant reduction of seizure frequency. In contrast to many other reports, completeness of lesionectomy was not significantly related to seizure outcome. Apparently, this was due to the high percentage of “lesion” patients who had successful reoperation despite a “complete lesionectomy” at their first surgery. An interesting observation in this patient series was that in all 33 patients the recurrent seizures after the first surgery were unchanged in semiology, while this was generally not true for the nonlesion patients (see below).

As noted in the prior section, the series from Indiana University[16] included two patients reoperated with posterior temporal gliomas. One of the two was seizure free after reoperation.

To summarize the published experience reviewed in this section, a total of 13 patients were reported seizure free after reoperation on a residual nonglioma structural lesion. It is difficult to determine the total number of patients that were operated on in this category to yield these seizure-free patients, but it seems that the rate of achieving seizure freedom was well over 50%. Two more patients were reported to have rare seizures after resection of a residual lesion and one patient was reported to have a 75% seizure reduction after a subtotal lesion resection. Interestingly, the series reported by Siegel et al.[20] included 21 patients who had a neocortical resection after having had a complete lesionectomy, with eight patients rendered seizure free and three patients having only rare seizures. These reports suggest that for patients with refractory seizures associated with a structural lesion, completeness of lesion resection appears to be important for seizure control in many, but there is a significant subgroup that requires resection of nonlesional neocortex to be rendered seizure free.

Nonlesional Neocortical Resections

In the Awad series,[1] 4 of the 14 resection patients had a neocortical resection and did not have structural lesions. One of these patients was seizure free at follow-up (only 9 months), having had an extensive lateral/inferior temporal resection after originally having primarily a medial temporal resection. Two of the four were reported to have a >90% seizure frequency reduction, including one patient who seemed to develop a new seizure type (frontal) after being seizure free for 7 months following a temporal resection. In the Montreal Neurological Institute series,[7] 28 of the 40 patients were either seizure free or had rare seizures. One of the 28 had only a temporal neocortical resection at the reoperation.

The Montreal Neurological Institute experience with reoperation after a prior frontal lobe resection for epilepsy was reported in 1994.[17] The initial surgery did not involve a primary motor/sensory resection, a tumor, or a multilobar resection. Of the 284 patients operated on between 1929 and 1980, 39 (14%) had a reoperation, with 26 being frontal lobe (three included supplementary motor area [SMA] and five included the leg, arm, or face motor area) and 13 being frontotemporal resections. Reoperation decision was based on seizure semiology and scalp interictal and ictal EEG findings, except for two patients who had bilateral depth electrode evaluations. Surgery was performed with the patient awake for ECoG-guided resection. At reoperation, 26 of the 39 patients had cortical stimulation, with 12 having habitual seizures elicited (seizure outcome was not separately reported for these patients). With the first operations, 257 patients had follow-up of 2 to 49 years, with 26% seizure free and 30% with worthwhile improvement ("occasional" seizures or no more than two per year). With the reoperation, follow-up (4 to 46 years) was available in 35 patients, with seven (20%) seizure free and 11 (31%) with worthwhile improvement. In the seven seizure-free patients, six had spikes eliminated or markedly reduced on postexcision ECoG. Patients who were seizure free or who only had occasional seizures had either SMA, frontal pole, or inferior frontal gyrus resections. Three of the 39 patients had a permanent neurologic deficit (mild facial weakness, mild hemiparesis, or leg paresis).

Miami Children's Hospital reported one of the few experiences with reoperation for epilepsy in the pediatric age group.[19] Of the 20 patients reported, 12 had a delayed operation involving a focal neocortical resection. Most of these patients had cortical dysplasia, but the report does not give adequate detail to determine which patients had resections at least in part guided by an MRI-visible abnormality. Most of the 12 (possibly all, but details were not included) had extraoperative evaluation with subdural electrode arrays before resection. Four patients had an extension of the original resection, with three (with ectopic neurons or cortical dysplasia) rendered seizure free and one (with posttraumatic encephalomalacia) having a >90% reduction of seizures. Four had a resection in a remote lobe, with two becoming seizure free and two without improvement. Four patients had multilobar resections at reoperation, with two becoming seizure free (one with cortical dysplasia and one with hippocampal sclerosis). All three unexpected neurologic deficits occurred in this latter group, including one with aphasia and hemiparesis and one with deterioration from an intraventricular hemorrhage 2 days after surgery.

As noted above, the University of Washington series reported in 1999[10] did not provide enough information to know if any neocortical (nonstructural lesion) resection provided a seizure-free outcome.

The failed patients analyzed by the Kings College Hospital of London[9] included 11 patients who had a neocortical temporal resection without a known structural lesion. Postoperatively, two were found to have nonepileptic seizures, one to have contralateral temporal seizures, one to have uncertain origin seizures, one to have ipsilateral central seizures, one to have ipsilateral frontal seizures, and one to have ipsilateral hemispheric origin seizures. The remaining four patients were diagnosed with ipsilateral temporal seizures, with three felt to be of neocortical origin and one from residual hippocampus (not reoperated due to a failed IAP). None of these patients had a reoperation.

In the Spencer series,[18] 4 of the 11 relevant reoperations involved temporal neocortical resections based on invasive electrode evaluations. None were rendered seizure free, while two were reported to have at least a 75% seizure frequency reduction. The authors postulated that the invasive recording of well-defined onsets was misleading in these patients and failed to reveal their probable widespread epileptogenic tissue.

In the Mayo Clinic series,[20] 31 of the 64 reoperations were in "nonlesional' patients. It appears from the reported data that only 3 of the 31 were nontemporal neocortical resections. One of these three patients was seizure free postoperatively. As stated previously, of the 28 temporal surgeries, eight patients became seizure free, but the number of these that did not include resection of mesial temporal structures is not reported.

A recent report provided evidence that an *α*-[11 C]methyl-l-tryptophan (AMT)-PET scan could be of value in pursuing reoperation for neocortical epilepsy.[11] They reported on seven patients who had a reoperation after an AMT-PET scan identified a localized area of increased uptake that correlated with the ictal scalp EEG focus. Six of these patients were "nonlesional," having dysplasia or gliosis, with five of these six having a subdural electrode evaluation before resection. One patient had DNET and thus would be classified in the structural lesion category, and was seizure free with at least a 1-year follow-up. Of the other six patients, four were seizure free and two had a >75% seizure frequency reduction. This report mentioned another ten patients who had a reoperation without a localizing AMT-PET scan, but did not provide the surgical outcome for that group. Interestingly, the authors reported that the AMT-PET scans were more likely to be positive within 2 to 3 years of the initial surgery. It remains unclear to what degree the AMT-PET scan findings improved or altered the surgical approach to these previously operated patients, since the reoperated patients with positive scans also had a localizing scalp ictal EEG.

To summarize the published experience reviewed in this section, of the reports that provide adequate information, of 64 patients who had a reoperation to excise nonlesional neocortical tissue, 19 were reported seizure free at follow-up. Clearly this is a very heterogeneous group of patients with varied surgical approaches. In any case, the reported experience provides evidence that reoperation for these patients can be successful in a significant percentage of patients. The overall morbidity reported was quite low, although somewhat greater than for initial surgeries (especially in the pediatric series).

Summary and Conclusions

The reported experience with reoperation for patients with medically refractory epilepsy is quite varied, but it does indicate that patients who continue to have refractory seizures after a resective surgery do have a significant chance of being rendered seizure free with a reoperation. The rate of seizure freedom appears to be significantly less than with the initial operation and the risk of significant morbidity is higher (although the risk remains quite low). The reported experience does not permit a conclusion about the best surgical strategy to employ, since significant success has been reported with very different approaches (including tailoring resections with intraoperative

ECoG and identifying epileptogenic cortex with ictal recordings using intracranial electrodes). Understanding the nature of the patient's original operation (including both the preoperative evaluation and the surgical procedure performed) appears to play an important role in determining the appropriateness of pursuing a reoperation that involves a further resection. The experience at one of the premiere epilepsy surgery centers[18] has suggested that a patient with recurrent seizures after surgery at the center is very unlikely to benefit from another resective procedure. However, as noted above, the reported experience with reoperation at that center was rather limited and may not be adequate to extend this conclusion to other centers. Postoperative changes (i.e., "scarring") present technical challenges with reoperation that are probably largely responsible for the increased morbidity. These include adherence of the dura to significant cortical veins and scarring of medial temporal structures to significant arteries, cranial nerves, and brainstem structures that raise the probability of causing infarctions. Prior scalp incisions and craniotomies complicate surgical planning. These considerations make the decision to pursue resective surgery more complicated for reoperation than for the initial surgery. These patients warrant consideration for "palliative" surgical options. These include multiple subpial transactions, vagal nerve stimulation, and implantable brain stimulation devices. The latter devices, including deep brain stimulation and responsive neurostimulation, are currently being subjected to clinical trials. These alternatives are discussed in other chapters. In the near future, it may be appropriate to pursue studies that will systematically compare reoperation for resection to alternative surgical approaches.

Chapter 182

Multiple Subpial Transections and Other Interventions

Charles E. Polkey

Michael C. Smith

Introduction

Disconnection and ablation are long-standing techniques in the surgical treatment of epilepsy. They are based on the rationale that epilepsy afflicts the brain by setting up and using abnormal pathways within the brain, and that therefore, if such pathways are interrupted or destroyed, then the abnormal pathways and activity will cease to influence the brain and thereby reduce or remove the clinical manifestations of epilepsy. These ideas, however, were not based on pure speculation but initially on observations from electroencephalographic (EEG) recordings in experimental models. The development of epilepsy surgery both in North America and in Europe was much accelerated after the Second World War, and in particular the growth of stereotactic techniques applied to the clinical problems resulted in the use of stereotactic lesions in various cerebral structures to try to control epilepsy. A more detailed account follows later, but there were two main groups of targets. One group was the thalamic nuclei because of the perceived relationship between the thalamus and cortex; the other group was the temporal lobe structures, especially the hippocampus and amygdala, when it was recognized that they were part of the limbic circuit and concerned with temporal lobe epilepsy. There had been a search by the early workers for models in EEG work in animals, which would suggest that interventions that changed the EEG features would control clinical seizures. The work of Erickson and others demonstrating that the corpus callosum played a major part in the generalization of seizures from an epileptogenic focus was part of the rationale for the next major procedure, callosotomy.[7] The present status of callosotomy is dealt with elsewhere in this volume. There were other operations of historical interest involving disconnection, as, for example, the temporal lobotomy described by Turner.[49]

By and large the field remained with callosal section and its variations until the description of multiple subpial transection by Morrell and Hanbery in 1969.[23] This was based on extensive experimental work over many years on secondary epileptogenesis. A detail of this work was the demonstration that epileptic discharges travel tangentially in the cortex, and that a minimal population of neurones was necessary to maintain the momentum of an epileptic discharge. As a result, Morrell and Hanbery hypothesized that if the connections within and from epileptic cortex were divided horizontally, then the propagation of the epileptic discharge would be prevented and the clinical manifestations of seizures abolished. As a result, and based on the animal work, a surgical intervention was devised using special instruments to divide the short tangential fibers within the cortex.

The final stage in the development of disconnection and lesioning takes a physiologic twist: The discovery by Benabid et al. that high-frequency stimulation is effectively lesioning the adjacent tissue, with the advantage that it can be reversed.[1]

Multiple Subpial Transection

Rationale

Morrell himself pointed out that multiple subpial transection (MST) was a technique that attacked the epileptogenic lesion at its source by compromising the capacity of the cortex to develop the synchrony necessary for epileptogenesis. He advanced three types of experimental evidence to support this idea. The first was the idea that a minimal volume of transversely arranged contiguous tissue was necessary for the initiation and propagation of an epileptic discharge. The second was the observation from many different sources that the vertically orientated column is the key to cortical organization and that a consequence of this is that normal cortical function is based on these radially orientated columns and their afferent and efferent connections, largely in the same plane. This was broadly confirmed by some work carried out in Sperry's laboratory in the 1950s, which showed that if the cortex was interrupted vertically by section and the insertion of mica plates, the normal function of that cortex was retained. Although not neglecting the subtle contributions of these tangential connections to normal cortical function, Morrell realized that the majority of cortical function would be available if the tangential fibers were interrupted. It was clear that the vertical cut had to involve the whole depth of the cortical ribbon, and from laboratory experiments he concluded that the distance between the cuts should be a maximum of 5 mm. The area of cortex to be transected (i.e., both the location and the actual area) was determined by defining the epileptogenic zone. This was performed mainly as a neurophysiologic exercise. As a check on the efficacy of the procedure, elimination of the abnormal discharges, which was not always possible, was taken as the end-point of the procedure.

Indications for Multiple Subpial Transection

Although MST can be used alone or in combination with cortical resection, the selection criteria remain the same. The selection criteria, based on the rationale for MST, are an identified area of epileptogenic cortex whose resection is precluded by potential loss of function. This translates into a number of clinical scenarios, some of which are listed in Table 1.

Table 1 Indications for Multiple Subpial Transaction

Epilepsia partialis continua
Focal motor seizures
Focal sensory seizures—somatosensory or visual
Transection in association with resection, where the epileptogenic zone includes an eloquent cortical area, especially the primary motor and sensory areas and speech cortex
Landau-Kleffner syndrome
Other indications that are more contentious

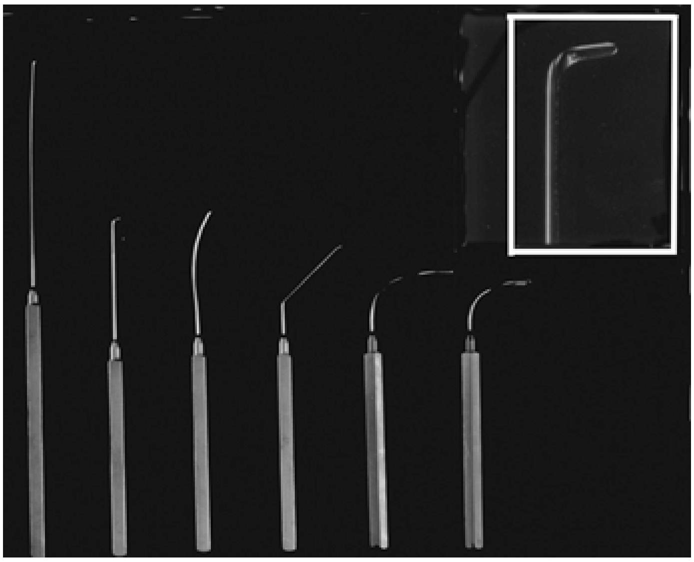

FIGURE 1. The six special hooks used for transection. The inset shows the tip of one of these hooks; the tip is the same in each of them.

Technique

A clear strategy for the use of MST is needed prior to surgery. In addition to the usual clinical details and investigations involved in a presurgical assessment program, it is necessary to identify the epileptogenic zone. This will frequently depend on the use of intracranial electrodes, often grid electrodes, since the accurate identification of epileptogenic cortex will be required to determine the extent and location of the craniotomy. In operations for Landau-Kleffner syndrome, it is almost always necessary to open the sylvian fissure. Although the record of MST suggests that functional complications such as hemiparesis and dysphasia are low, where circumstances are appropriate it may be prudent to perform the procedure under local anaesthesia. It is clearly necessary to use electrocorticography in these cases in order to determine the end-point of the procedure.

Technical aspects of the procedure are fairly straightforward. A set of specially designed instruments is used (Fig. 1). Each consists of a heavy steel wire flattened at one end to a thickness of 0.3 mm and turned up at an angle of 105 degrees with respect to the rest of the wire. The upturned portion is exactly 4 mm long (the thickness of most areas of cortical gray matter in humans). The other end of the wire is fused to a handle that is flattened at the sides so as to be exactly aligned with the flattened surface of the upturned end of the wire. The latter feature is important because the instrument must be maintained in a strictly vertical orientation with respect to the gyral surface (even when the tip is not visible to the surgeon) to avoid damage to the vertically arranged neural elements. The “springiness” of the wire is also critical, as the tip must be drawn along the undersurface of the pia, slightly elevating it but not producing a pial tear.

The gyri containing epileptogenic activity are delineated by the presence of epileptiform potentials on intraoperative electrocorticography (ECoG). A small hole is made in the pia, using the tip of a Beevor knife, or with a No. 20 needle, at a site situated as close to the lateral margin of the sulcus as it is possible to reach, access often being limited by the presence of large blood vessels. The instrument is introduced through this pial opening and then swept forward, dipping in an arc-like fashion underneath the gyrus (Fig. 2). The thin but blunt blade is maintained in a strictly vertical orientation to avoid undercutting the cortex. The tip is maneuvered so that it impinges, as low as possible, on the subpial surface of the vertical portion of the gyrus opposite the point of insertion. It is then drawn up this surface until it reaches the visible part of the gyrus opposite the point of insertion. From here, the tip is visible beneath the pia, which it just elevates but does not penetrate. The blade is then gently drawn straight back across the gyrus in the same plane as its forward movement, with the tip always kept visible through the pia until the gyrus is transected. Care is taken not to snag with the blade of the hook any cortical vessels, especially from the opposite sulcus, and this is largely a matter of feeling the movement of the tip of the blade. Finally, the hook is inserted vertically downward at the point of insertion to approximately 4 mm, with the tip against the vertical wall of the sulcus and withdrawn to the surface. The next transection is made parallel to the first and 5 mm away (Fig. 2). A small piece of card cut to an appropriate size and held between the jaws of a hemostat can be used to judge the position of the next transection. Transections are repeated as often as necessary to include the entire area of electrical abnormality, and they may encompass several gyri. The capillary bleeding associated with each traverse of the instrument results in a fine red line. The bleeding does not seem to cause damage, and the line is a useful landmark against which to gauge the location of the next transection. This is continued over the selected area until the abnormal discharges have been minimized on ECoG; it is not always possible to abolish them completely, although this has been achieved in the case illustrated in FIGURE 3. The operative appearance of the transected cortex is shown in FIGURE 4, and in FIGURE 5 there is a photomicrograph of transection from a patient who subsequently underwent hemispherectomy.

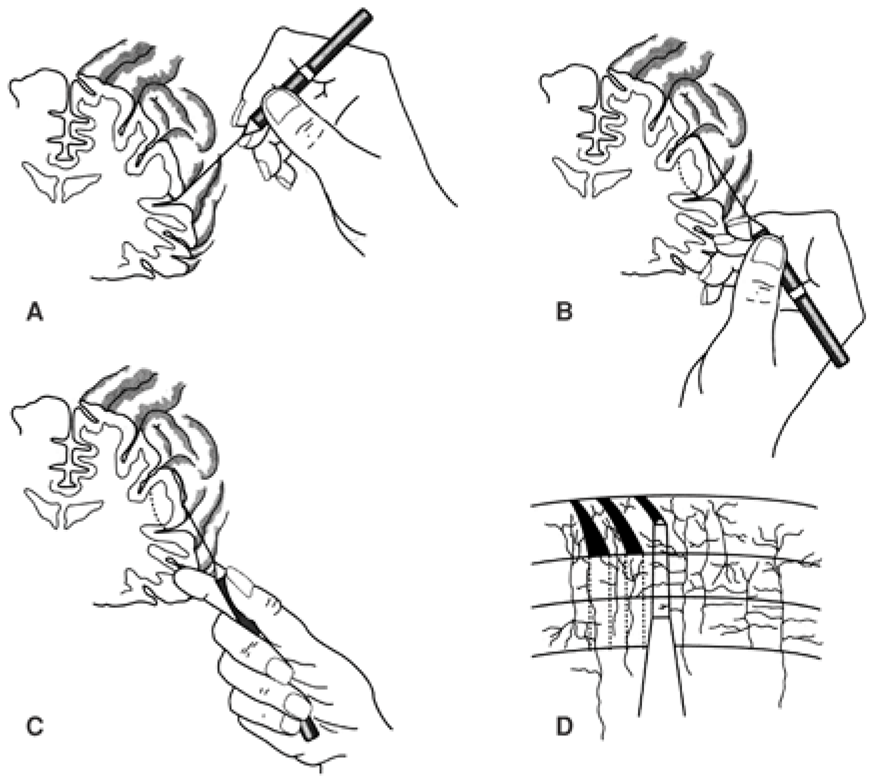

FIGURE 2. Technique of multiple subpial transaction. The hook is introduced at **(A)** and the transection is made by moving the hook appropriately **(B,C)** before being removed. **D:** The serial transections of a gyrus are shown.

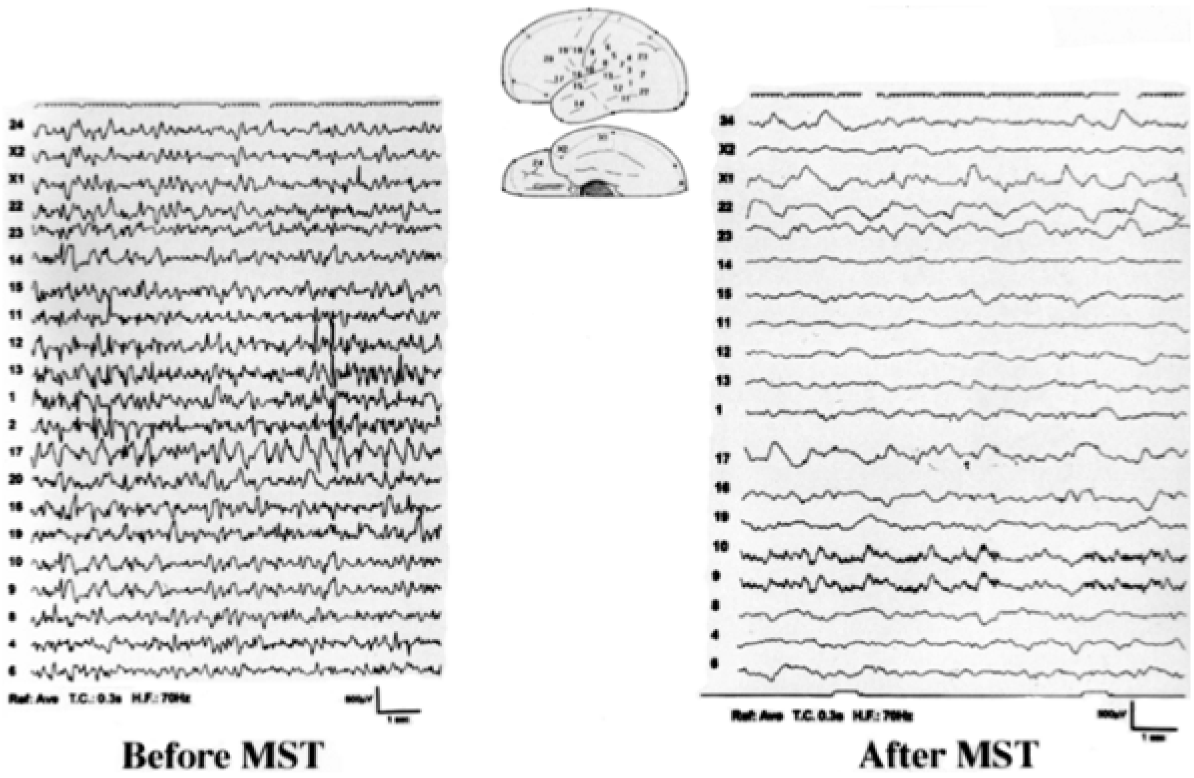

FIGURE 3. Electrocorticography recordings before and after transection. There are very obvious spikes in channels 11, 12, 13, 1 and 2. These channels in particular, and the record as a whole, are free of spikes after the transection. MST, multiple subpial transection.

There are technical limitations to the use of MST. Although the handles of the complete set of six instruments are designed to get into awkward areas, a minimal space is required in which to record and work. Furthermore, retraction to gain access may itself risk complications, and finally the distribution of venous drainage, especially in the posterior part of the hemisphere, may limit retraction. The buried part of the insular cortex can be exposed with careful microsurgical technique, and this is mandatory when using the technique for the treatment of Landau-Kleffner syndrome. Access to the orbital part of the frontal cortex is likely to be difficult, as is the primary visual area on the medial surface of the occipital lobe. However, in many of these areas access depends on the individual arrangements of vessels in any particular patient. As may be surmised, although the trauma is minimal, the technique is traumatic and therefore, after transecting large areas, some swelling might be expected. In the absence of clinically significant problems, the use of postoperative steroids is not mandatory.

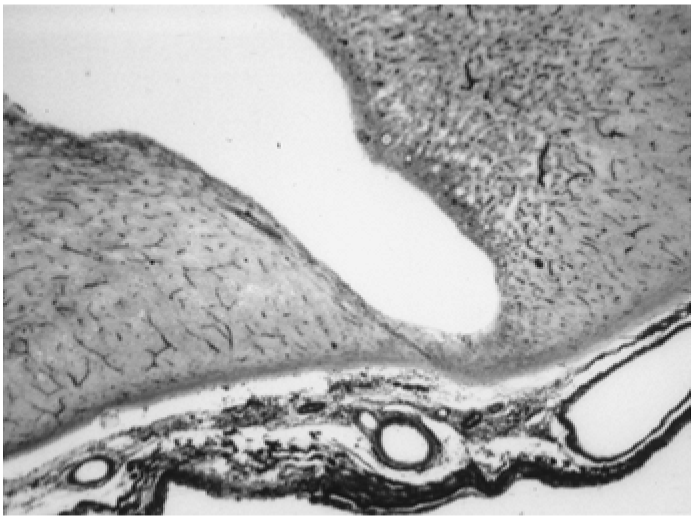

FIGURE 5. Photomicrograph of a patient who underwent hemispherectomy after multiple subpial transaction. The cut extends to the pial surface without breaching it or disturbing the pial vessels.

Outcome from Multiple Subpial Transection

A number of considerations apply to the assessment of the outcome from MST. These include whether the technique is used alone or in combination with a resection, the effect on seizure control using accepted outcome scales, and the frequency of complications, especially in relation to the normal function of the treated cortex. With the exception of some reports from China and the meta-analysis of Spencer et al.,[47] the number of patients described in series in the literature is <100. The methodology of this meta-analysis varies in two other respects from the other papers. The patients are grouped into those

P.1924

with >95% improvement in seizure control, so that it is not possible to discover how many patients were seizure free. It also deals with the response of individual seizure types to the intervention. In this respect the authors make two important observations. The first is that the procedure is more effective in partial seizures than generalized seizures and that this is the expected result from the physiologic basis of MST. They also noted that in their material the superiority of resection combined with MST over MST alone applied only to generalized seizures. Finally, they also reported that partial seizures sometimes increased in frequency after MST. The literature includes reports of patients varying in numbers from 10 to 200, and is invariably divided into those patients in whom the technique has been combined with resection and those in whom it was used alone. In general, and possibly at variance with the meta-analysis, complete seizure freedom is only seen where MST is combined with resection. In relevant series, seizure-free rates between 31% and 56% are reported.[2,5,13] Mulligan et al. reported that none of their 12 patients became seizure free, and although it was not statistically significant, it appeared that resection with MST was more effective.[25]

Similar outcomes are described in children. In a report of 158 pediatric cases, Shimuzu and Maehara used MST in 25 (15.8%) and reported an Engel class I or II outcome in ten of these cases.[45] Hader et al., in a series of children with focal cortical dysplasia (FCD), noted that when combined with incomplete resection MST did not improve the control of seizures, whereas complete resection of the lesion outside of an eloquent area gave the best results, with 87% of patients in Engel class I or II compared with 50% of patients who were treated with incomplete resection and MST.[11] Otsubo et al. reported the use of MST in seven children with malignant rolandic-sylvian epilepsy. In six children interictal scalp EEG spikes were seen over the frontocentrotemporal regions bilaterally and unilaterally in one. Magnetoencephalography (MEG) showed bilateral spike sources in the perisylvian region in two patients and in the perirolandic fissure in five, two of which were bilateral. Three patients required bilateral subdural strips to lateralize seizures before electrocorticography. ECoG showed an ictal onset zone around the rolandic region in four cases and the rolandic-sylvian regions in three cases. After cortical excision and multiple subpial transection, three were seizure free and four had seizures rarely with a mean follow-up of 30 months. Histology showed definite evidence of neuronal migration disorders in three cases and gliosis in two.[29]

There are a number of reports of MST being used alone. The largest series of 20 patients was described by Schramm et al. Although a good outcome, judged either by Engel's scale or by an alternative outcome scale, was seen in 45% and 50% of patients, respectively, only two patients (10%) were seizure free. A better outcome was seen when there was no magnetic resonance imaging (MRI) lesion and a worse one when the area of MST was greater.[42] Wyler's group described six patients in whom sensory motor cortex was transected. In four of these patients the MRI was normal. Where samples were taken the cortex showed gliosis. One patient was rendered seizure free and two of the remaining patients had a >90% decrease in their seizures.[50] Rougier et al. also reported seven patients with pure MST, and three patients had a >75% decrease in their seizure frequency with follow-up periods between 1 and 4 years.[41] Shimizu et al. described the use of MST in the exposed hippocampus, using abolition of seizure discharges as the end-point. They did not report the result with reference to seizure control but noted that postoperatively, verbal memory was preserved. In the absence of other details it is difficult to evaluate this report.[44] The two reports from Chinese groups do not distinguish between various combinations of treatment and therefore their seizure-free rates of 64% and 47.5% are difficult to interpret.[18,19]

The use of MST in Rasmussen's disease was first mentioned by Morrell in his original paper, where he noted that it would abolish seizures originating from the motor area but would not prevent the progression of the disease and therefore the appearance of seizures from other cortical areas. He made a useful summary in his contribution to Andermann's update on Rasmussen syndrome in 1991. There he gives a number of illustrative cases, but also summarizes their experience at the time of seven patients with pathologically verified Rasmussen's disease. In four of the seven the target seizures were eliminated but in three others they were not, including elimination of ECoG-monitored spikes in two cases.[24] In a personal communication Michael Smith noted the use of MST in delaying definitive hemispherectomy in older patients with dominant hemisphere involvement with functional language and hand use. The patients in whom MST failed were those where the epileptic abnormality was at the depth of the sulcus and unaffected by MST on the cortical surface. All of these patients developed an epileptic disturbance outside the transected cortex over time.

We have used the procedure in five cases, obtaining improved seizure control in four over follow-up periods between 18 months and 7 years. However, in one case it was combined with an extensive frontal resection. Two of the remaining three patients progressed and after 6 months in one case and 21 months in the other, they were subjected to hemispherectomy with class I outcome in both cases. The remaining patient obtained sufficient seizure control, Engel class 1C after 6 years, with MST alone. Hufnagel et al. noted one patient with no benefit.[13] There are no other recent reports; the meta-analysis does not describe such patients separately.

There are two reports on the use of MST in patients with refractory status epilepticus; on both occasions the intervention halted the status.[6,20] The major rationale for MST is the avoidance of complications when it is applied to eloquent areas of cortex, including those that have language and cognitive functions. The bulk of the evidence is in agreement with the conclusions of the meta-analysis that such complications do occur and that they are more often transient than permanent and equally associated with MST alone and MST when combined with resection. In the various series quoted above, the transient complications occur in 30% to 70% but permanent complications in 10% or less. The meta-analysis does not report the transient deficits, but permanent deficits were seen in 23% of patients treated with MST and resection, whereas in pure MST the permanent complications were 19% but did not include aphasia or psychiatric problems.[47]

The effects and mechanism of MST have been described in a number of papers. Sugiyama et al., who also investigated the physiologic properties of this model, described the appearances of the resected cortex in rabbits. Histology showed very little damage with transection of the horizontal fibers. By studying afterdischarges they showed that cortical hyperactivity was reduced but also that propagation of afterdischarges by kindling was also inhibited.[48] Another study, carried out acutely in the course of temporal lobectomy, showed that in most instances, midlevel horizontal fibers were damaged. However, one third of the specimens showed additional deep injury that would sever afferent and efferent axons.[14] Shimizu et al., investigating a child with simple partial seizures involving the left arm and cortical dysgenesis, found hyperexcitability of the relevant motor cortex using transcranial magnetic stimulation (TMS), which was modified by MST, improving the various abnormal responses. The patient showed a fair motor recovery and good seizure control after the procedure. Theoretically, MST depends on normal cortical organization to produce its effect, whereas in cortical dysgenesis the cortical organization is abnormal in terms of both structure and function. Shimizu et al. speculated that in this particular case MST might have improved abnormal synchronization in excitatory pyramidal neurones by cutting their recurrent axon branches and basal dendrites rather than the axons of inhibitory interneurones.[46] There are other anecdotal reports of the functional effects of MST. Leonhardt et al. investigated the effect of MST on positron emission tomography (PET) activation in a 30-year-old woman with MST where the right frontoparietal cortex was transected. Motor activation to a finger-to-thumb opposition task was preserved and additional areas of bilateral prefrontal and contralateral parietal activation were seen when compared with healthy controls.[16] Moo et al. examined the recovery of functional MRI (fMRI) activation in a patient who had undergone MST of the right sensorimotor cortex. Immediately after the procedure there was some transient loss of dexterity of the left hand. Seven weeks later dexterity returned to normal and left-hand finger tapping corresponded with multiple bilateral foci of fMRI activation. At 16 weeks, fMRI activation returned to pretransection levels. These data were interpreted to indicate that cortical injury due to MST resulted in the temporary recruitment of distant cortical sites, which presumably subserved normal motor function during recovery.[22]

MST has also been used in patients with multifocal epilepsy and in some patients with problems that may not be construed as primarily epileptic, such as autistic regression syndrome. Publications on these themes have been restricted to two groups. The first is Devinsky et al. in New York and the other is Patil et al. in Omaha. Both groups have used a similar strategy: Investigating the patients, often with intracranial electrodes, to establish the number and location of the epileptogenic zones. In two publications Devinsky et al. described a group of patients with multiple epileptic foci, either in both cerebral hemispheres or in several lobes in the same hemisphere. They described 13 patients who required MST together with resections. Only 6 of the 13 patients had no lesion on MRI. Wherever possible, resections were carried out and MST was used in eloquent areas. The only patients who achieved a grade I outcome were those in whom a discrete lesion was resected and the foci involved only two lobes.[5] In a second report the same group examined 36 patients diagnosed with autistic regression syndrome or autism. All the patients were evaluated with video-electroencephalography. Within this group they identified 15 patients with clinical seizures, 11 from the 19 patients with autistic regression syndrome and 4 of 12 with autism. Seven of these 15 patients were resistant to therapy. MST was carried out in the left neocortex in the temporal, parietal, and frontal regions, often including regions within the classic perisylvian language areas. One patient also had a left temporal lobectomy. In all seven patients, seizure control on EEG improved after operation. Language, social, and overall behavior improved to a moderate degree, although in most improvements were temporary.[27] Patil et al. have also used this technique in multifocal epilepsies. In two publications in 1997 they described patients with multifocal epilepsy. In one paper 19 patients are reported, all of whom had multiple seizure foci identified, and in all 19 MST was performed at the identified sites. Seven of these patients had additional topectomies and nine had amygdalohippocampectomies. Histology was available for five specimens from these resections; four showed gliosis and in the remaining one there were heterotopic neurones. Nine patients (47%) are either free of seizures or have only rare seizures; eight patients (41%) have >90% reduction in seizure frequency.[35] In the second paper, from a group of 31 patients 15 are reported who required further resection of dominant seizure foci, which are defined as discrete foci that did not respond to MST. Nine of the 15 patients are free of seizures, three have rare seizures, two have >90% reduction in seizure frequency, and one has >70% reduction in seizure frequency.[33]

A further publication in 2004 summarized the Patil group's experience with 61 patients. Follow-up ranged between 15 and 90 months with a mean follow-up of 41.5 months. Fifty patients had complex partial seizures, three had Lennox-Gastaut syndrome, four had myotonic seizures, two had infantile spasm, and two had myoclonic seizures. MST was the principal procedure, which was supplemented in 17 patients with minimal cortical resection when intraoperative EEG indicated that an area had failed to respond to MST. In five patients an additional epileptogenic focus in the amygdalohippocampus complex was treated with stereotactic amygdalohippocampectomy. The eloquent cortex was treated in 51 patients. Two lobes were treated in five patients, three in five patients, four in ten patients, five in two patients, six in 38 patients, and eight in one patient. Seizure outcome, based on Engel's modified classification, was as follows: 52.45% were class I, 8.2% were class II, 24.59% were class III, 4.9% were class IV, and 9.83% were class V. There was no statistical difference between those who were operated on in the first half of the series and those who were operated on in the second half of the series (p = 0.1636). There was no statistical difference between those who had MST

P.1926

alone and those who had MST plus minimal cortical resection (p = 0.1698). There was no permanent neurologic complication in this series.[34]

The possibility of using MST in the treatment of autism and in particular in a subset of patients with autistic regression syndrome, some of whom also have clinical epilepsy, arises out of the experience with multiple foci and with Landau-Kleffner syndrome. There are clear differences between the two populations as pointed out by Palac et al. in their article on this topic. They noted three points. First, there is no conclusive evidence that epileptic activity plays a major pathogenic role in autistic regression; second, the abolition of the epileptic activity does not result in a worthwhile improvement of the autistic symptomatology; and lastly, the epileptogenic areas in autistic regression are multifocal and not all accessible for surgical intervention.[30]

The application of MST to Landau-Kleffner syndrome is dealt with in detail in Chapter 242. It is one of the most successful uses of MST, provided the indications are strictly observed. The patients must have the correct syndrome, and in both the Rush series and our series on Denmark Hill, the unsuccessful cases have been those with a wrong diagnosis. It is also worth recalling that the primary focus is not always in the left hemisphere, that MEG may be helpful in lateralization, and that intracranial recording may occasionally be necessary to prove the lateralization. A few patients may relapse within weeks or months of the initial operation as evidenced by seizures, failure or slowing of language recovery, and recurrence of continuous spike-and-wave activity during slow sleep (CSWS) EEG patterns. In our experience on Denmark Hill, another MST will usually produce a further improvement and in no case have we had to operate a third time. The indications for surgery are genuine Landau-Kleffner syndrome with CSWS, severe speech difficulty or mutism for more than 1 year, and in our view permanent reliance on steroids to maintain improvement. Because the disruption is functional, we believe that there is a window of opportunity in which the procedure is most effective. Otherwise, surgery is relatively free of complications and brings about improvement in language and behavior, which, as Frank Morrell himself predicted, will not necessarily return completely to normal. Recovery will be at least as good as the natural history of the disease, but achieved sooner and with less disruption to the patient and his or her family.

Stereotactic Lesioning

Stereotactic lesioning was popular and prolific in the 1950s and 1960s. The results were difficult to assess for a number of reasons. Presurgical assessment was less rigid, it was rare to be able to verify the site and size of the lesion, and follow-up data were poor, being short and inaccurate. By the mid-1970s there was considerable literature replete with methodologic inconsistencies, some of which can only be perceived retrospectively, and the situation has been sensibly summarized by Ojemann and Ward.[28] In addition to a number of miscellaneous targets such as the internal medullary lamina, fields of Forel, and the hypothalamus, there have been two principal areas of interest. The first was the thalamic nuclei, based on a proposed relationship between these areas and the cortex, as suggested by bilateral secondary synchrony and 3/sec spike-and-wave. On this basis lesions were made in the ventroanterior, ventrolateral, and centromedian nuclei of the thalamus. The second area of major interest was the amygdala and hippocampus, as these areas became recognized as important structures in the genesis of seizures. In particular, the work of Narabayashi in targeting these structures in patients with aggressive behavioral disorders suggested that the main benefit from these procedures was relief of epilepsy.[26] Reports of lesions in these structures, both unilateral and bilateral, are numerous and the details are summarized by Ojemann and Ward.[28] The principal criticisms of this work, namely, poor selection criteria, no verification of the lesion site, and poor follow-up data, consign the results to history. Most of these procedures have been abandoned in their original form, although there is increasing interest in functional lesioning in these structures as represented by high-frequency stimulation. Exceptions in recent times include the application of stereotactic radiosurgery to produce lesions in the mesial temporal structures and to treat hypothalamic hamartomata.[37,38] Radiosurgery, using stereotactically implanted interstitial radiosurgery with I_{125}, in four cases of hypothalamic hamartoma has also been described,[43] However, there is some more recent work using stereotactically placed radiofrequency lesions in the amygdala and hippocampus. Parrent and Blume in 1999 described 22 operations in 19 patients using two different techniques. In one group the lesions were discrete and in the other group they were confluent. The success rate was 20% in the first group and 60% in the second. All lesions spared the parahippocampal gyrus, and in their discussion they admitted that exclusion of the entorhinal cortex may have contributed to the poor results compared with microsurgical procedures.[31] A report from Tianjin in China describes 23 patients who had radiofrequency lesions made unilaterally in the amygdala and hippocampus. With follow-up periods of 8 to 32 months, they obtained seizure freedom in 43.48% of these patients.[51] Radiofrequency lesions have also been used in the treatment of hypothalamic hamartoma. Most case reports are of single cases,[9,10,32] but Kuzniecky and Guthrie have reported more than one case[15] and our unpublished experience of two cases has shown significant and persisting improvement in seizure control (Fig. 6).

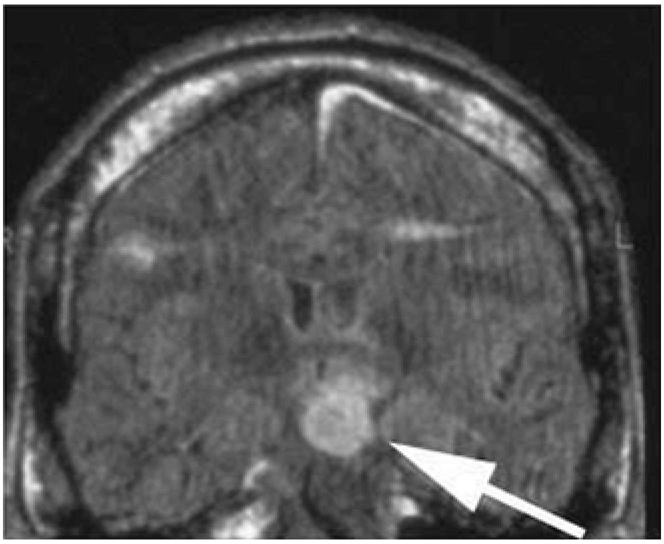

FIGURE 6. Coronal magnetic resonance imaging scan of a patient with a hypothalamic hamartoma. The hamartoma had been treated with stereotactically guided radiofrequency ablation a few days before.

Disconnections apart from Division, Partial or Complete, of the Corpus Callosum

In practical terms, disconnection, aside from multiple subpial transection, has been used in recent times almost exclusively in the treatment of hypothalamic hamartoma. These lesions, whose part in severe epilepsy has only recently been realized,

are difficult to access surgically. The most relevant approach at present is the transcallosal approach developed by Rosenfeld and his team in Melbourne. Although the complications are low, it involves a complex major intracranial procedure. Therefore, other approaches have been sought, including the disconnection technique described by Delalande and Fohlen in France and the use of neuroendoscopic techniques to minimize operative trauma and duration.

Between 1997 and 2002, Delalande's group treated 17 patients with refractory epilepsy due to hypothalamic hamartoma. Sixteen of these 17 patients were treated by disconnection. Sixteen patients had gelastic seizures, 14 had partial seizures, and three had generalized tonic–clonic seizures. The mean seizure frequency was 21 per day. Four patients had a borderline intelligence quotient and the others were mentally retarded. MRI in each patient showed the hamartoma as a stable homogeneous interpeduncular mass implanted either on the mamillary tubercle or on the wall of the third ventricle with variable extension to the bottom. Sixteen patients underwent disconnection through open surgery in 14 procedures and/or endoscopy in nine procedures. Among the 17 patients, eight patients became seizure free, one patient had only brief gelastic seizures, and eight patients were dramatically improved with a mean follow-up of 18.6 months (8 days to 43 months). Surgery was safe in all but two patients: The first patient had transient hemiplegia and third cranial nerve paresis, and the other developed hemiplegia due to ischemia of the middle cerebral artery territory. Quality of life and behavior and school performance were greatly improved in most patients. Endoscopic disconnection seems to be a very safe way to treat hamartomas in intraventricular locations.[4] Choi et al. reported a successful outcome in four patients where endoscopic disconnection was used. There were two patients who became seizure free; one third lost seizures that could be attributed to the hamartoma. Three of the four patients suffered a transient disconnection syndrome.[3]

Other Strategies

Cooling the epileptic focus has been suggested as a means of suppressing the epileptic discharge. Of course, it must be possible to identify the focus, which itself must be small and discrete to allow this method to work. There is convincing animal and human experimental work in acute situations. Recently a practical device has been described, and the practical aspects of applying this to drug-resistant focal epilepsy is discussed in a paper by Rothman et al.[40]

Gene therapy as a treatment for intractable focal epilepsy is still largely theoretical. A number of investigators have shown that various factors including release of adenosine and overexpression of neuropeptides and of galanin can all suppress seizures in animal models.[12,17,39] It has also been shown that adeno-associated virus vectors could be used to transfer genes into brain slices from temporal lobectomy specimens.[8] Peltekian et al. have pointed out the problems and uncertainty of adenovirus-mediated gene transfer, which are explored in detail in a recent review by McCown.[21,36]

Summary and Conclusions

This chapter has concentrated on multiple subpial transection, and others chapters of this book discuss in detail a number of other surgical interventions including callosotomy, vagus nerve stimulation, and deep brain stimulation. All of these interventions share a common feature, which is that they are functional interventions, different in character from the resective interventions, which rely, in large part, on the coincidence of the epileptogenic zone and structural pathology. There are also outcome implications in that the proportion of patients rendered and remaining seizure free as a consequence of the surgical intervention is greater with resective surgery. The use of MST and alternative procedures, both those covered in this chapter and elsewhere, is therefore dependent on the proper use of a presurgical assessment program. Within this structure there will be some patients unsuitable for resection in which these procedures are used as alternates or in addition to these resective procedures.

MST can be used in those situations where resective surgery is inappropriate or cannot cover the whole problem. In relation to these situations and in combination with resection, MST has resulted in sustained freedom from seizures in up to 50% of patients. When MST is used alone, the results originally reported by Morrell of 48% patients being seizure free have not been replicated. In this situation it appears to render only 10% or less seizure free. MST in Landau-Kleffner syndrome seems to give excellent results. The use of MST in multifocal epilepsy remains controversial, in part because this is a complex problem that few epilepsy surgery programs choose to address. The other interventions described in this chapter are of limited but sometimes useful application.

Outcome Measures

Anne T. Berg

John T. Langfitt

Samuel Wiebe

Introduction

During the nearly 10 years that have elapsed since the first edition of this book, there have been several new studies and reports that have advanced our understanding of the outcomes of epilepsy surgery. Large retrospective, single-center studies and one large prospective, multicenter study have been reported, and the first randomized trial of epilepsy surgery was successfully completed. The methodologic standards for operationalizing and studying the various outcomes considered important to epilepsy surgery have improved and seem to be converging toward consensus. Increasingly, there is an emphasis on the long-term outcomes that, in the early literature, had been largely ignored.

The following discussion summarizes the current state of outcome assessment and provides a brief summary of the current understanding based on the strongest, most methodologically rigorous studies. The outcomes to be covered are seizures, mortality, neurocognitive deficits, psychiatric disorders, health-related quality of life, utility measures, and employment. Although consensus is developing for measurement of these outcomes, the measurements themselves are of relatively little value if they are not done in the context of an appropriately designed and analyzed study.

Study Design: Some Basic Concepts and Principles

The Hypothesis

At the heart of any good study is one or more clearly articulated study questions. These questions are then operationalized into testable hypotheses. The term "testable" in part refers directly to the process of subjecting the data to statistical tests appropriate to their form. Thus, one plans a study based on the final form the results will take.

The Design

The value of a study's results also heavily depends on the quality of the study design (to ensure validity of results) and the size of the study sample (related to statistical power and stability of findings). There are a few common approaches used in studying epilepsy surgery.[5,12]

Retrospective Cohort Based on Chart Review

Such studies are easy and convenient to do. They can help to generate hypotheses and provide descriptive data or novel information useful in designing a rigorous prospective study. All else being equal, a retrospective chart review is the weakest design. It requires depending on information not recorded for research purposes, in general, and with the investigator's specific research questions in particular. Consequently, data are often inappropriate to the question being asked, incomplete, or just missing entirely. Follow-up—something absolutely front and center for an outcomes study—is of uneven intensity and completeness across patients, often as a function of outcome. This alone can invalidate a study's findings.

Retrospective chart review studies can be strengthened by (a) performing consistent and well-documented follow-up through the charts and (b) limiting the study to information that is reliably and routinely recorded in the medical records. An important advantage of a well-conducted retrospective study is that long-term data can be obtained without the need for actually waiting many years. It is an appropriate first approach to a question not previously addressed and should be followed with more definitive studies if warranted. In some cases, a cohort can be assembled retrospectively, and then continued follow-up can be conducted prospectively as in a recent study from Australia.[62,63]

Prospective Studies

In contrast to relying on chart review, in a well-done prospective study, one can ensure that patients are appropriately identified and enrolled; that baseline evaluations are made and their results recorded in a consistent, meaningful, and analyzable format; that outcome measures are assessed in a standardized manner; and that follow-up is consistent for all patients. There are at least three ways in which one might do a prospective study. We note that the first, a randomized trial, can never be done retrospectively; however, the other two approaches often are.

Randomized Clinical Trial.

For comparing the outcomes of two treatments, a randomized trial is the single best design. Although excellent for a basic test of treatment efficacy, randomized trials have several important limitations: (a) For practical or ethical reasons, the eligibility criteria are often very restrictive, making the results of limited generalizability outside of the highly selected trial population, (b) patients are typically less willing to participate in randomized clinical trials (RCTs) than in observational studies, especially in studies of highly invasive interventions; and (c) randomized trials are generally not powered to detect infrequent adverse events, which often only surface in large follow-up studies. All of these factors impose limits, sometimes severe, on the generalizability and scope of the trial's results.

A recent randomized trial of epilepsy surgery done in Canada overcame the first two of these concerns.[99] This was possible because there is a 1-year waiting period for surgery in Canada. Willing candidates were randomized either to immediate surgery (the waiting period was waived) or to the normal wait that they would have had were they not in the trial. Generalizability was not of concern either because the eligibility criteria captured typical temporal lobe epilepsy patients presenting for surgical evaluation.

Table 1 Summary of considerations in designing a clinical research study of outcomes

Study considerations	Comments
Clear testable hypotheses	Formulated in terms of specific statistical tests and comparisons
Study design	Appropriateness depends on level of knowledge and degree to which information will represent a contribution to extant knowledge; well-powered, prospective study designs are preferred

Sample-size considerations	Must be planned in advance; larger samples provide better statistical power and allow detection of smaller but still meaningful effects
Standardized outcome measures	Should reflect real outcomes of interest; when they are available, accepted, well-vetted measures should be used (e.g., for neuropsychological, psychiatric, and quality of life)
Standardized follow-up protocol	Explicit predetermined plans for periodic contact with patients to collect data, carried out consistently across study participants; use of clinic visits alone is often suboptimal
Consistent approach to measuring and collecting all other relevant data	Ideally, the investigator has some control over this information prospectively; if dependent on clinical records, do some preliminary exploration in advance and determine what reliably can be recorded from these sources; have a standardized procedure for collecting and recording information

For an intervention such as surgery, another significant limitation is that the outcomes of greatest interest today are those

that take years, even decades, to realize. In fact, after 1 year, most of the patients in the Canadian trial who were randomized to the usual delay before surgery went on to have surgery.

Nonrandomized Control Group.

Although it is appealing, a nonrandomized study is much more difficult to execute well. The comparison of treated to untreated patients will almost always be confounded by fundamental differences between the two groups. Well-designed and carefully analyzed studies can provide results of comparable quality to that of randomized trials[11,26]; however, this requires knowing what the differences are and being able to measure them adequately. In the end, there is often a lingering doubt about the accuracy if not the outright validity of findings from nonrandomized studies.

Surgical Cohort (Series).

Most surgical outcome studies are limited to a surgical cohort or case series. Although inappropriate for assessing the efficacy of surgery, it is reasonable to use this type of study for identification of pre- and early postoperative predictors of outcome. Such a design is also appropriate for studying the relationship between seizure control and other outcomes (e.g., employment, depression, health-related quality of life, etc.) after surgery. For example, "does someone who stops having seizures after surgery experience improvements in his employment status?"

There are several other considerations that cut across all study designs:

1. Sample size and statistical power. Statistical power refers to the ability of a study to detect a difference if one exists. It is a product of several factors, including sample size and the size of the effect to be detected.[25] All other things being equal, the larger the effect to be detected, the better is the statistical power. Likewise, the larger the sample size for a given effect, the greater is the statistical power. Any study should be planned with an adequate sample size to detect meaningful effects. This process is made quite easy today by the availability of software that help to determine the necessary sample size under a

variety of conditions and assumptions.[32]

2. A deliberate, standardized, and meaningful assessment of outcomes. Measures that reflect outcomes of real interest and that can be reliably assessed should be used. Use of published well-validated and accepted instruments, where they exist, to measure various outcomes is strongly encouraged. The use of idiosyncratic, unvetted instruments for factors and concepts for which well-developed methods already exist adds little to the literature.

3. Rigorous protocol for data collection. Whether the study is a randomized trial or not, all data should be collected according to a carefully designed rigorous protocol constructed to ensure accurate, complete, timely, unbiased collection of all data in the same manner for all study participants.

The basic considerations for study design are summarized in Table 1.

Seizure Outcome

In the earlier literature, seizure outcomes were assessed in a variety of idiosyncratic ways[94] at varying points after surgery. A recent guideline emphasized the importance of complete seizure freedom and of assessing seizure outcome each year.[100] The use of various outcome categories, although popular, leads to imprecision and difficulty in comparison and interpretation of results. With the widespread availability of fairly standard statistical techniques (as a class known as survival methods[31]) investigators are increasingly using remission (complete seizure freedom) and subsequent relapse and studying the determinants and patterns of these outcomes over prolonged (many year) periods of follow-up.[62,63,71,76,102] Thus, at least for resective surgery, the preferred and most consistently applied approach to studying seizure outcomes is to study remission and relapse over time since surgery. Other methods may still be preferred in drug trials or for studying the outcomes of palliative procedures (e.g., callosotomy or vagus nerve stimulation).

Only relatively recently was a randomized trial of temporal lobectomy successfully completed.[99] Once and for all, this study demonstrated the efficacy of surgery with respect to seizure control. One year after surgery (or randomization) 58% of surgical versus only 8% of nonsurgical patients (p <.001) were completely seizure free. Large-scale observational studies, some retrospective, some prospective, have also appeared. In addition to demonstrating the high rate of seizure freedom following epilepsy surgery, they have provided insight into the course of the long-term seizure outcomes after surgery. These have turned out to be complex.[34,63,80,101,102] In particular, patients who become immediately seizure free after surgery may not always remain so. Relapse rates can be high (25%–30%). To the extent to which it has been studied, it is found that many patients who relapse after a remission regain remission fairly

P.1931

quickly. In fact, some relapses may occur in association with discontinuation of antiepileptic drugs (AEDs), although at least two large studies failed to find a strong if any effect on relapse associated with AED withdrawal.[14,63]

Prediction of which patients deemed appropriate for surgery will be the most likely to become seizure free remains challenging. Many small reports pepper the literature with various findings, few of which are ever replicated. For an extensive review of the literature on this subject see McIntosh et al.[64] For temporal lobe epilepsy, the recent large-scale studies confirm the presence of unilateral mesial temporal sclerosis as the most important and consistently demonstrated predictor of a good seizure outcome. A history of generalized tonic–clonic seizures also seems to predict a poorer chance of remission. Apart from these factors, presurgical prediction of seizure outcome after temporal lobectomy has not advanced much. Current findings must be interpreted, however, in the context of the fact that patients are already highly selected. Recent reports do not provide any firm basis for recommendations that could improve current selection procedures and criteria.

Information about outcomes after extratemporal resection is much scarcer. In general, extratemporal surgery tends to be associated with a lower chance of complete remission after surgery.[89] Studies often report better outcomes if there is a discrete, resectable lesion and if electroencephalographic (EEG), clinical, and imaging findings are congruent. A recent meta-analysis exemplifies the difficulties in summarizing and pooling results from studies with differing methodologies, patients, and procedures and emphasizes the importance of adopting standard research methods. In this study, highly heterogeneous results precluded conclusions about the predictive value of congruence of EEG and magnetic resonance imagining (MRI), extent of surgical resection, and presence of interictal discharges. On the other hand, an abnormal MRI, history of febrile seizures, mesial temporal sclerosis or resectable tumors, and absence intracranial monitoring augured seizure freedom.[91]

Mortality

Mortality, especially unexpected death, is higher in people with epilepsy than in the population at large.[39,56,84] Among adults with epilepsy, it is highest in those with intractable seizures.[90,97] Assessing death is generally not difficult in a study with rigorous follow-up methods in place. Determining cause of death can be more complicated, especially if one is interested in determining whether a death was a sudden unexpected death associated with epilepsy (SUDEP),[90] and most especially when relying on death certificate data, a commonly used source of information.[10]

In separate studies, moderately to substantially lower mortality rates have been reported after surgery in patients who became seizure free compared with those who did not.[65,82,84] Ryvlin provided a critique of the methodologic difficulties of assessing the impact of surgery on mortality risk.[72] In particular, he suggested that the same factors that might render patients inappropriate for surgery or at highest risk of not becoming seizure free might also be associated with cardiac arrhythmias, thus independently placing them at increased risk of SUDEP. An RCT would address these concerns by balancing risk factors in medical and surgical groups. In the only surgical RCT, one patient died in the medical group and none in the surgical group at 1 year.[99] In children, there is agreement that SUDEP is rare, mortality is higher only in those with symptomatic epilepsy, and it is often related to the underlying neurologic condition.[13,19,21]

Cognitive Outcomes

Specific cognitive functions (e.g., memory and sensory and motor functions) may be impaired before or after epilepsy surgery as a result of the surgery itself. Assessment of such impairments involves several considerations including adequacy of pre- and postsurgical assessments, rigorous study design, and appropriate methods for determining whether a real and meaningful change has occurred. In the neuropsychological outcome literature for surgery, weaknesses in basic methodologic considerations (discussed earlier) are common. These include small sample sizes, retrospective designs, loss to follow-up, and inadequate controls.

Methodologic Issues in Assessing Cognitive Change

There are additional concerns that are more specific to assessing real and meaningful changes in cognitive function.

1. A difference of means. Early studies reported cognitive outcome as group mean change scores from pre- to postsurgery. When group mean scores improved, this was taken as evidence for beneficial effects of surgery on cognition. Even without biases introduced by selective loss to follow-up, group mean changes do not always reflect changes at the individual level. Furthermore, not all changes are clinically relevant.

2. Practice effects. When testing study participants repeatedly over time, the study design and particularly the analysis must account for the fact that all cognitive tests are subject to practice effects and test–retest variability. Regression to the mean for unusually high or low initial test scores can be expected. Therefore, a change score can simply reflect the change expected due to these statistical characteristics and not necessarily a true change in cognitive function.

3. Reliable change. Concerns about practice effects have led a number of authors to develop methods of determining how much a cognitive test score must change for it to be considered likely to reflect true change. Reliable change indices (RCIs) or standardized, regression-based (SRB) change scores are two methods for determining the incidence and direction of true cognitive changes. A RCI provides a confidence interval around a retest score that reflects the variability that is to be expected on the basis of test–retest variability and practice. An SRB score is a standardized score (i.e., z-score) that reflects these

factors along with regression to the mean. RCI and SRB scores are typically calculated from samples of clinically stable, medically managed patients tested on two separate occasions. For a given test, an individual change score outside the RCI/SRB-defined range is said to represent a "statistically reliable" change. Table 2 shows neuropsychological instruments used in two recent, large, multicenter studies of epilepsy surgery with references to the source of RCI/SRB data[43,59,73] and estimated administration time for each test.

Table 2 Neuropsychological tests that have been be used in assessing the cognitive effects of surgery

Cognitive domain	Test and source of RCI/SRB	Administration time (min)
General intelligence	WAIS-R,[a,b] WAIS-III[c]	90[20]

4. Meaningful change. A change in a test score that is "statistically reliable" may not always represent a change that is clinically meaningful or even noticed by the patient. Patients who show a reliable decline on objective verbal memory tests are more likely to report a subjective change.[57,58] On the other hand, correlations between objective memory performances and subjective assessments have generally been weak and confounded by emotional factors.[61,74,92] It has been suggested that these weak

relationships reflect the inclusion of large numbers of unchanged patients in these analyses. Because their judgments are more prone to other biases, they obscure the stronger relationship between objective and subjective measures in those who have truly experienced changes.[57] There is very limited information about the relationship between changes on neuropsychological tests and changes in functional status (e.g., employment or ability to carry out complex activities of daily living).

The Neuropsychological Assessment

A range of tests can be used in neuropsychological assessment of the epilepsy surgery candidate.[50] In principle, assessment should provide a robust estimate of cognitive domains that are affected by surgery. Test selection therefore depends in large part on the area and side of surgery. A typical assessment battery contains a measure of overall intellectual function—typically a Wechsler IQ test, which can be administered in its entirety or in an abbreviated form, using subtests sensitive to changes in affected cognitive domains. Batteries should employ redundant measures of affected domains to increase sensitivity to surgical effects because cognitive failures in epilepsy often are intermittent (e.g., word-finding problems). Measures of verbal learning and verbal retrieval are overrepresented in the tests listed in Table 2 because these domains are particularly affected by temporal lobe dysfunction. On the other hand, assessment of patients with frontal lobe epilepsy should be weighted toward "executive" functions such as working memory, concept formation and response initiation, inhibition, and shift.

Neurocognitive Changes After Surgery

Most of the available information has come from patients who have undergone mesial temporal lobectomies with partial or complete hippocampectomy. Estimates of the incidence of change from studies prior to the development of RCI methods are unreliable, for reasons stated earlier. In studies that have used RCI or SRB methods, improvements in cognitive scores are relatively uncommon at the group and individual levels. Specifically, most studies reported that <15% of patients improved on a measure of verbal memory.[23,42,60,74] Reliable decline in verbal memory occurred in 21% to 58% of patients after dominant temporal resections and in 2% to 34% of patients after nondominant temporal resections in these studies. Reliable declines on tests of nonverbal memory were reported in 2% to 34% of cases. Variability in incidence of change across studies probably reflects differences in patient selection, tests employed, and how reliable change was defined.

Psychiatric Disorders

For studying psychiatric conditions, perhaps most important and least realized is the need to do an independent, standardized assessment of psychiatric conditions. Reliance on medical records has been shown to be very insensitive to psychopathology because many individuals are never adequately if at all diagnosed.[22,33]

Table 3 Instruments frequently used for psychiatric assessments in research studies

	Type of measure	Adminstration and time	Comments
ASEBA[1,2,3]	Checklist for current/recent behavioral problems, not diagnostic	Self, 15–20 min	Multiple forms available for proxy and self-report at different ages, population norms
BAI, BDI[8,9]	Checklists for current anxiety or depression, not diagnostic	Self, ~5 min each	For BDI, good sensitivity and specificity when compared to diagnostic instrument
CES-D[67]	Checklist for current depression	Self, ~5 min	—
CIDI[70]	Complete psychiatric interview	Administered by trained interviewer, 15 min–1 hr	For adults
DIS,[69] DIS-C[77]	Complete psychiatric interview	Administered by trained interviewer, 15 min–1 hr	Adult and child versions are comparable

ASEBA, Achenbach System of Empirically-Based Assessment; BAI, Beck Anxiety Inventory; BDI, Beck Depression Inventory; CIDI, Composite International Diagnostic Interview; CES-D, Center for

Epidemiologic Studies Short Depression Scale; DIS, Diagnostic Interview Schedule; DISC, Diagnostic Interview Schedule for Children.

There are several high-quality instruments available for measuring psychiatric disorders (Table 3). Note that they do not all measure the same concept, or if they do measure the same concept, it is in ways that are not strictly comparable.

P.1933

Symptom Checklists Versus Diagnostic Interview

Symptom checklists such as the Beck Depression and Anxiety Inventories (BDI and BAI, respectively)[7,8,9] and the Center for Epidemiologic Studies Short Depression Scale (CES-D)[67] provide rapid assessments of the respondent's current or recent state. They are self-administered and only take a few minutes each to complete. The item responses can simply be summed to provide a continuous measure. Cut-offs are provided by the tests' developers to identify respondents with mild, moderate, and severe depression. A recent comparison of these checklists for measuring depression versus a diagnostic instrument indicated a very high degree of both sensitivity and specificity.[49]

A popular group of instruments used for children in studies of epilepsy is the Achenbach System of Empirically-Based Assessment (ASEBA). The Child Behavior Checklist (CBCL) is perhaps the best known of the instruments in this group, and several versions of this instrument are available.[1,2,3] For children of age 6 to 18 years, there are parent-completed and teacher-completed forms. A youth self-report version is available for children of age 11 to 18 years. A young adult self-report module was recently replaced with another for adults of age 18 to 59 years. Proxy respondent (parent, caretaker, spouse, or other) versions are available for the same age range. These instruments are worded in the present tense, and respondents are asked to respond based on their experiences over the last 6 months.

The Achenbach instruments provide a series of narrowly defined scales as well as broader scales for overall, internalizing, and externalizing behavior problems. Cut-offs for clinically significant behavioral problems are also provided. Some of the scales are "*Diagnostic and Statistical Manual* (DSM) oriented," that is, they tap into the concept of, for example, depression, but are not meant to be used as diagnostic instrument. For research purposes, however, these instruments provide numerous advantages. Results for each scale are reported as t-scores age and sex-normed to a population sample. A dichotomous assessment of clinically significant or not is also provided for each scale. In addition, the ASEBA instruments are self-administered and generally only take about 15 to 25 minutes to complete. At least in children with epilepsy, they have become a common means for assessing behavioral problems.[4,66] Because of the consistency in content across forms designed for different age ranges and because of the standardization procedures used, it is possible to follow someone from childhood into early adulthood. This should only be done using the same informant. A youth self-report can be compared to an adult self-report. A parent report on a child, however, should not be compared to a later self-report by that same individual. In fact, multiple proxy reports on a given individual should probably use the same proxy (e.g., the mother for all or the father for all). The ASEBA instruments for adults are relatively new and consequently have not been used as extensively as the instruments for children. This approach provides a well-validated means of quantifying current behavioral traits and is highly practical for research purposes.

Diagnostic Instruments

Instruments such as the Composite International Diagnostic Interview (CIDI),[70] the Diagnostic Interview Schedule (DIS),[69] and the Diagnostic Interview Schedule for Children (DISC)[77] are designed to cover a wide range of psychiatric disorders but are also designed in modular format so that selected parts of them can be given. Such instruments are designed to provide diagnoses according to DSM criteria. The diagnoses are not just for current state but for lifetime as well. The approximate timing of the initial diagnostic episode of a disorder can also be obtained from these instruments so that age at onset can be estimated. These instruments are administered by a trained lay interviewer. The training courses for these instruments can be costly and can take up to several days to complete. These instruments can also take >1 hour to administer, depending on whether the respondent endorses key questions pertinent to specific diagnoses. The DIS for adults and DISC for children are designed so as to be as comparable as possible, facilitating their use in a study group of mixed ages or for follow-up of younger study participants into adulthood. The Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS) is another popular instrument for use in children and has been used specifically in children with epilepsy.[52]

Although diagnostic instruments such as these seem ideal and provide information not obtained from a simpler checklist approach, they are much more cumbersome and expensive to use. It might be difficult to obtain cooperation of study participants with repeated use of such instruments. A very careful assessment of the precise research question and the purpose for asking the question is required before deciding which psychiatric instruments to use.

Psychiatric Outcomes of Surgery

Psychiatric disorders are an important component of understanding epilepsy, its consequences, and its outcomes. Epilepsy is intrinsically associated with a variety of other neurologic and cognitive disorders. Increasingly, depression, suicidal tendencies, and internalizing behavioral disorders have all been shown to be associated with the risk of developing epilepsy, that is, they are present before the onset of seizures.[44,45,46,66] Community surveys of prevalence in epilepsy patients find even high rates of these disorders, and depression has been reported to be present in up to half of patients with intractable epilepsy seen in specialty centers.[75]

The effect of surgery on psychiatric disorders and symptoms is slowly becoming better understood. Earlier reports based on relatively small samples of patients (<100) found improvements in levels of depression and anxiety after surgery. Improvements were seen largely in patients who became seizure free.[17,27] These and other studies have reported paradoxical increases or de novo cases of a variety of psychiatric disorders as well.[16,17,27] Recently, a large, prospective, multicenter study reported on psychiatric outcomes 2 years after surgery.[28] This study demonstrated substantial pre- to postsurgical declines in levels of depression and anxiety. As with previous studies, some patients with presurgically low depression and anxiety levels had developed these conditions when assessed 2 years after surgery. There was a significant but not absolute association between lower depression and anxiety levels and complete postsurgical seizure freedom.

Health-Related Quality of Life

Health-related quality of life (HRQOL) is defined as patients' perceptions of their physical, mental, and social health. Inclusion of HRQOL represents a relatively recent addition to the assessment of therapies.[6,47,93] Advantages of including HRQOL as an outcome measure include (a) detection of impacts of treatment that might be unanticipated and (b) assessment of patients' perceptions of their functioning and well-being; these can provide a summary measure of both the positive and negative impacts of a treatment.

Operationalizing Health-related Quality of Life

HRQOL cannot be directly measured, and there is no gold standard. Instruments for measuring HRQOL typically include a series of questions that are combined into an index or scale. Wherever possible, these instruments are obtained by self-report, either self-administered or interviewer administered. There are two kinds of HRQOL instruments: (a) profile instruments and (b) utility instruments. Both typically yield continuous scores. Utility measures have characteristics that make them appropriate for use in economic analyses of health care.

Selected Issues in Studying Health-related Quality of Life

Two issues in developing and using HRQOL profile and utility instruments are (a) generic versus disease-targeted approaches and (b) ability to detect change, or responsiveness.

Generic Versus Disease-specific Approaches

Generic HRQOL instruments are relevant to and can be used with anyone regardless of health status. A number of generic HRQOL instruments are available and have been used in epilepsy. Generic instruments are particularly useful for making comparisons among people with a variety of conditions or with healthy controls.[96] In contrast, disease-targeted instruments are tailored to a particular disease, although they can include "generic" HRQOL domains that are not specific to that disease. Several profile instruments of HRQOL for epilepsy have been developed over the last decade and applied in a growing body of research.[29,35]

Responsiveness

Ability to detect meaningful changes in actual HRQOL is critical for outcome measures for any longitudinal clinical study and is often the least well-studied property of any kind of outcome measure. Disease-targeted instruments may, in theory, be better able to detect change than generic instruments.[15] In general, instruments that assess a reasonably broad and diverse range of domains are better able to reflect the full impact of a disorder such as epilepsy.[54]

Profile Instruments

Examples of generic and epilepsy-targeted profile instruments of HRQOL are shown in Table 4. The most commonly used HRQOL instrument that has been developed for use in epilepsy contains both generic and disease-specific components.[29]

Results with Profile Instruments

The Canadian randomized trial clearly demonstrated significant and substantial improvements in health-related quality of life in the patients randomized to immediate surgery versus the usual 1-year delay starting immediately after surgery and persisting for the full year.[99] The Multicenter Study of Epilepsy (MSES), a prospective cohort study of surgical patients, has also documented a substantial improvement in HRQOL scores in patients who become completely seizure free after surgery. Most improvements occur within the first year but some continue to accrue at 2 years. After 2 years, no further improvements were seen.[81] Changes in HRQOL appeared to parallel seizure remission, and patients who never experienced a minimum of 1 year seizure free, despite some initial gains, ultimately experienced no meaningful change in HRQOL compared to presurgical levels.

Table 4 Selected generic and epilepsy-specific health-related quality-of-life Instruments

Instrument and reference	Content	Age	Administration time and comments
Impact of Epilepsy Scale[48]	Assesses eight areas, yielding a single score	Adults	Self-administered, 5 min
Epilepsy Concerns Index[35]	Epilepsy specific, derived from surveys of adults with epilepsy	Adults	Self-administered, 20 items

Child Health Questionnaire[53]	Generic measure with multiple domains including physical and mental health and impact on family	Children, 6–16 yr	There are separate child and parent report versions; each takes 15–20 min
SF-36[41]	Generic measure with physical and mental health aggregate scores and individual scales	Adult, >16 yr	Self- or interviewer administered; ~10 min; national age- and gender-adjusted norms available
Epilepsy Surgery Index (ESI)-55[95]	Epilepsy-specific with generic (SF-36) core; three composite scores in physical health, mental health, and role functioning; 11 individual scale scores	Adults	Self- or interviewer administered; 15 min
QOLIE-89[29]	Epilepsy specific with generic (SF-36) core; developed out of the ESI-55; has an overall score and four aggregate scores in domains of physical health, mental health, cognitive distress, and epilepsy-targeted health; also yields 17 individual scale scores	Adults	Self- or interviewer administered; 11 translations available; administration time ~25–30 min

Utility Instruments

Utility instruments measure HRQOL in cost-utility analyses (CUAs) of health care.[36] Utility instruments have two characteristics that most HRQOL profiles do not have. First, they are "preference based" (i.e., they reflect the relative preference, or value, that society expresses for different health outcomes) because the goal of a CUA is to assess how efficiently societies trade valuable resources (e.g., time and material resources,

P.1935

represented by money) to obtain something else of value (i.e., better and longer-lasting HRQOL). Second, utility measures capture the full range of HRQOL on a 0 to 1 scale, where 0 represents death and 1 represents perfect health. Changes on a measure scaled in this way can be directly combined and compared with changes in mortality, using a single index of treatment effectiveness, typically expressed as quality-adjusted life-years (QALYs). For example, an intervention that improves HRQOL over a 20-year period from a value of 0.5 to 0.75 produces 5 QALYs (i.e., [0.75 - 0.50] × 20 = 5). In a CUA, this effect is valued the same as increasing normal, healthy life expectancy by 5 years (i.e., 1.0 × 5 = 5).

Multiattribute utility scales (MAUS) are utility instruments that convert HRQOL profiles to utility scores, based on extensive normative data from community-based samples. A number of MAUS have been developed.[18,30,38,40,51,78,79] Most are generic because they are costly to develop and most CUAs aim to compare efficiency of resource use across different diseases. However, like the HRQOL profiles on which they are based, generic MAUS may be less responsive to change than are disease-targeted instruments.

MAUS have only recently been applied to studies of epilepsypatients.[55,86,87,98] In one study, more severe seizures were associated with lower scores on four MAUS instruments, but instruments varied considerably in their responsiveness to a seizure-free outcome after epilepsy surgery.[5] SF6D, a MAUS based on the SF-36, had the strongest overall evidence for validity and responsiveness, in part due to its focus on psychosocial aspects of HRQOL that are affected by seizures. The Quality of Life in Epilepsy Inventory-89 (QOLIE-89) was more valid and responsive than any MAUS, reflecting its disease-targeted focus and finer-grained measurement scale.

Employment

Many individuals with uncontrolled epilepsy are either under- or unemployed. To the extent that this situation is a result of the seizures, successful epilepsy surgery should, in theory, lead to an improvement in employment. Improvement in employment status could result in financial independence, reduced disability costs, and enhanced quality of life for the individual and greater productivity for society. Long-term documentation of employment outcome, however, has been minimal and problematic due to variability in duration of follow-up when assessed retrospectively and differences in categorization of employed, unemployed, and underemployed, a particularly elusive construct. A standardized and meaningful approach to studying this issue is much needed.

Despite methodologic (measurement) concerns, there are indications from some although not all studies that have examined employment that there are small gains in employment after surgery.[24,37,68,83,99] The Canadian trial found modest and ultimately nonsignificant gains after 1 year.[99] Studies with longer-term follow-up suggest that the gains may require several years to occur, and it is not entirely clear that all of these studies have measured the most important aspects of employment relevant to surgical patients.

Summary and Conclusions

The assessment of surgical outcomes has become more sophisticated and somewhat more standardized. Reasonable and high-quality approaches to study design as well as appropriately sophisticated approaches to measurement and analysis of

P.1936

outcomes are becoming increasingly accepted. The tables in this chapter provide a representative although by no means exhaustive selection of recommended instruments. This may have the beneficial effect of improving the cohesiveness of the literature by eliminating variation due to inadequate methodology and ensuring that investigators gather comparable if not identical information, thus allowing meaningful comparison and pooling of data from several studies. The methodologic bar has been set higher than in the past. For future studies to contribute to existing knowledge, they will need to be large, prospective, well designed, and adequately powered.

As it currently stands, it is amply clear that medial temporal lobe resection provides a significant chance of complete seizure remission. It is also clear that seizure outcomes are not entirely stable over prolonged periods of time. This is an area in need of further investigation. Improvements in seizure outcomes after surgery are linked to improvements in depression and anxiety, health-related quality of life, and employment. All of these factors are intertwined. Surgery also poses some calculable risk in the form of selective neurocognitive impairments, although gains may also be seen.

There are many questions that require continued consideration. Perhaps the two most vexing regard (a) the further refinement of the surgical evaluation and selection protocol to better target surgery to those most likely to experience maximum gains and to steer those unlikely to benefit toward other options and (b) a better understanding of the long-term course after surgery, including the reasons for seizure relapse after a significant period of being seizure free.

Chapter 184

Pre-/Postoperative Rehabilitation

Robert T. Fraser

Rupprecht Thorbecke

Introduction

Although evidence regarding the medical benefits of epilepsy surgery continues to increase,[11,13] the psychosocial benefits of the operation remain less well studied. Dasheiff et al.[9] suggest that the findings concerning the quality of life and functional capacities of patients undergoing resection are not uniformly good. It is important to realize, however, that changes in psychosocial status do not generally occur routinely without some targeted intervention.[6] This is particularly so when substantial neuropsychological impairments, behavioral difficulties, psychiatric problems, and limited cognitive functioning are involved. The patient's situation is further complicated if a difficult seizure disability has been experienced for years with some of the above-mentioned related difficulties. This chapter considers the types and intensity of psychosocial assessment and intervention that are required for psychosocial functioning to be maximized postoperatively.

Psychosocial Outcome in Epilepsy Surgery

Review of the Literature

Dodrill et al.[13] reviewed 17 studies on the psychosocial impact of epilepsy surgery. This review was limited to studies presenting actual data regarding changes in six major areas of functioning, including interpersonal relationships, vocational adjustment, capacity for independent living, impact of seizures on everyday functioning, personal adjustment, and overall psychosocial functioning. It is of interest that psychosocial changes are most commonly evaluated by professional ratings; in only a few instances were standardized tests to assess psychosocial adjustment utilized. Positive changes, however, were found both in the studies that used ratings and in those that used inventories.

Findings from these studies suggest that improvement in interpersonal relationships was noted about two thirds of the time. Changes in vocational functioning were examined more specifically than any other area, and it was noted that employment status generally improved. These positive vocational changes, however, tended to be reported only for patients who were seizure free or nearly seizure free. Individuals with major psychiatric or cognitive problems or who were chronically unemployed seldom made the transition to full-time employment. The criteria in these studies were not often stringent, did not always relate to paid employment, and sometimes included ratings of such items as positive employability and productive work activity in the home. In one investigation, 43 of 60 patients gained partial or full economic self-sufficiency who had had neither before surgery.[20]

The perceived impact of surgery has not been frequently reported in the literature, but in those studies in which it has been addressed, the typical patient has experienced a significant decrease in seizures. Impact on personal adjustment is more difficult to assess; part of the problem is that it has been examined in only a few studies with varying periods of follow-up and has been evaluated from various perspectives (e.g., sexual functioning, personal initiative, and self-image). A final perspective from the review by Dodrill et al. is on changes relative to an index of overall adjustment. Most patients seem to improve psychosexually in these studies, approximately 50% according to an overall index of adjustment. In a decided majority of cases, psychosocial improvement was linked to seizure relief.

More recent studies, not included in the review of Dodrill et al., have also examined aspects of psychosocial functioning. A study by the Montreal group[37] clearly shows positive changes in psychosocial functioning on the Washington Psychosocial Seizure Inventory at 1 year for 15 patients who gained complete relief from seizures; no appreciable positive changes occurred in 15 patients who did not gain complete relief, and on six of eight scales they actually showed a modest increase in problem scores. The importance of seizure relief relative to psychosocial gains is therefore underscored. This is especially the case if there are no accompanying interventions that might maximize the benefits of limited seizure relief.

At the Japanese National Epilepsy Center, Mihara et al.[35] developed a quality-of-life questionnaire with forms designed separately for surgical patients and their families. The questionnaire assessed the following quality-of-life domains: Seizures, role activities, social relationships, leisure activities, emotional well-being, physical well-being, financial status, and memory problems. All patients were followed for up to 2 years after surgery. Patients and their families rated overall quality of life as having markedly improved following surgery. However, the domains of financial status, role activities, and social and family relationships improved relatively little. These areas, including financial status, which subsumed vocational functioning, appear to be more resistant to change. The study underscores the importance of early intervention in order to have an impact on needs and life satisfaction. It is of interest that individual concerns, such as emotional well-being, tend to be affected by the operation, whereas others that are more environmentally determined (e.g., financial functioning or social relationships) are more resistant to change. This type of finding emphasizes the need for targeted psychosocial or rehabilitation intervention of an “ecologic” nature—assisting individuals to deal with the external world through systematic and interactional changes.

Spencer et al.[39] undertook a more sequenced review of quality of life (Quality of Life in Epilepsy [QOLIE]-89) and depression and anxiety (Beck Inventories) at 3, 12, and 24 months from surgery with a large multisite study involving 355 patients. At 3 months, all patients seemed to show significant improvement on quality of life (QOL) and decreased depression

and anxiety. Over time, however, only the seizure-free group showed significantly better QOL with reduced anxiety and depression, evincing a nonsignificant trend in the seizure-free versus the continuing seizure group. These authors concluded that 2 years may be an insufficient follow-up period to determine not only seizure outcome, but also concomitant QOL and psychiatric outcomes.

Gilliam et al.[18] compared the psychosocial status of 125 patients who had received an anterior temporal lobectomy for epilepsy 1 year postsurgery to a group of 71 patients awaiting the operation. Patients who had undergone the operation showed significantly less concern on living with epilepsy on 16 of 20 items of the Epilepsy Foundation of America (EFA) Concerns Index and 8 of 11 scales of the Epilepsy Surgery Inventory (ESI)-55 assessing quality of life. It is of interest that on the regression analysis, mood status, employment, driving, and antiepileptic drug cessation were all predictive of better quality of life, while IQ and seizure-free status were not. The authors cautioned that the controls were still receiving intensive attention and that future prospective, controlled studies are needed involving both surgical and psychosocial intervention. Another study by Aydemir et al.[1] involving a postsurgery versus a presurgery group comparison indicated that QOL was significantly better at a mean of 27 months postsurgery. Continuing seizures, comorbidity, and continuance of antiepileptic medication all negatively impacted QOL.

Findings related to employment outcome following temporal lobe resection deserve special attention. In several studies,[16,17] it appeared that on the whole unemployment rates did not change after temporal lobe resection, although underemployment may be decreased. A study by Guldvog et al.[23] revealed the same findings. Williams et al.,[46] however, reported that overall employment increased after epilepsy surgery from 42% to 62%. These findings may be confounded, however, by the inclusion of students and homemakers in the employed outcome category. There is a consistent trend throughout this literature, however, of individuals with better seizure outcomes correspondingly adapting more easily to the employment market.

Sperling et al.[40] evaluated employment following temporal lobe resection in 86 patients 3.5 to 8 years after surgery. Seventy-three patients qualified for the workforce before and after surgery. Unemployment rates declined after surgery from 25% to 11%. Underemployment was also reduced. Seizure-free status was related to improved employability (e.g., seizure-free patients did better than individuals with only some seizure-free years). Age at surgery also influenced vocational outcome, with older patients (above age 40) doing more poorly than young adults. It is also of note that employment gains came slowly, with some patients taking up to 6 years to obtain work. Individuals who were students at the time of surgery, however, tended to do quite well in regard to employment. This is one of the more detailed analyses of employment outcome that has been attempted. Although a few homemakers were included in the employed categories, the numbers would not significantly affect findings.

A more recent study by Jones et al.[24] followed 61 patients who had anterior temporal lobectomies versus 23 patients not undergoing the surgery and serving as a medical comparison group. Mean follow-up was approximately 6 years from the surgery. The surgical group had almost double the employment rate (69% vs. 39%) of the medical comparison group. Of more importance was the fact that the surgical group was experiencing gains in amount of hours worked and financial independence when compared to the nonsurgical group, which seemed to be "losing ground." There is, however, some doubt concerning the comparability of neuropsychological abilities between study and control groups, as controls were mostly persons for whom surgery was not possible.

A number of other studies focus on psychiatric outcomes. To date, findings appear to be relatively consistent, in that some type of postoperative psychosis develops in <10% of cases,[30] but depression and anxiety occur more often. Both of these disorders appear to be chiefly transient in nature. Fenwick[15] described depression as occurring in as many as 25% of operated patients and being more transient in nature than anxiety disorders, which tend to persist.[26] It would make sense, however, that anxiety could be persistent, particularly if individuals are adjusting to a new seizure-free status and concomitant responsibilities for employment, independent living, and social activity. Williams et al.[46] indicated that there appears be a correlation between some symptoms of emotional distress on the Minnesota Multiphasic Personality Inventory (MMPI) (elevated False and hypomania scales) and improved vocational outcome. They hypothesized that these elevated scales indicate frustration that may be channeled into later positive psychosocial outcomes.

In terms of predicting depression, Derry et al.[12] indicated that the Washington Psychosocial Seizure Inventory (WPSI) Emotional Adjustment Scale was a better predictor of postoperative adjustment than the Center for Epidemiological Studies Depression and other WPSI scales. Glosser et al.[19] indicated that the onset of new psychiatric problems in the months directly following epilepsy surgery may be as high as 31%. At 6 months postsurgery, the severity of these concerns is much lower than preoperation. The Glosser group described patient reaction as a complex symptom entity, involving mixed features of anxiety, depression, and irritability that cycle around the operation.

Most patients continue to be satisfied with the impact of surgical intervention on their psychosocial functioning—approximately 75%, according to Guldvog.[22] Some individuals report satisfaction even if they remain unemployed. Persons undergoing surgery before the age of 30 or as students tend to have significantly better outcomes, particularly vocationally. Patients with poorer cognitive functioning, impairing neuropsychological deficits—specifically of memory—and severe preoperative or postoperative psychiatric conditions can do less well. Koch-Stoecker[28] indicated a strong relationship between freedom from seizure involvement and lack of an axis I or axis II disorder (89%), while only 43% of those with a consistent axis I or axis II disorder reached seizure-free status. As pointed out by Mihara et al.,[35] changes that are more environmentally determined, which would include both employment and family interactions, may be more difficult or resistant to change. Work by Derry et al.[10] suggests the value of assessing the relationship between learned resourcefulness and internal locus of control relative to psychosocial outcome. These authors found that patients who tend to make internally oriented attributions to seizure control (i.e., a significant attribution to personal behaviors) enjoyed more a positive adjustment to their environment.

As reviewed by Dasheiff et al.,[9] the quality of life and functional capacities of patients is not uniformly good after epilepsy surgery. Batzel and Fraser[3] suggested that some of the difficulties relate to the ratings on life satisfaction scales, which because of scale stability require that interventions yield enormous impact to show useful outcome ("a whopper effect"), and also to basic difficulties entailed in using scale ratings. These become particularly problematic when patients and controls rate themselves as high in satisfaction through naiveté, cognitive impairment, or other psychiatric difficulties, or rate themselves as inordinately low because of transient, organically mediated moods. Studies from the Epilepsy Centers at the University of Washington and Bethel are discussed below. These studies have placed significant emphasis on the area of employment.

Another factor influencing postoperative outcome might be preoperative expectations. Several studies have addressed this

point. Thorbecke[43] asked for expected changes in several social domains. The greatest expectations were present for elimination of seizures followed by improved mobility, employment opportunities, sports, leisure time activities, more social contacts, and the hope to find a partner. In fact, the perception of difficulties in any social domain correlated consistently and highly with the strength of the expectation of change after surgery. Wheelock[44] and Wheelock et al.[45] asked patients and significant others for expected life changes following epilepsy surgery. Having more friends, being less dependent, others worrying less about the patient, improved marital/family relationships, ability to drive, ability to work, and ability to do more things on his or her own were mentioned most often. Taylor et al.[41] asked 69 patients for expected life changes who already had decided to get surgery, and who were able to depict their postoperative aims with respect to their cognitive and psychiatric status. The mean number of statements was 3 (range 1 to 5). Improved work situation, driving, independence, socializing, and relief of taking medication/relief of side effects were the five most often mentioned aims. Surprisingly, there was little expressed interest in improving cognitive functioning.

An interesting question addressed in these studies is what types of expectations have the best chances to be fulfilled. Wheelock et al.[45] presented the finding that those patients whose expectations were postoperatively fulfilled were more satisfied. This was associated with better psychosocial functioning. Wilson et al.[50] asked the patients preoperatively about their expectations with respect to surgery and postoperatively to rate the success. According to the authors, the successful subgroup primarily reported expectations that led to a practical or clearly identifiable result, such as seizure ablation, driving, employment, and the initiation of new activities. In contrast, the not successful subgroup reported less practical expectations (difference for expectations to become employed <.05) but more expectations of psychosocial nature and the expectation that the operation would generally enhance their QOL. In Wheelock's and Thorbecke's studies[43,45], it was the opportunity to do these practical things now that was delineated as postoperative changes.

In all three studies,[43,44,45,50] no differences with age or gender were reported and persons who had not become completely seizure free reported fewer changes. Wheelock et al.[44] and in a similar way Wilson et al.[50] showed that the expectations of those whose seizures were not completely eliminated but were improved were only slightly or moderately fulfilled. It is evident that these findings should have practical consequences for pre- and postoperative counseling, especially for a better adaptation of those improved but not completely seizure free.

Studies from Bethel, Germany, and the University of Washington

In March 1997, a specialized rehabilitation unit for people with epilepsy was launched within the Bethel Epilepsy Center in order to ameliorate the psychological, social, and vocational consequences of the patients' epilepsies. This program is mainly funded by the state pension insurance, and is run on an inpatient basis with a capacity of 17 places. Enrolled are mainly patients in danger of losing their work or their working capacity, as well as those with a recently diagnosed epilepsy or with a first seizure for whom the question of suitability for their job and the need for retraining is raised. A further group is patients after surgical treatment of their epilepsy with early relapses or with neuropsychological or psychiatric complications or a high risk for such complications. Interventions mainly include modification of the antiepileptic drug regimen; psychotherapy to improve adaptation to epilepsy; patient education about epilepsy; neuropsychological assessment, counseling, and training; sport/recreational activities; assessment and training of vocational abilities in occupational therapy and in real work environments; assessment of the risks inherent in the patients' seizures for driving, sports, everyday activities, and certain types of employment; and extensive counseling of patients and relatives. The interventions are carried out by a multidisciplinary team.[38]

In an ongoing study, a group of 103 patients having temporal lobe resection (TLR) having had surgery after opening of the short-term inpatient rehabilitation unit (STRU) was compared with a group of 103 patients having had surgery before its opening. There were no differences in respect to seizure outcome, side of operation, gender, IQ, and frequency of personality and psychiatric disturbances. The patients operated on after the opening of the STRU were 4 years older than the patients from the early group ($p < .05$). Of the patients operated on after opening of the STRU, 65 postoperatively were enrolled in the program of the STRU, staying there about 3 weeks. Outcome of the 103 patients with respect to employment was compared between the 103 patients operated on before opening of the STRU and the 115 patients operated on after the opening. “Employed” was defined as “employed in the general labor market, homemakers,” “unemployed” but available in the labor force, on early disability, or “sheltered employment.” Unemployment in both groups preoperatively was 34% 2 years after surgery; without specific rehabilitation intervention, unemployment had risen to 34%, whereas it had fallen to 24% in the intervention group.

At the University of Washington Epilepsy Center,[3] differences were assessed in psychosocial functioning utilizing an interviewer-administered protocol, the Washington Structural Psychosocial Review (WSPR), and the Washington Psychosocial Seizure Inventory (WPSI). The study sample included 108 adult patients who had had surgery 5 or 10 years earlier and 83 unoperated controls who had similarly been assessed at 5 and 10 years and were matched by age and education to the surgical group. (Because there were no statistical differences between the 5- and 10-year surgical and control groups, the data were combined.)

On the WSPR protocol, five areas were assessed: Interpersonal skills, emotional adjustment, vocational functioning, adjustment to seizures, quality of life, and an overall adjustment score. Controlling for interaction effects, surgical patients improved significantly more than the controls only on adjustment to seizures ($p < .001$) and overall adjustment ($p < .01$). It appears that both the surgery and control groups perceived themselves as improving at follow-up, and only somewhat more so with substantial seizure relief. Batzel and Fraser[3] concluded that this finding suggests that there may be some type of “halo effect” to the interview, which may be compounded by a patient's neuropsychologic impairment, social naiveté, and other factors.

On the self-report psychometric measure, the WPSI, again controlling for interaction effects, the surgical patients improved more than the controls in four areas: Emotional adjustment, vocational adjustment, adjustment to seizures, and overall psychosocial functioning ($p < .001$). Improvement on the inventory was clearly related to better relief from seizures within the surgery group. Findings appear to be more consistent on this expanded psychometric inventory than in the structured WSPR interview, with its briefer rating format and fewer domains of functioning. It should be noted that changes are not reported in areas more environmentally determined (e.g., interpersonal functioning, family background, and financial status).

One of the more interesting aspects of the findings from the University of Washington research series is related to employment functioning. Discrete aspects of job functioning were compared between surgery patients and controls during the 2 years preceding surgery and the 2 years preceding follow-up.

P.1942

Student functioning was examined separately; persons staying at home and individuals receiving workers' compensation or disability subsidies were excluded from the study. Surgery patients gained in mean number of weeks worked during the second 2-year span (51 weeks after surgery vs. 40 before surgery), whereas the controls actually lost ground (39 weeks before surgery vs. 28 after surgery; significant at $p < .01$).

The surgery patients also did better than controls in earnings and ratings of job performance. The salary gain was particularly impressive; surgery patients were earning $7.09 hourly at follow-up, a gain of $2.88 from before surgery, whereas controls were earning only $5.19 (significant at $p < .01$). There was also a consistent trend for patients whose seizures decreased to do better than those whose seizures did not decrease, with the latter faring about the same as the controls or a little worse on job performance. As reported earlier,[3] the student surgery group did considerably better at follow-up than the student control group, with 18 of 20 (90%) surgical patients working part to full time at follow-up versus 7 of 15 (47%) of the controls ($p < .001$). This study makes a strong case for the vocational and financial benefits of epilepsy surgery, which obviously affects a number of psychosocial domains.

Conclusion

As indicated by Dodrill et al.,[13] improvement is often selectively found in one or more areas of psychosocial functioning after epilepsy surgery but is certainly not universal in nature. Significant relief from seizures obviously can be associated with significant improvement in various domains of functioning. For patients with a significant neuropsychological, behavioral, or psychiatric disability, there is a general limit or occasional decrement in psychosocial improvement. This group does not routinely experience psychosocial improvement. These patients may specifically require targeted counseling and vocational or other types of intervention preoperatively to realize significant gains or at least adjust better to their outcome status. To date, research has focused on assessment of psychosocial outcome, and controlled studies have related preoperative status to outcome or the benefits of targeted intervention. More detailed analysis of preoperative and postoperative status, as in the studies by Fraser et al.,[17] Sperling et al.,[40] and Jones et al.,[24] provides a better understanding of what is happening and the impact of important variables, such as time from surgery.

Psychosocial Adjustment Modeling around Epilepsy Surgery

Recent studies and perspectives are moving the field toward a more uniform and holistic understanding around the surgery event and a better understanding of points for intervention. Derry and Wiebe[11] provide the perspective that preoperative positive psychosocial adjustment, good perceived quality of life, low neuroticism, a tendency toward learned resourcefulness, and available social support all increase the possibility of positive postsurgical outcomes. Poorer prognosis relative to psychosocial outcome related to marked psychological distress, anxiety, and neuroticism; a helpless attitude toward medical self-management; strong unrealistic expectations; and a poor relationship with the patient's physician. A second domain, as illustrated by Wilson et al., relevant to psychosocial outcome is preoperative expectations.[50] Wilson et al.[47,48] added the construct of the “burden of normality” or the demand on medically improved patients to discard the sick role. McLachlan et al.[33] and Wilson et al.[47] added the perspective of lag time in the adjustment process in dealing with this burden and other aspects of psychosocial adjustment. Wilson et al.[47] emphasized that it is important to track the burden of normality demands across different domains of psychosocial functioning to include the psychological, behavioral, affective, and sociologic during 2 years postsurgery and ideally more.

Psychosocial Intervention and Goal Planning

Presurgical Expectations of Patient and Family

As discussed, there can be some very unrealistic preoperative expectations on the part of both the patient and family members. This is particularly true for individuals with lower cognitive levels, neuropsychological impairment, and various types of psychiatric disturbances. Minimally, counseling interventions may be necessary to shape these expectations and build a better bridge to goal realization. More probably, however, activities will be needed that help identify the steps involved in realizing goals made attainable by an improved seizure status. Such activities might include preparations for a change in functional status, such as informational interviews with employers, an actual job tryout, visits to technical schools, entrance into training programs, and training in independent living skills (e.g., managing a budget, using public transportation, cooking). An earlier article[17] presents one case from the Bethel Epilepsy Center, in which preoperative monitoring was delayed until a patient actually began training in independent living skills, counseling, relaxation exercises, and consideration of vocational options. This patient naively believed that an operation would “fix everything,” and involvement in more purposeful and targeted activity was required by the medical team before further medical intervention was considered. As indicated by Dasheiff et al.,[9] patients too often have unrealistic expectations about epilepsy surgery and its outcome. It is often viewed as a method of turning one's life around without having to invest any more effort into the process other than having surgery. As also indicated by Dasheiff et al., individuals who show the greatest degree of psychosocial improvement (unless they are very young at the time of surgery) have been functioning at a higher level of independence before surgery, so that it is important to promote more independent activity as soon as possible.

Work by Langfitt et al.[29] indicated that a family's predominantly positive affect (e.g., affection, appropriate concern, indications of connectedness, etc.) presurgery was significantly related to postsurgery adjustment on the part of the patient. This group recommended further research on treatments that can improve positive family affect in the patient's environment and support of autonomous behavior on the part of the patient. Wilson et al.[50] also suggested that having both patient and family focus on practical expectations (e.g., driving or making vocational gains) as a function of the operation is a better intervention focus than less tangible psychological or social goals (e.g., self-change or new relationships).

Importance of the Assessment Planning Function

Assessment is generally very carefully done, taking into account the medical variables related to surgery and other significant variables, including duration of disease and age at onset. If a functional change is to occur, it is very important that neuropsychological, psychiatric, and social functioning status also be carefully assessed. Another type of assessment described in a prior study[17] includes the actual setting of psychosocial

P.1943

goals using goal attainment scaling as developed by Kiresuk and Sherman[25] for community mental health programs. In this prior article, specific scales developed for each goal constituted a graded series of possible intervention outcomes. Five-point scales are assigned numerical values: –2 for the least favorable outcome and +2 for the most favorable, with a midpoint at 0. These ratings could be established, for example, in relation to a specific vocational goal. Thorbecke[43] used a similar scaling procedure to rate expected levels of functioning in different domains of life on expectation “ladders” with rating rungs numbered from 1 to 10. It is obvious that the more precise the proposed goal and level of expectation, the more probable it is that expectations can be shaped as necessary and goals—or at least more realistic goals—can be achieved. This type of effort would typically be coordinated by a unit social worker, counseling psychologist, or perhaps a nursing coordinator. In the United States today, this type of assessment, goal planning, and scaling of achievements are seldom performed. If a treatment team is interested in effecting significant psychosocial outcomes and quality of life changes with some expediency, it must be performed. Otherwise, the patient may either experience few changes; or, if he or she does achieve them, do so in a more protracted manner, particularly in areas that are more environmentally determined; or could actually lose functional ground, particularly if the operation is not successful.

Steps in Goal Identification

Presurgical Cognitive, Psychiatric, and Social Assessment

Intellectual and neuropsychological assessment is a standard part of the surgical consideration process. With regard to psychiatric or emotional functioning, a psychiatric interview or assessment on the MMPI I or II is also a standard part of the screening process. Because the identification of psychiatric or character issues can have a significant impact on functional outcome, particularly depression or longstanding personality disorders, additional structured psychiatric interviews such as the SCID-II or computerized psychosocial report instruments such as the WPSI are also often used. The Millon Clinical Multiaxial Inventory (MCMI I to III) can be very helpful in identifying personality disorders and longstanding behavioral propensities that relate to axis I diagnoses, such as depression, and can at times benefit from intensive intervention. Personality disorders often go unidentified in the assessment process. Psychiatric conditions are not necessarily a contraindication for surgery, but such individuals may need more monitoring; they can generally benefit from surgical intervention.[27,28] If assessment is minimal in this area, it can be difficult to delineate psychiatric and psychosocial issues carefully, and consequently conditions that may be unlikely to change despite changes in seizure status. Additional methods can be very helpful in planning. A series of studies by Derry et al.[10,12] suggest that assessment of personal responsibility for seizure occurrences and learned resourcefulness may be key variables in predicting psychosocial functioning and predictive of the need for intervention with certain patients. These authors utilized a modification of a questionnaire by Affleck et al.[2] to assess the influence of personal behavior on the occurrence of myocardial infarction. They also utilized a self-control schedule developed by Rosenbaum et al.[36] to assess an individual's level of learned resourcefulness. These measures appear to be very promising in predicting postsurgical psychosocial functioning. Both variables of learned resourcefulness and acceptance of some personal responsibility for seizure occurrences were very predictive of postoperative psychosocial functioning. With severity of illness controlled for, attribution of seizures to stress factors and low level of learned resourcefulness were predictive of postoperative unemployment and receipt of disability benefits. Patients with low levels of learned resourcefulness and high levels of seizure attribution to external stressors might obviously require more intervention than those patients accepting more responsibility for seizure occurrence and having higher levels of learned resourcefulness. Derry et al.[12] also considered measurement of perception of social support as relevant to postoperative adjustment.

Steps in Presurgical Planning

The clinical interview, cognitive and neuropsychological testing, and utilization of psychiatric and psychosocial self-report measures can be very helpful in identifying concerns. Individuals who are cognitively and psychiatrically compromised and also perceive themselves as less in control of their seizure status or have low levels of learned resourcefulness may be particularly in need of intervention. As discussed, planning steps can be based on a goal attainment scaling procedure developed by Kiresuk and Sherman,[25] in which goals across different domains of psychosocial functioning are clearly established and scaled relative to outcome desirability. The method of Thorbecke[43] of scaling levels of expected postoperative outcome relative to functioning in diverse domains of life (e.g., school functioning, social activities, relationship with significant others) on the "1 to 10" rungs of a domain ladder provides a very graphic and simplistic format in which the patient can write expectations that can then be discussed in detail. Necessary steps to reach these goals can subsequently be outlined, which often would be required irrespective of any positive changes in seizure status. Bladin[5] described a very comprehensive interview process to explore patient and family issues most germane to adjustment, including the burden of normality.

Approaches to Rehabilitation

Psychosocial Team

To achieve a favorable outcome with regard to psychosocial status, in addition to the neurosurgeon, neurologist, neuropsychologist, and nursing staff, several psychosocial team members are generally necessary. These may include a vocational rehabilitation counselor to assist in educational and vocational planning, a job site coach or mentor, an occupational therapist for training in independent living skills, a rehabilitation psychologist as a primary therapist for the patient and family members, an educational consultant or tutor, and occasionally an assistive technologist or rehabilitation engineer, who can recommend changes in work site procedures, physical modifications to a setting, or assistive equipment (e.g., dictating machines, palm-top computers, electronic toggle switches that cut off power) that will enable individuals to compensate for cognitive limitations and sometimes alleviate physical safety issues. In any case, referral to state or national departments of vocational rehabilitation or developmental disabilities can be very helpful in securing the services of personnel and funding that are critical to making functional gains in the community. These personnel and services are not available at most epilepsy surgery centers.

Type and Timing of Interventions

Presurgical Interventions

As soon as an individual is identified as a surgical candidate in need of intervention, it should be initiated. This obviously

P.1944

begins with a comprehensive assessment and proceeds to the identification of optimal psychosocial goals and steps required to reach those goals. Individuals with better independent living skills and vocational and educational functioning before surgery will do better after surgery; any incremental gains that can be established in these and other psychosocial areas before surgery are ideal. Education is an obvious area of intervention for all patients undergoing the surgery. Such education should not be related simply to surgical and presurgical procedures but should also involve some discussion of the transitory emotional stages (e.g., anxiety or depression) and headaches, double vision, and other problems that often affect patients temporarily after surgery. The patient must be made to understand by some key member of the allied health team, ideally a social worker or psychologist, that psychosocial changes do not occur magically as a function of the operation, and that planning for functional changes needs to occur presurgically as soon as possible. As an example, one patient was able to complete a full 6-month course in bookkeeping before surgery. Another voluntarily began a job tryout at a science museum, which evolved into a well-paid job in the wood shop following surgery and an ideal gain in seizure control. The education of family members and significant others can be just as important to the patient's psychosocial gains. They often need to begin to change expectations and gradually reduce their level of support so that the patient begins to break away from a "dependent and lower resourcefulness" status before surgery; this is particularly important within families that have not supported the patient's autonomy.

Postsurgical Interventions

Intervention after the operation again often begins with education. Some centers have groups to which the extended family can come to learn more about the postsurgical adjustment process, and more specifically about their loved one's cognitive, emotional, and physical functioning and seizure status. They can also be further oriented or reoriented to realistic expectations for the patient and appropriate modes of interaction with the patient. At the Bethel Center, formal postoperative workshops of this type have been scheduled.

Cognitive, Psychiatric, and Psychosocial Interventions

Interventions related to optimal postsurgical psychosocial functioning, as discussed above, should begin as soon as possible. Goal setting very obviously needs to take into account the individual's general intelligence level and any specific neuro-psychological deficits. This can be problematic when certain interventions are being proposed by external state vocational rehabilitation counselors or school personnel, who may not have a complete appreciation of the individual's difficulties with memory, level of language, capacity for problem solving, or other neuropsychological concerns. Much can actually be accomplished through a team meeting of all involved allied health and service parties; this can be done via speaker phone or other form of telecommunication if the patient lives at some distance from the center and it is difficult to have all members physically present. In one case at the University of Washington Epilepsy Center, a child's school speech and language pathologist, school psychologist, and teacher were all sent for individualized instruction with members of the allied health team. Future communication will be accomplished by conference calls. Knowledge of the individual patient's cognitive strengths and areas of weakness is crucial, and this basic understanding is often lacking or partially lacking.

If patients have difficulty in a specific area of cognitive functioning (e.g., receptive speech, visual-spatial memory, speed of information processing), changes in procedures, physical modifications to an activity site, or assistive equipment at the workplace can be very beneficial. The input of the neuropsychologist can be very helpful in regard to procedural changes. The arrangement of physical modifications or assistive equipment required because of a cognitive problem is often discussed and negotiated by a neuropsychologist and a rehabilitation engineer (assistive technologist) or speech and language pathologist. Most interventions in this area relate to procedural changes (e.g., an individual performing a job from late afternoon to early evening because of attention deficits in a chaotic work setting) or low-cost assistive equipment (e.g., an electronic timer on a watch as a reminder to take medication or a palm-top computer to store important dates, car maintenance schedules, and other organizational aspects of daily living).

Interventions related to emotional functioning generally consist of efforts to ameliorate anxiety or depression, sometimes through antidepressant and antianxiety agents. Verbal psychotherapy that includes supportive interpersonal counseling, utilization of cognitive behavioral strategy, encouragement of moderate programs of physical exercise, building social support, scheduling of social events within budget, and other psychotherapeutic interventions are common. Psychotherapy for individuals with dependent personality propensities can be particularly significant. This intervention can involve Socratic questioning regarding goal identification and steps needed to reach goals, reinforcement of gains, and a general effort to empower the patient and family members to choose and implement steps toward improved psychosocial functioning in the home, at work or school, and within the community.

With regard to social deficits, action steps must be taken presurgically to enable the patient to reach expected changes or precise psychosocial goals. If there are deficits in independent living, this issue can often be remedied through training by an occupational therapist or an assigned trainer from a developmental disabilities agency, or through formal training in budgeting, shopping, or cooking provided by local epilepsy associations. In sum, psychosocial functional changes do not occur spontaneously, and specific steps must be taken to ensure that an individual is functionally capable of living independently, particularly if there is a dramatic reduction in seizure activity.

Remediation of employment or educational deficits can often be accomplished through referral to a local vocational rehabilitation agency within the United States. This agency will assist in providing funding for a vocational evaluation, community-based assessment, and structured job tryout; develop a formal on-the-job training program or job coaching program; or simply assist the patient in obtaining direct placement. In some cases, technical or formal academic education may be recommended, depending on the individual's cognitive capacities, age, and personal desires. Germany and several other countries have specialized work training centers for individuals with epilepsy.

Whenever possible, a representative of the school system should be included in the planning process if the patient is a youngster or an adolescent. In the United States, specific required transition steps may be built into the individual education plan (IEP), for which the school system is responsible. These plans are often more effective if a vocational rehabilitation counselor, social worker, or neuropsychologist affiliated with an epilepsy center provides direct input. For a number of youths, there needs to be a very delicate balance between mainstream and special educational experiences and the development of independent living skills and work-related abilities. Some students within the United States who are eligible for generic developmental disabilities services are kept in school until the age of 21, supposedly as a service to the family. This is often done simply because of lack of direction or considered options on the part of school personnel, parents, and

P.1945

other concerned parties. For youngsters with improved seizure status and residual cognitive disabilities, development of school-to-work plans, vocational and technical training, and interpersonal skills training programs need to be fostered as soon as possible. Activities such as observing people at work, instruction in work-related interpersonal skills, trips to job sites at an appropriate cognitive level for a youngster, and vocational skill development often need to begin during the freshman year of high school. For youngsters with improved seizure status but residual associated disabilities postoperatively, a routine school-to-work transition is often not to be anticipated.

Youngsters with severe epilepsy and accompanying cognitive limitations can be socially isolated to a considerable degree. Assessment by therapeutic recreational specialists can be very helpful to identify leisure time activities and hobbies in which such children can develop competency and that they can use as a social medium. Their peers who are not disabled often develop social skills while engaging in such leisure time activities, and youngsters with severe epilepsy who are anticipating surgery need similar experiences. Work at the University of Washington Epilepsy Center[7] indicates that groups for teenagers are very well attended, as these children seldom have contact with other teenagers because of the problem of frequent, unanticipated seizures. This type of contact can help them to become less self-absorbed and more interested in directed and positive life activities. It can be particularly helpful if formal psychotherapeutic group experiences are mixed with social trips and activities within the community. Adults can similarly profit from this type of leisure time assessment services. On a one-to-one basis, a social worker or counselor can arrange participation in local programs, such as a YMCA physical conditioning program or an age-appropriate social group. When possible, involving several individuals who are to undergo surgical intervention in a specific group can be helpful. Community mobility is often a problem for individuals with severe seizures. Some of these issues can be remedied by training in use of the bus system and any specialty transportation that may be available in the community. Involvement in social groups can also be helpful because transportation options are often available for all group members, or the significant others of group members can alternate in providing transportation.

McCullough et al.[34] have described a multidisciplinary follow-up program for 40 patients who underwent temporal lobe resection at the UCLA neuropsychiatric hospital. In addition to a number of medical and cognitive concerns, several psychosocial concerns needed to be addressed and referrals made. Difficulties at school or work, family readjustment concerns, transitory depression, and changes in attitudes and expectations were common. Through standard monthly contact by an assigned member of the multidisciplinary team, many of these concerns could be triaged effectively and referral made as necessary. Interdisciplinary staffing was also helpful in resolving concerns with appropriate interventions. It would seem that this type of follow-up approach, which can involve simple reassurance and triage, not only fosters and maintains effective psychosocial functioning, but also reduces demands on the medical system and reinforces medication compliance and other aspects of the medical regimen.

Bladin[5] discusses the use of the comprehensive Austin Comprehensive Epilepsy Program (CEP) interview at intake, but more importantly at follow-up periods of 1, 3, 6, 12, and 24 months postsurgery. The interview explores in-depth both patient and family concerns, and that the interview's focus differs over the follow-up period reflects the evolution of the adjustment process. Wilson et al.[48] indicated that a 2-year follow-up period could be minimal. Work by Wilson et al.[49] suggests that psychosocial outcome trajectories can be identified by temporal markers and that patients evidencing markers for negative psychosocial outcome might be better identified for intervention. Cost-effective models of phone follow-up at scheduled intervals can also be borrowed from other disability groups (e.g., the problem identification and triage approach as applied in the field of traumatic brain injury by Bell et al.[4]). Currently, there is a lack of standardized approach to pre- and postsurgical assessment and intervention throughout the industrialized world, while the epilepsy operation itself is becoming relatively common.

Assessing Effect of Surgery with Regard to Rehabilitation and Psychosocial Functioning

Psychometric Measures

(See also earlier section on Psychosocial Outcome in Epilepsy Surgery.) Cramer[8] has reviewed a number of the new psychometric instruments for assessing quality of life, including the QOLIE-89, QOLIE-31, and QOLIE-10. These have been developed as measures of overall patient functioning, with those quality-of-life instruments that comprise a larger number of items and the ESI-55 measuring a number of domains of functioning. These tools provide a means for comparing the effect of different surgical outcomes on diverse areas of functioning, including psychosocial, cognitive, and physical health status. To some degree, they can be helpful for assessing the psychosocial impact of an intervention, as can the WPSI. For purposes of planning rehabilitation and fostering psychosocial gain, however, more specific instruments relating to goal attainment and level of expectation within specific domains of functioning are probably more appropriate, as are other comprehensive interview methods as previously discussed.

Community-based Measures of Effectiveness of Rehabilitation

Although it is at present not done at most centers, it will be necessary to utilize discrete measures of community-based functioning to evaluate more precisely the impact of surgery on psychosocial outcome. Clarification of outcome will be based on scaling of goal attainment or other direct measures of community functioning, such as discrete measures of independent living competencies, number of credit hours taken in school (mainstream vs. special education), grade point average, number of weeks worked full time or part time, hourly wage, promotions, and other indications of upward job mobility. Currently, assessment of functioning in these areas is not routinely done because it is time-consuming and costly, and because of a community re-entry time curve, these discrete measures may not reveal changes for some time postoperatively.

Synthesizing Psychometric and Community-based Measures of Functioning

As underscored by Fabian[14] and Batzel and Fraser,[3] accurate assessment of the psychosocial impact of surgery will eventually require an approach that includes follow-up interview, quality-of-life and WPSI self-report measures, and discrete measures of functioning within the community. Thorbecke[42] pointed out that it must be differentiated between quality-of-life measures, which are subjective in nature and strongly determined by emotional well-being,[31] and more objective measures of life

P.1946

functioning. In this context of reasoning the Bethel group developed the PESOS (Performance, Sociodemographic aspects, Subjective evaluation/estimation) questionnaire. The PESOS questionnaire comprises demographic and clinical data, items on performance in daily activities, and quality-of-life scales.[32] Use of multiple types of measures allows better assessment of different domains of functioning and a more comprehensive view of postsurgical psychosocial outcome.

Future Directions

Postoperative Lifestyle

In years to come, there will be an increasing emphasis on the postoperative lifestyle of the patient. The study by McCullough et al.[34] indicates a number of postoperative issues that deserve attention and intervention, such as independent tapering of drugs by the patient, sexual concerns, sleep disruption, pain, and limited jaw motion. These patients may be "trying on" new life activities and behaviors, and at times the overly confident or naive push their capabilities and place themselves at risk for additional difficulties. It would appear that monthly monitoring by an assigned team member might dramatically curtail injurious or negative behavior while reinforcing positive, goal-related steps. This postoperative period, associated with a number of physical or emotional complications of the desire and expectations for life gains, is a difficult time. For a number of patients, particularly those with poor social support, it can be a particularly confounding experience. This period of time requires more team attention and an emphasis on intervention follow-through.

Social Support

In addition to monitoring by an assigned team member, promotion of social support activities can be very helpful for postoperative patients. Linking patients presurgically with successful postoperative patients can be both inspiring and comforting. Receiving instruction regarding to the diverse aspects of the operation in a group setting can also be very comforting. Promoting preoperative and postoperative development of small groups that include patients' significant others can have a very positive effect but should be monitored to some degree based on patient homogeneity. Individuals with a number of associated impairments, particularly postoperatively, are simply not going to do as well psychosocially as successful peers, and group experiences may be rather difficult within the context of others who are doing well and making significant life gains. Phone networks can be helpful for individuals who are coming into a center from rural areas and have no contact with others who have experienced surgery and, in some cases, no contact with others who have the disability. Parents who are attempting to change expectations and set new realistic goals for a son or daughter could benefit from contact with other parents and the significant others of those undergoing similar experiences.

Dealing with Postoperative Complications

There are a number of postoperative issues that occur infrequently but present decided concerns for individuals who experience them. These can include visual field problems, double vision, memory decrements, word-finding problems, and other, usually subtle, neuropsychological concerns. In some cases, these problems are transitory in nature. When visual problems are not temporary, referral to a neuro-optometrist or neuro-ophthalmologist can be helpful. In some cases, those with visual problems can profit from training in scanning and visual perception techniques,[21] but longer-term concerns can require considerable time for adjustment.

Memory problems can be overcome through training in association techniques and categorization of information that needs to be remembered, as well as the use of electronic calendars, palm-top computers, notebooks, and diverse electronic cueing devices. Some patients who make the effort and are well organized can perform as well or actually better than peers. Individuals with language problems, particularly word finding, can be coached to "stall" or have a question repeated until they can respond appropriately. For individuals with more complicated cognitive problems, such as paresthesias, psychotherapy can aid in adjustment. It must be emphasized that complications occur in a minority of cases, but unforeseen complications do occur.

New Research Directions

As mentioned earlier, future research should focus on more detailed analysis of preoperative and postoperative psychosocial functioning using a multimethod approach that includes structured interview quality-of-life inventories and discrete measures of community functioning. A multimethod approach would thus include the perception of patients and their significant others of the psychosocial impact of the surgery. The inclusion of more discrete measures of community functioning (e.g., weeks worked on a full-time or part-time competitive basis) provide more of a "tire meets the road" view of outcome. Detailed, multimethod preoperative and postoperative assessment, including new measures such as learned resourcefulness, burden of normality, and causal attribution of seizures, will make possible more precise identification of those most in need of preoperative and postoperative intervention, leading in turn to better characterization of those who require interventions, even among the group that are currently anticipated to have problems (i.e., those with associated disabilities, who are older, and have a longer seizure history). Eventually, it is hoped that preoperative and postoperative evaluation of interventions will be done more frequently.

Summary and Conclusions

This chapter has reviewed the literature on psychosocial outcomes following epilepsy surgery and predictors of postoperative functioning. A perspective has been offered on both the preoperative psychosocial assessment process and the importance of refining the expectations of patients and their significant others to establish realistic postoperative goals. It has also been emphasized that psychosocial or rehabilitative intervention must begin before surgery and that psychosocial functional changes will not take place incidentally, except perhaps in the case of those who are relatively young at the time of surgery. It is also critical that more detailed, multimethod analysis of psychosocial functioning be conducted preoperatively and postoperatively as progress is made toward more targeted intervention to improve postoperative functioning. Much remains to be done to improve the psychosocial functioning of a patient who is being rendered physically functional through the benefits of epilepsy surgery. Progress in overcoming rehabilitation challenges is made difficult by limited personnel, limited funding, geographic distances, and to some degree limited emphasis on the part of the medical community. It is hoped that this attitude will change in the future, with greater emphasis placed on evaluating psychosocial interventions before and after the operation, as opposed to assessing quality-of-life changes as a function of the medical intervention.

Chapter 185

Special Considerations for Pediatric Epilepsy Surgery

Michael S. Duchowny

J. Helen Cross

Gary W. Mathern

Introduction

The surgical treatment of pharmacoresistant partial seizures in children has come into its own as a primary therapeutic option. Several factors have contributed to this important trend. First, an increasing body of information concerning the natural evolution of many clearly defined pediatric epilepsy syndromes suggests that early definitive surgical intervention is the most effective and perhaps the only way to completely eliminate seizures. Second, chronic epilepsy is now understood to be a progressive disorder with deleterious consequences for cognition, behavior, and socialization. Finally, evidence is now emerging that surgically induced seizure freedom may have positive and lasting benefits on the quality of a child's life and improve overall family functioning. This chapter reviews key elements of the evaluation of pediatric patients for epilepsy surgery, special aspects of the surgical procedures, and the outcome of epilepsy surgery.

Preoperative Evaluation

Ictal Semiology

The presurgical evaluation of children with medically resistant seizures must accurately assess the nuances of ictal semiology in the developing brain. The manifestations of partial seizures in very young patients often differ considerably from those in adolescents and adults. For example, complicated behavioral disturbances, auras, and other sensory alterations are decidedly unusual in young children.[57] Automatisms in the infant are typically primitive, consisting of simple sucking or chewing movements or simple gestures.[10] There is also an enhanced tendency for partial seizures to secondarily generalize in infants and toddlers, not uncommonly almost immediately after seizure onset. In contrast, complex partial seizures with pure loss of awareness are less common in children and rare in infants. Similarly, formed hallucinations and illusions are uncommon, suggesting that limbic-cortical networks have not fully matured.[52]

Video/electroencephalographic (EEG) analysis of seizure patterns in children reveals that certain ictal seizure manifestations consistently lateralize seizure onset throughout childhood, whereas others have lateralizing value only at the end of the first decade.[34] Unilateral tonic or clonic seizures, Todd paralysis, nystagmus, and postictal nose wiping lateralized seizure onset in children of all ages. In contrast, unilateral manual automatism, dystonic posturing, version, postictal dysphasia, and postictal facial wiping occur more frequently in older children. Thus, older children have a greater tendency to manifest lateralizing seizure semiologies, which suggests that the evolution of seizure manifestations in childhood occurs in step with increasing brain maturation.

Infants constitute a particularly challenging population to evaluate for surgery because their ictal manifestations may be subtle or nonlateralizing. Attempts to classify seizures in infants according to International League Against Epilepsy (ILAE) criteria are often difficult.[85] Automatisms are typically brief and simplified in appearance. Head version, a classical lateralizing finding in adults with partial epilepsy, may be less forceful and sustained and less likely to have true lateralizing value.[1] Whereas focal motor seizures are reliably contralateral to the hemisphere of seizure onset, hypomotor patterns are common in childhood and more likely to be accompanied by generalized EEG discharges.[45] Hypomotor seizures associated with regional EEG onsets are usually of longer duration and begin in the temporal or parietal lobes.[62] Epileptic spasms are particularly frequent in infants with intractable epilepsy. They are more often observed in the context of generalized syndromes but may also accompany localization-related epilepsy syndromes.[24]

Electroencephalogram

The EEG evaluation continues to be the cornerstone of the pediatric evaluation for epilepsy surgery. The identification of a discrete focus of seizure origin greatly simplifies surgical planning and increases the likelihood of seizure freedom. In a study of the value of preoperative scalp EEG in 47 children who had focal resections for intractable epilepsy, Vossler et al.[97] found that children with a single interictal focus (or a single focus with rare discordant discharges) or who demonstrated unilateral well-localized or lateralized seizure onsets in serial routine scalp EEG recordings obtained high rates of seizure relief. Localized EEG findings are especially useful when they converge to the same anatomic location represented in other diagnostic modalities such as anatomic or functional imaging.

Pediatric long-term monitoring units use recording equipment similar to that in adult units. Higher overall activity level in children, however, requires certain modifications in the recording protocol. More frequent periods of physical activity may be necessary to ensure completion of the monitoring. Frequent assessment of electrode contact and integrity of the recording system will prevent excessive movement artifact. For infants and toddlers, replacing the metal side rails of the hospital crib with a sheet of clear Plexiglas assists in viewing video-recorded seizures.

Satisfactory localization of the primary epileptogenic zone is more often achieved in adults who are more likely to have temporal lobe epilepsy and hippocampal sclerosis (HS) as the underlying pathologic substrate. The detection of HS is now

routine using high-field-strength magnetic resonance imaging (MRI) magnets, and the scalp EEG is then viewed as a confirmatory tool in preparation for temporal lobectomy. Even the necessity of long-term monitoring in adult patients has been questioned at some centers because MRI evidence of HS in conjunction with the ictal semiology is deemed sufficient for establishing the diagnosis of the temporal lobe syndrome.

In contrast, medically resistant localization-related seizures in children are less often anatomically and functionally specific. Developmental anomalies of the cerebral cortex are particularly prevalent in children referred for surgical evaluation and arise throughout the cortical mantle.[27,100] Although a certain proportion of children have discrete lesions that are amenable to resection, multiple or poorly defined epileptogenic regions are common. Despite advanced neuroimaging techniques, there remain a significant proportion of children with cryptogenic seizures with normal imaging.

Even seizures arising in the temporal lobe pose a significant challenge in the child. Early-onset temporal lobe seizures are often neocortical in origin, and HS typically occurs as “dual pathology” with cortical dysplasia rather than as an isolated lesion. In these situations, the spike field may be less well defined on scalp EEG recording. Additional electrodes such as sphenoidal or nasopharyngeal recording are unlikely to yield definitive localizing data and are rarely employed at pediatric centers.

Magnetoencephalography (MEG) has recently been advocated for localizing seizure origin in pediatric epilepsy surgery candidates. In an MEG study of 11 children undergoing evaluation for intractable, nonlesional, extratemporal localization-related epilepsy, 10 demonstrated anatomic localization of epileptiform discharges that corresponded to the ictal onset zone established by intracranial EEG recording.[80] Three-dimensional magnetic source imaging (MSI) data has been successfully interfaced with neuronavigation in pediatric patients.[53] Ictal MEG identification of epileptic foci has also been correlated with zones of hyperperfusion on ictal SPECT studies.[103]

Invasive Recording

The limitations of the scalp-recorded EEG and the higher proportion of cryptogenic cases in childhood have led to the use of invasive EEG recording in many children. Depth electrodes record very few data points and are employed primarily in adults with temporal lobe epilepsy where targeted recording from mesial temporal structures provides adequate localization. Children with neocortical epilepsy are less likely to benefit from depth electrodes due to their limited ability to monitor widespread convexity and basal cortical surfaces. The pediatric epilepsy surgical evaluation therefore relies more on subdural electrodes accurately to localize seizure origin and functionally map the neocortex. Subdural electrodes accurately localize seizure origin while maintaining an acceptably low complication rate, even in very young children and infants.[29,101]

Potential indications for implanting subdural electrodes in children include the following:

- Normal or nonlocalizing neuroimaging. Without accurate localizing information, it is often difficult precisely to define a surgical target. Electrocorticography has been advocated for defining the epileptogenic zone but is often inadequate. Intraoperative recording under general anesthesia provides only limited interictal data. Furthermore, cortical malformations often present with diffuse borders that are not easily characterized. In a series of 53 children undergoing excisional procedures for intractable epilepsy, seizure freedom was achieved in 70% of patients who had complete resections. In contrast, only 10% became seizure free when the resection was incomplete, typically due to critical cortex precluding complete removal of the epileptogenic region.[58]
- Widespread epileptogenic zone. Lesionectomy guided by electrocorticography is generally adequate for evaluating developmental tumors and other noninfiltrative lesions rather than low-grade cortical dysplasia. If MRI and scalp EEG data are discordant, especially with regard to subtle developmental lesions, subdural recording may yield valuable information to help tailor the resection.
- Multilesional and multifocal epileptiform activity. This situation is not uncommon in children with intractable epilepsy. Subdural electrode placement assists in determining which lesion and which epileptogenic region are clinically relevant. For example, children with tuberous sclerosis complex may have so many tubers that it proves difficult to accurately identify the tuber responsible for seizure origin. Alternatively, more than one tuber may be triggering seizures, necessitating a more complex presurgical evaluation of multiple sites.
- Subcortical epilepsy. In rare situations, subcortical lesions may be responsible for intractable partial seizures. Hypothalamic hamartomas are most often defined on neuroimaging, but direct recording from the hamartoma reveals focal spiking and confirms seizure origin.[72] Heterotopic gray matter[71] and cerebellar gangliogliomas in infants[49] have also been implicated in intractable seizures through the use of invasive EEG recording.

Functional Cortical Mapping

The application of adult stimulation parameters to children has produced equivocal results. In childhood, the response to direct cortical stimulation using increments in stimulus intensity to a maximum of 15 mA can be inconsistent, and when studies of electrical stimulation are controlled for age, reduced motor responses are observed, especially in children younger than age 4 years.[84] Careful analyses of elicited responses reveal that the thresholds for afterdischarges and sensorimotor responses both have an inverse linear correlation with age.[4]

One solution to the problem of maturational influences on cortical responsiveness is to modify the standard adult stimulation paradigm by delivering stimulation in stepwise increments.[55] By alternating the stimulation sequence between increases in amplitude and time rather than amplitude alone, responses in children are reliably generated at the chronaxie, the point on the strength–duration curve corresponding to the lowest amount of energy. Eliciting responses at the chronaxie is especially welcome because there are no established guidelines for electrical safety using prolonged stimulation. The dual-stimulation paradigm successfully elicits sensorimotor responses in infants <2 years of age.[25]

Neuroimaging

The application of magnetic resonance imaging (MRI) and spectroscopy (MRS) protocols in the pediatric evaluation for surgery is similar to that in adults. For example, protocols for imaging hippocampal sclerosis are similar because the incidence of hippocampal sclerosis in children with intractable temporal lobe epilepsy is approximately 60%.[43] Recent evidence suggests that high-resolution MRI also enhances the detection of subtle surgically amenable lesions in children with intractable epilepsy. In a study of 13 children who underwent MRI examination using four-coil phased surface array MRI after a recent standard MRI evaluation, high-resolution MRI identified previously undiagnosed focal abnormalities in 5 of 9

nonlesional patients.[42] These included hippocampal dysplasia, hippocampal atrophy, and dual pathology.

MRS has been used successfully to lateralize seizure onset in children with temporal lobe epilepsy.[17] MRS findings generally complement the MRI exam, but rare children will demonstrate a previously undetected localized abnormality or evidence of bilateral involvement. Although no systematic studies of MRS have been performed in children with cortical malformations, studies conducted in adults indicate variability in the detection of metabolic abnormalities that are pathologically based. Patients with focal cortical dysplasia showed significant metabolic abnormalities corresponding to structural lesions, whereas patients with heterotopia and polymicrogyria did not.

Single Photon Emission Computed Tomography

The widespread availability of single photon emission computed tomography (SPECT) cameras in nuclear medicine facilities, the low cost of γ-emitting isotopes, and the introduction of more stable radiopharmaceuticals have facilitated SPECT studies at many pediatric epilepsy centers. SPECT has been employed successfully to evaluate a wide spectrum of pediatric epilepsy surgical syndromes, including Sturge-Weber syndrome,[11] tuberous sclerosis complex,[65] Rasmussen syndrome,[33] hemimegalencephaly,[96] and focal cortical dysplasia.[44]

Ictal SPECT studies remain the procedure of choice for localizing a high proportion of children with partial epilepsy.[51] Ictal SPECT revealed hyperperfusion in 14 of 15 children with temporal lobe epilepsy undergoing preoperative evaluation.[48] In 4 children, ictal SPECT provided additional localizing information that was absent from ictal EEG recordings. Similarly, Cross et al.[17] reported abnormalities on ictal SPECT in 13 of 14 children with both temporal and extratemporal seizures. The timing of injection was critical because injections >30 seconds postictally were less likely to yield reliable measurements of regional cerebral blood flow. Pediatric ictal SPECT studies also reliably colocalize the epileptogenic zone demonstrated by intracranial EEG recording and correlate with higher rates of surgical success.[64]

In contrast, interictal SPECT injections are a significantly less reliable localizing tool in pediatric patients.[47] Normal studies or uncertainty regarding regions of hypoperfusion may potentially be misleading and are rarely relied on for surgical decision making. Ictal SPECT studies may be used to confirm localizing data from EEG and MRI investigations or to define the epileptogenic region in children with normal or discordant EEG and imaging data. SPECT may also play a role in clarifying the extent of the epileptogenic region and assist in placing intracranial electrodes.

Positron Emission Tomography

Although it is less widely used in the pediatric setting, positron emission tomography (PET) studies successfully localize seizure origin in patients with West syndrome[14] and other epileptic encephalopathies,[87] Sturge-Weber syndrome,[13] tuberous sclerosis complex,[61] frontal lobe epilepsy,[21] and generalized tonic–clonic seizures.[67] PET studies are particularly useful in children with extratemporal epilepsy and childhood syndromes with apparently generalized epileptic discharges.

PET also has been used in the presurgical localization of eloquent cortex in children with seizures. PET mapping of eloquent language, motor, and visual areas was accomplished in 15 children by coregistering PET images of task-activated cerebral blood flow onto MR images.[30] All patients had lesional epilepsy. PET mapping was well tolerated in all cases.

The absolute reliability of PET as a stand-alone localizing tool in the pediatric epilepsy surgical evaluation has been questioned.[93] Whereas [^{18}F]fluorodeoxyglucose (FDG)-PET studies in older children and adolescents yield results similar to those in adults,[38] with one exception,[87] there are no longitudinal studies of PET in younger children. It has also been shown that [^{11}C]flumazenil PET is significantly more sensitive than 2-deoxy-2-[^{18}F]fluoro-D-glucose for detecting cortical regions of seizure onset and frequent spiking in children with extratemporal epilepsy and that both radioisotopes have low sensitivity with rapid seizure spread.[83]

Functional Magnetic Resonance Imaging

Functional MRI (fMRI) has reliably been used to localize language, sensory, motor, and visual functions in children and can influence surgical planning.[7]

Language mapping with developmentally appropriate paradigms generates localizing data in children that are similar to those in adults. Cooperative children as young as age 5 years have been studied successfully.[37] It is now clear that networks for auditory processing are regionally localized and lateralized by age 5 years.[2] Receptive language sites are located primarily along the superior temporal sulcus, similar to the case in adults, suggesting that language localization and network formation are established in early life. False lateralization of language cortex to the homologous nondominant hemisphere may occur in children in the postictal state.[56]

Sensorimotor cortex can be positively identified using paradigms in which the child taps a finger or toe, wiggles the tongue, or has an extremity brushed. All of these paradigms are simple to apply and achieve reliable results, even in very young children. The location of sensorimotor function by fMRI agrees with localization data obtained by direct cortical stimulation.

Surgical Procedure Issues

Neurosurgical procedures pose special challenges for smaller children, and this is especially true for epilepsy surgery, in which younger patients undergo larger cortical resections than do older children and adults. In 2004, the Pediatric Sub-Commission of the ILAE conducted a survey of 20 pediatric epilepsy surgery centers in Europe, Australia, and the United States, collecting presurgery information on >500 patients of age <18 years.[50] Of infants of age 1 year or less at surgery in the ILAE survey, 90% underwent multilobar resections or hemispherectomy, and the most frequent etiologies were multilobar cortical dysplasia (37%), hemimegalencephaly (30%), and Sturge-Weber syndrome (13%). By comparison, 65% of 10-year-olds had focal or lobar resections, and the substrates were tumors (20%), hippocampal sclerosis (20%), and focal cortical dysplasia (20%). In other words, the younger the child at epilepsy surgery, the greater was the likelihood that his or her symptomatic substrate involved hemispheric etiologies requiring large cerebral cortical resections.[78]

Large cerebral operations are associated with significant operative blood loss relative to total vascular volume in small children.[9,15,41,68,69] In children, brain weight is proportionally larger than body volume compared with adults. At age 2 years, for example, the brain is approximately 70% of its adult size, whereas body weight is about 12% of adult weight. At 10 years of age, brain weight is 95% of adult values and body weight is 50% of adult weight. Put another way, the vascular cerebral cortex receives a large proportion of cardiac output in infants and children compared with teenagers and adults. Of equal importance is that total vascular volumes are smaller in young children than in adults. Infants weigh between 6 to 10 kg at 6 months and 8 to 12 kg by 1 year. Estimated total blood volume (75 cc/kg) is 450 to 750 cc at 6 months and 600 to 900 cc at 1 year. By comparison, 10-year-olds weigh between 23 and 51 kg, and estimated blood volumes range from 1,700 to 3,800 cc.

P.1952

Expected blood loss varies by operation, and generally ranges from 200 to 500 cc for a focal or lobar resection to 1,500 cc or more for an anatomic hemispherectomy.[88] Thus, in a 6-month-old, even relatively small epilepsy surgery procedures will result in blood loss equal to half or more of total blood volume, and larger operations, like hemispherectomy, will involve more than a total body transfusion of red cells and corresponding blood-clotting factors like fresh-frozen plasma. Blood loss and other complications appear to be more common in cases of hemimegalencephaly because the cortex is very vascular and dysmature.[6,23,60,77,91] Anticipating these operative and postsurgery problems requires a dedicated team of neuro-anesthesiologists and pediatric intensive care physicians who treat problems before they occur, adequate vascular access and monitoring for ongoing blood loss during surgery, and a surgical approach that minimizes operative blood loss.[19]

Waiting for the child to grow larger before performing surgery does not reduce operative risks over the first 3 years of life and significantly increases the probability for poorer cognitive outcomes in children at risk for epilepsy-induced encephalopathy. Two-year-olds weigh between 10 to 15 kg, whereas 3-year-olds weigh from 11.5 to 17.8 kg, and calculated vascular volumes are 750 to 1,100 cc for 2-year-olds and 860 to 1,300 cc for 3-year-olds. Thus, hemispherectomy operations, where blood loss is expected to range from 500 to 1,000 cc with newer disconnection procedures, is still associated with operative blood transfusion in young children, especially those with large regions of cortical dysplasia and hemimegalencephaly.[15,60] Thus, the risk of surgery is not significantly reduced in a 2- or 3-year-old compared with an infant. In addition, recent data indicate that operative delays in infants that exceed 12 to 18 months from seizure onset to surgery are associated with poorer development quotients compared to children with shorter seizure durations.[6,22,59] Hence, although operating in young children is riskier than in adolescents and adults, increased operative risks are justified to prevent permanent epilepsy-related cognitive and developmental deficits.

In infants, the earlier the surgery and the sooner the seizures are stopped, the better are the long-term cognitive outcomes. Surgery should be performed at epilepsy centers with the necessary experience and dedicated personnel to minimize operative risks, especially for infants and small children.[19]

At pediatric centers, close to 20% of surgical cases are performed on an urgent or emergent basis because the child presents with escalating seizure frequencies, including infantile spasms or status epilepticus, that require hospitalization or intensive care unit admission for continuous intravenous antiepilepsy medications or ventilator support.[3,66] These children require relatively rapid presurgical evaluations to detect symptomatic substrates, and the surgical team must be available to react promptly to these urgent situations. Fortunately, operative outcome in urgent cases in children are similar to more routine epilepsy surgery cases. Similarly, the pediatric epilepsy team should consider the risks of agents, such as valproic acid and aspirin, that interfere with platelet and clotting functions in the presurgery evaluation of surgery for children, especially younger children undergoing large resections in which operative blood loss must be minimized.[94] Similarly, the epilepsy team should be aware of diseases associated with epilepsy that affect other organ systems, such as the cardiac and renal tumors associated with tuberous sclerosis complex.[20,92,99] Comprehensive evaluation of these organ systems may be necessary before inducing general anesthesia.

Similarly, it is relevant to discuss the presurgical risk/benefit ratio for Wada or other language tests in young children. These procedures require participation and cooperation, which may be difficult in children with developmental disabilities, and in very young patients they might not be necessary because language cortex can be shifted to the nondominant hemisphere. Finally, it should be emphasized that the perioperative management of children should include sensitivity to reduce excessive intramuscular or subcutaneous injections, appropriate identification of pain in a nonverbal child, and staff ready to deal with children with significant emotional and behavioral issues.

Outcome of Pediatric Epilepsy Surgery

Seizure Outcome

Seizure freedom remains the primary aim of epilepsy surgery in children, although secondary aims may be equally if not of primary importance to some families and require careful consideration and consequent counseling prior to surgery. Seizure outcome in children undergoing resective surgery appears to relate to degree of resection, underlying pathology, and the type of procedure performed, with a wider range of procedures performed and greater proportion with developmental malformations compared to cases in adults.

Adult series suggest that individuals undergoing extratemporal resection have a lesser chance of seizure freedom than do those undergoing temporal lobe resection. Because pediatric series have a greater proportion of extratemporal procedures,[27,78,82,102] one may expect lesser chance of seizure freedom in overall series. Success appears to be related to the underlying pathology as well as the degree of resection. Studies of series of children undergoing focal resection for the treatment of epilepsy suggest that completeness of resection is relevant, whether electrically[86] or structurally[31] determined. Of course, the underlying pathology may influence this.

Some studies of series of children undergoing temporal lobectomy for hippocampal sclerosis have reported similar seizure outcome to adults.[79] These studies, however, appear to have selected children for temporal lobectomy on the basis of adult criteria. More inclusive series of children with higher rates of comorbidities indicate a lesser chance of seizure freedom,[79] but a more recent study reviewing the outcome of children undergoing temporal lobectomy for hippocampal sclerosis did not demonstrate that IQ predicted seizure outcome. Low IQ should therefore not be included in selection criteria for epilepsy surgery.[16] Other studies of a wider range of procedures have agreed with this.[39]

In children undergoing larger procedures such as hemidisconnection, seizure outcome appears to be primarily related to underlying pathology, with lower rates of seizure freedom reported for developmental malformations, particularly hemimegalencephaly,[22] although the completeness of disconnection is relevant. In such studies reporting seizure outcome, however, whether such has been determined is unclear. In addition, the choice of disconnection procedure performed—whether anatomic or functional hemispherectomy, hemispherotomy, or hemidecortication—depends on the neurosurgeon, who in turn may decide on a procedure relative to pathology and structure. Data to date give little comparison outcome figures for different procedures in the hands of a single neurosurgeon.[15]

One question that may arise is whether there is an optimal age for surgery; is outcome likely to be more favorable if surgery is performed at an earlier rather than a later age? Limited studies of surgery performed in the very young (<3 years) suggest that initial 12-month outcome with regard to seizure freedom is similar to that for the older child and again is more likely to be related to the underlying pathology and procedure performed.[27] In addition, many of these children have

catastrophic epilepsies with multiple seizures per day, and significant seizure reduction and/or severity may be of equal importance to seizure freedom, which is achieved in the majority.

A further factor that needs to be considered with regard to seizure outcome following surgery is at which point in time outcome is measured. Studies vary according to the time over which seizure outcome has been determined—anywhere from 12 to 36 months—and there are limited studies of longer-term outcome. This of course is of a high degree of relevance when considering the very young for surgery. Two studies reviewed outcome at up to 10 years following surgery; they again found that pathology can determine whether seizure freedom is seen long term. Mathern et al.[78] reviewed children at 2, 5, and 10 years following surgery and found that those who underwent resection for cortical malformations were less likely to be seizure free at 10 years than were children who had other pathologies. Hamikwa and colleagues[46] reviewed seizure outcome at 10 years in a series of children undergoing surgery for cortical malformations and tumors; the outcome was 32% seizure free for the cortical malformation group as compared to 72% for those with tumors, although little difference was reported between 2 and 10 years.

This is also important when considering children with possible multifocal disease such as tuberous sclerosis.[54,74] It has become clear that when seizures are demonstrated to be arising from a likely single tuber, resection of that tuber may lead to significant reduction in seizures if not seizure freedom.[65] Some data have suggested that in a selected few patients, multiple procedures may lead to benefit.[90] It is difficult, however, to counsel the likelihood of long-term seizure freedom with few long-term outcome data. Jarrar et al.[54] reviewed 21 patients 1 to 14 years following surgery; at 12 months, 59% (13/22) were seizure free, as opposed to 42% (9/21) at 5 years. The likely developmental consequences of this are self-apparent although unproven.

Often, an overall parental aim of surgery is not necessarily seizure freedom, but reduction in anticonvulsant medication. Unfortunately, although there is accumulating data on seizure outcome, very little work has been done on antiepileptic drug reduction in children in particular. Different centers have varying practices with regard to perioperative and postoperative drug reduction. The data suggest that although there are predictive factors with regard to seizure freedom, reduction or withdrawal of anticonvulsants cannot be guaranteed, and such information should be included in the counseling of families preoperatively. In their report of 10-year outcome data for children undergoing surgery for cerebral malformations, Hamikwa et al.[46] noted that 71% were still taking anticonvulsant medication at this time, whereas Mathern et al.[78] reported that 75% were after 5 years.

Functional Outcome

Functional outcome is obviously important, and, in children, particularly the very young, the likelihood of functional reorganization needs to be taken into consideration. One major aim of presurgical evaluation is to determine whether functional deterioration may take place; certainly in the majority of cases that are to undergo focal resection, whether temporal or extratemporal, utmost evaluation is important to minimize the risk of this, proceeding to invasive EEG monitoring and functional stimulation if there is any concern. The advent of functional MRI has enabled this to be precluded in older selected cases.[75,76] Some consideration has been given to the presumption that with early onset of epilepsy in children with temporal lobe epilepsy, reorganization of memory is likely to have taken place. Presumptions cannot be made, however, and language has been found to be localized within malformed cortex even in the presence of early-onset epilepsy in contrast to epilepsy associated with early postnatal insults.[26]

In the case of hemidisconnection procedures, certain functional deficits may be inevitable, such as visual field defects in patients in whom they do not preexist (homonymous hemianopia) or increased motor dysfunction in cases in which preoperatively fine finger movement had been preserved. In the majority of cases, preexistent structural disease and contralateral hemiplegia indicate it as unlikely that deterioration will be seen. With regard to language dominance, again preexistent structural abnormality and early-onset epilepsy imply contralateral hemisphere dominance. In certain progressive conditions, however, such as dominant-hemisphere Rasmussen encephalitis, the likely timing of surgery will be influenced by the likelihood of language recovery, compared to the severity of the disease and degree of cognitive decline. Although the original data suggested that early onset of disease optimized outcome, cases have now been reported of later surgery with subsequent limited recovery of language.[8] Motor deficit is inevitable, and again the decision as to when this should be inflicted is influenced by the degree of clinical progression of the disease.

The decision to perform surgery is often challenging because the risk–benefit assessment requires considerable clinical experience and review of the individual. Such cases mandate careful review in centers experienced in the medical and surgical care of this condition. Children with Sturge-Weber syndrome (see later discussion) may also require risk–benefit decision making regarding the benefits of seizure control through surgery versus functional deterioration. Some children, however, may show improvement in motor function on the hemiplegic side with control of seizures.[22,32]

Developmental and Cognitive Outcome

The rate of cognitive dysfunction in those coming to surgery is high; Vasconcellos et al.[95] reviewed 100 children coming to resective surgery for epilepsy and showed that most had IQ <70, and that this was much more likely with seizure onset <2 years. This was unrelated to the underlying pathology. A further series of children presenting for temporal lobectomy showed 57% with intellectual dysfunction and a high degree of correlation with age of onset of epilepsy, with 82% of children with seizure onset younger than age 1 year showing intellectual dysfunction.[36] One argument for early surgery is the likely presumed improved developmental outcome with seizure control. There are, however, few prospective studies providing clear evidence for this. A recent study reviewed children who underwent resective surgery: 16 temporal lesionectomies, 9 frontal lesionectomies, and 25 more extensive resections (18 multilobar resections and 7 hemispherotomies). It reviewed developmental outcome at least 6 to 12 months following surgery (40 were reviewed for >2–3 years, 70% of whom were seizure free). Of the 40 who underwent longer follow-up, 29 continued to perform at their preoperative levels (gains of <15 and losses of <10 in IQ score) and 8 showed significant gains (>15 IQ points). The study implied that longer follow-up was required to see such changes.

Temporal Lobe Epilepsy

Early data from children undergoing temporal lobectomy suggested little overall risk to cognitive function.[98] A multicenter collaboration of centers in the United States accumulated data from 43 children who underwent left resection and 39 who underwent right resection. For the whole sample, there were no significant reductions in cognitive status. Analysis of individual scores showed that a small percentage either declined or improved in verbal or nonverbal functioning. By definition, all

children included in the study had a full-scale IQ >69. Gleissner et al.[40] examined whether children recovered from memory deficits better than did adults as a consequence of temporal lobe surgery. They matched children with adults for pathology, onset of epilepsy, side of surgery, and type of surgery. This study showed that only children undergoing left resections recovered verbal learning capacity, reaching preoperative levels 12 months following surgery. Children undergoing right resection showed improvement in visual memory compared to adults, who showed deterioration.

Hemispherectomy

Most studies report little longitudinal change in IQ following hemidisconnection procedures, although a “significant” change is regarded to be at least 15 IQ points, which would demonstrate an increased rate of progress relative to peers.[8,22,89] Some report gains, and very few report loss. However, even loss of IQ may reflect poor progress relative to peers and not necessarily frank regression. Pulsifer et al.[89] reported poorer developmental outcome following surgery for developmental pathology compared to acquired lesions such as Rasmussen encephalitis, stroke, or vascular pathology, although numbers in the last two groups were small. They determined that children with developmental pathology had a significantly lower IQ presurgery and did not evidence significant postoperative gains. It was also evident, however, that children undergoing surgery for developmental malformations had a significantly lower age of seizure onset (<12 months) than the postnatal group. A review of children who underwent surgery for epilepsy related to Sturge-Weber syndrome, the majority of which were hemidisconnection procedures, showed that early surgery was likely to improve developmental outcome.[5]

Comparative studies are required over a much longer duration of follow-up to determine the relative merits of surgery with regard to developmental outcome, although even the limited studies available suggest seizure outcome and age at surgery are likely to influence this.[36,89]

Behavioral Outcome

Behavior is often the most problematic issue in children with chronic epilepsy and developmental delay, providing the most challenging aspect for management. The rate of psychiatric diagnosis in children coming to epilepsy surgery is high; in a series of children coming to temporal lobe resection, Mclellan et al.[79] showed that 83% had a *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[4a] diagnosis at any time pre- or postoperatively. It is understandable that questions will arise as to how much impact resective surgery is likely to have. This is more difficult to predict. In the same series, 72% of cases showed at least one diagnosis preoperatively and a similar percentage postoperatively; in 16%, mental health problems resolved postoperatively, but in 12% they evolved. There was no clear relationship between seizure freedom postoperatively and psychiatric disorder, although there was a suggestion that children who were seizure free following surgery were more likely to lose a DSM-IV diagnosis (24%) than were those who continued to have seizures (4%). There was no correlation with antiepileptic drugs, type of surgery, or cognitive ability for the group as a whole.

In children undergoing hemispherectomy, the data are more encouraging. The procedure was originally advocated for infantile hemiplegia, epilepsy, and behavior disorder.[70] In a group of 33 children undergoing the procedure for a variety of pathologies, Devlin et al.[22] found 10 reported by parents to have preoperative behavior difficulty. Fifteen reported postoperative improvement. In a large series of 71 children who underwent hemispherectomy for cortical dysplasia, Rasmussen encephalitis, or vascular etiologies, there were no differences on the Child Behavior Checklist scores pre- and postoperatively.[89]

It is important to consider what realistic benefit may be conferred by surgery, with or without seizure freedom. For this reason, detailed neuropsychiatric evaluation should be advocated as part of the presurgical assessment.

Summary and Conclusions

Pediatric epilepsy surgery is an effective treatment modality for children with medically resistant seizures. Knowledge of pediatric seizure presentations and the natural evolution of defined pediatric epilepsy syndromes helps to facilitate case selection and the preoperative evaluation. In particular, the pathologic substrates of intractable pediatric epilepsy differ from those in adults in being more heavily weighted toward developmental lesions such as malformations of cortical development. Based on knowledge of how these lesions influence seizure patterns and brain functionality, it is possible to achieve rates of seizure freedom that rival the adult experience.

Chapter 186

Overview: Clinical Biology of Epilepsy

Timothy A. Pedley

Introduction

Neither seizures nor epilepsy occur in isolation from the rest of the body's functions. Epilepsy is regularly associated with complex biologic interactions as a result of the seizures themselves, an underlying medical or neurologic disorder, or antiepileptic drug treatment. Epileptic seizures, especially when frequent or in the form of status epilepticus, result in significant physiologic stress to the autonomic nervous system and to the cardiovascular, pulmonary, and endocrine systems. The occurrence of seizures and epileptiform electroencephalographic (EEG) abnormalities is strongly influenced by circadian and ultradian rhythms. In some cases, this is sufficiently distinct that it is included among the features defining some epilepsy syndromes. Antiepileptic drugs can have profound consequences for reproductive health including hormonal effects, fertility, and pregnancy outcomes. Finally, seizures occur frequently with many medical conditions that affect the brain, either as part of a systemic disease process or secondarily as the result of he-patic or renal failure and other causes of metabolic dysfunction. Successful management of patients with epilepsy and seizures must take these broader biologic considerations into account, and that is the purpose of the chapters in this section.

Chronobiology and Wake–Sleep Cycles

Sleep and epilepsy are intimately related, at multiple levels and in multiple ways, as discussed in two chapters by Dr. Shouse et al. Hippocrates and Aristotle were perhaps the first to write of the occurrence of epileptic seizures during sleep. More modern views linking biologic rhythms, epitomized by the waking–sleep cycle, to epilepsy began to appear in the late 19th and early 20th centuries, both in the French (Echeverria, Fere) and English (Gowers) literature. Several biologic clocks influence the occurrence of epileptic seizures. A number of epileptic syndromes are strongly related to circadian (24-hour) rhythms. Representative examples include both primary generalized epilepsies, such as grand mal seizures upon awakening and juvenile myoclonic epilepsy, and focal epilepsies, such as autosomal dominant frontal lobe epilepsy. EEG epileptiform discharges may be even more entrained to the wake–sleep cycle than clinical events, as illustrated by the phenomenon of continuous spikes and waves during slow-wave sleep and the discharges of benign partial epilepsy with central-midtemporal spikes. Ultradian rhythms (shorter than 24 hours), such as the basic rest–activity cycle (BRAC), interact with the circadian rhythm to further influence the occurrence of both seizures and, especially, interictal discharges at shorter periodicities (e.g., 90 minutes). These effects have been described in both generalized and localization-related epilepsies. Infradian rhythms (longer than 24 hours) characterize the secretory patterns of hormones and hormone-releasing factors; their influence is evident in catamenial epilepsy. Among the exciting discoveries in neuroscience today is a growing understanding of the neurobiologic mechanisms underlying biologic clocks. The master circadian clock involves the suprachiasmatic nuclei of the anterior hypothalamus; other areas of the hypothalamus, such as the orexin-containing cells of the lateral hypothalamus, are specifically important in the sleep–wake cycle. Brainstem mechanisms are central to generation of the BRAC type of ultradian rhythm.

The distribution of ictal events and interictal discharges differs in rapid eye movement (REM) and non-REM stages of sleep, and the effects are different for primary generalized epilepsies and localization-related epilepsies. The effects of sleep and of sleep deprivation on interictal EEG discharges are well known and clinically useful.

Sudden Unexpected Death in Epilepsy

The recognition that patients with epilepsy have increased mortality rates has been an important finding. Part of this increase is related to underlying diseases (e.g., brain tumors) or to accidental death (e.g., drowning). In recent years, however, there has been growing awareness that death also occasionally occurs unexpectedly in otherwise healthy people for no apparent reason. Indeed, sudden unexpected death in epilepsy (SUDEP) is now recognized as the most common cause of seizure-related mortality in people with chronic epilepsy. Compared to persons without seizures, the incidence is particularly high in young adults with epilepsy. Early age of onset of epilepsy, frequent generalized tonic–clonic seizures, and intractability appear to be risk factors, and polytherapy may independently add additional risk, at least in adults. Drs. Nashef and Tomson provide a critical analysis of data related to SUDEP, and suggest that SUDEP is a direct consequence of an epileptic seizure, perhaps involving a cardiac mechanism. They conclude with an emphasis on optimizing seizure control and raising considerations that are important in informing patients about the condition.

Disturbances of Autonomic Function

Drs. Goodman, Stewart, and Drislane review the anatomy of the autonomic nervous system and the many clinical features of seizures (e.g., tachycardia, increased blood pressure, apnea, pupillary changes, sweating, salivation, incontinence, skin flushing or pallor) that indicate autonomic activation. Because the autonomic nervous system is controlled by a central autonomic network that involves the limbic system and lower brainstem, autonomic symptoms and signs are especially common with partial seizures that originate in the mesial temporal

lobe, the cingulate gyrus, and other medial frontal cortical areas. Such autonomic features can occur before, during, or after a seizure. Occasionally, autonomic dysfunction may be life threatening, as in some cases of seizure-related neurogenic pulmonary edema or cardiac arrhythmias. Involvement of neurons that innervate the heart can produce tachyarrhythmias as well as heart block, and this particular manifestation of autonomic dysfunction may be a contributing factor to SUDEP.

Comorbidities

All patients with epilepsy will have a concurrent medical illness requiring treatment at some time. Whether benign and self-limited or severe and life threatening, comorbidity frequently complicates seizure management. Two chapters provide broad overviews of the importance of general medical disorders in children and adults. Drs. Aminoff and Parent review comorbidity in adults. Because seizures are among the most common symptoms of brain dysfunction, they occur frequently in medical disorders associated with encephalopathy (e.g., renal or hepatic failure). In addition, a number of systemic diseases, such as lupus erythematosus, nonketotic hyperglycemia, and HIV infection, also frequently involve the brain directly causing seizures as one manifestation. Seizures are also a well-known feature of substance abuse, especially alcohol and cocaine. Medical disorders can also complicate epilepsy treatment, especially when the liver or kidney is involved. Uremia, for example, affects protein binding and thus the proportion of bound and unbound antiepileptic drugs such as phenytoin and valproate. Renal failure reduces the clearance of drugs like gabapentin and topiramate that are excreted primarily through the kidneys. Advanced hepatic failure also affects protein binding and, of course, clearance of drugs metabolized in the liver.

In addition to the same interactions anticipated in adults with general medical disorders, children present unique comorbidities, especially in terms of complex developmental, behavioral, and psychiatric interactions, as discussed by Drs. Resnick and Duchowny. A major reason is undoubtedly the added dimension caused by the effects of recurrent seizures on the developing brain, although the details of this have not yet been fully specified. A few observations illustrate the point, however. Children with developmental disabilities have an increased risk of epilepsy, and behavioral problems are more common in children with epilepsy than in the general population. There is growing recognition that depression is more common in children and adolescents with chronic epilepsy than previously realized. Similarly, cognitive impairment due to diverse causes, and even cognitive deterioration occur with increased frequency in children with epilepsy. Nearly one third of children with autism or autistic spectrum disorder have seizures. Another aspect of childhood that is considered in this chapter is the impact of complications arising from immunizations on risk of seizures and neurologic dysfunction. This has been an extremely contentious area over the years, but several studies and careful analyses have brought clarity to some—but not all—allegations and assumptions about the adverse consequences of routine immunization, and this has allowed sensible recommendations to be made for the majority of children and circumstances.

Drs. Devinsky and Nordli discuss the important and practical topic of procedures and anesthesia in persons with epilepsy. This is a frequent and understandable source of concern raised by both patients and families. Although few studies have documented significantly increased risks for medical or dental procedures, providing specific information can lessen apprehension on the part of both patients and caregivers. This chapter reviews steps that can be taken to reduce the risk of seizures at the time of a scheduled procedure; the need for health care workers involved with procedures on patients with epilepsy to be familiar with first aid for seizures; and considerations for choice of drugs for premedication and anesthesia. Helpful guidelines are given for both medical and dental procedures. In children with severe epilepsy, it is especially important to exclude genetic defects that may lead to serious adverse metabolic effects from anesthesia.

Reproductive Biology and Health

In recent years there has been a substantial increase in knowledge about the modulatory effects of hormones on neuronal excitability on the one hand, and on the hormonal changes induced by seizures on the other. Four chapters summarize current knowledge of the relationships between hormones and epilepsy, the mechanisms underlying these changes, and the impact of these changes for reproductive health in men and women.

Drs. Harden and Frye review the disruptive effects that seizures have on endocrine function and the consequences of this. Neuroactive steroids that increase following seizures have mixed effects on brain excitability, with some being proconvulsant and others anticonvulsant. Alterations in the normal feedback loop between reproductive hormones and the hypothalamus may lead to infertility and an increased incidence of reproductive endocrine disorders in women with epilepsy including hypogonadotropic hypogonadism and polycystic ovary syndrome. Endocrine changes at the time of menopause affect seizure frequency, and menopause tends to be early in women with frequent seizures. Hormonal changes also underlie the particularly clustering of seizures seen in catamenial epilepsy.

Dr. Bäckström describes the effects of both endogenous and exogenous steroid hormones, including adrenocorticotropic hormone (ACTH), adrenal corticosteroids, and gonadal hormones. ACTH has anticonvulsant effects, whereas adrenal corticosteroids have both pro- and anticonvulsant effects. For example, desoxycorticosterone has anticonvulsant effects, but cortisol increases brain excitability. Estradiol is proconvulsant, whereas progesterone is anticonvulsant. In addition, the adrenocortical axis may be dysfunctional in patients with epilepsy. Finally, Dr. Bäckström discusses receptor actions for steroid hormone actions in the brain, as well as their distribution and metabolism, and the clinical changes that occur in hormonal profiles across the reproductive life span.

Dr. Herzog discusses the prevalence and mechanisms of reproductive dysfunction in men and women. Reproductive dysfunction is common in both men and women with epilepsy. Women experience an increased frequency of menstrual disorders and hirsutism, whereas men have increased rates of diminished libido and impotence. Infertility is more common in both men and women. Reproductive dysfunction is most likely the result of abnormal neuroendocrine regulation including gonadotropin secretion. Menstrual disorders occur in up to one third of women with epilepsy, and the polycystic ovary syndrome occurs in up to 20%. Antiepileptic drugs contribute to the development of reproductive endocrine disorders. Men with epilepsy have impaired gonadal function with low serum testosterone levels and/or decreased or abnormal sperm production. Enzyme-inducing antiepileptic drugs contribute to reduced testosterone levels by several mechanisms.

Both men and women with epilepsy appear to have increased rates of sexual dysfunction, although the exact frequency is not known. Dr. Morrell reviews the neuroendocrinology underlying sexual behavior (i.e., the interaction between desire and arousal) and then describes the sexual dysfunction that occurs in people with epilepsy. Both physiologic

P.1959

and psychosocial causes have been implemented, but in many patients, physiologic mechanisms (e.g., limbic brain dysfunction, antiepileptic drugs, seizure-related changes in pituitary and gonadal hormones) may be more important than psychosocial disability (depression, poor self-esteem, poor disease acceptance) in many patients, although both play a role sexual dysfunction. Because of the centrality of sexuality to quality of life, it is important to actively evaluate the possibility of sexual dysfunction in patients with epilepsy, as few will volunteer information. Depending on the results of this evaluation, a plan for therapeutic intervention can be designed.

Pregnancy

The final chapter is a discussion of the very special challenges that women with epilepsy face when they decide to have children. As noted in preceding chapters, infertility, sexual dysfunction, and reproductive disorders occur more frequently in women with epilepsy than in the general population, and thus pregnancy may be difficult to achieve. Antiepileptic drugs may adversely affect reproductive hormones and their regulation. Seizure frequency may increase during pregnancy, in part because of the decline in antiepileptic drugs levels. There are increased complications during pregnancy, including fetal death and spontaneous abortions, and both low birth weights and prematurity are increased in babies of mothers with epilepsy. Antiepileptic drugs increase the risk of fetal malformations and developmental delay. Despite these concerns, the great majority of women with epilepsy have successful pregnancies and healthy babies, and the chance of a successful outcome can be greatly enhanced by informed management of the unique issues presented by women with epilepsy who desire to become pregnant.

Summary and Conclusions

This section emphasizes the necessity for neurologists to maintain a broad perspective when evaluating and treating patients with epilepsy. Seizures and epilepsy occur in the context of multiple interacting factors, including the patient's general medical health, a woman's childbearing potential, concurrent medical disorders and treatments, and physiologic and psychological consequences of the seizures themselves. Some of these are readily apparent, but others are subtle and need to be actively sought. Treatment is optimal only when all of these factors are taken into account and addressed systematically. This section also illustrates that for patients with epilepsy (and probably other chronic neurologic disorders), neurologists are most effective when they assume the role of a primary health care provider.

Chapter 187
Chronobiology

Margaret N. Shouse
Mark S. Quigg

Introduction

The term chronobiology refers to the clocking of biologic events. There are many biologic clocks that control behavioral and physiological processes.[54] Epilepsy is affected by biologic clocks, a phenomenon that has been documented for more than a century.[22,24,33,34,35,57,82,83]

This chapter focuses on three kinds of clocks or periodicities as they pertain to epilepsy: (a) circadian rhythms, which recur at about 24-hour intervals, (b) ultradian rhythms, which recur at <24-hour intervals, and (c) infradian rhythms, which recur at >24-hour intervals (e.g., monthly or seasonal).

More than one periodicity can exist. For example, some patients have 24-hour seizure peaks, whereas most have multiple peaks within 24 hours, sometimes at about 90-minute intervals defined by the basic rest–activity cycle (BRAC). Many patients with circadian and ultradian seizures also exhibit strong infradian patterns, as evidenced by multiple cyclic variations in hormonal secretions (Chapters 194,195,196,197,198). The way in which these periodic rhythms affect epilepsy depends on several interrelated variables that define epileptic syndromes,[15] including (a) seizure type, (b) etiology, (c) age-dependent course, and (d) prognosis.

Circadian (24-Hour) Rhythms/Variations and Seizure Events

A circadian rhythm in the strict sense refers to any periodicity (hormones, temperature, mobility, etc.) that fluctuates over the course of approximately a 24-hour day and does not necessarily refer to the sleep–wake cycle. The sleep–wake cycle is a circadian rhythm in many mammals, such as rats and humans, but it recurs several times a day in cats. The "time of day" difference does not alter the fact that interictal discharges (IIDs) and clinically evident seizures exhibit similar distributions during different sleep and waking states in all these species. Accordingly, most studies of epilepsy have focused on variables that exhibit variation in the sleep–wake cycle without examining the role of circadian "time of day" rhythms per se.

There are several reasons for the paucity of clear-cut data on circadian rhythms. Perhaps the most relevant is that, in contrast to the sleep-wake cycle, circadian periodicity is not directly measurable because it is not simply a matter of clock time. It requires robust circadian markers or reference points, the use of various mathematical constructs, and data collection over prolonged sampling intervals. True, endogenous circadian rhythms recur on a "free-running" basis regardless of exogenous cues, such as the light–dark cycle, or of any other endogenous factors, such as linkage to sleep versus waking states.

Findings on biologic events that are clearly under circadian rhythm versus sleep–waking state control are difficult to interpret. Masking effects, or perturbation of circadian markers, can complicate interpretation of observations on circadian seizure modulation. For example, cortisol secretion has a circadian periodicity, but seizures themselves elevate cortisol (e.g., Quigg[83]). Cortisol secretion is also modulated by stress, which is itself a seizure precipitant (e.g., Frucht et al.[27]). Melatonin is intimately involved in light-related circadian organization of the sleep–wake cycle and, by definition, is susceptible to masking effects by exogenous clues. Exogenous melatonin administration can improve seizure control in experimental animals[90] and in clinical trials.[23] However, the ameliorative effects of melatonin cannot be dissociated from improvements in sleep, which is disordered in epilepsy (see Chapter 188),[44] or from seizure-related factors (e.g., Bazil[5]).

These issues have been extensively reviewed by Quigg.[82,83,84] In this section, we review the evidence on circadian variation in seizure activity as function of the sleep–wake cycle vis-à-vis time of day (clock time) and show examples of endogenous circadian rhythm modulation, when available.

Clinical Findings

Three epilepsy categories are classified according to the timing of generalized myoclonic or tonic–clonic seizures in the sleep–wake cycle. Timing categories are referred to as awakening (diurnal), sleep (nocturnal), and diffuse epilepsies, the latter including epileptic syndromes in which seizures occur randomly in sleep or waking states as well as in the day or night.[44,46] These three epilepsy groups are also classified as a function of the different epileptic syndromes with which they are affiliated.[15,45,46,75,77]

Epilepsies Characterized by Seizures on Awakening (Diurnal): Primary Generalized Epilepsies

Epilepsies characterized by seizures on awakening are a special class of diurnal seizures, which are considered more entrained to the sleep–wake cycle than to endogenous circadian rhythms.[31] They are most often primary generalized epilepsies in which the etiology is assumed to be genetic. These include patients with typical absence, juvenile myoclonic epilepsy (JME), and generalized tonic–clonic seizures.[2,45,46,47,77]

Patients with absence and JME often have generalized tonic–clonic seizures.[29,30,48] Greater than 90% of these patients have generalized tonic–clonic convulsions (GTCs) only on arousal from sleep,[45,46] most frequently during prolonged drowsy periods occurring between 10 minutes and 2 hours after morning awakening.[8,45,46] Myoclonic and absence seizures are also common at this time. Table 1 shows the prevalence of generalized myoclonic seizures after awakening from nocturnal sleep.[119]

Table 1 Distribution of 51 primary generalized myoclonic seizures in relation to the time of predilection for occurrence of seizures and to the efficacy of treatment in 33 patients

Time of predilection for occurrence	Total (*n* = 33 patients)	Satisfactory control (*n* = 18)	Unsatisfactory control (*n* = 15)
Morning awakening	26	17	9
Evening period of relaxation	6	5	1
Sleep onset	3	2	1
Sleep	6	2	4
Nocturnal wakening	10	9	1

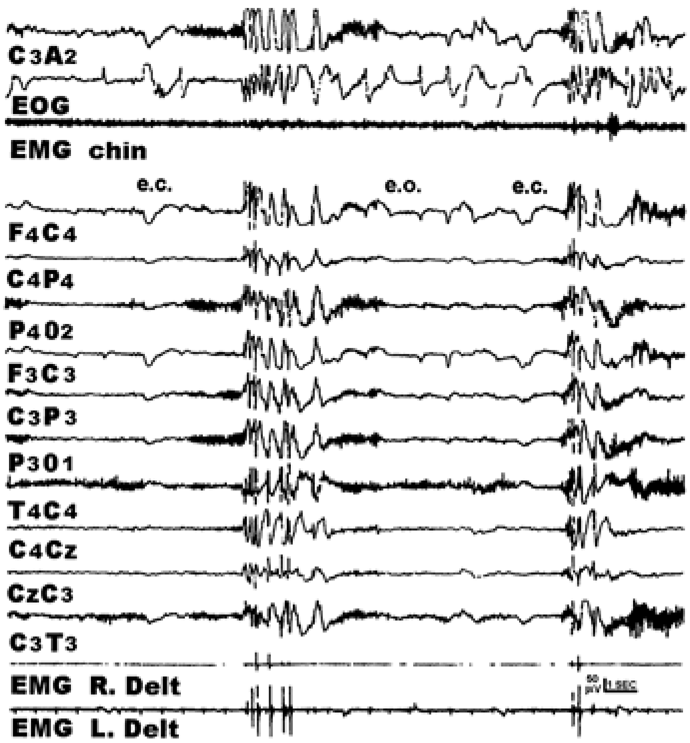

FIGURE 1. Electroencephalogram (EEG) recorded after morning awakening. Eye closure elicits a series of polyspike-and-wave (PSW) discharges associated with electromyographic (EMG) activity. Subsequent eye opening inhibited such EEG manifestations, which resumed again on closing the eyes. e.c., eyes closed; e.o., eyes opened; EOG, electrooculogram; L. Delt., left deltoid; R. Delt., right deltoid. (From Gigli GL, Calia E, Luciani L, et al. Eye closure sensitivity without photosensitivity in juvenile myoclonic epilepsy: polysomnographic study of electroencephalographic epileptiform discharge rates. *Epilepsia*. 1992;32:677–683; with permission.)

Many patients also exhibit more frequent and prolonged interictal epileptiform discharges after awakening.[37,51,52,77,78] Polyspike-and-wave complexes of JME often occur after awakening from nocturnal sleep, as depicted in FIGURE 1.[31] FIGURE 2 shows that the duration of 3/sec spike–wave complexes

P.1962

associated with absence seizure disorders can be longer after awakening than at other times in the sleep–wake cycle.[52]

Ictal events are more entrained to awakening than are IIDs. Frequent polyspike-and-wave and spike-and-wave complexes also occur during non–rapid-eye-movement (NREM) sleep (e.g., Fig. 2), even when myoclonic and absence seizures occur only on awakening.

Epilepsies characterized by seizures on awakening typically exhibit an age-dependent clinical course.[15,70,73,97,98,99] Onset is usually between 4 and 15 years of age. Spontaneous remission, reduction of seizures, or complete medication control is common between puberty and 20 to 25 years of age, although some patients can be more drug refractory.[70,78,98]

These relatively benign epileptic syndromes are associated with normal developmental and neurologic functions. The presumed pathophysiology[32] is a disturbance in the electrophysiologic and neurochemical response of neocortical cell populations to synchronous synaptic inputs resulting from inhibition of arousal cells located in the hypothalamus and in the ascending reticular activating system (ARAS).[4,74,103,104]

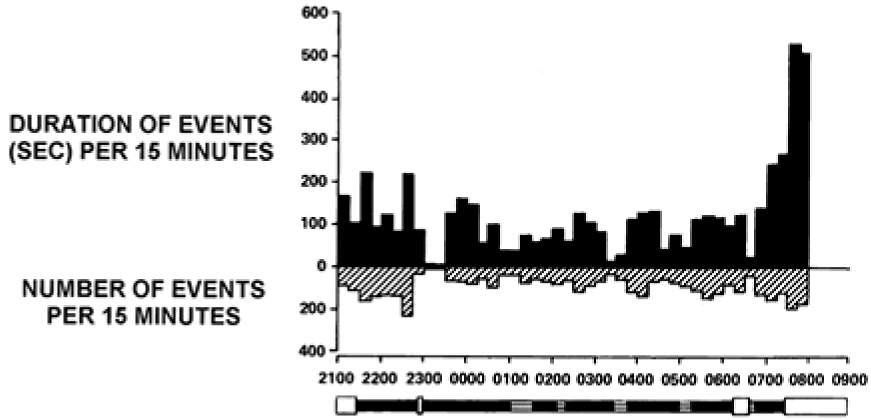

FIGURE 2. Circadian distribution of 3/sec spike-and-wave activity per 15 minutes. Discharge duration is longest at awakening and so is more likely to represent a clinical seizure. Discharge rate is also high at the beginning and end of sleep. Time of day along the abscissa is in terms of the 24-hour clock. The bar along the abscissa indicates the sleep or waking state: Unfilled, awake; filled, non–rapid-eye-movement (NREM) sleep; slanted lines, rapid-eye-movement (REM) sleep. (From Kellaway P, Frost JD Jr, Crawley JW. Time modulation of spike-and-wave activity in generalized epilepsy. *Ann Neurol*. 1980;8:491–500; with permission.)

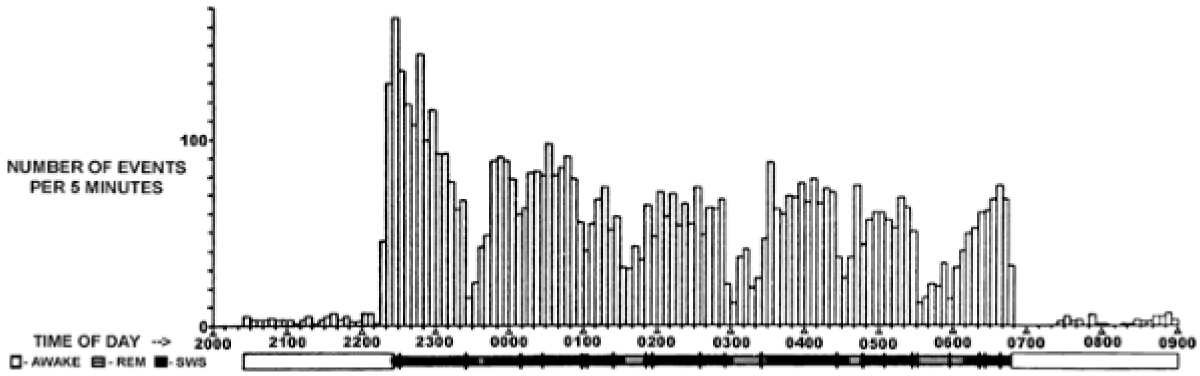

FIGURE 3. Spike density distribution at 5-minute intervals in benign epilepsy with centrotemporal spikes (BECT) showing a decremental pattern. An abrupt increase in spike activity is associated with sleep onset and is followed by an overall decline during subsequent non–rapid-eye-movement (NREM) sleep and particularly on awakening. Periodic troughs occur throughout sleep in relation to REM onset. SWS, slow-wave sleep. (From Kellaway P, Frost JD Jr. Biorhythmic modulation of epileptic events. In: Pedley TA, Meldrum BS, eds. *Recent*

Advances in Epilepsy, Vol. 1. London: Churchill Livingstone; 1983:139–154; with permission.)

Epilepsies Characterized by Seizures During Sleep (Nocturnal): Localization-Related Epilepsies

Circadian ictal and interictal discharge patterns occur during the "subjective night" and/or during sleep in epilepsies arising from a focal region of dysfunction (e.g., Frost et al.[26]). These may be relatively benign or not. For example, some frontal lobe syndromes, notably nocturnal paroxysmal dystonia[62,63,94] and autosomal-dominant nocturnal frontal lobe epilepsy (see Chapter 251), display bizarre partial motor seizure manifestations during NREM sleep. The seizures do not secondarily generalize in NREM sleep and are readily controlled by antiepileptic medication. Other "benign" localization epilepsies have an age-dependent course with a specific time frame for onset and spontaneous remission. The prognosis for spontaneous remission of seizure manifestations, is usually good.[2,6,7,15,70,78,98,99] These patients also display frequent IID and partial seizures with or without secondary generalization during NREM sleep. Examples are benign partial epilepsy with centrotemporal spikes (BECT, also called benign rolandic epilepsy),[58] benign epilepsies with occipital spikes,[6,7] Landau-Kleffner syndrome (acquired epileptic aphasia), and patients manifesting electrical status epilepticus during slow sleep (ESES).[113] FIGURE 3 shows an example of BECT in which the interictal spike discharge peaks at sleep onset.[51]

Simple partial or complex partial seizures, particularly those accompanied by secondary generalized tonic–clonic seizures, have long been thought to occur more frequently in sleep than in waking (e.g., Janz[45,46]). Greater than 50% of patients with temporal or frontal lobe foci reported secondary generalized tonic–clonic seizures only in sleep, whereas complex partial seizures without secondary generalization were reported to occur more often during waking.[45,46] Because localization-related epilepsies are more likely to be symptomatic than are primary generalized epilepsies,[15,45,46,78] it is not surprising that the prognosis is not always benign. For example, complex

partial seizures of temporal or frontal lobe origin do not have an age-dependent course. Onset frequently occurs before the age of 20 years, spontaneous remission is rare, and seizures are often drug refractory.[15,45,46,78]

Recent findings using continuous electroencephalogram (EEG)-video monitoring for presurgical evaluation have revealed some interesting new developments in drug-refractory localization-related epilepsies.[17,39,48,81] Different timing patterns emerge when patients with drug-refractory complex partial seizures are evaluated as a function of the presence or absence of secondary generalized seizures and as a function of foci in frontal, temporal parietal, or occipital lobes (Fig. 4).[40] Partial seizures occur more frequently in waking than in sleep, regardless of the location of the seizure focus (Fig. 4A). Complex partial seizures with secondary generalization occur significantly more often in NREM than in waking at all seizure foci except in frontal lobe (Fig. 4B). It was concluded that different mechanisms govern the timing of seizure initiation versus propagation.

Quigg proposed that circadian diurnal rhythms govern the initiation of symptomatic partial seizures with *limbic* foci, whereas nocturnal sleep-related mechanisms trigger onset of focal seizures in symptomatic focal seizure disorders with *nonlimbic* foci. Several findings have been assembled to address this hypothesis:

1. The timing of symptomatic limbic seizures (mesial temporal lobe sclerosis) can be differentiated from that of nonlimbic (extralimbic) seizures with respect to linkage with circadian versus predominantly vigilance-related seizures. Table 2 summarizes this difference on the basis of recent studies dating from 1998 to 2004.[84]
2. Figure 5[83] illustrates the 24-hour distribution of seizures in two patients with left hippocampal sclerosis and temporal lobe onset of seizures (Fig. 5A, B) and in a single patient with dual pathology (Fig. 5C, D). The three patients with symptomatic mesial temporal lobe epilepsy (MLTE) (Fig. 5A–C) all showed complex

partial seizures during the subjective day, whereas the timing of symptomatic, parietal lobe seizures occurred nocturnally and during sleep (Fig. 5D).

3. Figure 6 contrasts the absence of a circadian rhythm in extratemporal focal seizures (Fig. 6A) with the presence of a circadian seizure distribution in an animal model and in patients with MTLE.[83] Findings are plotted as a function of clock time in humans (Fig. 6A, B) and with reference to the circadian temperature cycle in the 12-hour/12-hour light/dark cycle in animals (Fig. 6C). A comparison of findings in Figures 6B and 6C supports the conclusion that MLTE in both species is regulated by a circadian rhythm.[82,84,87] This circadian pattern was also maintained in rats during constant darkness when plotted in relation to the free-running circadian temperature cycle (Fig. 6D).[87]

The interpretation of these findings is complicated by the fact that rats are nocturnally active and humans are diurnally active. Thus, seizure activity seems dissociated from circadian

rest–activity rhythm regulation. In addition, circadian entrainment disappeared when the data from free-running rhythms were plotted with reference to circadian rest–activity patterns (not shown in Fig. 6). Both discrepancies could suggest an underlying circadian modulation of limbic seizure occurrence that does not involve rest–activity or sleep–wakefulness patterns.

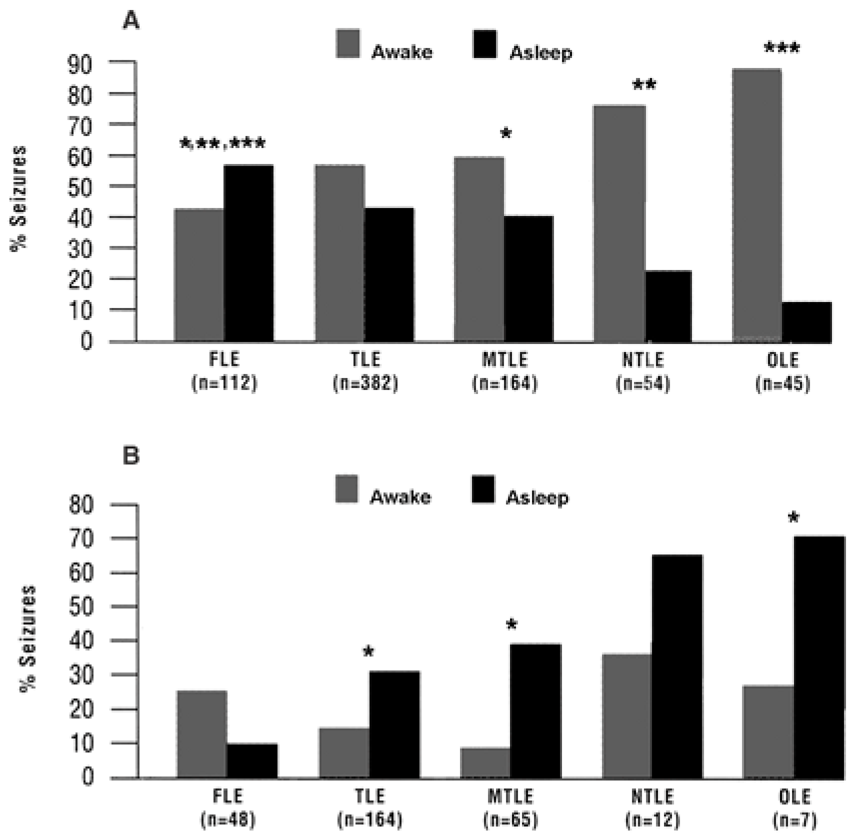

FIGURE 4. A: Percentage of partial seizures arising from various brain regions during waking (*gray bars*) or sleep (*black bars*). Partial seizures with or without secondary generalization of seizures (n = 579 of 613 partial seizures in 133 patients) were included. **B:** Percentage of partial seizures with secondary generalization (n = 396 of 613 partial seizures in 133 patients) during waking (*gray bars*) or sleep (*black bars*). In both histograms, data are presented for each location assessed. Overall, partial seizures were more likely to occur during wakefulness regardless of seizure onset site **(A)**, whereas partial seizures with secondary generalization were significantly more likely to occur in sleep at all onset sites except

fron-tal lobe **(B)**. Sleep refers to non–rapid-eye-movement sleep because no seizures were registered during rapid-eye-movement sleep. Data were obtained during in-patient monitoring of patients who were candidates for epilepsy surgery due to refractory complex partial seizures. FLE, frontal lobe; MLTE; mesial temporal lobe; NTE, neocortical temporal lobe; OLE, occipital or parietal lobes; TLE, temporal lobe. *p <0.05; **p <0.001; ***p <0.0001. (From Herman ST, Walczah TS, Bazil CW. Distribution of partial seizures during the sleep–wake cycle: differences by seizure onset. *Neurology*. 2001;56:1453–1459; with permission.)

Epilepsies in Which Seizures Occur Randomly (Diurnal and Nocturnal): Symptomatic Generalized Epilepsies

In these epileptic syndromes, ictal and interictal discharges occur in all sleep and waking states.[45,46,67] This random seizure distribution is often associated with diffuse, severe cerebral dysfunction.[43,52,79,97] Three well-known examples are West,[14,123] Lennox-Gastaut,[30,79] and progressive myoclonus[36] syndromes.

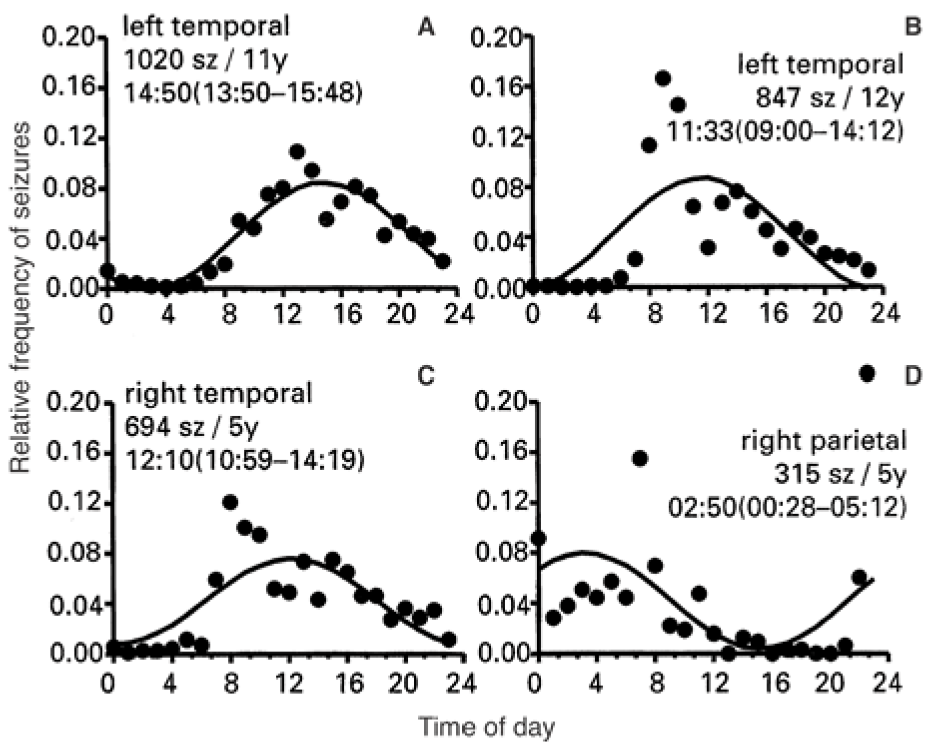

FIGURE 5. Daily distribution of seizures revealed by detailed, long-term diaries maintained by three subjects with medically refractory epilepsy and their spouses. Localization of seizures was later confirmed during epilepsy surgery evaluation. Curves provide the best-fit estimate of time of peak occurrence (95th confidence interval). **A, B:** Patients with left hippocampal sclerosis and left temporal lobe seizures. **C, D:** Patient with a pattern of seizures with different symptomatology and a dual pathology: Right temporal lobe seizures associated with ipsilateral hippocampal sclerosis occurred diurnally **(C)**, and parietal lobe seizures associated with a cortical malformation occurred nocturnally and out of phase with temporal seizures **(D)**. (Composite from Quigg[83] as follows: Panels A, B from Quigg M. Seizures and circadian rhythms. In: Bazil CW, Malow BA, Sammaritano MR, eds. *Sleep and Epilepsy: The Clinical Spectrum*. Amsterdam: Elsevier; 2002:127–142; panels C, D adapted from Quigg M, Straume M. Dual epileptic foci in a single patient express distinct temporal patterns dependent on limbic versus nonlimbic brain location. *Ann Neurol*. 2000;48:117–120; with permission.)

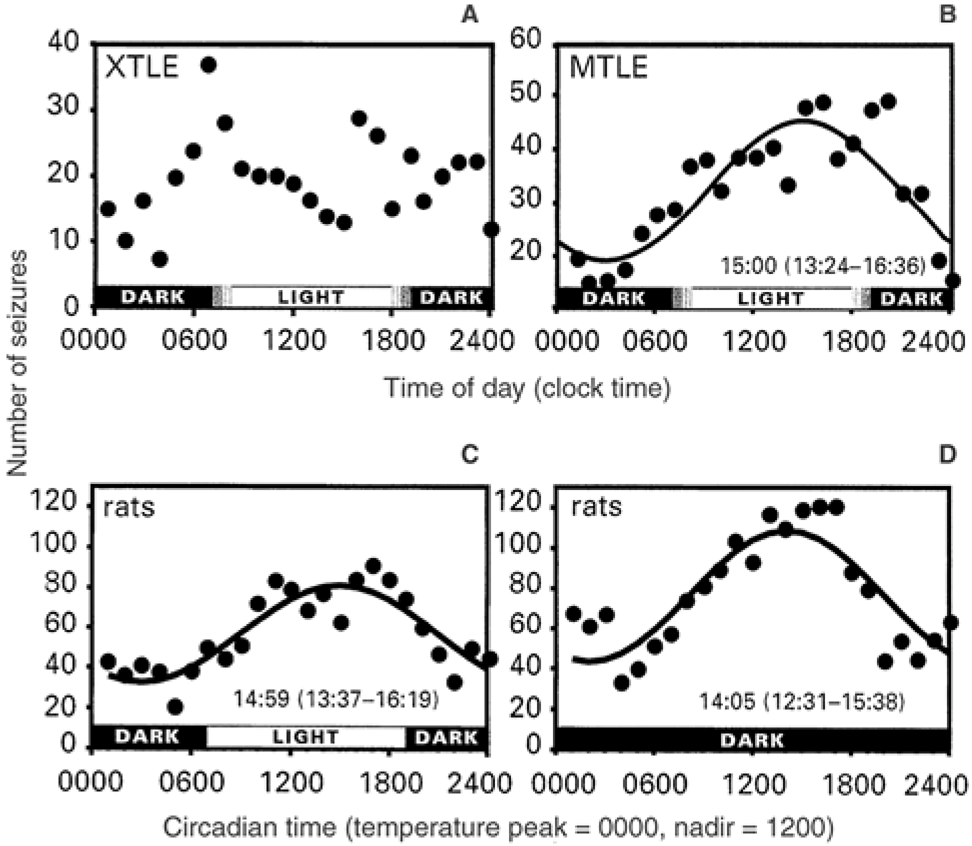

FIGURE 6. Distribution of spontaneous epileptic seizures in humans and in the self-sustained electrical status epilepticus rat model of limbic epilepsy. The times of seizure occurrence in humans were determined using continuous video-electroencephalogram (EEG) recordings from either scalp or intracranial electrodes. In rats, continuous EEG and hippocampal depth electrodes provided times of seizures. Where appropriate, data were fitted using cosinor-nonlinear least squares analysis. **A:** A biphasic distribution of seizures in patients with extratemporal lobe partial epilepsy (XTLE). When the observed distribution is compared with the expected uniform rate of seizure occurrence using chi-square analysis, the distribution is statistically random. In contrast, limbic seizures in humans with mesial temporal lobe epilepsy (MTLE) **(B)** and in rats **(C, D)** occur in similar patterns. Seizures of limbic origin are accurately modeled by a cosine function with the calculated time of peak occurrence reported with the 95% confidence limit. Both species have diurnally predominant seizures despite the fact that rats are nocturnal and humans are diurnal in activity. The limbic seizures of rats occur in similar distributions when entrained to a 12-hour/12-hour light/dark cycle **(C)** as compared to free-running circadian rhythms in constant darkness or a 12-hour/12-hour dark/dark cycle **(D)**. Note that the times of seizure occurrence are normalized to a 24-hour circadian clock provided by each animal's circadian rhythm of temperature because, once in constant darkness, the period of circadian rhythms may run slightly shorter or longer than exactly 24 hours. The plot in panel D confirms that the occurrence of limbic seizures is modulated in an endogenous, circadian fashion. (Composite from Quigg M. Seizures and circadian rhythms. In: Bazil CW, Malow BA, Sammaritano MR, eds. *Sleep and Epilepsy: The Clinical Spectrum*. Amsterdam: Elsevier; 2002:127–142; as adapted from Quigg M, Clayburn H, Straume M, et al. *Epilepsia*. 2000;41:502–509; and Quigg M, Straume M. Dual epileptic foci in a single patient express distinct temporal patterns dependent on limbic versus nonlimbic brain location. *Ann Neurol*. 2000;48:117–120; with permission.)

Onset can be early in life, but average age at onset in this category of seizure disorders is otherwise evenly distributed across the age spectrum.[45,70] Seizures tend to be medically refractory, and the prognosis is poor.[6,15,30,77,78,123] In some cases, morbidity and even death is expected (e.g., Lafora, essential hereditary myoclonus, or Unverricht-Lundborg syndrome).[36,78] In other cases, conversion to other serious seizure disorders is common (e.g., West syndrome, which is also called infantile spasms, to Lennox-Gastaut syndrome[79]). Spontaneous remission does not occur. Cases with extreme neurologic complications display substantial disruption of sleep states and of the sleep–wake cycle (see Chapter 188). Extreme neurodegenerative disorders also provide the only example in which endogenous circadian rhythm disorders are clearly manifested.[39,44]

Basic Mechanisms

Strong rhythms of circadian ictal and to some extent interictal discharge patterns arise in two groups of epilepsy.[26,33,34,35,36,37,41,42,43,45,46,47] In primary generalized epilepsies, ictal and interictal discharges often appear on awakening, although interictal discharge is common in NREM sleep as well. Localization-related epilepsies frequently exhibit generalized ictal and interictal discharges events during sleep, often at sleep onset or at the end of sleep. The same ictal and interictal patterns seen in humans have also been reported in experimental animal models of sleep versus awakening epilepsy (Fig. 7A vs. Fig. 7B).[99]

What is known about basic chronobiology mechanisms that might explain these differences? To address this question, it is necessary to consider two main hypothalamic regulatory systems: (a) the suprachiasmatic nuclei of the anterior hypothalamus, which is the “master” circadian clocking mechanism, and

(b) the anterior/preoptic, lateral, and posterior hypothalamic cell populations, which generate the sleep–wake cycle.

The suprachiasmatic nucleus (SCN) of the hypothalamus regulates nearly all circadian rhythms, including the subsystems linked to the sleep–wake cycle.[13,54,82,83] Sleep-dependent processes include NREM-related changes such as plasma growth hormone secretion and urinary calcium excretion. Lesions of either the SCN or its afferent retinal pathway eliminate most physiologic and behavioral circadian rhythms, including the sleep–waking circadian cycle.[21,73,102] Cells of the SCN continue to exhibit circadian discharge patterns in isolation[122] and also restore normal circadian patterns when transplanted into animals with genetically abbreviated periodicities.[88] These findings confirm that the SCN is the primary circadian clock. Various afferent and efferent anatomic interconnections have been identified to account for modulation of component circadian rhythms, such as the adjacent cell populations generating the sleep–wake cycle. Circadian oscillation in the SCN is genetically determined.[1,88] Several genes encode clocking proteins to create an autoregulatory feedback loop using transcription and translation.[61] γ-Aminobutyric acid (GABA) is the main transmitter.[69] GABA release is well known to have antiepileptic effects.

Considering the undisputed, pervasive influence of the SCN on circadian rhythms, it is difficult to understand why there is so little evidence linking this structure or the circadian light–dark cycle to ictal or interictal seizure events and vice versa. A number of reasons have been suggested (e.g., Quigg[83]). Examples are masking effects, which can occur as a result of extraneous environmental or internal factors, and the only fairly recent availability of prolonged polysomnographic and video recordings needed to capture sufficient seizure events for “time of day” analysis.

Independent oscillators also exist, even in structures normally entrained to discharge patterns of cells in the SCN. Destruction of the SCN abolishes circadian “time of day” rhythms, but the usual result is a replacement with other rhythms. FIGURE 8 shows the persistence of sleep–wake behaviors and unchanged overall percentages of sleep and wake time after SCN lesions. The circadian rhythm is replaced by an ultradian rhythm. It is curious that no one has attempted to differentiate “time of day” effects from sleep–waking-state effects on seizures before and after SCN lesions.

Another complication is that cells of the SCN discharge in the light phase of the light–dark cycle and are silent during the dark phase, regardless of whether mammals exhibit sleep nocturnally or diurnally. Taken alone, this fact is not disturbing because many circadian rhythms are totally out of phase with cellular discharge patterns of the SCN (e.g., melatonin release). The troublesome aspect is that rats, which are nocturnally active, still exhibit IIDs during diurnal sleep (e.g., Ascapone and Penry[2] and Kostopoulos[53]). In contrast, humans frequently exhibit seizures on awakening (primary generalized epilepsy [PGE]) or in sleep (most localization-related epilepsies), even though humans are typically awake diurnally and asleep nocturnally. Thus, with few exceptions, circadian effects on seizures and of seizures on circadian rhythms are so far primarily entrained to sleep and waking states.

The only way in which to eradicate or substantially diminish sleep or waking states is to destroy the generators of these states. Well-documented clinical (e.g., Von Economo[121]) and experimental findings, including transection, lesion, unit recording, microdialysis, *c-fos* expression, and/or regional blood flow studies, localize control of the sleep–wake cycle to the hypothalamus.[4,13,69,76,120] Histaminic cells in the tuberomammillary nucleus of posterior hypothalamus, orexin (hypocretin)-containing cells of the lateral hypothalamus, and cholinergic cells in the magnocellular region of the anterior hypothalamus generate awakening and maintain arousal, whereas GABAergic and galanin-containing cells of the anterior/preoptic hypothalamic areas (ventral lateral preoptic [VLPO]) generate sleep onset and maintenance.[60,69,88,95,110,111,112] These hypothalamic regions are reciprocally connected[60,95,96] and dominate all the EEG, behavioral, autonomic, and, conceivably, hormonal correlates of the sleep–wake cycle.

In the intact animal, these forebrain regions are also reciprocally interconnected and functionally interact with brainstem cholinergic, noradrenergic, and/or serotonergic cells originating in the pontine tegmentum. These brainstem cells also discharge during onset and maintenance of wakefulness and, with the exception of occasional bursts of cholinergic cell discharge (see Chapter 188), are silent during NREM

P.1966

sleep.[4,10,49,69,76,120,121] For this reason, the coverage of basic mechanisms focuses on these particular regions.

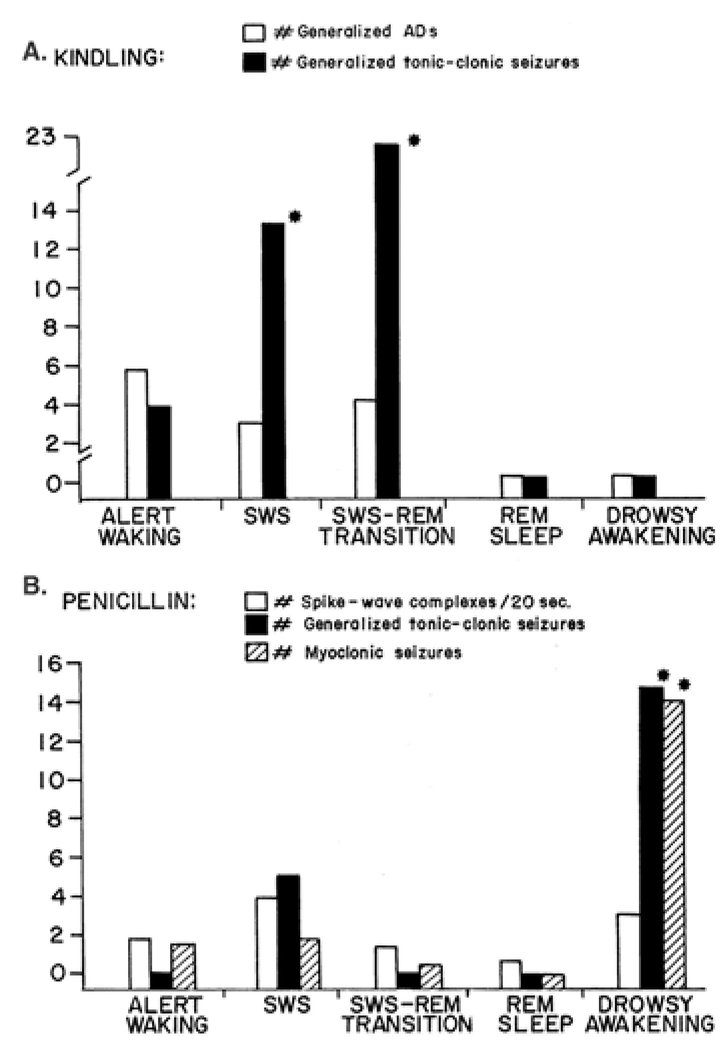

FIGURE 7. Timing of spontaneous seizures during the sleep–wake cycle in **(A)** 9 amygdala-kindled kittens and **(B)** 12 cats with systemic penicillin epilepsy (300,000–400,000 IU/kg). Temporal lobe kindling is a model of localization-related epilepsies, whereas systemic penicillin epilepsy is a model of primary generalized epilepsy. Slow-wave sleep (SWS) in cats is equivalent to non-rapid-eye-movement (NREM) sleep in humans. AD, afterdischarge. (From Shouse MN, King A, Langer J, et al. Basic mechanisms underlying seizure-prone and seizure-resistant sleep and awakening states in feline kindled and penicillin epilepsy. In Wada JA, ed. *Kindling 4*. New York: Plenum Press; 1990:313–327; with permission.)

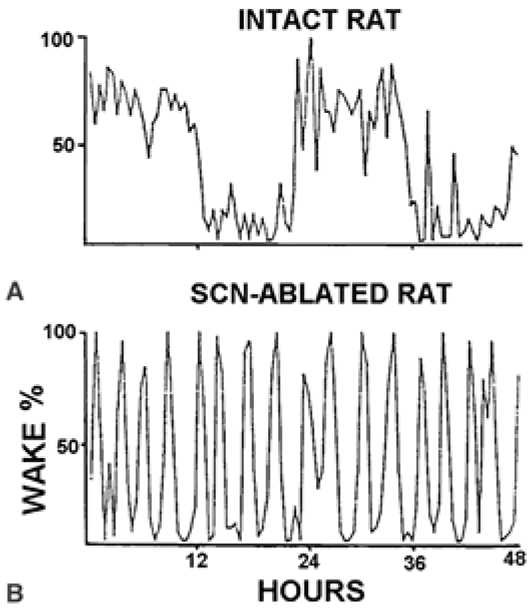

FIGURE 8. Percentage of polygraphically recorded wake time in each 30-minute period over 48 consecutive hours in two adult male rats recorded in constant dim light. **A:** An intact control rat, showing a typical 24-hour circadian rhythm of sleep–wake time. **B:** A rat with complete ablation of the suprachiasmatic nuclei (SCN). The 24-hour rhythm of sleep–wake time was completely lost. This rat shows prominent ultradian rhythms in the 3- to 4-hour range. (Modified from Mistlberger HE, Bergmann BM, Rechtschaffen A. Relationships among wake episode lengths, contiguous sleep episode lengths, and electroencephalographic delta waves in rats with suprachiasmatic nuclei lesions. *Sleep*. 1987;10:12–24; with permission.)

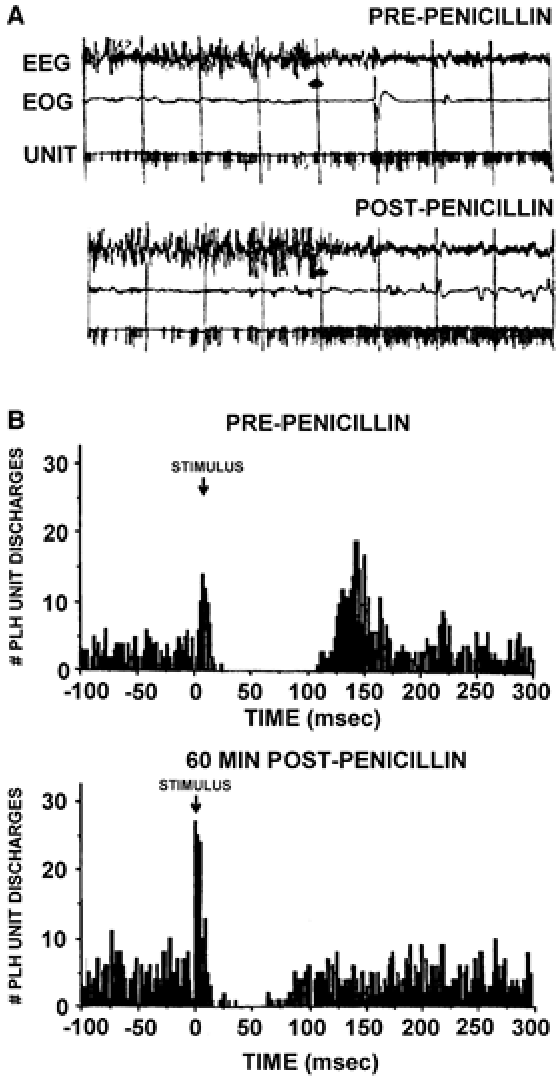

FIGURE 9. A: Spontaneous unit activity in a posterior lateral hypothalamic (PLH) neuron during slow-wave sleep (SWS), which here refers to non–rapid-eye-movement (NREM) sleep, and at awakening (*arrow*) before and during a subconvulsive dose of penicillin (200,000 IU/kg) in a cat. **B:** Evoked orthodromic response in a PLH neuron induced by stimulation of the external capsule (100 pulses, 0.8 mA), before and after penicillin (200,000 IU/kg) in a cat. Stimulus onset was at time 0. Note the increased amplitude of evoked excitation and the reduced duration of postexcitatory inhibition after penicillin when compared to the pre-penicillin record. (From Shouse MN, King A, Langer J, et al. Basic mechanisms underlying seizure-prone and seizure-resistant sleep and awakening states in feline kindled and penicillin epilepsy. EEG, electroencephalogram; EOG, electrooculogram. In: Wada JA, ed. *Kindling 4*. New York: Plenum Press; 1990:313–327; with permission.)

Epilepsies Characterized by Seizures on Awakening (Diurnal): Primary Generalized Epilepsies

The morphology of interictal discharges, including 3/sec spike-and-wave and polyspike-and-wave complexes,[15,29,77] is compatible with stimulus-evoked or recruited cortical EEG patterns resembling drowsiness. This may explain why interictal discharges arise during drowsy wakefulness.[32,37,77,78] Conversion to an ictal discharge pattern associated with myoclonic or tonic–clonic seizures could be precipitated by corticopetal influences originating in arousal cells of the hypothalamus, the brainstem reticular formation, or both, as follows.

Arousal cells in the magnocellular basal forebrain and in the posterior hypothalamus are also called waking-active neurons. These cells have direct projections to the entire neocortical mantle.[49,92,93] Sudden bursts of "excitatory" input from these arousal cells might exacerbate the diffuse, relatively mild cortical hyperexcitability thought to underlie this group of seizure disorders (e.g., Gloor[32]). One hypothesized mechanism is a direct (monosynaptic) effect mediated by normal or abnormal secretion of several transmitters such as acetylcholine (Ach) and/or histamine (e.g., Jones[49]).

Figure 9 shows spontaneous (Fig. 9A) and evoked (Fig. 9B) unit discharge of a waking-active neuron in the posterior hypothalamus during slow-wave sleep and awakening before and 1 hour after a subconvulsive dose of penicillin in a cat.[99] Note that spontaneous cellular discharge increases on awakening and is exacerbated at this time by penicillin (Fig. 9A). The

peristimulus histogram shows increased amplitude of evoked excitation and reduced duration of postexcitatory inhibition in the penicillin model of PGE on awakening (Fig. 9B; also see Fig. 7B).

Alternatively, indirect (polysynaptic) effects could be responsible. For example, waking-active neurons of the posterior hypothalamus and orexin-containing cells of the lateral hypothalamus also project to and synergize actions of the arousal cells in the ARAS,[74] including norepinephrine (NE), serotonin (5-HT), and/or Ach. These brainstem arousal cells in turn have widespread terminals in thalamus and cortex.[49,68,92,93,104] An impressive body of data supports the hypothesis that inhibition of arousal cells promotes synchronized thalamocortical discharges associated with NREM sleep and also the sleep-related interictal discharges in the penicillin and genetic models of awakening epilepsy.[3,28,53,103,104]

Sustained activation of the pontine arousal cells is thought to have tonic antiepileptic effects (e.g., Corcoran[16]; see Chapter 188), but the abrupt increase in discharge of these cells on awakening may be epileptogenic. For example, NE is thought to promote the ability to focus neuronal attention in wakefulness. The outcome is a coordinated sensorimotor act.[103] A surge of NE release on awakening might simply focus neuronal attention on and activate the epileptic neocortical cell populations in this group of seizure disorders. A similar effect could accompany the release of 5-HT and/or Ach.

Epilepsies Characterized by Seizures During Sleep (Nocturnal): Localization-Related Epilepsies

Seizures and interictal discharges arising during sleep could be provoked by monosynaptic and polysynaptic projections from sleep-active neurons of the anterior/preoptic hypothalamus to cortical or subcortical seizure foci. Hypothalamic sleep-active neurons suppress waking-active neurons located in the ARAS,[4,44,69] notably, the Ach, NE, and/or 5-HT cells of the pontine tegmentum. These cells in turn have widespread monosynaptic and polysynaptic projections to the entire neocortical mantle as well as to archicortical and subcortical limbic sites[49] and could thus precipitate seizure discharge during NREM sleep. The role of the thalamocortical system and its regulation of epileptogenic phasic events such as sleep spindles also cannot be overlooked (see Chapter 188).

Epilepsies in Which Seizures Occur Randomly (Day or Night): Symptomatic Generalized Epilepsies

Circadian patterns of ictal and interictal discharges are not prominent in these epileptic syndromes (e.g., Horita[41,42]). The extensive cerebral pathology associated with these syndromes could encompass the SCN, the hypothalamic generators of the sleep–wake cycle, and other brainstem and forebrain regions that ultimately express circadian rhythms.

Ultradian (<24-Hour) Rhythms and Seizure Events

Historically, the ultradian rhythm most often linked to epilepsy is called the basic rest–activity cycle

(BRAC).[12,105,107] The BRAC pervades the circadian sleep–wake cycle. During sleep, the synchronized EEG discharges of NREM sleep represent "rest" periods and alternate with the asynchronous EEG discharges of REM sleep, which represent "activity" periods. During waking, rest periods (drowsiness) alternate with activity periods (alert waking). In humans, this periodicity occurs at roughly 90-minute intervals. There is great individual variability, and 100- to 120-minute intervals have often been detected (e.g., Kellaway et al.[52]).

A second, more recently described ultradian rhythm refers to periodic microarousals, defined as a cyclic alternating pattern (CAP) of EEG desynchronization occurring on a background of prolonged, homogeneous EEG synchronization (noncyclic alternating pattern [NCAP]). CAPs have two components or phases.[114,115] Phase A corresponds to the initial or peak level of EEG desynchronization with sleep EEG transients, whereas phase B follows phase A and reflects a return to the stable synchronized-EEG NCAP state. Three different subtypes of CAP A have been identified and related to various seizure disorders. CAPs have been studied during NREM sleep, in which brief EEG microarousals are most readily detected (e.g., Parrino et al.[80]).

Clinical Findings

Ultradian BRAC seizure patterns are most evident in localization-related epilepsies of temporal or frontal lobe origin. In contrast to ictal events, IIDs with BRAC periodicities can occur in all seizure disorders. Ultradian CAP rhythms have been studied mostly in idiopathic epilepsies,[31,38,115,116] although studies have been performed in three types of localization-related epilepsies.[80,119] The observations are depicted in epileptic syndromes characterized by awakening, sleep, and random seizure patterns as follows.

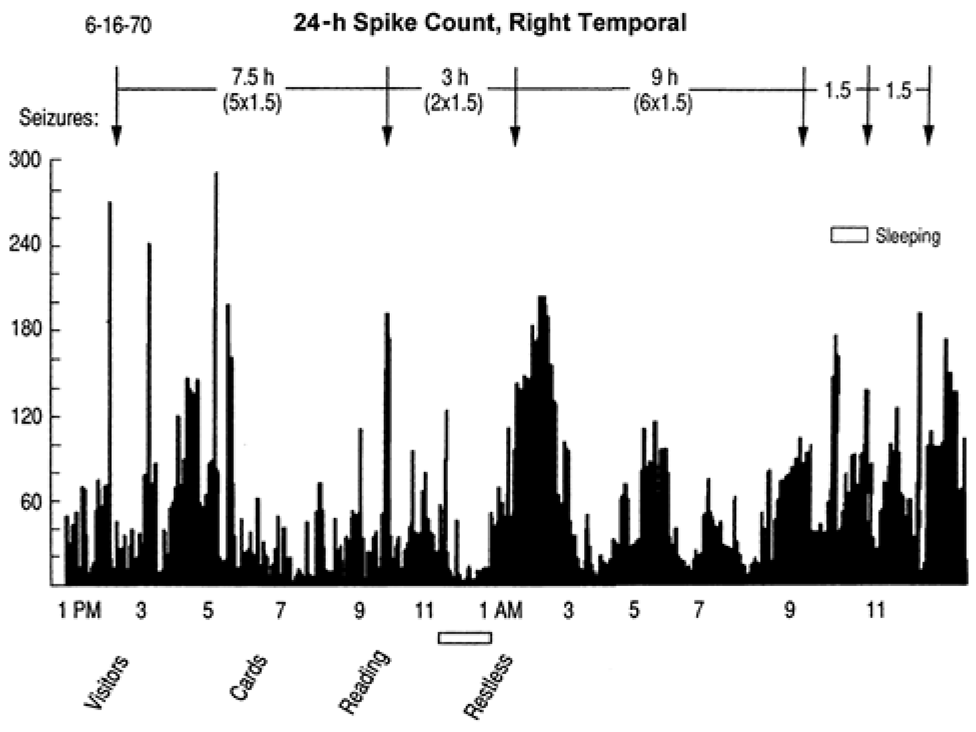

FIGURE 10. Timing of ictal and interictal discharges at 90-minute intervals in a patient with temporal lobe epilepsy. A 24-hour spike count per 4 minutes was recorded from the right temporal electrode of a patient with six seizures recorded during this period. Seizures (*arrows*) occurred at intervals or multiples of intervals of 1.5 hours. No distinct rapid-eye-movement sleep was recorded in the patient. (From Stevens JR, Lonsbury B and Goel SL. Seizure occurrence and interspike interval. *Arch Neurol*. 1980;26:409–411; with permission.)

Epilepsies Characterized by Seizures on Awakening (Diurnal): Primary Generalized Epilepsy

Seizures occur primarily on arousal from nocturnal sleep, but there are less prominent, secondary peaks on arousal from daytime naps and sometimes at sleep onset, as seen in Table 1.[33,57,119] The appearance of more than one peak constitutes an ultradian rhythm, but it does not reflect a BRAC pattern per se. Interictal discharges, on the other hand, can show strong ultradian rhythms corresponding to a BRAC pattern.[51,65,66,105,106,107,108]

Ultradian CAP patterns of IIDs have been studied most thoroughly in JME.[21] However, Terzano et al.,[114] who developed the CAP concept and methodology, studied a small and heterogeneous population of patients with various idiopathic (presumed genetic) seizure disorders[115,116] and found that the rate of spike-and-wave or polyspike-and-wave complexes is highest in the arousal phase (CAP A) and lowest in the sleep recovery phase (CAP B) when compared to NCAP. Seizure discharge is most often affiliated with k-complexes and bursts of slow waves, which are thought to represent phasic arousal events during CAP A.

Epilepsies Characterized by Seizures During Sleep (Nocturnal): Localization-Related Epilepsies

This group of epilepsies, especially those of temporal or frontal lobe origin, is known to be predisposed to ultradian seizures related to the BRAC.[11,106,107,108] Many authors have reported peaks in the timing of complex partial seizures and of interictal discharges, notably spikes and sharp waves, at about 90-minute intervals throughout the sleep–wake cycle,[11,106,107,108] as depicted in FIGURE 10.[107] Similar findings have been detected in animal models. An example is the prevalence of spontaneous convulsions emanating from kindled temporal lobe foci during the REM transition in FIGURE 7A.[99]

A CAP factor similar to that seen in awakening epilepsies also applies to certain sleep epilepsies, notably those of temporal or frontotemporal origin.[80] CAP modulation of IIDs in benign epilepsy with rolandic spikes (BERS) has not been detected.[118] The basis for this negative outcome is speculative. Amygdala-kindled kittens shows EEG microarousals

P.1969

associated with subclinical and possibly clinical seizures, which occur throughout the sleep–wake cycle at much shorter time intervals than the ~20-minute BRAC in cats and might reflect a CAP cycle.[100]

Epilepsies in Which Seizures Occur Randomly (Waking and Sleep): Symptomatic Generalized Epilepsies

These patients show weak ultradian seizure patterns. Some, such as those with West syndrome, can have demonstrable ultradian BRAC periodicities when a discernible REM cycle exists.[43,51,52,79]

Basic Mechanisms

The ultradian BRAC has been localized to the brainstem. This conclusion is based on its persistence in the brainstem but not the forebrain following transection at the midcollicular level (cerveau isolé preparation).[10,76,91,120] Transection findings are confirmed by other experimental methods such as selective lesion, extracellular unit, microdialysis, *c-fos*, and immunohistochemical studies (e.g., Baghdoyan and Lydic[4] and Beaussart[7]). The same brainstem neurotransmitters released during the awakening phase of the circadian sleep–wake cycle are also thought to serve as the brainstem generators of the BRAC. Discharge of NE and 5-HT cells in the medial and medial-lateral pontine tegmentum declines in the transition into REM, whereas Ach discharge in the dorsolateral pedunculopontine tegmentum increases and generates the phasic “arousal” events of the transition. These phasic arousal events are proposed to precipitate seizure discharge and its propagation at this time (Fig. 7A vs. Fig. 7B) (see Chapter 188).[37,99] The tonic discharge of Ach cells during REM is proposed to have antiepileptic effects in sustained periods of alert waking and REM (see Chapter 188). The combination of reduced cellular discharge and transmitter release of NE and 5-HT cells and increased Ach activity is mediated by local GABAergic interneurons (e.g., Baghdoyan and Lydic[4] and Lin et al.[60]).

Reduced NE and 5-HT release plus the phasic discharge bursts and chemical release of Ach cells at these times may promote ultradian ictal or IID manifestations or both. Because each cell type has widespread projections,[49,68] epileptogenic effects could be mediated by direct or indirect projections to epileptic cells anywhere in the brain. On the other hand, the periodic EEG microarousals associated with the arousal phase of CAP (i.e., CAP A) might reflect transient activation of the same brainstem arousal mechanisms regulating the BRAC or the forebrain hypothalamic mechanisms generating matutinal awakening.

Infradian (>24-Hour) Rhythms and Seizure Events

The existence of infradian or long-running rhythms, such as seasonal patterns, has been known for well more than a century.[22,24,34,35,56] Here, we provide two better-known examples relevant to seizure disorders.

Primary generalized epilepsies, which are characterized by seizures on awakening, have an age-dependent course paralleled by changes in the amplitude of EEG transients, such as the spike component of k-complexes. The k-complexes are associated with aborted arousals in sleep and with IIDs during sleep in this group of seizure disorders.[37,77,78] The clinical course also corresponds to the age-dependent secretory patterns of hormones and/or hormone-releasing factors such as melatonin, sex, and steroid-releasing factors. All of these chemicals have been implicated in arousal as well as in the ictal and interictal discharges in these epileptic syndromes.[83,91,125] Common genetic variables potentially related to an arousal dysfunction have been proposed to underlie these correlated age-dependent changes.[19,20,71]

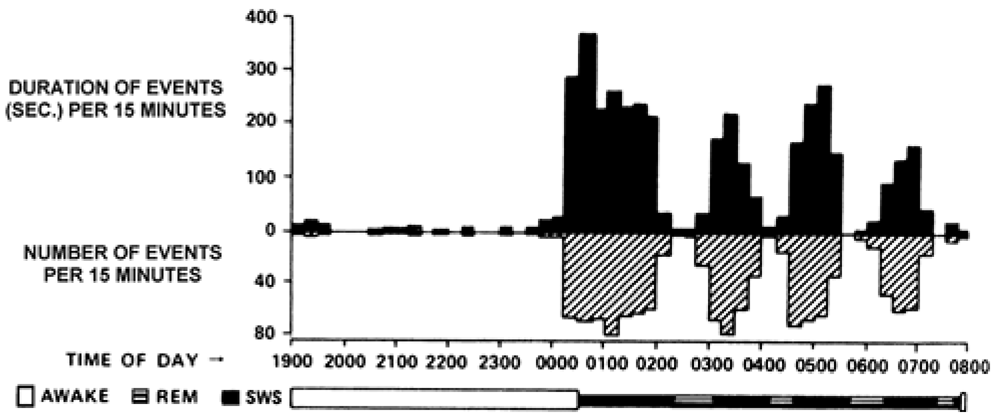

FIGURE 11. A decremental epileptic discharge pattern in which the duration and number of 3/sec spike-and-wave discharges per unit time peaks at the onset of non–rapid-eye-movement (NREM) sleep (here called slow-wave sleep [SWS]) and declines in successive NREM sleep cycles over the night. The suppression of spike-and-wave activity that occurs during REM sleep is comparable over successive REM cycles. Time of day on the abscissa is according to the 24-hour clock. The bar along the abscissa indicates the sleep or waking state: Unfilled, awake; filled, SWS; slanted lines, REM sleep. (From Kellaway P, Frost JD Jr, Crawley JW. Time modulation of spike-and-wave activity in generalized epilepsy. *Ann Neurol*. 1980;8:491–500; with permission.)

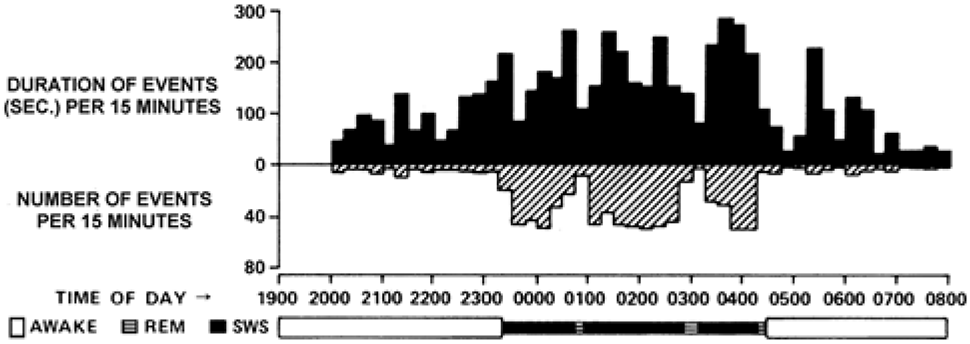

FIGURE 12. An incremental–decremental epileptic discharge pattern in the duration and number of 3/sec spike-and-wave discharges per 15 minutes. The augmenting effect of non–rapid-eye-movement (NREM) sleep (here called slow-wave sleep [SWS]) on 3/sec spike-and-wave discharges at first increases and then declines toward the end of sleep. An equivalent reduction in spike-and-wave activity occurs in each REM period. Time of day along the abscissa is according to the 24-hour clock. The bar along the abscissa indicates the sleep or waking state: Unfilled, awake; filled, SWS; slanted lines, REM sleep. (From Kellaway P, Frost JD Jr, Crawley JW. Time modulation of spike-and-wave activity in generalized epilepsy. *Ann Neurol*. 1980;8:491–500; with permission.)

Hormonal regulation of various seizure disorders is detailed elsewhere (see Chapters 194,195,196,197,198), including catamenial epilepsy. Hormonal changes associated with catamenial epilepsy also affect monoamines, as also covered elsewhere. Once menses develop, a monthly or near-monthly periodicity in seizures is exhibited before or during menstruation in 30% to

P.1970

70% of women with epilepsy (e.g., Foldvary-Schafer et al.[25]). Once menopause occurs, a monthly cycle disappears.

Interactions Between Periodicities

Most ictal and interictal discharge patterns show admixtures of peaks and troughs related to circadian and ultradian variables as well as to different sleep stages (e.g., Kellaway and Frost[51] and Kellaway et al.[52]), sometimes regardless of epileptic syndrome. For example, circadian peaks are seen at sleep onset in centrotemporal spikes (Fig. 3) and in 3/sec spike-and-wave discharges (Fig. 11).[52] During subsequent ultradian NREM/REM cycles, a stepwise decline in seizure discharges may occur during successive NREM cycles (a so-called decremental pattern) and alternate with a near-complete suppression during REM epochs. FIGURE 12 illustrates a different pattern, in which spike-and-wave discharges at first increase and then decrease during successive NREM cycles (a so-called incremental–decremental pattern), again alternating with a suppression of spike-and-wave activity during REM sleep.[52] With this diversity, a logical question is: How do different biologic rhythms interact with state-related variables to generate different temporal seizure patterns?

This is a complex issue that is partially addressed by the statistical model of sleep-related epileptic discharges illustrated in FIGURE 13.[51] Here, the joint probabilities associated with hypothesized circadian (Fig. 13A) and ultradian (Fig. 13B) rhythms are calculated to predict the distribution of 3/sec spike-and-wave complexes during 8-hour sleep periods as a function of different sleep onset times (Fig. 13C–F). The model assumes a constant sinusoidal 24-hour circadian rhythm (Fig. 13A) and a sleep-related, sinusoidal 1.5-hour ultradian rhythm (Fig. 13B). The apexes of these curves correspond to peak circadian and ultradian effects. The 1.5-hour ultradian rhythm represents the NREM–REM cycle, which is shown only for one sleep onset time in FIGURE 13B but is assumed to be present throughout each hypothetical 8-hour sleep period depicted in FIGURE 13C–F.

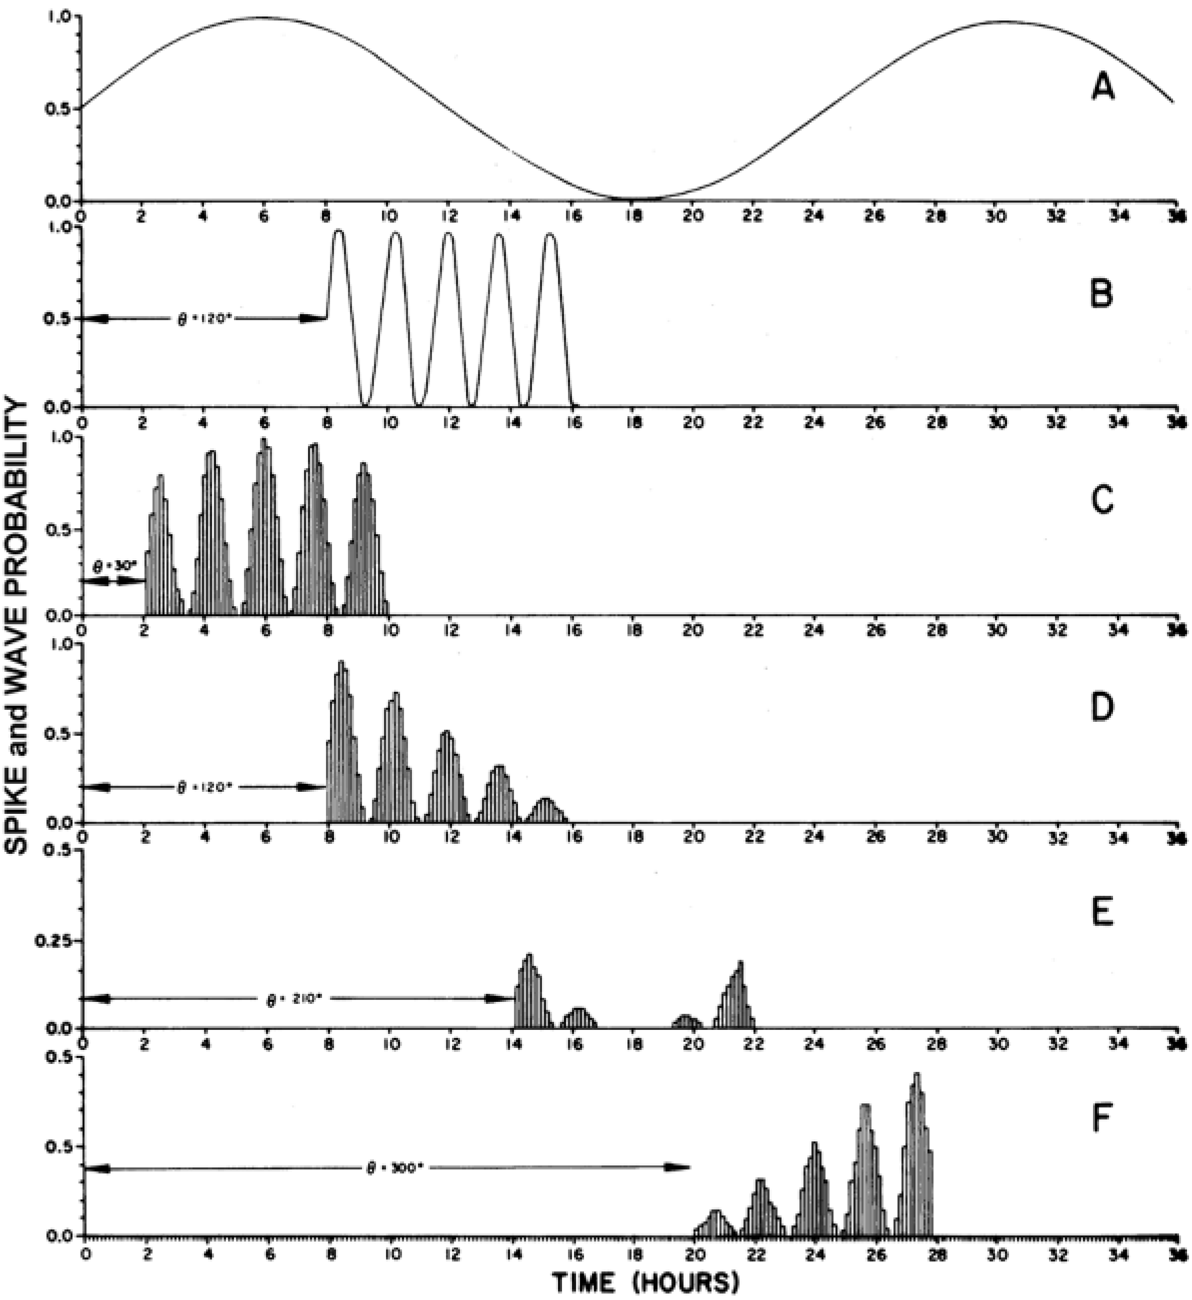

FIGURE 13. A statistical model showing the circadian (**A**) and ultradian (**B**) periodicities and how they predict the distribution of spike-and-wave probabilities over 8-hour sleep cycles as a function of sleep onset time. **C:** Sleep onset at 30° from A results in an incremental–decremental pattern in which spike-and-wave incidence at first increases after sleep onset and then subsides at the end of the sleep cycle. **D:** A 120° sleep onset lag results in a decremental pattern in which peak spike-and-wave discharge occurs at sleep onset and declines thereafter. **E:** A 210° sleep-onset lag with a bimodal pattern in which spike-and-wave incidence peaks at the beginning and end of the sleep cycle. **F:** A 300° sleep-onset lag produces an incremental pattern in which spike-and-wave incidence increases with the duration of sleep. (From Kellaway P, Frost JD Jr. Biorhythmic modulation of epileptic events. In: Pedley TA, Meldrum BS, eds. *Recent Advances in Epilepsy*, vol. 1. London: Churchill Livingstone; 1983:139–154, with permission.)

Spike-and-wave discharge probabilities range from 0.0 to 1.0 on the ordinate. The highest joint probabilities are generated when the apexes of circadian and ultradian curves coincide. Conversely, the lowest joint probabilities are predicted when the troughs of the two curves coincide. Intermediate probabilities reflect interaction between the heights of the

different curves at a given time. In FIGURE 13C–F, spike-and-wave probabilities are plotted as a function of different sleep onset times, expressed as phase angle θ from circadian time 0 on the abscissa.

Figure 13C shows that when sleep onset occurs at a 30° phase angle, the first two ultradian cycles occur on the ascending slope of the circadian curve, the middle cycle occurs at the apex of both the circadian and ultradian BRAC curves, and the last two ultradian cycles fall on the descending slope of the circadian curve. This interaction generates an incremental–decremental pattern like that depicted in FIGURE 12, in which spike-and-wave incidence at first increases in successive NREM sleep bouts, peaks in the middle, and declines toward the end of sleep.

Figure 13D shows that when sleep onset occurs at a 120° phase angle, the first ultradian cycle occurs at the apex of the circadian and ultradian curves, and the subsequent ultradian cycles fall on a progressively descending slope of the circadian curve. This generates a decremental probability pattern similar to those seen in Figures 3 and 11, in which epileptic discharge rates decline over successive NREM cycles.

Figure 13E shows that when sleep onset occurs at a 210° angle, the first two ultradian cycles occur on the descending slope of the circadian curve, the middle at the base of the circadian curve, and the last two on the ascending slope of the circadian curve. This generates a bimodal probability pattern similar to that seen in FIGURE 2, in which spike-and-wave discharge peaks at the beginning and end of sleep.

Figure 13F shows that when sleep onset occurs at a 300° angle, successive ultradian cycles fall on a progressively ascending circadian curve. This generates an incremental spike-and-wave probability distribution, which is the opposite of the pattern predicted in FIGURE 13D.

Notwithstanding limitations of this model (e.g., waking is ignored), it can predict epileptiform discharge patterns that are not explained by state-dependent variables such as NREM versus REM sleep stage alone. For example, sleep stage does not seem to explain distinctive patterns observed over the course of the sleep cycle, particularly during successive NREM sleep epochs. Effects of hypothesized phase advance and delay manipulations, as exemplified by irregularities in sleep habits in FIGURE 13, suggest how time-dependent factors associated with chronobiology, provide this modulation.[51,52]

Subsequent experimental findings did not support these hypotheses about sleep displacement effects.[50] For example, acute sleep delay (6 hours) sufficient to produce a 90° phase shift did not significantly alter the distribution pattern of 3/sec spike-and-wave discharges over successive NREM epochs during a 12-hour sleep recording period when compared to the two, preceding 12 baseline polysomnograms. The authors concluded that the presence of sleep per se is the critical regulatory factor and that the timing of spike-and-wave discharge is secondarily modulated by ultradian REM-NREM cycles.

Summary and Conclusions

Clinical Findings

1. There are no studies of interictal discharges and few studies of seizures in which endogenous circadian “time of day” patterns have been clearly differentiated from the sleep–wake cycle. This gap needs to be filled.

2. The timing of IIDs in sleep and waking states sometimes corresponds to the timing of seizures, but there is no

empirical basis for suggesting that IIDs routinely predict state-dependent seizure occurrence in humans or animals (e.g., Herman et al.,[40] versus Marlow et al.[64]). This dissociation prompted Stevens et al.[108] to state, “all that spikes isn't fits,” meaning that an IID is a seizure that did not occur. The reason that IIDs do not generate seizures, especially in seizure-prone sleep and waking states, is still enigmatic, although some aspects are addressed in Chapter 188.

3. Circadian (24-hour) state-related ictal and to some extent interictal discharge rhythms are strong in epilepsies with awakening seizures, which are primary generalized epilepsies of hereditary or idiopathic origin (e.g., absence and benign juvenile myoclonic epilepsy with or without tonic–clonic convulsions). Circadian state-related seizure patterns are also strong in sleep epilepsies, which often originate from temporal or frontal seizure foci, but also include BERS, benign epilepsy with occipital spikes, Landau-Kleffner syndrome, and ESES. Circadian sleep–wake seizure patterns are rarely seen in epilepsies with extensive organic complications (e.g., West syndrome).
4. Ultradian (<24-hour) state-dependent ictal patterns are most frequently detected in epilepsies with awakening or sleep seizures. Ultradian interictal discharge patterns also frequently occur in various seizure disorders regardless of the timing of ictal events. Ultradian interictal discharge patterns reflect both 90- to 120-minute BRAC cycles and the briefer CAP cycles associated with transient EEG arousals, especially k-complexes and bursts of slow waves.
5. Infradian rhythms, as seen in catamenial epilepsy, are not contingent on seizure type, timing, or etiology. Other long-running rhythms can be selective. For example, primary generalized epilepsies of hereditary origin and good prognosis show an age-dependent course, here meaning a relatively specific age at onset and spontaneous remission.
6. Multiple periodicities seem to interact with other factors, such as sleep stage, to generate diverse but predictable temporal seizure discharge patterns.

Basic Mechanisms

1. The circadian sleep–wake cycle has been localized to the hypothalamus. The posterior histaminic, anterior cholinergic, and possibly the lateral hypocretin-secreting areas induce awakening, whereas the GABAergic and galaninergic cells of the anterior hypothalamic/preoptic basal forebrain area induce sleep. These arousal- or sleep-active cells could provoke seizures via direct or indirect innervation of the epileptic cells involved in the genesis of awakening or sleep epilepsies.
2. The ultradian BRAC has been localized to the brainstem, likely the pontine tegmentum. Activation of BRAC-related ictal or interictal discharges could result from increased electrochemical activity via direct or indirect projections from these reticular formation neurons to epileptic cells anywhere in the brain. Similarly, activation of ultradian CAP-related interictal discharges could reflect transient increases in electrochemical activity of cholinergic, noradrenergic, and/or serotonergic cells in the brainstem ARAS or of the forebrain hypothalamic generators of arousal.
3. Infradian rhythms seem governed by age-dependent genetic and hormonal influences.

Chapter 188

Sleep

Margaret N. Shouse

Carl W. Bazil

Beth A. Malow

Introduction

Sleep states influence the expression or suppression of seizures. The two main sleep states, non–rapid-eye-movement (NREM) sleep and rapid-eye-movement (REM) sleep, have different physiologic components and contrasting effects on generalized ictal and interictal discharges (IIDs). Epileptiform discharges are likely to propagate during NREM sleep and its transitional EEG "drowsy" periods. In contrast, REM sleep is resistant to the propagation of epileptic potentials even though focal IIDs persist at this time.

This chapter describes the distribution of ictal and IID events during NREM versus REM sleep, differentiates NREM from REM sleep substrates, and suggests how the neural generators for seizure-prone or seizure-resistant sleep states modulate the timing of seizures. We also discuss the effects of seizures, antiepileptic drugs (AEDs), and vagus nerve stimulation on sleep. Finally, we consider the impact of sleep disorders and sleep deprivation on seizures.

Seizures and Interictal Discharges in Non-Rapid-Eye-Movement Versus Rapid-Eye-Movement Sleep

Clinical Findings

During NREM sleep, focal and generalized epileptic discharges are common, even if clinical seizures do not occur.[52,78,95] During REM sleep, generalized epileptiform discharges are infrequent. Focal interictal discharges are less numerous but persist during REM sleep and are highly localized (e.g., Sammaritano et al.[113]). Seizures are common during NREM sleep but rarely occur during REM sleep.[53,93,95] The effects of NREM sleep versus REM sleep on interictal and ictal epileptiform discharge depend somewhat on the epileptic syndrome (Table 1).

Primary Generalized Epilepsies of Genetic or Idiopathic Origin

In the primary generalized epilepsies (PGEs), interictal and ictal discharges begin simultaneously in all or most of the cerebral cortex bilaterally.[25,48,95] Most PGEs are thought to be genetic with age-related penetrance (e.g., Delgado Escueta et al.[32] and Niedermeyer[95]). Examples are childhood and juvenile absence epilepsy and juvenile myoclonic epilepsy (JME), which can occur with or without primary generalized tonic–clonic convulsions[2,25,95] (see Chapters 239, 240, and 244).

These primary generalized epilepsies presumably result from a diffuse abnormality of cortical excitability that is less severe than that seen with a focal epileptogenic lesion.[48,49] This concept is illustrated in FIGURE 1, which contrasts the surface electrographic and intracellular discharge patterns in cortex associated with normal rhythmic activity (Fig. 1A), PGE (Fig. 1B), and localization-related epilepsies (Fig. 1C).

In PGE, the membrane potentials of individual cells are within normal range, and intracortical inhibitory mechanisms are generally intact. The underlying neuronal hyperexcitability is expressed only in populations of cortical neurons entrained to a synchronous burst–pause firing pattern by the glutaminergic and aspartate-mediated thalamocortical volleys that normally evoke spindles and recruiting responses. Sequences of cortical excitatory postsynaptic potentials (EPSPs) alternate with inhibitory postsynaptic potentials (IPSPs) to generate spindles and recruiting responses. The sequential pattern persists in PGE but is altered by the increased amplitude of temporally and spatially summed EPSPs and IPSPs. The enhanced population excitatory response generates the action potentials underlying the spike or multispike component and is followed by a longer-lasting period of neuronal silence that gives rise to the slow-wave component of the complex (Fig. 1B, left). Preservation of γ-aminobutyric acid (GABA)-mediated intracortical inhibitory mechanisms is considered critical to the generation of the slow component and terminates the spike train, which, if unopposed, could lead to a convulsion (Fig. 1B, right).

Interictal and ictal discharges often arise during transitional "drowsy" arousal periods, which occur throughout the sleep–wake cycle.[52,57,95] For example, awakening from sleep presents a high risk for the occurrence of IIDs and/or ictal seizure events in idiopathic generalized epilepsies such as awakening "grand mal" seizures and juvenile myoclonic epilepsy. Such periodicities imply mediation of seizure events by both circadian and ultradian cycles. Chronobiology issues are primarily covered in Chapter 187.

This chapter focuses mainly on *stable* sleep, defined by the physiologic components that persist after initial onset of a specific NREM or REM sleep stage (e.g., Carskadon and Dement[21]) vis-à-vis IID and ictal events. Below, we describe sleep-related interictal and ictal discharges in this group of seizure disorders for (a) light NREM sleep (stages 1 and 2), (b) deep NREM sleep (stages 3 and 4), and (c) REM sleep.

Light Non–Rapid-Eye-Movement Sleep: Stages 1 and 2.

Interictal discharges, such as typical spike-and-wave (3/sec) and multispike-and-wave or polyspike-and-wave complexes, are more often detected in light NREM sleep (e.g., Niedermeyer[95]) than in deep NREM sleep or in REM sleep (e.g., Carskadon and Dement[21]). The longest trains of typical spike-and-wave complexes (>5 seconds) occur in stage 1 NREM sleep. Discharges of similar duration in an awake patient would typically be accompanied by a clinically evident seizure.

The next-most-prominent time for spike-and-wave and multispike- or polyspike-and-wave complexes is stage 2 NREM sleep. During this stage, IID complexes are frequent but of short duration. They usually coincide with sleep transients, which have an EEG configuration similar to epileptiform potentials[95] such as sleep spindles, K-complexes, vertex waves, and bursts of slow waves. Some evidence suggests that these events, particularly K-complexes, reflect aborted arousals during sleep.[95] For example, exogenous stimulation during NREM sleep, such as a loud noise, can evoke any of these transient waveforms.

Table 1 Generalized epileptiform discharges by sleep states in three epilepsy syndromes with convulsions at different times in the sleep-wake cycle

	Interictal discharges		Ictal discharges	
Epilepsy syndrome/circadian seizure rhythm	NREM	REM	NREM	REM
Primary generalized epilepsies of idiopathic or hereditary origin: awakening epilepsies	Common	Rare	Rare[a]	Rare
Localization-related epilepsies with or without known pathology: sleep epilepsies	Common	Rare[b]	Common	Rare
Symptomatic epilepsies with extensive encephalopathy: sleep and waking epilepsies	Common	Rare[c]	Common	Rare[c]

NREM, non-rapid-eye-movement sleep; REM, rapid-eye-movement sleep.

[a]Except stage 1 (≥ trains of spike-wave complexes would likely be associated with an absence seizure in waking).

[b]Note maximal focalization.

[c]As long as REM is intact.

Adapted from Shouse MN, da Silva AM, Sammaritano M. Sleep. In: Engel J Jr, Pedley TA, eds. *Epilepsy: A Comprehensive Textbook*, Philadelphia: Lippincott-Raven; 1997:1929–1942; **with permission**.

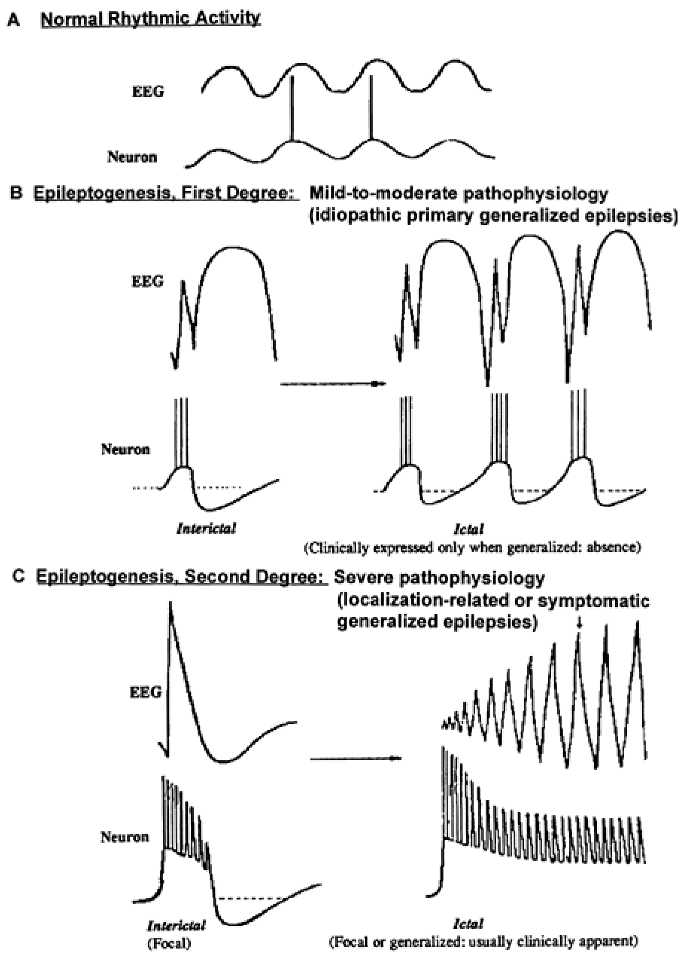

FIGURE 1. Relationship between surface electroencephalogram (EEG) and intracellularly recorded activity of cortical neurons in cats without epilepsy **(A)**, with primary generalized epilepsy (PGE) induced systemically or by diffuse, dilute cortical application of penicillin **(B)**, and with partial epilepsy induced by local application of higher-dose penicillin **(C)**. Normal rhythmic background activity **(A)** is contrasted with two types of interictal **(left)** and ictal **(right)** epileptic conditions representing two degrees of epileptogenesis seen in arousal-related **(B)** or in sleep-related and symptomatic **(C)** seizure disorders. (Adapted from Gloor P. Generalized epilepsy with spike-wave discharge: a reinterpretation of its electroencephalographic and clinical manifestations. *Epilepsia*. 1979;20:571–588; with permission.)

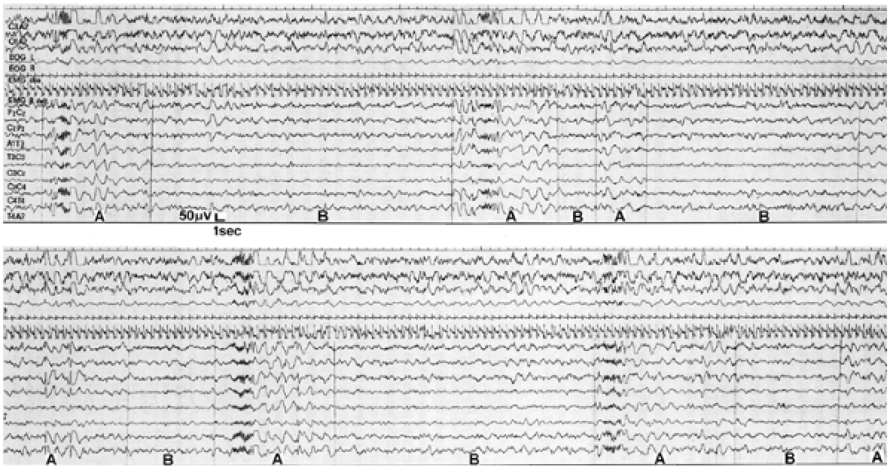

FIGURE 2. Polyspike-and-wave complexes associated with sleep spindles in juvenile myoclonic epilepsy (JME). Spindles and other sleep electroencephalogram (EEG) transients are thought to represent aborted arousals during sleep, and both aborted and actual arousals can provoke seizure events. This conclusion is supported by the higher incidence interictal discharges during the "arousal" phase **(A)** versus the reduced "arousal " phase **(B)** of Terzano's cyclic alternating patterns[142] (see Chapter 187 for more detail) and also by reports (e.g., Touchon[143]) that induced or spontaneous behavioral arousal from sleep most often provokes clinical seizure manifestations in JME. (Reprinted from Gigli GL, Calia E, Marciani MG, et al. Sleep microstructure and EEG epileptiform activity in patients with juvenile myoclonic epilepsy. *Epilepsia*. 1992;333:799–804; with permission.)

Figure 2 shows polyspike-and-wave complexes, which occur in relation to sleep spindles during the "arousal phase" of Terzano's cyclic alternating pattern (CAP) in a patient with juvenile myoclonic epilepsy (JME). CAP refers to sequences of transient electroclinical events that are distinct from homogeneous background EEG activity in NREM sleep and recur at up to 1-minute intervals.[142] See Chapter 187 for an explanation of ultradian rhythms, including CAPs (e.g., Parrino et al.[100] and Terzano et al.[142]). For the purpose of this chapter, note that induced or spontaneous behavioral arousals from sleep most often provoke clinical seizure manifestations in JME (e.g., Touchon[143]), regardless of CAPs.

Deep Non–Rapid-Eye-Movement Sleep: Stages 3 and 4.

Deep NREM sleep stages are usually considered least likely to activate typical spike-and-wave and multispike-and-wave or polyspike-and-wave complexes. However, some evidence suggests that deep NREM sleep is equally if not more conducive than light NREM sleep to these IIDs.[110,117] The IID trains are briefer and less organized in deep NREM than in light NREM sleep. This probably results from the prolonged hyperpolarization of thalamocortical cells[1,135,137] that generate the delta-wave oscillation of deep NREM and disrupt the rhythmic burst–pause discharge pattern as well as the morphology of spike-and-wave and multispike-and-wave complexes seen in light NREM sleep.

Rapid-Eye-Movement Sleep.

Generalized IIDs can occur during stable REM sleep (e.g., Billiard[17]) but are uncommon. "Breakthrough" generalized IIDs are less diffuse in REM than in NREM sleep. Even when generalized epileptic EEG potentials do occur in REM sleep, there is rarely clinical accompaniment.[53,93,113,114]

Localization-Related Epilepsies

This group of seizure disorders is thought to result from one or more focal regions of cerebral dysfunction (e.g., Commission Report[25]). Localization-related epilepsies are thought to reflect a more severe pathophysiology than that seen in PGE because individual neurons in the focus exhibit a sudden depolarization shift representing summated or giant EPSPs.[48] Depolarization shifts are characterized by high-amplitude, long-lasting depolarizations with superimposed high-frequency action potentials corresponding to spikes and sharp waves on the surface. Recurrent GABAergic inhibitory mechanisms are present but impaired, as evidenced by the absence of rebound inhibition during interictal discharge (Fig. 1C, left).[48,49] The intense hyperexcitability of focal epileptic neurons could increase the likelihood of seizure discharge propagation in response to synchronous bursts of excitatory synaptic inputs during NREM sleep (Fig. 1C, right).

Figure 3 shows that a spindle-like train of high-frequency epileptiform discharge in depth electrodes precedes seizure onset (Fig. 3A) and propagation during NREM in a patient with temporal lobe epilepsy (TLE).[73] It was concluded that, unlike PGE, EEG and behavioral arousal events most often follow seizure onset,[73] although others have concluded

P.1978

that localization-related seizures are often precipitated by behavioral or EEG arousals during NREM sleep (e.g., Silvestri et al.[134]).

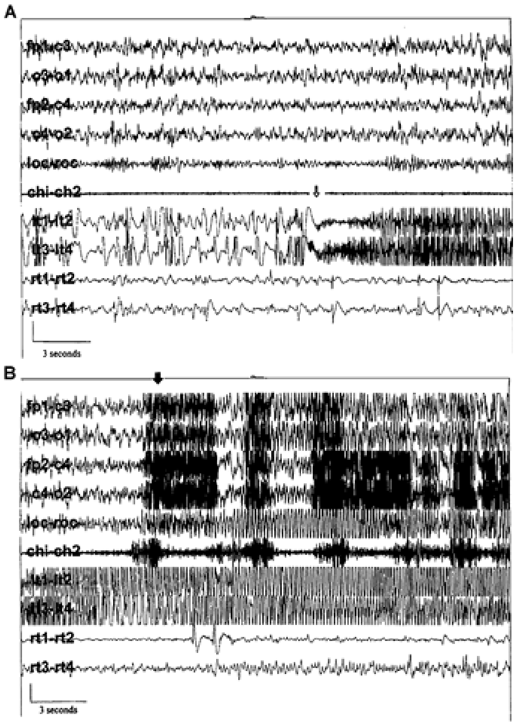

FIGURE 3. Combined scalp electrode (first six channels) and intracranial montage (last four channels). Lt1-lt2 and lt3-lt4, left temporal depth electrode contacts; rt1-rt2 and rt3-rt4, right temporal depth electrode contacts. Other depth electrode contacts are not shown. Calibration for scalp electrodes is 100 μV. Each figure represents 30 seconds. The open arrow in panel A indicates the intracranial electrode seizure onset in the left temporal depth electrode contacts, characterized by the cessation of interictal epileptiform discharges and their replacement by high-frequency sinusoidal activity. The solid arrow in panel B indicates the clinical arousal from sleep noted on the videotape, marked by myogenic artifact. (Reprinted from Malow BA, Bowes RJ, Ross D. Relationship of temporal lobe seizures to sleep and arousal: A combined scalp–intracranial electrode study. *Sleep*. 2000;23:231–234; with permission.)

There is significant variation in the severity of specific localization-related epileptic syndromes, based upon differences in medical refractoriness, spontaneous remission, and organicity.[91,121,123] Etiologies include but are not limited to trauma (see Chapter 253), lesions (see Chapter 251), and/or genetics (e.g., autosomal-dominant nocturnal frontal lobe epilepsy [ADNFLE] and some temporal lobe epilepsies; see Chapters 248, 249 and 255). Localization-related epilepsies with frontal or temporal lobe foci tend to be associated with more frequent clinically evident seizures, are more likely to be medically refractory[119] (although there are notable exceptions; e.g., nocturnal paroxysmal dystonia and ADNFLE), and are less likely to spontaneously remit than are the so-called "benign localization-related epilepsies." Regardless of these differences, localization-related epilepsies are most likely to display interictal and ictal discharges during NREM sleep.[7,8,9,40,53,57,58,78,91,95,121]

Table 2 Interictal discharges (IIDs) and visually scored sleep stage in 21 patients with medically refractory temporal lobe epilepsy

Sleep stage	IIDs	Total minutes	Average IIDs per minute
REM	179	1,327.5	0.135
Stage 1	393	1,118.5	0.331
Stage 2	2,193	4,284	0.512
Stage 3/4	882	883.5	0.998
Total	3,647	7,683.5	0.475

Arousals: Fewer than 1% of IIDs were preceded or followed by an arousal from sleep (defined as a shift of frequency to the alpha or theta range for at least 3 s).

Frontal and Temporal Lobe Epilepsies.

Frontal and temporal lobe epilepsies comprise the largest group of localization-related seizure disorders[25,90] (see Chapter 25) and the largest group of "pure sleep epilepsies":[57,58] Up to 59% of patients have been reported to exhibit convulsions mostly or only during sleep.[57,91] Recent evidence indicates that secondary generalization during sleep is less prominent in frontal than temporal lobe epilepsies, although 55% of secondary generalized complex partial seizures occur in sleep regardless of onset site or the timing of other seizure types.[53] In addition, IIDs, such as anterior spikes or sharp waves, have higher amplitudes, longer durations, and rounder peaks in NREM than in other sleep or waking states (e.g., Frost et al.[40]).

Although both clinical seizures and IIDs are more common in NREM sleep than in REM sleep, evidence suggests that deep NREM sleep is the most vulnerable period for IID,[78,113] whereas lighter NREM sleep is the most vulnerable period for clinical seizures.[53,93] This dissociation between clinical seizures and IIDs is illustrated by comparing Table 2[78] to FIGURE 4.[53] Table 2 shows that the incidence of IIDs per minute peaks during NREM stages 3 and 4 sleep,[78] whereas FIGURE 4 shows a peak in the incidence of secondary generalized seizures in stage 2 sleep.[53]

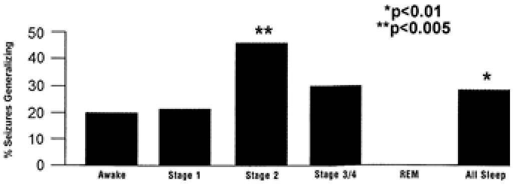

FIGURE 4. Percentage of partial seizures undergoing secondary generalization of complex partial seizures during various sleep stages. Sleep promoted the secondary generalization of seizures (n = 613 partial seizures in 133 patients) from all locations assessed (temporal lobe, mesial temporal lobe, neocortical temporal lobe, and occipital or parietal lobes) except the frontal lobe. REM, rapid-eye-movement sleep. (Reprinted from Herman ST, Walczak TS, Bazil CW. Distribution of partial seizures during the sleep–wake cycle: differences by seizure onset. *Neurology* 2001;56:1453–1459; with permission.)

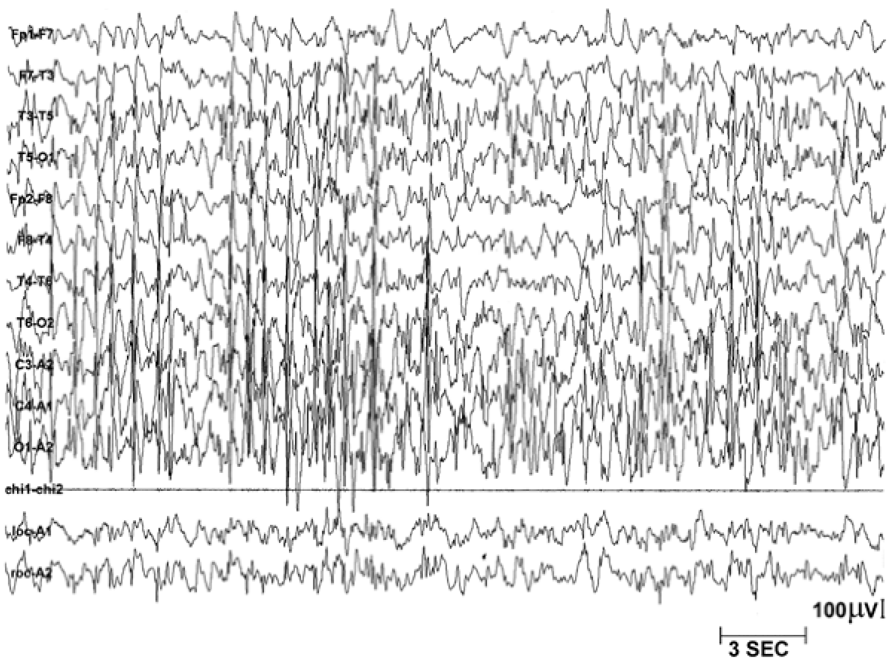

FIGURE 5. This 30-second epoch depicts non–rapid-eye-movement (NREM) sleep in an epileptic patient with electrical status epilepticus during sleep (ESES), also known as the syndrome of continuous spike-waves during slow-wave sleep (CSWS). The interictal discharges (IIDs) are so frequent that NREM sleep cannot be differentiated accurately into stages. Paroxysmal events in sleep and the EEG were recorded at 7 μV/mm. (Reprinted from Marzec ML, Malow BA. Approaches to staging sleep in polysomnographic studies with epileptic activity. *Sleep Med*. 2003;4:409–417; with permission.)

Several authors have emphasized a connection between REM sleep and partial or complex partial seizures originating from temporal lobe foci. However, most of these seizures occurred during NREM transitional states to or from REM rather than in stable REM sleep (e.g., Cadhillac[19] and Shouse et al.[123]). Because REM sleep transitions reflect an ultradian rhythm, this topic is described in more detail in Chapter 187. Herman et al.[53] saw few focal and no secondary generalized seizures during REM in a large series with 613 partial seizures in 133 patients regardless of seizure onset site, and Minecan et al.[93] noted that only 5% of seizures occurred during REM sleep in a separate series with 117 seizures in 55 patients. Neocortical seizures can be an exception (e.g., Mendez and Radtke[91]). Other evidence of the protective effects of REM sleep include the correlation between elevated REM percentages and reduced seizure incidence in human TLE[104] as well as the relative difficulty in evoking seizures[20] and the absence of

P.1979

spontaneous seizures during REM sleep in amygdala-kindled cats.[124,125]

Benign Localization-Related Seizure Disorders.

Examples of "benign" localization-related seizure disorders are benign epilepsy with centrotemporal spikes (BECT, also called benign rolandic partial epilepsy; see Chapter 236), benign occipital localization epilepsies (see Chapters 237 and 238), electrical status epilepticus during sleep (ESES; see Chapter 242), and Landau-Kleffner syndrome (acquired epileptic aphasia; see Chapter 242). Like seizure disorders of deep temporal or frontal lobe origin, these epilepsies are associated with diffuse IIDs during NREM sleep and maximal localization during REM sleep. Unlike many seizure disorders of temporal or frontal lobe origin, these childhood seizure disorders are considered benign because the seizures are responsive to AEDs and are likely to remit spontaneously (e.g., Mendez and Radtke[91] and Shouse[121]). Patients may be referred for a variety reasons other than seizures (e.g., slow progress in school in ESES, sudden deterioration of language skills related to auditory aphasia in Landau-Kleffner syndrome), and the seizure disorder may only be noted in a polysomnogram. FIGURE 5 shows an example of ESES, in which spike and wave discharges occupy at least 85% of NREM sleep. These types of pervasive seizure discharges in sleep are hypothesized to generate the nonepileptic symptoms of ESES and Landau-Kleffner syndrome as well, even though clinical seizures are rare and may not occur at all. In both ESES and Landau-Kleffner syndrome, cognitive, social, and linguistic anomalies tend to mitigate with seizure remission, but residual "nonepileptic" effects often persist (e.g., Mendez and Radtke[91] and Shouse et al.[121]).

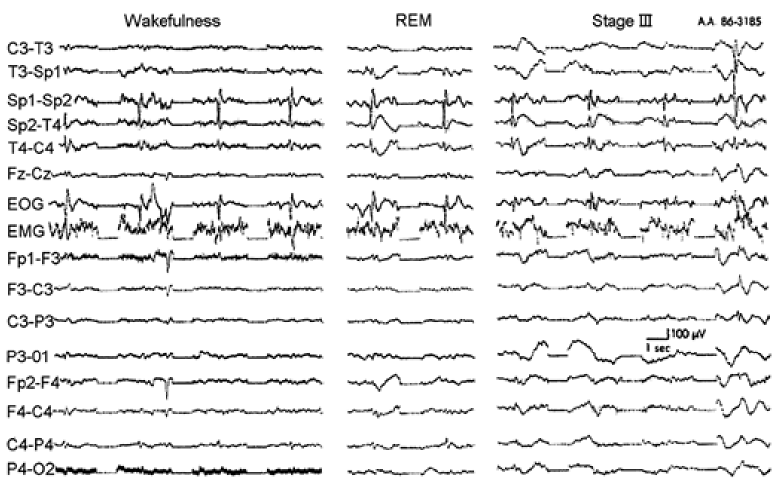

FIGURE 6. Electroencephalogram from scalp and sphenoidal electrodes during wakefulness, sleep stage 3, and rapid-eye-movement (REM) sleep for a patient with a temporal lobe focus. Sp1 and Sp2 are the left and right sphenoidal electrodes, respectively. Note the similarity of spiking fields in wakefulness and bilateral spiking in stage 3. Also note the maximal localization during REM. (Reprinted from Sammaritano M, Gigli G, Gotman J. Interictal spiking during wakefulness and sleep and the localization of foci in temporal lobe epilepsy. *Neurology*. 1991;41:290–297; with permission.)

Interictal Discharge Versus Ictal Seizure Discharge Propagation During Non–Rapid-Eye-Movement Sleep.

Differences in ictal seizure discharge propagation patterns cannot entirely be attributed to whether or not the localization-related seizure disorder is "benign." An unanswered question is why IIDs, which

P.1980

spread during NREM sleep, do not end in secondary generalized seizures. One possibility is the apparent location of the seizure focus. For example, many of the "benign" localization-related epilepsies appear to have neocortical foci. Ictal seizure discharge propagation seems to occur less often from neocortical foci than from subcortical sites during NREM sleep, as described previously. The presence of "inhibitory surrounds" has long been invoked to explain the confinement of cortical interictal and ictal discharges. This concept has recently been elaborated to include mechanistic interactions between glial and neuronal cell populations in neocortex and in deep cortical sites such as the hippocampus (e.g., Amzica and Steriade[1]). On the other hand, Herman et al.[53] found that seizures of mesial and neocortical temporal lobe origin exhibit secondary generalization more often than do those of frontal neocortical origin. See FIGURE 4 and the discussion of different findings between Herman et al.[53] and Crespel et al.[28] in Chapter 187. Another complication is the difficulty in verifying the actual site of the seizure focus and/or the propagation patterns even when subcortical leads are available. A third complication is that rapid seizure discharge propagation can occur in symptomatic localization-related syndromes, particularly those with neocortical tumors, and may initially present as primary generalized seizures (e.g., Malow et al.[79]).

Longitudinal Course of Sleep Epilepsies.

In temporal or frontal lobe epilepsies, seizures may occur initially only during sleep, although a random seizure pattern can develop later in the clinical course (e.g., D'Alessandro et al.[29]). For example, Janz reported that 38% of 100 patients with a 2-year or shorter history of epilepsy manifested complex partial seizures only during sleep, but a large percentage of these patients soon developed diurnal seizures as well.[58] Other studies[45,99] used patients with primary generalized, secondary generalized, and partial seizures that occurred only in sleep epilepsy at initial diagnosis. Over a 2-year follow-up, they found that patients with generalized seizures exhibited few seizures and tended to remit or to retain a sleep seizure pattern, whereas those with focal seizures tended to develop waking seizures as well. Effective medical management may also cause seizures to disperse across the sleep–wake cycle.[63]

The degree to which seizure patterns are state dependent may predict response to medication. Frequent seizures that are entrained to a specific sleep or arousal state usually respond better to medical treatment than epilepsies in which seizures are randomly distributed across the sleep–wake cycle.[55,84,99,152] Particular epilepsy syndromes are associated with different patterns of seizure occurrence. For example, benign or idiopathic localization-related epilepsies are more likely to retain nocturnal seizure patterns than are localization-related epilepsies with a documented lesion.[29,42,58]

The reason seizure patterns become random is uncertain. Frequent seizures may exacerbate cell dysfunction as well as response to synaptic input at the seizure focus and can ultimately influence cell discharge patterns in extrafocal brain areas (e.g., McNamara[90] and Shouse et al.[123]). Cells in certain limbic system areas, such as the hippocampus, are particularly sensitive to cerebral insult (e.g., McNamara[90]). Epilepsies in which there is widespread or progressive cerebral dysfunction usually have random distribution of interictal discharges and clinical seizures throughout the sleep–wake cycle.[16,42,44,50,57,58,84,98]

Regardless of the timing of clinically evident partial seizures, the rate, amplitude, and spread of IIDs peak during NREM sleep. Diffusion of spikes decreases during waking and further declines during REM sleep (e.g., Frost et al.[40]). The rate and amplitude of spikes may also be lower in REM sleep than in waking.[65,95,113] Because most partial seizure disorders are associated with focal cerebral dysfunction, it is not surprising that autonomous discharges persist during alert waking and REM sleep. Some authors suggest that optimal “focalization” occurs during REM, as seen in FIGURE 6.[113] Localizing epileptogenic foci during REM may assist in targeting the epileptogenic region for surgical resection.[71,113,114]

Symptomatic Generalized Epilepsies

This third group of seizure disorders is associated with variable degrees of diffuse cerebral dysfunction that can disrupt sleep, dissociate its components, and disperse IID and ictal discharges throughout the sleep–wake cycle (see footnote *b* of Table 1). Examples are West[42,54,98,159] (see Chapter 229) and Lennox-Gastaut[44,84,98] (see Chapter 241) syndromes and progressive myoclonic epilepsies such as Lafora-Unverricht-Lundborg syndrome[16,50] (see Chapter 252).

When NREM and REM states can be differentiated from waking, there is sleep-state modulation of IID and ictal seizure manifestations (e.g., Fukuyama et al.[42]). For example, hypsarrhythmia, the characteristic EEG manifestation of infantile

P.1981

spasms (West syndrome; Fig. 7), and the atypical slow spike-and-wave discharges of Lennox-Gastaut syndrome show a peak in NREM and subside during intact REM sleep. The prognosis for response to medical treatment is improved if IID or clinical seizures exhibit a sleep–waking state dependency, even if it is confined to a suppression of overt seizure activity in REM sleep.[42,54,55,84]

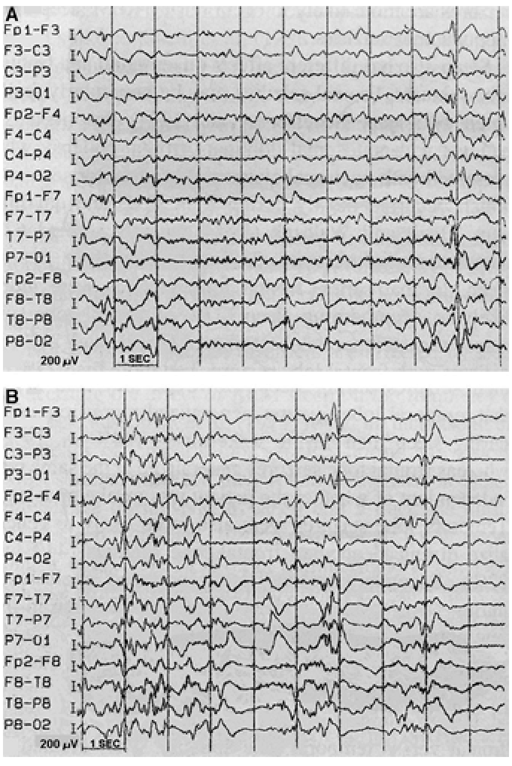

FIGURE 7. Effect of sleep on hypsarrhythmia. Electroencephalogram (EEG) from a 15-month-old girl with new onset of infantile spasms. **A:** EEG during waking shows multifocal high-amplitude sharp and slow-wave discharges, with intermittent periods during which a 5- to 6-Hz background could be seen. Note that the amplitude of this activity is 100 to 300 μV. **B:** The tracing from the same patient during sleep showed more prominent bursts of spike discharges, with periods of relative attenuation, which was not seen during wakefulness. Note that the high-voltage activity is in the range of 200 to 500 μV. (Reprinted from Mendez M, Radtke RA. Interactions between sleep and epilepsy. *J Clin Neurophysiol*. 2001;18:106–127; with permission.)

Basic Mechanisms

Three conclusions are supported by these clinical observations. First, in virtually all seizure disorders, interictal discharges are more likely to occur and to propagate during NREM sleep than in any other state. Second, the epilepsy syndrome, defined by seizure type, etiology, and prognosis, often determines whether clinically evident seizures occur exclusively or mainly during NREM sleep as opposed to waking. Finally, interictal discharges, particularly propagated IIDs, are least likely to occur during REM sleep. When epileptiform discharges do occur, they are unlikely to lead to a clinically evident seizure.

The contrasting effects of NREM and REM sleep on seizures and interictal discharges raise two questions: (a) which characteristics of NREM sleep account for the activation of interictal and ictal discharges and (b) which characteristics of REM sleep suppress them?

Many studies employing transections, lesions, pharmacologic manipulations, microdialysis, *c-fos* expression, regional blood flow, and individual cellular recordings indicate that different neural substrates mediate NREM and REM sleep states. These studies are summarized with references in Chapter 187 and are described in more detail in recent reviews.[3,22,60,89,131,135] Briefly, the NREM cell generators are localized to the forebrain, specifically the GABAergic and galaninergic cells of the anterior/preoptic hypothalamus (ventral lateral preoptic [VLPO]). The REM cell generators are localized to the brainstem, particularly the pontine tegmentum.[60,131]

Both NREM and REM sleep have a number of distinguishing physiologic characteristics, called components, that influence the likelihood that an electrographic or clinical seizure will occur. These include the degree to which cellular discharge patterns are synchronized and alterations in antigravity muscle tone.[105,128] NREM sleep differs from waking in that EEG activity is synchronized and postural muscle tone is diminished[21,60,131,135]; REM sleep differs from NREM in that EEG activity is desynchronized, and it differs from waking and NREM in that postural muscle tone is absent. REM sleep has sometimes been called “paradoxical sleep” because it is characterized by a “highly active brain in a paralyzed body.”[21]

During NREM sleep, virtually every cell in the brain discharges synchronously.[21,135,136,137] Lasting oscillations of rhythmic burst–pause firing patterns result in convergent synaptic actions. Synchronous synaptic effects, whether excitatory or inhibitory, are likely to augment the magnitude and propagation of postsynaptic responses, including epileptic discharges. During REM, cells discharge asynchronously.[131] The divergent synaptic signals of asynchronous discharge patterns are less likely to augment seizure magnitude or propagation.

Skeletal muscle tone varies by sleep state. Antigravity muscle tone is preserved in NREM[21] and thus permits seizure-associated movement.[24,128] Profound lower motor neuron inhibition occurs in REM,[21,22,131] creating virtual paralysis.

These different EEG and skeletal muscle tone components can be experimentally dissociated,[128] as depicted in FIGURE 8. FIGURE 8A shows normal feline REM sleep. FIGURE 8B shows that NREM-sleep–like EEG synchrony can be selectively induced during REM by systemic administration of atropine, which blocks acetylcholine (Ach) release from cells in the pedunculopontine and peribrachial nuclei of the brainstem and nucleus basalis of the forebrain. These cholinergic cells are one of the critical generators of global asynchronous EEG discharges in waking and particularly REM (e.g., Jones[60] and Siegel[131]; see also Chapter 187). FIGURE 8C shows selective loss of postural muscle tone induced by a lesion of the pontine generators of REM sleep atonia. Neural generators are thought to be cholinoceptive and glutaminergic cells in the brainstem atonia regions.[131]

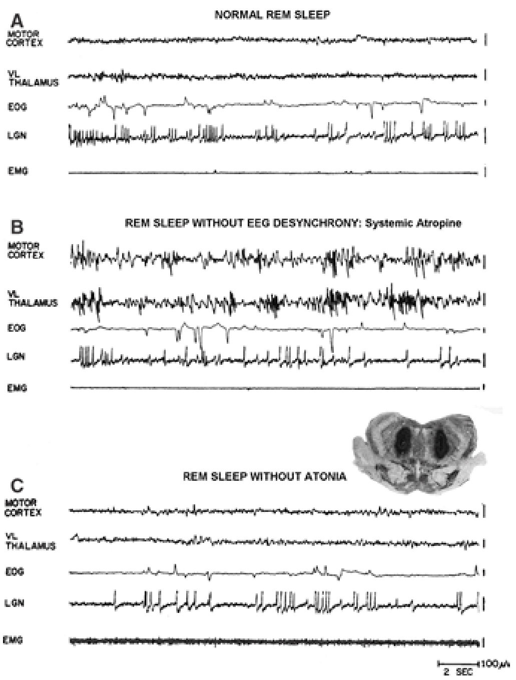

FIGURE 8. A: Normal feline rapid-eye-movement (REM) sleep, with electroencephalographic (EEG) desynchronization and atonia with periodic bursts of phasic events, including rapid eye movements and ponto-geniculo-occipital (PGO) spikes. **B:** Systemic atropine selectively abolishes EEG desynchronization. Instead, there is a non–rapid-eye movement (NREM)–sleep-like EEG with synchronized background and sleep spindles. However, atonia, eye movements, and PGO spikes persist. **C:** A pontine lesion selectively eliminates atonia. Note the presence of tonic EMG activity in the bottom channel of this tracing. EMG, electromyogram; EOG, electrooculogram; LGN, lateral geniculate nucleus; VL, ventral lateral nucleus of thalamus. (Reprinted from Shouse MN, Siegel J, Wu F, et al. Mechanisms of seizure suppression during rapid-eye-movement (REM) sleep in cats. *Brain Res.* 1989;505:271–282; with permission.)

Figure 9A shows the distribution of spike-and-wave complexes during intact NREM (left) and REM sleep (right) states. FIGURE 9B shows the effects of atropine administration. The REM-sleep EEG is synchronized, and seizure discharge rate is comparable to that in NREM (compare left and right panels). However, there is no clinical manifestation because of the skeletal motor paralysis in REM. FIGURE 9C shows that a pontine lesion eliminates REM sleep atonia so that a clinically evident seizure occurs in REM. These observations have been confirmed in three epilepsy models—penicillin

P.1982

epilepsy (shown), electroconvulsive shock (ECS), and amygdala kindling[124,125,128]—suggesting that cellular discharge patterns and alterations in tone can affect electrographic and clinically evident seizure manifestations in diverse epileptic syndromes.

The effects of NREM and REM sleep on interictal and ictal discharges may also vary as a function of epilepsy syndrome. The question is, what accounts for the activation or suppression of selective seizure manifestations at different times? For simplicity, hypothesized basic mechanisms for only two classes of seizure disorders are considered. These are the primary generalized disorders of idiopathic or hereditary origin versus secondary generalized disorders originating from temporal lobe foci.

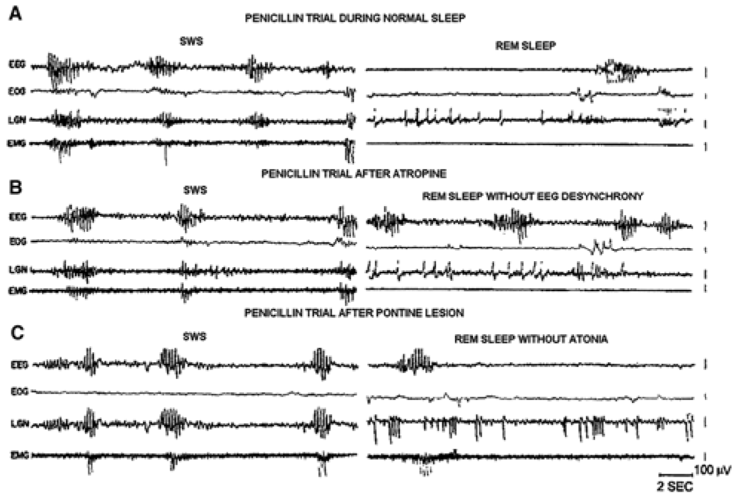

FIGURE 9. Systemic feline penicillin epilepsy during slow-wave sleep (SWS), the equivalent of non–rapid-eye-movement (NREM) sleep in humans, and REM sleep before and after dissociation of REM sleep components. Spike-and-wave paroxysms are visible in the electro-encephalogram tracing, and myoclonic seizures were associated with electromyogram (EMG) discharges in this cat. EEG, motor cortex EEG; EOG, electrooculogram; LGN, lateral geniculate nucleus. (Reprinted from Shouse MN, Siegel J, Wu F, et al. Mechanisms of seizure suppression during rapid-eye-movement (REM) sleep in cats. *Brain Res.* 1989;505:271–282; with permission.)

Cells of ascending reticular activating system are believed to promote propagation of interictal and ictal discharges in stable NREM sleep[1,4,123,124,125,126] (see Chapter 187 for a review), mostly via reduced cellular discharge and chemical release in cholinergic (Ach), noradrenergic (NE), and serotonergic (5-HT) cells. However, bursts of cholinergic cells in the pontine tegmentum generate arousal-related phasic events called ponto-geniculo-occipital waves (e.g., Shouse and Siegel[127]), which can provoke seizure discharge and sometimes its propagation in feline temporal lobe epilepsy (e.g., Shouse et al.[124,126]). Reduced electrochemical activity in reticulothalamic pathways appears conducive to IID propagation in primary generalized epilepsies,[1,41,136] probably by enhancing thalamocortical (EEG) synchronization patterns. Synchronized sleep transients, such as sleep spindles and possibly even delta waves, are contingent on sequenced hyperpolarizing GABAergic input from the thalamic reticular nucleus (RE) to thalamocortical relay cells.[1,41,135,136,137,149] Altered discharge patterns in RE cells are thought to inhibit thalamocortical neurons during cortically generated spike-wave discharge and also to explain the sensory isolation, lack of awareness, and behavioral arrest during absences as well as the absence of postictal depression afterward.[1,41,136] These synchronous thalamocortical discharge oscillations are abolished by activation of ascending brainstem afferents, particularly NE projections, which discharge maximally during alert waking, and cholinergic projections, which discharge maximally during alert waking and REM sleep.[60,89,132,135,136,149]

Reduced electrochemical activity in reticulolimbic pathways most parsimoniously explains interictal and/or ictal discharge propagation from temporal lobe foci during NREM sleep,[123,124,125,126] perhaps from direct or indirect innervation of focal epileptic neurons (refer to Jones[60] for anatomy). NE and 5-HT dialysates in pontine tegmentum and amygdala decline prior to sleep and spontaneous seizure activity after kindling.[129] Microinfusion studies indicate that local application of NE-receptor antagonists to limbic seizure foci promotes ictal discharge propagation, whereas NE-receptor agonists block seizure discharge generalization (e.g., Shouse et al.[122]). Microinfusion of cholinergic agonists into the pontine tegmentum promotes REM sleep and reduces amygdala-kindled seizure susceptibility.[67] The basis for reduced secondary generalization of frontal lobe foci is unclear and requires further investigation; however, similar mechanisms may be involved in the prevalence of partial and complex partial seizure during sleep. For example, Ach receptor dysfunction has been implicated in ADNFLE (e.g., Rodrigues-Pinguet et al.[108]).

Sleep Abnormalities

Clinical Findings

Just as sleep affects the expression of seizures, seizures influence sleep. Nocturnal seizures do not simply result in brief interruption of sleep; in fact, they can result in significant changes in sleep structure, particularly decreased sleep efficiency and decreased REM sleep (e.g., Bazil et al.[11]). The results are often seen clinically when patients with even very brief nocturnal seizures report inability to function adequately the following day. This may be confusing in the case of unrecognized nocturnal seizures. Treatment with anticonvulsant drugs can improve sleep by stopping seizures, but anticonvulsants can also have independent neuromodulatory effects that cause sleep disruption.[10,15,18,68,106,112,147,148]

Patients with epilepsy may, in addition, have a coincident sleep disorder such as periodic limb movements of sleep or sleep apnea that disrupts normal sleep, resulting in hypersomnolence. Disorganized and disrupted sleep may lead to complaints of poor sleep quality, excess daytime sleepiness, and a general decline in quality of life, including mood, cognitive, and memory deficits, as well as to increased refractoriness of the seizure disorder.[6,7,8,14,35,37,133,147] Once recognized, many of these complications may be improved or resolved by direct intervention aimed at treating the sleep disorder,[34,76,82,147] tailoring AEDs to avoid adverse side effects, or giving instructions on improved

sleep hygiene with respect to routine sleep habits, reduced environmental distractions (e.g., exposure to light at times nonconducive for sleep), and other personal habits such as substance abuse.[7,8,37] A number of assessment tools are available to identify the nature of sleep disturbance in patients with epilepsy and to differentially diagnose epileptic from nonepileptic disorders. Many of these are discussed in more detail in related chapters, including those on sleep disorders (Chapter 276), affective disorders (Chapter 205), nonepileptic psychogenic seizures and epilepsy (Chapter 207), and nonepileptic psychogenic seizures (Chapter 282).

Briefly, there are several diagnostic tools ranging from patients' and significant others' logs, diaries, and questionnaires to polysomnography (PSG) with simultaneous behavioral video recordings. Particularly in patients with epilepsy and complicated histories or when differential diagnosis of nocturnal events is an issue, it may be helpful to include a full EEG array to detect and differentiate ictal and interictal abnormalities from other nocturnal disorders simultaneously with polysomnography. All may provide important information to supplement a thorough patient history and a routine EEG.[9,70,147] For example, the Epworth Sleepiness Scale is a simple questionnaire, and the outcome correlates positively with the multiple sleep latency test (MSLT), the gold standard of PSG for confirmation of excess daytime sleepiness (e.g., Foldvary-Schaefer[37]).

There are obvious limitations to the value of questionnaires, but they provide important data that may lead to referral for PSG. It seems generally accepted that patients with evidence of disordered sleep or a confusing clinical picture are candidates for a PSG, particularly when complaints of excess daytime sleepiness occur in epilepsy patients on monotherapy, with low AED serum levels, or with poor seizure control.[147] Simultaneous video can be particularly valuable in cases in which EEG seizure events are difficult to record or are absent in the waking EEG, clinical seizures are subtle, and differential diagnosis of seizures from sleep disorders or from pseudoseizures is difficult.[9,68,70] For example, epileptic seizures originating from mesio-orbito-frontal areas may have bizarre manifestations and ambiguous EEG correlates leading to a misdiagnosis of parasomnia.[8,70,88,101] Most patients with paroxysmal dystonia have sleep-related frontal lobe seizures, but the EEG alone is inconclusive (e.g., Montagna[94] and Sellal et al.[118]). In other cases, parasomnias coexist with limbic epilepsy without a common etiology.[43,51,141]

Sleep complaints are common in the general population and are particularly prevalent among those with epilepsy. In a study of 30 children with partial or generalized seizure disorders, 80% of sleep complaints were confirmed by PSGs indicative of obstructive sleep apnea, disturbance of sleep architecture, or sleep fragmentation. Sleep disturbance was more highly correlated with parent-reported daytime behavioral problems, notably inattention/hyperactivity, than was seizure incidence.[14] In other studies, large series of children with or without idiopathic epilepsy showed high ratings for poor quality sleep, anxiety about sleep, and disturbed breathing when compared to controls; correlations could be established with seizure frequency, incidence of IIDs and duration of seizure disorders, in addition to behavioral problems.[27,140]

Adults with focal seizure disorders with and without secondary generalization report sleep disturbances about twice as often as age-matched controls and also report a poorer quality of life than occurs with epilepsy alone.[35] Complaints of excessive daytime sleepiness have also been identified as predictors of seizures, particularly in relation to sleep disorders, such as sleep apnea, and have been also linked to increased seizure frequency and/or number of AEDs.[37,76,83] Poor sleep hygiene, such as irregular sleep habits, more substance abuse, and poor exercise, also has been related to excess daytime sleepiness and insomnia, particularly in younger patients, including children.[37]

Epilepsies prone to state-dependent IIDs or seizures are accompanied by similar sleep abnormalities, including increased sleep onset latency, increased number and duration of awakenings after sleep onset, reduced sleep efficiency, reduced or abnormal K-complexes and sleep spindles, reduced or fragmented REM sleep, and increased stage shifts.[4,16,55,65,95,144,145] FIGURE 10 illustrates some of these deficits by comparing statistics of a normal hypnogram (Fig. 10A) to those of a medically refractory patient with temporal lobe epilepsy during a seizure-free night (Fig. 10B). For an update of automated seizure detection programs, see Chapter 95.

Sleep abnormalities have been observed on PSGs in patients with juvenile myoclonic epilepsy,[47,145] primary generalized tonic–clonic seizure disorders,[148] and localization-related epilepsies of frontal or temporal lobe origin (e.g., Bazil et al.[11] and Versavel[148]). Reports are in conflict about sleep anomalies

in patients with pure absence seizures (e.g., Ross et al.[110]). No sleep abnormalities have been reported in BECT.[29] Comprehensive reviews are also available.[91,121,123]

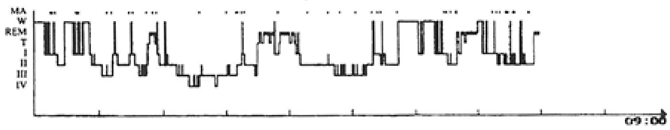

FIGURE 10. A comparison of hypnograms and related statistics using Somnis C software (AMISYSE), a semiautomatic method for sleep analysis of polysomnograms. Normally, the stages of sleep vary throughout the night in a somewhat predictable order.[19] Sleep onset typically begins with non–rapid-eye-movement (NREM) sleep, which predominates during the first one third of the night. Then, NREM and REM alternate with a periodicity of about 90 minutes. Finally, REM sleep predominates during the last one third of the night and is linked to the circadian rhythm of body temperature. A normal range of percentages for NREM stages 1 to 4 and for REM sleep in a young adult are as follows: stage 1, 25%; stage 2, 45% to 55%; stage 3, 38%; stage 4, 10% to 15%; REM, 20% to 25%, the latter occurring in four to six discrete episodes. **A:** Normal sleep organization in a typical young adult. Percentages of NREM and REM are normal. The REM latency of 86 minutes and number of REM cycles are within normal limits. Sleep efficiency, continuity, number of movement-related arousals, and awakenings are normal. **B:** Disorganized sleep architecture in a young adult with medically intractable temporal lobe epilepsy during a seizure-free recording. Sleep analysis shows a decrease in percentage of stage 4 and REM sleep together with increased stage 1 sleep. The increased number of movement-related arousals, number of awakenings after sleep onset, and stage shifts contribute to the fragmented sleep architecture. The REM latency (107 minutes) and number of REM cycles (four) are normal, but REM fragmentation is detectable. Sleep efficiency and continuity are decreased. I, stage 1 sleep; II, stage 2 sleep; III, stage 3 sleep; IV, stage 4 sleep; MA, movement arousal; REM, REM sleep; T, transitional stage; W, wakefulness. Time is indicated by h (hours) or mn (minutes). Recording started at 23 hours and ended at 7 hours, 14 minutes. Each line on the X axis divides the hypnogram into intervals of 1 hour. Sleep efficiency = total sleep time/(final awakening time-lights-off time). Sleep continuity = total sleep time/(final awakening time-time of sleep onset). (M. Sammaritano, reprinted from Shouse MN, da Silva AM, Sammaritano M. Sleep. In: Engel J Jr, Pedley TA, eds. *Epilepsy: A Comprehensive Textbook*. Philadelphia: Lippincott-Raven; 1997:1929–1942; with permission.)

Some sleep abnormalities, especially delayed REM onset, can occur as a result of recent daytime or nighttime convulsions (e.g., Bazil[5] and Bazil et al.[11]) or specific anticonvulsant drugs[5,6,7,8,9,10,146] (also see next section on anticonvulsant drugs), but sleep abnormalities can persist in spite of these factors. Sleep abnormalities have been reported to be more common in patients with primary or secondary generalized seizures than in those with simple or complex partial focal epilepsies,[91,121,123] but other studies have concluded that focal and complex partial seizures, especially in patients with temporal lobe epilepsy with frequent or medically refractory seizures, are also likely to have PSG-confirmed sleep disorders (e.g., Shouse[120,121] and Touchon et al.[145]).

Severe sleep abnormalities occur in symptomatic epilepsies that are associated with significant neurologic deficits. The sleep abnormalities described in the previous paragraphs are exaggerated, and sleep cycles may be poorly organized. In very severe epileptic disorders, a sleep cycle may not even be discernible.[16,42,44,50]

In conclusion, practitioners have in the past tended to dismiss patients' sleep complaints as unavoidable side effects of medications. The upsurge in the use of PSG and PSG-video during the last decade has confirmed sleep complaints as well as the chronic, deleterious effects of seizure-related or non–seizure-related sleep disorders on daytime activities, including exacerbation of seizure activity. It is appropriate and essential to consider treating the sleep abnormality and the seizure disorder as separate but related entities; however, both must be addressed before the patient will be able to perform at his or her best.[8,70,146]

Basic Mechanisms

Major motor seizures, especially tonic–clonic convulsions, substantially increase NE release. This presumably causes acute NE depletion in the postictal period. Norepinephrine release is normally suppressed during REM sleep,[103] which causes receptor upregulation or desensitization of NE receptors.[132] Postictal NE depletion may also lead to receptor upregulation. This is consistent with the hypothesis that seizures replace REM sleep (e.g., Stevens et al.[138,139]) and could also explain postictal delays in REM sleep onset.[4]

Other sleep abnormalities could result from neurotransmitter abnormalities associated with seizure disorders. For example, abnormalities of GABA synthesis and transmission have been implicated in the pathophysiology of most seizure disorders.[1,48,90,136] Fluctuations in other transmitters, such as Ach and NE, have been implicated in EEG and behavioral arousal.[3,60,89] Deficient GABA or increased Ach and NE could provoke the frequent stage shifts, increased wakefulness after sleep onset, and poor sleep efficiency seen in many epilepsy patients. The diffuse encephalopathies that accompany severe seizure disorders, such as infantile spasms and Lennox-Gastaut syndrome, seem likely to produce a significant neurochemical imbalance affecting sleep. Such an imbalance would be consistent with the notable disruption of sleep cycles recorded in these patients.

Antiepileptic Drugs

Clinical Findings

For many reasons, it is difficult to disentangle the effects of antiepileptic drugs (AEDs), sleep, and seizure disorders. AEDs have many side effects, which raises ethical considerations for testing in normal controls. Testing in normal individuals must in any case be limited to the relatively short term, unlike epilepsy patients, who typically take these medications for years. Seizures themselves (as described previously) have many effects on sleep, and therefore it can be difficult to isolate sleep benefits due to seizure control in epilepsy patients from other sleep effects (positive or negative). Particularly refractory patients often take more than one AED, further complicating results, but withdrawal of adjunct AEDs poses a risk for increased seizure activity, including status epilepticus. Most of the data are therefore based on findings in medicated epilepsy patients. An additional drawback is that AEDs are not site specific and thus affect neuronal networks involved in both sleep and seizure generation (recent reviews are available[7,37,81,91,102,146]).

State-dependent seizures are usually more responsive to AEDs than are seizures that occur randomly in the sleep–wake cycle.[91,99,121,152] AEDs can reduce seizure frequency but can also cause seizures to be randomly dispersed in the sleep–wake cycle.[63] The reason for this is unknown.

Table 3 summarizes effects of various AEDs on sleep architecture and complaints. Many traditional AEDs promote normalization and stabilization of sleep by increasing sleep latency, reducing stage shifts, and minimizing arousals during sleep (phenytoin,[107,151] carbamazepine,[47,107,148] pheno-barbital,[107] and benzodiazepines[26,115]). These AEDs rarely increase total sleep time or reduce complaints of daytime sleepiness because of the tendency to affect other components of sleep, including increasing light NREM stage 1 sleep, reducing deep NREM (stages 3 and 4) sleep, and reducing REM sleep. Other conventional AEDs, such as ethosuximide, promote arousals, elevate NREM stage 1 sleep, decrease NREM stages 3 and 4 sleep and REM sleep, and induce complaints of insomnia. Some of these medications are associated with weight gain (e.g., valproate) and diminished upper airway tone (e.g., phenobarbital and benzodiazepines), which promote sleep disorders such as sleep apnea. As mentioned previously, these drugs can improve sleep by stopping seizures, but anticonvulsants can also have independent neuromodulatory effects that cause sleep disruption.[10,15,18,68,106,112,147,148]

Table 3 Antiepileptic Medication Effects on Sleep Architecture and Complaints

Drug	Sleep efficiency	Total sleep time	Sleep latency	Arousals	Stage 1	Stage 2	Stage 3/4	REM sleep	Sleep complaints/ disorder effects
Phenytoin	Decrease	None	Decrease	Decrease	Increase	Increase	Decrease	None	Sleepiness
Carbamazepine	Increase	None	Decrease	Decrease	None	None	Increase	Transient decrease	Sleepiness; treats RLS
Phenobarbital	Decrease	None	Decrease	Decrease	Increase	Increase	None	Decrease	Sleepiness; OSA
Ethosuximide	Decrease	Unknown	Unknown	Increase	Increase	None	Decrease	Increase	Unknown
Valproate	None	None	None	Increase	Unclear	None	Increase	Mild decrease	Sleepiness; OSA
Felbamate	Decrease	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Insomnia
Lamotrigine	None	None	None	None	None	None	Unclear	Mild increase	Insomnia (rare)
Gabapentin	Increase	Increase	Decrease	Decrease	Decrease	None	Increase	Increase	Treats RLS

Topiramate	None	None	None	None	None	None	None	None	Unknown
Vigabatrin	Unknown	None	None	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown
Tiagabine	Increase	None	None	None	None	None	Increase	None	Unknown
Levetiracetam	None	None	None	None	None	Increase	Decrease	None	Insomnia (rare)
Zonisamide	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Unknown	Insomnia (rare)
Pregabaelin	Increase	None	Decrease	Decrease	None	None	Increase	None	Unknown

OSA, obstructive sleep apnea; REM, rapid eye movement; RLS, restless leg sleep syndrome.
[a]Sleep efficiency is the ratio of total sleep time to total waking time after sleep onset.
Updated from Vaughn BV, D'Cruz OF. Sleep and epilepsy. *Semin Neurol*. 2004;24:301–313; with permission.

Acute and chronic effects of AEDs on sleep and epilepsy can sometimes be dissociated, as suggested in Table 3, and AEDs may affect sleep in ways that are not relevant to seizure control. Virtually all first-generation AEDs delay REM sleep onset or suppress REM sleep percentages,[7,8,147] even though many AEDs differentially affect specific seizure types. For example, "petit mal" AEDs can exacerbate complex partial seizures, and "temporal lobe" AEDs can exacerbate absence seizures.[109] Furthermore, since the early work in this area, many new anticonvulsant drugs have been developed that are also specific for seizure types. Their effects on sleep-related IID or clinical seizures and on sleep are not known, but preliminary evidence suggests that felbamate has stimulant effects, lamotrigine may have no effects on sleep, and gabapentin may increase NREM stages 3 to 4 sleep and also increases or has no effect on REM sleep.[8,9,10,37,68,115,147]

Vagus nerve stimulation (VNS) has been accepted for use in intractable seizure conditions. Although VNS has been shown to improve daytime alertness,[75] it can induce obstructive respiratory events in sleep (see Chapter 131).[74,86,147]

It is not possible to state whether the favorable or adverse effects of AEDs or VNS on sleep materially affect seizure control in general, although it is clear that in some patients, particularly those with juvenile myoclonic epilepsy,[57,59,95] seizure occurrence is extremely sensitive to sleep deprivation of any kind. However, sleep disorders do independently influence quality of life, and this should be taken into account particularly when seizures are refractory or when AEDs or alternative treatments that do not influence sleep or that can mitigate sleep

P.1986

disturbance are available. Treatment of coexisting sleep disorders (e.g., obstructive sleep apnea, inadequate sleep hygiene) can improve both daytime sleepiness and seizures. In a subgroup of patients with epilepsy, changing AED to better treat coexisting sleep disorders may be warranted; the first step in this process is of course recognition of the sleep problem (e.g., Legros and Bazil[68] and Malow and Vaughn[81]).

Basic Mechanisms

The mechanisms of action of individual AEDs are covered in the section on antiepileptic drugs (Chapters 144,145,146,147,148,149,150,151,152,153,154,155,156,157,158,159,160,161,162,163,164). Many are thought to act on seizures by altering sodium, calcium, or chloride channels, sometimes in relation to specific transmitter binding, and may similarly influence sleep.[147] The systemic nature of effects, even with monotherapy, and the additional confounding influences posed by polytherapy significantly complicate evaluation of the basic mechanisms governing AED–sleep interactions. For example, the benzodiazepines act at $GABA_A$ receptors to increase neuronal inhibition. The resulting reduction in ictal and interictal discharges that results is associated with an increase in the rate of sleep spindles, with which many IIDs are associated. In contrast, ethosuximide, an AED that effectively suppresses absence seizures, reduces both the reticular thalamic Ca^{2+} spikes involved in the generation of sleep spindles and spike-and-wave complexes in some slice preparations.[135,149] This implies that ethosuximide might suppress spike-and-wave complexes by affecting the same mechanisms that produce sleep spindles. In humans and some animal models, however, ethosuximide suppresses spike-and-wave complexes without affecting spindle incidence (e.g., Kellaway et al.[63]), possibly by altering the Ca^{2+}-mediated t-current without eliminating it.[56] Caution must therefore be used in extrapolating proposed in vitro mechanisms to in vivo findings. Collectively, however, the clinical and basic findings suggest that AEDs can correct sleep and seizure anomalies concurrently, but they need not (see Table 3).

VNS has been hypothesized to improve daytime alertness through its effects on thalamocortical projection neurons. Even patients who did not show improvements in seizure control with VNS exhibited a reduction in daytime sleepiness as manifested by the Multiple Sleep Latency Test.[75] VNS may influence respiration during sleep via central pathways, peripheral mechanisms, or both. Activation of motor efferents alters neuromuscular transmission to the upper airway muscles of the pharynx and larynx to produce upper airway narrowing. Alternatively, VNS may influence respiration via central projections to the reticular formation of the medullar or medial pons, which connect with pontomedullary nuclei involved in regulating breathing and upper airway musculature.

Sleep Deprivation

Clinical Findings

Sleep deprivation can precipitate clinically evident seizures (e.g., Degen[30]). Methodologic problems, including control of extraneous seizure precipitating factors such as stress, fatigue, and substance abuse (e.g., Frucht et al.[39]), likely contribute to some clinical and self-report findings. Malow et al.[79] found no activation of seizures in patients with partial epilepsy after acute sleep deprivation and studied in the controlled setting of in-patient video monitoring of presurgical candidates. Other presurgical evaluation units have examined the utility and cost of sleep-deprived EEG, magnetic resonance imaging (MRI), and positron emission tomography (PET). PET was the most expensive and effective. It was concluded that sleep-deprived EEG and MRI should be done on an outpatient basis for presurgical evaluation.[33]

Most sleep deprivation studies have focused on activation of IIDs for diagnostic purposes in patients with normal, borderline, or minimal epileptiform discharges in routine waking EEGs. The range of experimentally induced sleep deprivation is usually briefer in children than in adults (3–4 hours vs. >24 hours), although partial sleep deprivation has been studied in adults as well. The results of sleep deprivation have been compared to routine waking EEGs and to natural or drug-induced sleep with or without hyperventilation and photic stimulation. Nearly all studies showed sleep deprivation activation exclusively in epilepsy patients with or without medication.[91]

The benefits of sleep deprivation, particularly when compared to waking and to natural or drug-induced sleep, have been debated. Methodologic issues include the longer duration of postdeprivation sleep versus waking records, the absence of baseline sleep recordings, and differences in composition of study populations. The majority of findings indicate that sleep deprivation increases IIDs by 30% to 50% in postdeprivation sleep versus ~15% to 30% in postdeprivation waking records.[38,145] However, Klinger et al.[66] controlled for sleep and waking state duration by analyzing rate rather than total percentage of activation and found more activation in postdeprivation waking records. Rowan et al.[111] evaluated patients with normal or borderline routine waking EEGs and found that epileptiform discharges were activated in 44% after sleep deprivation versus 14% during drug-induced sleep. Sleep deprivation is not necessarily superior to drug-induced or natural sleep, including naps,[85] as an activation technique. Eschenne et al.[36] found activation in 73% of sleep EEGs as compared to 36% of sleep deprivation records. However, other authors obtained lower yields from natural sleep (28.6% gain over waking EEGs) with a further gain of 10% after sleep deprivation.[111]

Sleep deprivation is effective in provoking all focal and generalized interictal discharges in patients with state-dependent or random seizures in the sleep–wake cycle.[30] Increased activation has been seen at all ages, although there is evidence that children <10 years of age are more responsive than 11- to 30-year-olds, who are in turn more responsive than adults >30 years of age.[30] These age-dependent effects are not surprising, given the increased sleep requirements in the young.[21] Unexpected gains in activation have been seen in the postdeprivation response to photic stimulation and sometimes hyperventilation (e.g., Rowan et al.[111]).

Basic Mechanisms

The mechanisms whereby sleep deprivation affects epilepsy are not well understood, mainly because it is difficult to control for other confounding variables such as stress and hormones.[39,57,97] The activating effects of behavioral sleep deprivation on seizures can be duplicated by lesions of NREM sleep generators in the preoptic basal forebrain.[130] Behavioral sleep deprivation also reduces spontaneous discharge rates of cells in the vicinity of the locus ceruleus in cats. These cells of the pontine tegmentum contain Ach, NE, or 5-HT.[60,61] Any change in these or other neuromodulators could account for the increased “drowsiness” and rapid NREM sleep onset in sleep-deprived subjects and for increased susceptibility to ictal and interictal discharges.

Summary and Conclusions

1. Both NREM sleep and drowsiness after awakening from NREM sleep are conducive to electrographic and clinically evident seizures, whereas REM sleep is not. Epileptic discharges are most focal during REM sleep and are also least prevalent.
2. Neural generators of synchronous EEG oscillations may provide a natural mechanism for electrographic seizure propagation during NREM and drowsiness, and antigravity muscle tone permits seizure-related movement.
3. Neural generators of asynchronous neuronal discharge patterns may reduce electrographic seizures during alert waking and REM sleep, and skeletal motor paralysis seems to block seizure-related movement in REM sleep.
4. Clinical neurophysiologic techniques, such as video-EEG polysomnography, can assess disturbances in nocturnal sleep or excessive daytime sleepiness. Sleep disturbances often parallel the severity of seizure disorders, possibly because seizures and the pathophysiology underlying epileptic syndromes may have disruptive effects on generators of sleep and arousal.
5. Antiepileptic drugs (AEDs) can lessen or exacerbate sleep disturbances and complaints. Improvement in sleep architecture is not usually a critical factor in seizure control, but efforts to ameliorate deleterious effects on quality of life should be taken seriously by practitioners.
6. Sleep deprivation appears superior to both routine waking EEGs and drug-induced sleep for activation of epileptiform discharges, possibly by inducing neuronal discharge patterns that normally promote drowsiness and NREM sleep.

Chapter 189

Sudden Death in Epilepsy

Lina Nashef

Torbjörn Tomson

Introduction

Mortality in epilepsy is increased two- to threefold (see Chapter 10). Much of the excess mortality is due to associated or underlying disease, but there is also a smaller amount of excess related to the epilepsy itself, due to accidental injury, drowning, status epilepticus or sudden death. Sudden unexpected ("unexplained") death in epilepsy (SUDEP), in which an otherwise well person with epilepsy dies unexpectedly in benign circumstances with no cause found at autopsy, is the most important category of epilepsy-related deaths. As discussed in this chapter, we believe that such deaths are most likely related to epileptic convulsions. In recent years, some significant risk factors have been recognized through case–control studies. Nonetheless, it is not understood why some individuals are more at risk than others with a similar profile.

Historical Perspective

It has long been recognized **t**hat otherwise well individuals with epilepsy can die suddenly. Suffocation or asphyxia during a convulsion was considered a likely mechanism, as described in 1854 by Delasiauve[13] in his treatise on epilepsy, under the section Terminaisons:

> La mort est due souvent à une suffocation mécanique spéciale. Atteints dapops;accès dans leur lit, les malades se retournent instinctivement sur le ventre; le paroxysme les surprend dans cette position et les cloue, en quelque sorte, la face contre les oreiller ou le traversin. L'interruption de l'air ne tarde pas, si tous secours fait défaut, à provoquer l'asphyxie. On constate alors la bouffissure violacée du visage, du cou, et quelquefois de la partie supérieure de la poitrine; l'aplatissement des lèvres collées à la lange, qui se présente a leur ouverture; l'écrasement des narines et différents signes de congestion cérébrale et pulmonaire.

This description focuses on extrinsic mechanisms. It was also recognized that intrinsic mechanisms could account for such deaths. Early in the twentieth century, based on experience at the Craig Colony, Spratling[61] described epilepsy as

> a disease which destroys life suddenly and without warning through a single, brief attack, unaided by an accident to the patient at the moment, such as suffocation or fracture of the skull from falling, and does so in from 3% to 4% of all who suffer from it.

In Munson's mortality series[36] from the same colony, death from status epilepticus/series of seizures was relatively common and had declined compared to earlier years at the colony, unlike the category of sudden death. Nocturnal deaths were considered accidental and potentially preventable. Of note was "a definite and fairly large group where neither accident of any kind nor suffocation can be assigned as the cause of death which seemed to be intrinsic rather than extrinsic." He concluded "that death is imminent at the time of seizures, unless help is at hand. The cause may be traumatic, suffocation may take place, or deaths may occur without any apparent cause…. The epileptic should be by himself as little as possible." Many of the observations made by these earlier physicians are reflected in current knowledge. Despite a period of denial from some quarters in the second part of the twentieth century, SUDEP is now acknowledged as a real phenomenon and one that engenders concern. Not all that long ago, however, its existence was disputed. The efforts of investigators in the 1970s and 1980s, on both sides of the Atlantic, in drawing due attention to it should be acknowledged. These include Terrence, Hirsch, Brown, Earnest, Lathers, Schraeder, Leestma, Schwender, their colleagues, and others. SUDEP, however, is not a "cause." It is but a convenient category in which to classify such deaths. Different risk factors may operate through a final common pathway of cardiorespiratory compromise.

Definition of Sudden Unexpected Death in Epilepsy

This has been the subject of debate. To be classified as SUDEP, a death occurring in benign circumstances has to be sudden, unexpected, and without a clear cause. The latter requirement differentiates SUDEP from sudden death in general, in which autopsy may reveal a cause for death. Some investigators exclude observed peri-ictal deaths. However, most SUDEP cases are unwitnessed, with the person found dead, more often in bed, having been well the evening before. Evidence suggestive of a terminal epileptic seizure, such as tongue biting or incontinence, may be found at autopsy, but such evidence cannot be regarded as conclusive, nor indeed does its absence exclude an epileptic seizure. Thus, it is often not possible to be certain that the death occurred during or shortly after an epileptic seizure.

The following is a pragmatic, workable, if rather cumbersome, definition of SUDEP: Sudden, unexpected, witnessed or unwitnessed, nontraumatic and nondrowning death in patients with epilepsy with or without evidence for a seizure, and excluding documented status epilepticus, in which post mortem examination does not reveal a (structural or toxicologic) cause for death.[37] This definition makes no assumption of mechanisms(s) and allows similar deaths to be conveniently grouped. However, autopsies are not always performed, and, when they are, may be limited.[42] Annegers and colleagues[1] suggested that deaths in epilepsy should be classified into (a) definite (with autopsy), (b) probable (suggestive circumstances but no autopsy), or (c) possible SUDEP cases or (d) cases with a clear cause of death. The definition above has been helpful in case–control studies. It has a major limitation, however. By excluding cases with coexisting pathology that predisposes to sudden death, it does not allow us to assess any increased risk of sudden death from epilepsy in such cases.

P.1992

Incidence of Sudden Unexpected Death in Epilepsy

This needs to be viewed with reference to the background risk of sudden death in the general population of around 0.05 to 0.1/1,000 for those <45 years of age and 3/1,000 for those older.[1] Reported rates of SUDEP vary depending on the cohort studied, as addressed in previous reviews.[46,63] Broad estimates are presented below. Most cohorts are selected. Population-based studies of adequate size are difficult to achieve. The U.K. prospective population-based study of newly diagnosed epilepsy[32] observed only 1 SUDEP case among 792 patients in 11,400 person-years of follow-up. One needs to consider, however, the excess mortality due to underlying or associated disease and the observation that 70% developed lasting remission. In a population-based study based on 9 SUDEP cases from Rochester, New York,[18] the rate observed was 0.35/1,000 person-years. Two SUDEP cases were observed in 5,000 person-years of follow-up in the Medical Research Council antiepileptic drug (AED) withdrawal study[35] among patients with controlled epilepsy randomized to continued treatment or gradual drug withdrawal after a minimum of 2 years of seizure freedom. A multicenter unselected hospital series from the United States reported a rate of 1.21/1,000.[73] Rates of 1 per 200 to 300 person-years of follow-up were reported for selected cohorts with epilepsy and other disability or cohorts seen at specialist centers.[46,63] These reflect more intractable epilepsy or associated morbidity. Higher rates are suggested for series considered for epilepsy surgery and for failed surgery cohorts as discussed in more detail later. Another group with severe epilepsy is that of patients undergoing vagal nerve stimulation. A sudden death rate of 4.5/1,000 for definite/probable SUDEP cases was reported (6/1,000 if possible cases were included). This is comparable to that expected in an intractable cohort. The rate seemed to decrease with longer follow-up, but this has not been studied further.[1] More publications reflect risk for younger adults rather than children or the elderly, and extrapolation to other age groups is not appropriate. In the elderly, sudden death as defined earlier is less amenable to study. Attribution is difficult in the presence of competing comorbidity, and epilepsy-related excess mortality is "lost" within much higher overall death rates. SUDEP is known to occur in children more often in symptomatic than idiopathic epilepsy and is thought to be rare, but studies are limited and sometimes small.[9,14,21,58,74] Mortality is considered more often related to the underlying neurologic disorder or associated deficit than to seizures. A long-term study of outcome in children with epilepsy, one that separates deaths in a seizure from SUDEP cases, observed an overall mean age of death of 18.6 years (range of 1–41 years), suggesting a greater risk as children enter adulthood.[58]

Epilepsy Surgery and Sudden Unexpected Death in Epilepsy

There has been increasing interest in SUDEP in relation to epilepsy surgery, discussed here in more detail. The risk of SUDEP appears to be particularly high among patients with refractory epilepsy considered as candidates for epilepsy surgery, with an estimated incidence of 1/100 patient-years.[12] Follow-up studies after epilepsy surgery have initiated a discussion on whether epilepsy surgery could reduce mortality and lower the incidence of SUDEP in this high-risk group.[55] Stavem and Gudlvog[62] reported survival in patients operated for focal epilepsy in Norway from 1948 to 1988. Operations for known brain tumors were excluded, but the pathology was otherwise not provided. With an average postoperative follow-up of 25 years, there were 34 deaths among 139 surgery patients (4 considered SUDEP and another 4 with "epilepsy" as cause of death). The risk ratio for death in relation to the general population was 6.2 (95% confidence interval [CI] 3.1–12.6). The survival of the epilepsy surgery group was not significantly different from that of matched controls with medically treated intractable epilepsy, although there was a trend toward a lower death risk ratio, 0.6 (95% CI 0.4–1.1). Patients who were seizure free 2 years after surgery did not differ from patients with recurrent seizures, but data on longer-term seizure control were not available. Unfortunately, the report does not clarify whether the postoperative SUDEP cases occurred among the patients rendered seizure free. The comparatively small number of epilepsy surgery patients included in this study may also have contributed to the failure to demonstrate a difference between surgery patients and controls. Furthermore, the fact that this cohort was operated on before the introduction of modern neuroimaging in presurgical workup calls for caution in generalization.

Outcomes have also been reported in 248 patients who had diagnostic evaluations for epilepsy surgery at UCLA from 1974 to 1990.[71] Of these, 202 underwent surgery (anterior temporal resection in 175) and 46 did not. On follow-up, 14 (7%) of the surgery patients had died compared to 9 (20%) in the nonsurgery cohort. Among those who died, 81% had seizures, whereas only 47% of the surviving patients had seizures. Unfortunately, no detailed account is given on the causes of death, and there is no mention of SUDEP in this report, although the observations indicate a lower mortality in patients with refractory epilepsy that undergo surgery, in particular among those who become seizure free. There were 11 deaths in a follow-up of 215 patients treated surgically for refractory temporal lobe epilepsy at another U.S. center.[56] Three patients died during seizures, another 3 were classified as SUDEP, and 2 patients died in accidents. Mortality was lower (2%) among patients rendered seizure free than among those who continued to have seizures after the operation (11.9%). Survival was assessed among 305 patients who had surgery for temporal lobe epilepsy from 1975 to 1995 at the Maudsley Hospital in London.[22] There were 20 deaths (6 SUDEP), resulting in a standardized mortality ratio (SMR) of 4.5 (3.2–6.6) and a SUDEP incidence of 2.2/1,000 person-years. Only 2 of the 6 cases of SUDEP were reported to be seizure free postoperatively. A population-based nation-wide Swedish study followed 596 patients who had undergone epilepsy surgery and 212 patients referred to epilepsy surgery evaluation that did not lead to an operation.[43] There were 14 deaths (6 SUDEP) in the surgery group, yielding an SMR of 4.9 (95% CI 2.7–8.3) and a SUDEP incidence of 2.4/1,000 person-years, very similar to the U.K. data. Among the nonsurgery patients, 5 died (4 SUDEP), resulting in an SMR of 7.9 (2.6–18.4) and an incidence of SUDEP of 6.3/1,000 person-years. Seizure outcome data for the entire cohort were available only at 2 years after surgery and did not seem to affect mortality or risk of SUDEP. However, none of the 6 cases of SUDEP were seizure-free.

A follow-up of 393 patients who had epilepsy surgery in the United States identified 11 deaths, of which 7 were epilepsy related (6 SUDEP).[59] None of the 199 patients who became seizure free after surgery died, whereas the SMR for those with recurrent seizures was 4.7 (2.3–7.9). This series has been extended to include 583 patients prospectively followed after epilepsy surgery.[60] In total, 19 deaths (10 SUDEP) were observed, 18 of which were in patients with recurrent seizures. The only death in the seizure-free cohort was due to breast cancer, and all 10 SUDEP deaths were among patients with recurrent seizures. The SMR was 5.8 (3.5–9.3) for the patients with seizures despite epilepsy surgery, whereas the mortality rate for those who stopped having seizures after surgery was indistinguishable from that of the general population.

Hence, available follow-up data after epilepsy surgery strongly suggest that SUDEP preferentially occurs among those with recurrent seizures, whereas the risk is remarkably low in patients that are rendered seizure free. The lower SUDEP risk is likely, at least in part, to be a consequence of the successful surgery, but other interpretations also need to be considered. Because these observations are from nonrandomized studies, it is possible that there may be underlying preexisting biologic differences between patients who respond favorably to surgery and those with recurrent seizures. Such difference, for example, in the spread of the epileptogenic zone, could be linked to the risk of SUDEP. The reported divergence in preoperative HRV between patients with good and poor outcome of surgery for temporal lobe epilepsy lends support to this latter interpretation.[50]

Is Sudden Unexpected Death in Epilepsy a Seizure-Related Event?

The previous definition, by being inclusive, acknowledges the difficulties of separating SUDEP cases directly related to a “terminal” epileptic seizure and those occurring independent of such a seizure. In an unwitnessed case, circumstances that suggest, but do not prove, an epileptic seizure include fresh tongue, cheek or lip biting, secretions, incontinence, disrupted environment or bedding, fall off the bed, contorted facial expression, or timing and triggers of per habitual seizures. The absence of such clues does not exclude a terminal epileptic event. Whereas a number of studies suggest that SUDEP is frequently a peri-ictal event, the evidence is mostly indirect. The proportion of witnessed cases varies among studies from 7% to 38%. Of those witnessed, between one third and all were reported to be related to convulsions.[29] A series of witnessed SUDEP cases,[30] among the first 135 ascertained for a case–control study, reported convulsions in 12 of 15 cases. An older study, based on detailed interviews of bereaved relatives or partners, addressed circumstances of death in 26 SUDEP cases (2 witnessed), and reported evidence suggestive of an epileptic seizure around the time of death in 23.[39] Signs of preceding seizures were reported in 67% in a case–control study of 42 SUDEP cases from Norway.[28] Monitored and reported SUDEP cases are rare. One such case occurred in a video telemetry unit during a secondarily generalized epileptic seizure.[6] Birnbach et al.,[7] in an early case–control study, reported an association with convulsive seizures. Observations from more recent case–control studies report a higher relative risk in people with more frequent seizures and in those with a history of generalized convulsive seizures (Table 1). This supports the premise that most SUDEP cases are seizure related. We believe that the majority of SUDEP cases are likely to be related to an epileptic seizure occurring close to the time of death.

Risk Factors, Descriptive Cohorts, and Case–Control Studies

The association with convulsive epileptic seizures accounts for some of the evidence only, and other risk factors need to be considered. Some individuals might be more at risk because of social factors, lifestyle, suboptimal management, and lack of adherence to treatment. Others might have additional biologic susceptibility. Descriptive cohorts suggested risk factors for study. These included youth, male gender, remote symptomatic epilepsy, structural findings on neuropathology, severe epilepsy, unwitnessed seizures, alcohol abuse, abnormal electroencephalograms (EEGs) with epileptiform changes and greater variations, mental disability, psychotropic medication, African American race, lack of adherence to treatment, abrupt medication changes, and low AED levels.

Certain risk factors have been shown to be associated with SUDEP in case–control studies. These studies have different methodologies and are not directly comparable. Some studies, for example, only include patients on long-term treatment for epilepsy or in specified age ranges. Not all studies are nested. Control groups vary and include living patients known to have epilepsy or patients with epilepsy who died of other causes. SUDEP cases are identified from a variety of sources, which could result in different data being available. Table 1 lists significant findings in some more recent case–control studies. Negative findings and older studies have not been listed.

Sudden Unexpected Death in Epilepsy and Antiepileptic Drugs

SUDEP was observed and documented well before the era of modern AED therapy, and we are not aware of data to suggest increased incidence in comparable populations. Medications taken by SUDEP victims in cohort studies appear to reflect prescribing practices. Nevertheless, potential risk factors relating to AED treatment, including drug levels, adherence to treatment, abrupt withdrawal, polytherapy, and choice of AED, are potentially very important because they are amenable to manipulation in routine management.

The Stockholm study,[35] which only included SUDEP cases with treated epilepsy, identified polytherapy and frequent medication changes as independent risk factors for SUDEP. These risk factors may still be surrogate markers for epilepsy severity, but they could make SUDEP more likely. Medication changes, prescribed or otherwise, particularly if abrupt, could result in instability both of the epilepsy and of the autonomic nervous system. AED therapy could, in theory, also affect post-ictal respiratory depression or predispose to cardiac arrhythmias.

The Swedish group further investigated the potential of AEDs to inhibit the cardiac rapid delayed rectifier potassium ion current (I_{Kr}) because other drugs known to have such an effect can be proarrhythmic, with their clinical use associated with sudden unexpected death due to cardiac arrhythmia. They recorded tail currents in I_{Kr} channels expressed from human ether-a-go-go–related gene (hERG) in a whole-cell patch-clamp technique. Phenytoin, phenobarbital, and lamotrigine had the potential to inhibit the I_{Kr} channel at potentially clinically relevant concentrations. Carbamazepine, topiramate, and gabapentin also had blocking effects but at concentrations outside the range usually associated with such a clinical effect.[10,11] The effect of AEDs on heart rate variability is discussed separately later.

The effect of medication changes on modifying seizure severity including the postictal phase, as opposed to seizure type or frequency, has not been adequately studied; anecdotally, such an effect is familiar to practicing clinicians and is often reported by caregivers. One of the authors recalls a patient with poorly controlled posttraumatic epilepsy who on a particular combination of AEDs was observed in hospital on more than one occasion to have a prolonged postictal phase lasting hours with deep coma and secondary obstructive apnea. Substituting one medication with another resulted in a "normal" postictal phase and later seizure freedom.

Table 1 Significant risk factors from different case-control studies with different designs

Reference	Cohort	SUDEP number (age)	Risk factor	Increased risk
Kloster et al. (1999)[28]	Hospital-based refractory; controls = non- SUDEP deaths	42	Body position	Prone > supine; see text
Nilsson	Hospital-based AED on treatment; controls = living epilepsy patients	57 (15–70 yr)	More frequent sizures	RR = 10.16 (95% CI 2.94–35.18), >50 seizures/yr vs. 2 seizures/yr

et al.[45]				
			Epilepsy type	Lower risk in symptomatic focal vs. idiopathic generalized epilepsy, but numbers are small
			Epilepsy age of onset	RR = 7.72 (95% CI 2.13–27.96) for age 0–15 yr vs. 45 yr
			Polytherapy	RR = 9.89 (95% CI 3.20–30.60), 3 AEDs vs. monotherapy
			Frequent medication changes	RR = 6.08 (95% CI 1.99–18.56), 3–5 changes/yr vs. none
Nilsson et al. (2001)[44]			Carbamazepine >usaual range	See text
Walczak	Hospital based; controls = non-SUDEP epilepsy patients	20	IQ <70 vs. >79	OR = 5 (95% CI 1.3–19.3)
			>2 AEDs vs. 0–2	OR = 4.0 (95% CI 1.4–11.7)
			Tonic–clonic seizure in last year	1–3 GTCS, or 2.4 (95% CI 1.8–30.5); >3 GTCS, or 8.1 (95% CI 2.2–30.0)
			>50 seizures/mo	OR = 11.5 (95% CI 1.3–99.3)

et al. (2001)[73]				
Langan et al. (2005)[30]	Through coroners, neurologists, and bereaved relatives; controls = living epilepsy patients in community	154 (16–50 yr)	>History of GTCS in last 3 mo Bedroom shared with supervising individual (protective)	OR = 13.8 (95% CI 6.6–29.1) OR = 0.4 (95% CI 0.2–0.8)
			Listening devices (protective)	OR = 0.1 (95% CI 0.0–0.3)
			>4 AEDs ever compared to 1–2	OR = 3.1 (95% CI 1.4–7)
			Never taken AEDs	OR = 21.7 (95% CI 4.4–106)
			Carbamazepine	OR = 2 (95% CI 1.1–3.8)

AED, antiepileptic drug; CI, confidence interval; IQ, intelligence quotient; OR, odds ratio; RR, relative risk; SUDEP, sudden unexpected death in epilepsy.
Note that relative risks/odds ratios are not comparable.

A large U.K.-based case–control study did not confirm polytherapy as a risk factor.[30] The study found, however, that total number of AEDs ever taken was associated with increased risk, most likely reflecting intractability of the epilepsy. The same

P.1994

study found untreated epilepsy to be a significant risk factor. This is an important observation, which, along with the association of SUDEP with convulsive seizures, supports active treatment of epilepsy with AEDs. Although we acknowledge that treatment interventions, surgical or medical, have potential adverse effects, including the potential to worsen seizure frequency and severity, we believe that the risk/benefit ratio clearly favors appropriate AED treatment.

Studies on adherence to treatment are contradictory, some supporting nonadherence to treatment as a risk factor, others not.[8,20,33,47,69] This is not surprising. Such studies have inevitable limitations. Historical details about medication taken or omitted by the patient during the last days preceding death often cannot be obtained from other sources. Post mortem AED blood levels can be unreliable, and interpretation needs to consider that levels below the usual quoted ranges can be therapeutic; it is not absolute levels that are important, but a difference in levels from usual. Furthermore, even if previous AED levels were available for comparison, the time of previous sampling would need to be taken into account as well as the degradation of post mortem samples. A recent study from Cardiff in the United Kingdom[31] avoids some of these problems

P.1995

by measuring AED levels in sequential 1-cm hair segment samples corrected for the washout effect. The results, however, do not reflect changes immediately before death. Interestingly, the study showed greater coefficient of variation in SUDEP cases than in three other cohorts studied: (a) An epilepsy cohort dying of other known causes, (b) an outpatient cohort, and (c) a residential cohort, with the latter showing the lowest variation. The difference, as far as the authors could ascertain, was not attributed to prescribed medication changes. This study suggests that nonadherence to treatment may indeed be a significant risk factor and amenable to modification.

It has been suggested that specific AEDs may be associated with a higher risk of SUDEP. Older descriptive series simply reflected the then-current prescribing practices. Walczak et al.'s study[73] did not identify any specific association with any particular AED. In a recent review, Walczak[72] argued that, on current evidence, there is no strong reason to avoid any particular AED, stressing the importance of preventing tonic–clonic seizures with as few AEDs as necessary to achieve complete control, a view with which we concur.

Timmings[66] reported that carbamazepine was disproportionately represented in patients suffering SUDEP. Further analysis of Nilsson et al.'s case–control study[44] suggested an increased risk in patients with frequent dose changes and polytherapy, with carbamazepine levels greater than the commonly quoted target range. There were only 6 such cases among 33 on carbamazepine and 57 SUDEP cases in total. Langan et al.'s case–control study also showed a small excess risk, with carbamazepine treatment just reaching significance.[30] Rare cases of heart block secondary to carbamazepine are documented, and carbamazepine has an effect on heart rate variability. The relevance of this association to the majority of people with epilepsy is uncertain. It is highly likely that patients with more-severe seizures were prescribed higher doses of carbamazepine, a mainstay of treatment in the last two decades. It is worth emphasizing, however, that AEDs needs to be appropriate to the epilepsy syndrome. In one study, some SUDEP cases on carbamazepine had uncontrolled idiopathic generalized epilepsy, whereas a broad-spectrum medication may have had better success.[39]

Mechanisms

Post mortem examination in SUDEP cases may reveal tongue bite or ptechial hemorrhages, a nonspecific finding in hypoxia and increased venous pressure. Pulmonary edema is very frequently noted, sometimes with other organ congestion. A study[65] of neuropathology in SUDEP cases showed microscopic evidence of hypoxic change in a small proportion of cases, suggesting that death may not be immediate in all cases. Routine autopsies in SUDEP cases, by definition, do not reveal a cardiac or other cause for death. Two studies reported on specialized cardiac pathology.[41,48] Perivascular and interstitial cardiac fibrosis, mainly subendocardial, was found in 4 SUDEP cases and myocyte vacuolization in a fifth but not in the control group.[41] In another study, morphologic abnormalities of the cardiac conduction system were observed in 4 of 10 SUDEP cases, a similar finding to 6 of 10 in the control group. This does not exclude these changes contributing to death in either group.[48] Nevertheless, the overall lack of evidence from pathologic studies suggests that the terminal event is likely to be due to functional disturbances.

Respiratory Mechanisms

Respiratory changes frequently occur in seizures, with well-documented central and obstructive apnea, excess bronchial and oral secretions, pulmonary edema, and hypoxia. Pulmonary edema is present in a large majority of SUDEP cases. Central apnea can occur secondary to the ictal discharge or postictally, perhaps, as has been suggested, due to secondary endogenous opioid release. During postictal coma, hypercapnea and hypoxia may be less potent respiratory stimuli. A sheep model of ictal sudden death supports an important role for ictal apnea/hypoventilation; animals that died were those with a greater rise in pulmonary vascular pressure and hypoventilation. When airway obstruction was excluded in a second study of tracheostomized sheep, central apnea and hypoventilation were observed in all animals, causing or contributing to death in two. A third animal developed heart failure with significant pathologic cardiac ischemic changes.[25,26]

Most unwitnessed SUDEP deaths occur in bed, presumably during sleep. One can postulate a number of different explanations for this observation, which are not mutually exclusive. It may reflect an individual's predisposition to sleep-induced cardiac arrhythmia. Nocturnal seizures may differ pathophysiologically; for example, they may be associated with an increase in vagal tone or with more marked respiratory depression. It may reflect lack of assistance at the time of the terminal event as Delasiauve believed. There is some evidence to suggest that he was at least partly right. A case–control study from Norway[28] found a significant difference in the position in which the body was found compared to that expected, with 71% of patients found prone and only 4% supine. In another study of circumstances,[29] in 11 of 26 SUDEP cases, the body was found in a position that predisposed to respiratory obstruction. In a study of a cohort of residential school children with epilepsy and other disability[53] in which children were monitored at night by awake staff aided by a continuous nocturnal sound monitoring system, 14 SUDEP cases occurring during the period of study all took place while the children were away from school. Finally, the use of listening devices or sharing the room with someone capable of giving assistance was associated with a reduced risk in Langan et al.'s case–control study.[30] The evidence that supervision within the community provides some protection favors an important primary role for respiratory factors, manipulated by relatively unskilled intervention such as adjusting position, ensuring an adequate airway, and perhaps physically stimulating respiration. An unknown proportion of SUDEP cases may be preventable by such intervention. Near-miss cases are recognized anecdotally but have not been systematically studied.

Cardiac Mechanisms

Primary or secondary cardiac mechanisms are also likely to be important through a number of possible scenarios as discussed later. Studies of routine interictal ECG changes in people with epilepsy have had a low diagnostic yield. ECG changes, both of rhythm and repolarization, are documented during seizures. The most common change is that of sinus tachycardia, but malignant tachyarrhythmias are relatively rare. Sinus bradycardia/arrest, although still infrequent, is more often documented.[63] One study observed ictal cardiac asystole in only 5 of 1,244 inpatients undergoing prolonged EEG-video recording.[53] Another study highlighted the potential yield, and dilemma, associated with long-term cardiac rhythm monitoring using an implantable device in a highly selected patient group with poorly controlled epilepsy.[55] This eventually revealed episodes of sinus arrest, for which pacing was carried out, in 4 of 19 patients studied. It remains to be seen how often such changes would be observed in a larger cohort and in other populations with epilepsy and what the indications for pacing should be in relation to preventing seizure-associated syncope and sudden death.

P.1996

Sudden Unexpected Death in Epilepsy and Heart Rate Variability

Autonomic cardiac control can be assessed clinically by analysis of heart rate variability (HRV) based on ECG recordings. Reduced HRV has been shown to predict mortality and, more specifically, sudden death in other conditions than epilepsy.[5,64,67] HRV can be analyzed in time (standard deviation of RR intervals in the ECG) and frequency domains. Spectral analysis of HRV thus allows partly separate assessments of the sympathetic and vagal components of the power spectrum.[52] The high-frequency band (HF) is related to parasympathetic activity and low-frequency (LF) oscillations mainly with sympathetic activity, whereas the mechanism behind very low frequency (VLF) activity is not completely understood.

Several studies have assessed HRV in epilepsy. Interictal HRV has been analyzed in patients with chronic temporal lobe epilepsy and compared to age-matched healthy controls in cross-sectional studies with reduced HRV in the epilepsy patient groups as the major finding.[4,34,17,68] Adult patients with temporal lobe epilepsy were reported to have reduced total power, LF, and HF[60]; lower LF and LF/HF ratio[61]; or a decrease in all frequency-domain measures.[4] This reduction in HRV appears to be more pronounced during the night than during the day.[54] Sleep recordings in 11 children with different types of partial epilepsy revealed a decrease in HRV, most evident in the HF domain.[17] Another study of 30 children with unspecified epilepsy found other indications of disturbed autonomic modulation.[75]

The reason for the observed impaired autonomic cardiac regulation in patients with temporal lobe epilepsy is unclear. Treatment with antiepileptic drugs may contribute. Total power, LF, VLF, and HF all decreased after initiation of carbamazepine treatment in newly diagnosed partial epilepsy,[67] but little is known of the effect of other antiepileptic drugs. A Turkish study reported reduced HF and increased LF in young men with newly diagnosed generalized tonic–clonic seizures.[16] These patients, however, were not representative of new-onset epilepsy. Mean seizure frequency was 8/year for on average 5.6 years before diagnosis. An increase in LF/HF ratio during sleep, that is, enhanced sympathetic activity, was observed after sudden withdrawal of carbamazepine during seizure monitoring in patients with intractable seizures.[23] In another study, total power, VLF, and VF decreased when carbamazepine or phenytoin were withdrawn abruptly.[27] Although they slightly diverge, the results demonstrate the effects on HRV of sudden changes in medication.

Candidates for epilepsy surgery are at particularly high risk of SUDEP.[70] Patients with refractory temporal lobe epilepsy were also found to have significantly reduced HRV in all frequency domains before surgery, but only those that eventually continued to have seizures after temporal lobe surgery had so.[51] In contrast, patients with favorable outcome of surgery did not differ from their matched healthy controls in preoperative HRV measures, suggesting an a priori difference in autonomic cardiac control between good and poor candidates for epilepsy surgery. Differences in presurgical HRV patterns between poor candidates for epilepsy surgery and those with excellent outcome of temporal lobe resection have been reported.[19] A recent study assessed HRV in 16 patients who had undergone surgery for temporal lobe epilepsy, 8 with good outcome and 8 with poor outcome.[24] LF power and LF/HF ratio decreased after surgery in those rendered seizure free but increased in patients with persistent seizures. Decreased HRV might be a marker for an increased risk of SUDEP, in line with recent preliminary observations of lower HF in 9 patients who later died suddenly compared with epilepsy and nonepilepsy controls.[15]

In conclusion, epilepsy is associated with altered autonomic cardiac control. Although the impairment varies in extent and type, the most frequent finding is reduced HRV similar to that observed in other patient groups at increased risk of cardiac death. Several factors, for example, seizures, interictal discharges, underlying brain pathology, and drugs, may contribute. Most consistently, decreased HRV has been observed in patients at particular risk of SUDEP such as those with refractory epilepsy. This suggests that impaired autonomic cardiac control might contribute to the risk of SUDEP.

Can There Be a Coexisting Susceptibility to Epilepsy and Sudden Cardiac Death?

A number of hypotheses can be postulated, which are not mutually exclusive, as discussed in a recent review.[40] First, malignant cardiac tachy/bradyarrhythmias or cardiac failure might occur secondary to the ictal discharge and/or apnea/hypoxia. Second, long-term cardiac changes secondary to uncontrolled epilepsy might predispose to excess sudden death. Third, some individuals with epilepsy might have a coexisting “mild” susceptibility to sudden cardiac death that can manifest in the presence of uncontrolled seizures and, theoretically, can be modified by AEDs.

The third hypothesis could apply equally to acquired or genetic disorders. Of particular interest is the possibility of a coexisting “mild” genetic susceptibility to sudden cardiac death as a complex trait involving cardiac conduction/ion channel disorders. Such a genetic susceptibility might be unrelated to the epilepsy but become manifest because of uncontrolled seizures or medication, the latter less likely to be significant since inherited cohosts are at low risk. Alternatively and in theory, the same genetic variants may confer increased susceptibility to both epilepsy and to sudden cardiac death, both paroxysmal conditions in which similar disorders of ion channels, sometimes coexpressed in the brain and heart, are causally implicated. Against this suggestion is the lack of epidemiologic data indicating a higher incidence of epilepsy among relatives of those with inherited susceptibility to arrhythmia, the absence of reported family history of early sudden cardiac death in SUDEP cases, the uncommon observation of malignant tachyarrhythmias with seizures, and the clear pointers to respiratory mechanisms in SUDEP. These arguments can be addressed. Relevant epidemiologic data are not available. Studies looking at epilepsy in families of sudden cardiac death victims and at syncope in idiopathic epilepsy are needed. A clear family history of early sudden death in relatives of SUDEP cases, would not be expected in a complex trait. Finally, although inherited susceptibility to tachyarrhythmias is widely recognized, it is perhaps less widely appreciated among neurologists that such genetic susceptibility is also very well documented in sinus node dysfunction and bradyarrhythmias. As for respiratory mechanisms, one can draw an analogy with sudden infant death syndrome (SIDS). The dramatic success in reducing the incidence of SIDS through respiratory mechanisms simply by recommending the supine rather than the prone position at a vulnerable stage of the infant's life has not precluded other mechanisms being implicated, including genetic susceptibility to cardiac dysrrhythmias.

Summary and Conclusions

Our understanding of SUDEP has increased over the last two decades, but further research is needed. With the aim of prevention, we need to seek a better understanding of mechanisms and a better way to identify at-risk individuals. More generally, research into seizure prediction and detection could help to optimize response to seizures. The effects of therapy (mono

P.1997

or polytherapy) and its withdrawal on ictal and postictal states in relation to depressed consciousness and respiratory and cardiac parameters need to be explored. We also believe that further studies exploring the potential role of cardiac mechanisms outlined here are required.

The present focus in management, with the aim of preventing some SUDEP cases, is on seizure prevention and response to seizures. The former requires optimal medical and surgical therapy, guided by the studies mentioned earlier, as well as self-management and understanding by the patient of the importance of avoiding seizure triggers. The latter implies being with other people and impinges on hard-won independence. Informed patients will vary as to the level of risk they want to take, whether in considering independent living, or, if their condition is being controlled, in choosing to withdraw medication. It is important, however, to acknowledge that whereas some SUDEP deaths may be preventable, at present it is not possible to estimate the proportion nor is it possible to give more than broad estimates of risk in individual cases.

Chapter 190

Autonomic Disturbances

Jeffrey H. Goodman

Mark Stewart

Frank W. Drislane

Introduction

Seizures are often accompanied by alterations in autonomic function such that any system controlled by the autonomic nervous system (ANS) has the potential to be disrupted before, during, or after the ictal event. Seizure-induced alterations in cardiovascular and gastrointestinal function occur most often, but pulmonary, sexual, pupillary, and cutaneous changes are also common. Symptoms can be subjective (sensory only) or the ictal event can actually change peripheral organ function. With simple autonomic seizures the sole clinical manifestation is an alteration in autonomic function, while complex partial seizures are often preceded by an autonomic aura. The ultimate manifestation of the autonomic disturbance is dependent on the type of seizure and the brain areas involved.

In order for a seizure to alter autonomic function, it must propagate to brain areas that comprise the central autonomic network (CAN). Limbic and cortical structures in the network control the output of the parasympathetic and sympathetic branches of the ANS through the hypothalamus and brainstem structures. Early clinical studies by Penfield and Kristiansen[87] and Van Buren[107,108,109] identified autonomic changes after stimulation of specific limbic and cortical structures. Van Buren also detected seizure-related autonomic changes in patients treated with the convulsant pentylenetetrazol (PTZ).[107,109] More recently, the experimental seizure models of kindling,[32,33,53] penicillin,[61,73,74] and PTZ[62,99] have been used to examine the mechanisms that underlie seizure-induced alterations in the ANS.

Seizure-related changes in autonomic function do not typically result from a generalized activation of one or both branches of the ANS. Symptoms are often restricted to an isolated system, which in some cases can be used as a diagnostic tool to localize seizure onset. However, the same set of symptoms can lead to misdiagnosis given that some seizure-induced changes mimic autonomic dysfunction related to other diseases. The proper diagnosis of syncope versus epilepsy and cardiac arrhythmias due to cardiovascular disease versus seizure-induced alterations in cardiovascular function remains a clinical challenge. Cardiovascular and respiratory disruption are particularly significant in that they have the potential to be life threatening and possibly play a role in sudden unexplained death in epilepsy (SUDEP).

Anatomy of the Autonomic Nervous System

The Central Autonomic Network

By definition, the ANS refers to the portion of the central and peripheral nervous systems that regulates autonomic function through the sympathetic and parasympathetic branches. The ANS is under the control of the CAN, whose anatomy and physiology have been extensively reviewed by Benarroch.[6] Structurally, the CAN consists primarily of the insular cortex, medial prefrontal cortex, amygdala, hypothalamus, and ventrolateral medulla. These areas can be functionally divided into those areas that relay sensory information and those that have a motor or effector action. There are reciprocal connections among all the structures within the CAN that help to integrate autonomic responses. The insular cortex is involved with visceral sensory function, while the anterior cingulate and other medial frontal structures appear to have primarily effector roles in autonomic seizures. Stimulation of the cingulate gyrus in humans can lead to intense vagal effects, including bradycardia and even cardiac arrest.[91] Deeper mesial temporal and limbic structures including the amygdala are also involved. Activation of the insular cortex and amygdala can produce cardiac arrhythmias, whether initiated by epileptic seizures or by other lesions such as stroke.[6,82] The amygdala is involved with the autonomic response to emotion. Stimulation of the amygdala can produce salivation and mydriasis in cats.[51]

In the diencephalon, the hypothalamus has a major role in visceral motor, neuroendocrine, and sexual function.[38] The hypothalamus controls both sympathetic and parasympathetic activity and is also involved in temperature regulation. There is evidence that subpopulations of neurons within the hypothal-amus can selectively activate subpopulations of preganglionic neurons.[16]

Finally, in the brainstem, the nucleus of the tractus solitarius (NTS) and the ventrolateral medulla are crucial. These medullary structures have major roles in regulating cardiovascular activity, respiration, and other autonomic motor phenomena. The NTS is important both in the afferent relay of viscerosensory information from the periphery to higher centers and in the efferent control of cardiovascular function.

Parasympathetic and Sympathetic Branches

Central control of autonomic function is mediated though the parasympathetic and sympathetic branches of the ANS.[5] Cells bodies for the parasympathetic branch are located for the most part in the brainstem. Parasympathetic innervation through cranial nerves III, VII, and IX mediates pupillary constriction, salivation, and lacrimation. Cranial nerve X (the vagus nerve) supplies parasympathetic innervation from the medullary structures of the dorsal motor nucleus of the vagus and the nucleus ambiguous to areas throughout the cardiovascular and gastrointestinal systems. Parasympathetic fibers in the second through fourth sacral spinal nerves largely influence genitourinary function.

Sympathetic innervation descends from the brainstem, synapsing on neurons in the intermediolateral cell columns located from T1 to L2 of the spinal cord. Axons from these cells exit the spinal cord through spinal nerves synapsing on neurons

P.2000

in the paravertebral chain ganglia. These preganglionic neurons are organized into functional units such that different functions under sympathetic control can be selectively activated.[46] Postganglionic axons provide extensive innervation of the cardiopulmonary system and the smooth muscle of blood vessels throughout the body, playing a role in blood pressure maintenance and vasodilation.[5]

Clinical Symptoms

Many of the clinical phenomena associated with seizures are mediated by the ANS. Seizures often induce tachycardia, hypertension, apnea, borborygmi, altered gastric motility, decreased galvanic skin response, diaphoresis, mydriasis, increased secretions, or incontinence.[69,107]

Occasionally, simple partial seizures have solely autonomic manifestations, including cardiac rhythm disturbances; epigastric or intestinal sensations; skin changes such as flushing, pallor, or piloerection; and changes in pupillary or sexual function. In one series, one third of all simple partial seizures included autonomic features.[21] Complex partial seizures often begin with autonomic symptoms, especially those seizures with onset in mesial temporal areas (hippocampus and amygdala), medial frontal cortex (cingulate), or the insula. In one series of patients with refractory temporal lobe epilepsy, almost all had auras, which a large majority described as epigastric or abdominal.[27] Fear was the next most common aura.[10] The character of the aura symptoms can help with seizure onset localization, but not necessarily with lateralization.[84]

Cardiovascular Manifestations

Tachycardia and hypertension are impressively common in all types of seizures. In one study, 96% of seizures included increased heart rate; none produced bradycardia.[54] A study that recorded ambulatory electroencephalograms (EEGs) and simultaneous cardiograms during temporal lobe seizures showed an increased heart rate in 92% of 74 seizures; 30% had heart rates above 140.[12] These arrhythmias, consisting of irregular bursts of increased heart rate, occurred in 42% of seizures, typically late in the seizure. In a series of 145 seizures in 58 patients, 87% included tachycardia, which correlated with a mesial temporal seizure onset.[68] Only two (1.4%) had bradycardia, both with a left hemisphere seizure onset. Heart rate changes preceded EEG changes in 110 seizures, were simultaneous in five, and followed the EEG change in 30. Tachycardia preceded epileptic activity by a mean of 14 seconds in patients with temporal seizures and was more likely with a right-sided origin. With implanted depth electrode recording, there was no predominant laterality of seizures causing tachycardia, and tachycardia did not ensue from amygdala stimulation alone.[25] Rather, spread of seizures was necessary to produce tachycardia; its likelihood correlated with the extent of cortex involved.[25]

Bradycardia, generally considered to be mediated through the hypothalamus and vagus nerve, is far less common than tachycardia during seizures. However, it can be a more severe clinical problem, occasionally leading to sinus arrest[55] or asystole,[44] and in some cases necessitating placement of a cardiac pacemaker.[20] Bradycardia causing syncope often correlates with visceral symptoms and left hemisphere epileptogenic sites.[20] Antiepileptic drugs (AEDs) may treat the bradycardia by preventing seizures.[20] A literature review of ictal bradycardia in the setting of focal seizures indicated a modest but clear left-sided predominance for the epileptogenic site; seizures could originate in medial temporal or frontal areas.[104] Bradycardia is more likely to occur in temporal lobe seizures than in seizures of other origin.[29]

Other cardiac arrhythmias associated with epileptiform discharges include supraventricular tachycardia,[92] paroxysmal atrial tachycardia,[97] and sinoauricular heart block.[90] In one case report, paroxysmal atrial tachycardia occurred during seizures with a right frontal focus due to a tumor. The seizures and the arrhythmia ceased following tumor resection.[97] Sinoauricular heart block can accompany right temporal seizures, associated with an epigastric aura, diminished responsiveness, and syncope, presumed to represent a vagal effect.[90] This arrhythmia was treated successfully with anticholinergic agents, and with phenytoin.

Abnormal autonomic activity in patients with epilepsy is not restricted to the ictal state. Interictally, many patients with temporal lobe epilepsy have reduced heart rate variability, independent of AED use.[2,3] In another study, patients with complex partial seizures had large interictal fluctuations in heart rate that were not seen in controls.[28]

A major alteration in the variability of autonomic nerve activity innervating cardiovascular structures may be a risk for potentially serious arrhythmias.[61]

Analysis of the R-R interval (RRI), the period of time separating successive heartbeats, revealed RRI fluctuations at the respiratory frequency that were parasympathetically mediated, and RRI fluctuations at higher frequencies that were mediated by the combined effects of sympathetic and parasympathetic inputs to the heart.[80] In this analysis, complex partial seizures produced a marked imbalance in parasympathetic and sympathetic drive to the heart. Parasympathetic activity fell rapidly 30 seconds before seizure onset, while sympathetic activity continued to rise, peaking at seizure onset. In a report of two patients with temporal lobe epilepsy, investigators observed that a period of acute deterioration of seizure control was accompanied by increased parasympathetic function and that bradycardia began up to 40 seconds before seizure onset.[105]

Gastrointestinal Manifestations

Gastrointestinal symptoms are by far the most common epileptic seizure symptoms mediated by the ANS. While the most common gastrointestinal manifestation is the rising epigastric sensation initially described by Gowers,[34] other symptoms include vomiting, cramping, bloating, and diarrhea. Abnormal visceral sensations can arise from the normal perception of abnormal intestinal motor activity due to abnormal autonomic activity. However, most symptoms appear to remain restricted to altered sensory perception by the brain. Indeed, during complex partial seizures there is typically an inhibition of gastric motility.[109]

Van Buren[108] reviewed the histories of 100 patients who had depth electrode monitoring for refractory epilepsy and had chest, abdominal, or pelvic symptoms considered epileptic in origin. Symptoms characteristically began as partial seizures (auras) leading to complex partial seizures, with half of the patients reporting the spreading or rising epigastric sensation. Viscerosensory auras in patients with refractory seizures were temporal in onset in 90% of cases, with 10% from frontal and other areas.[84] In a series of patients with visceral symptoms, Mulder et al.[78] also noted that abdominal pain could be a manifestation of a sensory seizure alone or could be due to spasm induced by epileptic motor activity. Two thirds of these patients had gastrointestinal symptoms, especially nausea, which could occur in isolation. Abdominal discomfort occurred in another one third. In nine patients evaluated for epilepsy surgery with temporal lobe seizures and ictal vomiting, Kramer et al.[58] found a right-sided predominance of interictal and ictal discharges. In another study of patients with focal-onset seizures, one third

of auras that began in the right hemisphere were autonomic in nature versus only 8% from the left, and 84% of all autonomic auras originated on the right.[36] Almost all consisted of abnormal epigastric sensations.

Gastrointestinal manifestations of seizures can also include motor or effector autonomic phenomena such as vomiting, swallowing, and salivation, suggesting involvement of the hypothalamus and lower medullary structures that coordinate such motor activity through the nucleus of the tractus solitarius and dorsal motor nucleus of the vagus.[78,107] Vomiting is the most prominent autonomic motor manifestation of seizures, with cyclic vomiting a major symptom of partial seizures in children.[77] An anterior temporal focus can cause vomiting, accompanied by olfactory hallucinations followed by loss of consciousness or generalized convulsions. Especially in children, this has been labeled *abdominal epilepsy*. Many children have benign overlap syndromes including features of both epilepsy and migraine, often with occipital spike discharges.

Panayiotopoulos syndrome is a remarkably common "idiopathic susceptibility to early-onset benign childhood seizures" with primarily autonomic manifestations.[57] Patients (usually children aged 3 to 6) have recurrent gastrointestinal symptoms distinct from migraine.[85] Nausea and vomiting upon arousal from sleep are the primary clinical manifestations. Pallor and flushing are also common. Other epileptic manifestations include eye deviation and loss of consciousness, some with hemibody or generalized convulsions. Seizure-induced vomiting is presumed to represent epileptic activity transmitted from cortical areas through the hypothalamus and medulla. Epileptiform discharges are often occipital but may be multifocal, usually in posterior areas. Seizures may be prolonged to the point of status epilepticus,[57] but many children have just single episodes, and the prognosis is generally excellent. Most children recover without AED treatment. About 20% go on to have later epilepsy.

The sensation of *fear* (often localized by patients to intestinal sensations) has a strong correlation with seizures involving the amygdala,[31] and amygdala stimulation can produce such feelings in conscious patients. Ictal fear is usually accompanied by gastrointestinal or epigastric symptoms.[108] In one series, fear correlated better with amygdala atrophy than with hippocampal structural abnormalities.[17]

Genitourinary Manifestations

Urinary incontinence is common, but not invariant, in generalized convulsions, often occurring after the clonic phase. It occurs far less frequently in partial seizures, and fecal incontinence occurs even less often. Focal seizures can prompt a sensation of urinary urgency. We were unable to find unambiguous reports of urination as the sole manifestation of epileptic seizures.

Sexual Manifestations

Normal sexual function is dependent on the sensory nervous system and on motor and behavioral effector autonomic function. Seizures can affect sexual function in many ways. Epileptogenic foci in parietal or temporolimbic structures subserving sensation from genital and pelvic regions can produce "pure" sensations in those areas, without autonomic involvement or a more extensive sexual perception or feeling.[78] Erickson reported one woman with ictal sensations of pelvic "hotness," proceeding to left leg jerking, left abdominal sensations, and loss of speech, all resolving after resection of a right frontal parasagittal tumor.[26]

More typical sexual sensations arise from epileptogenic areas in temporolimbic regions, more often in the right hemisphere.[93] Remillard et al.[93] reported a series of 12 women with such sensations—generally unpleasant at first but later pleasurable in many. Seven of the 10 localizable seizure foci were on the right side. They were able to produce such feelings (sometimes progressing to arousal or orgasm) with mesial temporal depth electrode stimulation in two. A female predominance of these phenomena (20 of the total 23 patients reviewed) suggested that limbic structure organization differs between the two genders and offered a partial explanation of the behavioral differences in men and women with temporolimbic seizures.[93]

Infrequently, seizures progress to the more complicated symptom of orgasm, involving motor autonomic nerves and implicating involvement of motor areas.[15] Women and men have reported orgasmic auras.[47,48] Ruff[96] reported two patients with right parietal tumors and unpleasant or even painful orgasm caused by seizures. This combination of sensory and autonomic motor components suggests spread of seizures to the hypothalamus and then peripheral autonomic nerves.

Cutaneous Manifestations

Seizures can also produce flushing, pallor, and pilomotor erection.[76] Unilateral flushing is rare but can arise from a contralateral seizure focus.[78] Pilomotor erection or "goose flesh" is seldom the sole manifestation of a seizure and is usually accompanied by other autonomic phenomena.[24] Some seizures cause bilateral pilomotor phenomena.[1] Occasionally, they are unilateral[78] and sometimes ipsilateral to the seizure focus.[35] Shivering and bilateral piloerection were traceable to left temporal seizures in 18 of 22 localizable cases.[103]

Pulmonary Manifestations

Episodes of apnea are common in temporal lobe seizures, usually with the chest in an expiratory position.[107] Especially when generalized, seizures can progress to include respiratory arrest.[78] Some seizures cause abnormal throat sensations that induce a feeling of shortness of breath or choking. Others lead to hypoventilation and oxygen desaturation.[11] Stimulation of the insula or hippocampal gyrus inhibited respiratory function in man.[52] Nevertheless, respiratory or pulmonary manifestations of seizures appear to be far less common than cardiovascular or intestinal symptoms.

Pupillary Manifestations

Unilateral mydriasis can occur with contralateral frontal seizures, but bilateral pupillary dilation is more common in seizures. Unilateral mydriasis is often presumed to arise from an ipsilateral seizure. In the largest series describing this phenomenon, this was the case in three patients, but five patients had mydriasis ipsilateral to the unilateral motor activity, thus from the contralateral hemisphere.[86] Unilateral mydriasis did not have localizing or even lateralizing value and was never the sole manifestation of seizures.

Experimental Observations: Clinical

In addition to the numerous clinical reports that describe seizure-related alterations in autonomic function, there have been a number of experimental clinical studies that have helped to elucidate the structures, pathways, and mechanisms that

underlie these changes. PTZ is a γ-aminobutyric acid $(GABA)_A$ receptor antagonist initially used as an "artaleptic" to reverse the effects of sedatives, and was also used as a forerunner of electroconvulsive therapy. Early work that described many of the features of PTZ-induced seizures reported increases in heart rate, blood pressure, and cerebrospinal fluid pressure during the seizures.[107,109,113] In patients who were not pharmacologically paralyzed, periods of apnea were also reported.[30,107] Autonomic consequences resembled events associated with spontaneous seizures[107] and included many of the same visceral sensations reported during auras at the onset of seizures.[109]

Table 1 Lateralized Epileptic Autonomic Manifestations

All autonomic auras	85% right hemisphere[36]
Ictal vomiting	All right temporal (nine cases, depth electroencephalogram)[58]
Pilomotor erection (bilateral)	18 of 22 cases: Left temporal onset[103]
Sexual auras	More right hemisphere[93]
Bradycardia	Left hemisphere onset[104]
Tachycardia	*Not* lateralized[25,54]
Parasympathetic effects (bradycardia)	Left insula stimulation[83]
Sympathetic effects (tachycardia, hypertension)	Right insula stimulation[83]
Hypotension,	Right Wada testing[39]
decreased sympathetic effects	
Sympathetic effects, hypertension	Left Wada testing[39]

Electroconvulsive therapy (ECT) for psychiatric illness has also been used as a model system in which to examine autonomic changes associated with seizures. The period of electroconvulsive stimulation[14,110] caused intense seizure activity with a tonic phase lasting 10 to 12 seconds followed by a clonic phase lasting 30 to 50 seconds. Respiratory changes were marked by a period of apnea that outlasted the tonic phase, followed by expiration and then inefficient ventilation during and after the clonic phase, and finally hyperventilation. Heart rate changes were characterized by a brief initial sinus bradycardia that appeared to be due to vagal activity, followed by sinus tachycardia up to 190 bpm. Heart rate returned to normal over a period of several minutes. Similar life-threatening changes in blood pressure and heart rate were seen when convulsions were prevented by curare administration, indicating that the autonomic changes were central in origin and not provoked by motor activity.

Stimulation of the amygdala or mesial temporal region produced a typical abdominal aura, always with a rising character.[108] Similarly, right hemisphere suppression (in Wada testing) can cause hypotension without heart rate changes, suggesting that the right hemisphere is dominant for sympathetic effects.[39] Left-sided suppression led to hypertension (a presumed sympathetic excess) suggesting left-sided control of parasympathetic function. More recent intraoperative studies of patients undergoing epilepsy surgery found that left-sided insular stimulation caused bradycardia and blood pressure decreases, while right insular stimulation led to tachycardia and hypertension.[39,82] Oppenheimer[81] has suggested that insular cortex seizures might desynchronize the harmonious workings of the sympathetic and parasympathetic systems and lead to cardiac arrhythmias. A summary of lateralized epileptic autonomic manifestations can be found in Table 1.

Experimental Studies: Animal Models

Animal studies offer model systems that replicate features of human epilepsy and autonomic dysfunction, which can be used to study the mechanisms whereby interictal and ictal paroxysmal activity affect autonomic function. Goodman et al.[32,33] monitored blood pressure and electrocardiogram (ECG) in amygdala-kindled rats during the seizure. Kindled seizures activated both sympathetic and parasympathetic systems and produced ictal hypertension and bradycardia that could each be blocked pharmacologically. These changes were not observed when the kindling stimulus was delivered to the amygdala in naïve animals. There is also evidence that the baroreflex responses are altered interictally in amygdala-kindled rats.[53]

Oppenheimer et al.[83] examined the effects of left insular stimulation in rats on cardiac function and found an increasing degree of heart block and resultant ventricular escape rhythms that eventually resulted in asystole. Lathers et al.[62,99] observed autonomic changes during PTZ-induced seizures in anesthetized cats. During the seizure there was increased variability of cardiac autonomic nerve discharge rates. Cardiac sympathetic and parasympathetic activity was intermittently synchronized with interictal spike activity (lockstep phenomena).[63] It was also observed that "unstable lockstep" (periods when interictal spikes and synchronized autonomic activity occurred at irregular intervals) was associated with large fluctuations in blood pressure.[102] The following ECG abnormalities were observed during seizures induced by the direct injection of penicillin into the hippocampus of the cat: P-R interval changes, increased P-wave amplitude, QRS complex changes, T-wave inversion, and ST elevation.[62] Animal studies have shown that imbalance between the parasympathetic and sympathetic drive can produce ECG abnormalities, such as sinus pauses and prolonged QTc, which could predispose to malignant cardiac arrhythmias.[106]

Mameli et al.[73,74] used anesthetized and hemispherectomized rats to investigate which brain regions control cardiac function. These investigators found that application of penicillin G to the hypothalamus produced bradyarrhythmias and a small (4% to 6%) decline in systolic blood pressure. Creating an additional penicillin focus at the mesencephalic level increased paroxysmal activity, and produced second-degree atrioventricular (AV) block and impaired AV conduction, created bundle branch blocks, and caused an additional 17% reduction in systolic blood pressure. Coactivation of hypothalamic and mesencephalic centers by focal injection of penicillin G resulted in death in 25 rats.[73]

In a model of SUDEP, bicuculline was used to induce status epilepticus in chronically instrumented sheep.[49] The only parameter that correlated strongly with seizure-induced death was marked hypoventilation. In a subsequent study, Johnston et al.[50] showed that the hypoventilation was central in origin.

Autonomic Dysfunction as a Diagnostic Tool

Simple autonomic seizures can be defined as focal seizures with purely autonomic signs and symptoms. We have already described autonomic auras and autonomic consequences of seizures, particularly for focal limbic seizure activity. In circumstances where the aura is clearly followed by a seizure, the features of the aura can help with diagnosis. In other cases, where auras occur without an apparent seizure, diagnosis of a seizure disorder can be made more difficult, similar

P.2003

to the difficulty in differentiation of syncope from seizure described below. Some epileptic abdominal pain can be difficult to distinguish from nonepileptic intestinal problems, prompting urgent medical evaluations.[88]

Seizure Versus Syncope

Transient loss of consciousness presents diagnostic challenges for the clinician because in many cases there are no detectable signs to identify an underlying disorder by the time a patient is seen. Part of the differential diagnosis for transient loss of consciousness is consideration of an isolated seizure or syncopal episode.[8,23,40,41,42] Reports by eyewitnesses are among the most valuable data for differentiating seizures from syncope. A rapid return to alertness reported by witnesses and specific autonomic symptoms (e.g., sweating, nausea) preceding attacks reported by patients are more commonly associated with syncope. By contrast, clonic movements or automatisms and early disorientation are more often reported in patients who have had seizures.[41] It has been argued that a syncopal episode of unknown origin may actually be one of the first signs of a developing seizure disorder.[4]

Although numerous reports suggest strategies for the differentiation of seizures from syncopal episodes, seizures, and syncope may occur in relation to one another[13] (see also Chapter 68, "Differential Diagnosis," and Chapter 271, "Syncope"). Of course, many seizures cause loss of consciousness. In addition, seizures occasionally lead to typical syncope, through ictal bradycardia and other mechanisms. In turn, syncopal episodes often include a few brief jerking movements and may even trigger a seizure.[7] As described above, bradycardic episodes have been shown in a couple of examples to clearly precede patients' seizures.[105] In each of these examples, the seizure "trigger" may be increased neural activity that occurs during reperfusion. On the other hand, Saito et al.[98] have stopped seizures in rats by reducing blood flow to the forebrain.

Seizures Misdiagnosed as Cardiovascular Dysfunction

Cardiac manifestations of seizures have been widely reported because they can be life threatening and may explain some cases of sudden death in epilepsy patients.[22,56] Whereas most descriptions of bradycardia and arrhythmia suggest a predominantly parasympathetic outflow, tachycardia has been reported as the principal cardiovascular feature in some subclinical seizures.[111] The differential diagnosis for cases that involve bradyarrhythmias is similar to that described for the differentiation of syncope from seizures. Seizure-induced increases in sympathetic activity have been confused in some cases with pheochromocytoma,[76] but in some cases pheochromocytoma can trigger seizures.[67]

Autonomic Dysfunction, Neurogenic Edema and Sudden Unexplained Death in Epilepsy

Neurogenic Pulmonary Edema

Neurogenic pulmonary edema (NPE) is a rapidly developing increase in pulmonary interstitial and alveolar fluid due to an acute central nervous system catastrophe.[19,60,72,100] NPE includes dyspnea, sometimes hemoptysis, tachypnea, tachycardia, and rales on examination. Fortunately, NPE may resolve on its own within hours or days. Many cases may be subclinical.

Three conditions account for most cases of NPE: Hemorrhage, head injury, and epileptic seizures, especially status epilepticus.[60,70,95,100] Seizures appear less likely to cause NPE, but they are more prevalent than the other precipitants. Some diagnoses of postictal aspiration pneumonia may actually be mild forms of NPE. Postictal NPE may be recurrent in some children.[79]

The autonomic nervous system is clearly implicated in NPE. Major disruption of intracranial function is always present, frequently with hypothalamic dysfunction.[94] Consistent with other examples of altered autonomic effector function, the medulla (especially the NTS) is crucial in the pathogenesis of NPE.[18] Section or denervation of splanchnic sympathetic fibers to the lung or spinal cord transection at the C7 level or above (or α-adrenergic blockade) may abort NPE experimentally.[37,71]

There are two major theories to explain the development of the lung pathophysiology in NPE: (a) changes in systemic hydrostatic pressure and (b) changes in pulmonary capillary permeability.[43] Neither is required for all cases, and each can contribute.[101] Some patients have evidence of increased pulmonary vascular permeability,[70,75] including an elevated alveolar fluid protein concentration indicative of pulmonary capillary leak; others have low lymphatic fluid protein.[101] A combination of factors, with initial pulmonary hypertension damaging capillary linings and causing permeability changes, could be responsible.[112]

Sudden Unexplained Death in Epilepsy

ANS disruption is probably a major factor in SUDEP (see Chapter 189). Its incidence is about 1 per 1,000 people with epilepsy per year but 3.5 per 1,000 per year in refractory epilepsy.[64] Seizures may cause apnea directly, but respiratory failure is generally not considered the best explanation for SUDEP. At least some degree of pulmonary edema occurs in many cases of SUDEP,[66] but rarely does neurogenic pulmonary edema become life threatening from single seizures alone. Life-threatening cardiac arrhythmias accompany relatively few seizures, but they may be the best explanation for SUDEP given the overall occurrence of seizures in patients with refractory epilepsy.[65]

Even interictally, some epilepsy patients have cardiac rhythm disturbances that may implicate a greater vulnerability to arrhythmias. Some of this autonomic dysfunction may be related to AEDs,[45,59,89] but some patients have autonomic dysfunction even before treatment.[9] Nevertheless, dysfunction can be worse with refractory epilepsy, suggesting that it may be the *undertreatment* of epilepsy that is of greatest concern for SUDEP.[2]

Summary and Conclusions

In this chapter we have identified autonomic disturbances that commonly occur before, during, or after a seizure. The specific disturbance is dependent on the type of seizure, the brain areas involved, and propagation of the seizure to structures in the central autonomic network. While some autonomic changes have diagnostic value, seizure-induced changes in autonomic function can resemble autonomic changes associated with non–seizure-related diseases, leading to misdiagnosis and delay in treatment. Autonomic disturbances in cardiovascular and respiratory function are particularly significant given their possible role in SUDEP.

Chapter 191

Comorbidity in Adults

Michael J. Aminoff

Jack M. Parent

Introduction

Seizures commonly occur in the setting of general medical disorders, and their occurrence may then have significant implications regarding the prognosis and treatment of the primary disease. In addition, the treatment of seizures—whether secondary to some general medical disorder or the manifestation of a primary disturbance of central nervous system (CNS) function—may be complicated or influenced by nonneurologic factors. This chapter discusses these varying aspects.

Seizures and Renal Failure

Seizures occur in about one third of patients with acute or chronic renal failure. The seizures that occur in acute uremia tend to be associated with a severe encephalopathy, usually occurring between 7 and 10 days after the onset of renal failure and during its anuric or oliguric stages.[21,200] They are commonly generalized tonic–clonic seizures and are often multiple. Partial seizures also occur, and epilepsia partialis continua has been described.[158] When recurrent seizures or single partial seizures occur in uremic patients, however, investigations should be undertaken to exclude an underlying structural lesion.

The uremic convulsions complicating chronic renal failure are most likely to occur with advanced disease and develop especially in patients with a significant encephalopathy or who are preterminal.[21,158] Fewer than 10% of patients with chronic renal insufficiency now experience convulsions.[157,200] The decline in the incidence of seizures may reflect more aggressive treatment of renal failure and its various complications, such as hypertensive encephalopathy, abnormalities of fluid and electrolyte balance, and altered metabolism of proconvulsant medications such as penicillin.[21,158,200]

The convulsions associated with chronic renal failure are typically generalized tonic–clonic seizures; partial motor and generalized myoclonic seizures occur less often.[21,158] Treatment involves correction of renal failure and associated metabolic abnormalities, but it may also necessitate anticonvulsant treatment, especially when no specific cause of the convulsions is evident.[21,157] Phenytoin is commonly used, but other agents, such as phenobarbital and valproic acid, are also effective.[12,21,158] Status epilepticus, a rare complication of chronic renal failure, is managed as when it occurs from other causes.[158]

Treatment of renal failure may itself lead to seizures. Generalized convulsions sometimes occur during the late stages of hemodialysis or several hours after a session in patients with the dialysis disequilibrium syndrome.[157] They may relate to fluid shifts associated with the hemodialysis and resulting in cerebral edema.[59] With improved dialysis techniques, seizures are now a less common occurrence.[59,157]

Dialysis encephalopathy is characterized by a distinctive speech abnormality, psychiatric and cognitive disturbances, asterixis, myoclonus, gait ataxia, and seizures. It often has a fatal outcome. Clinical dysfunction is preceded by electroencephalographic (EEG) abnormalities, especially paroxysmal bursts of frontally predominant high-voltage delta or spike-and-wave activity.[86,143] The syndrome, which generally develops after treatment by dialysis for several years, may relate to increased aluminum levels in the brain.[10] The origin of the aluminum may be the water in the dialysate, phosphate-binding compounds that are ingested, or both. Treatment of the dialysate to remove aluminum has reduced the incidence of the disorder.[10,59,143,157] Seizures, usually of the generalized tonic–clonic variety, occur in almost two thirds of patients with dialysis encephalopathy and are especially likely during or immediately after dialysis. Myoclonic, simple partial, and complex partial seizures are less common.[21] Convulsions usually respond initially to diazepam, phenytoin, or carbamazepine but become harder to control as the disease progresses.[21,143,185]

The use of anticonvulsants in patients with preexisting renal disease is sometimes problematic. Uremia complicates anticonvulsant therapy because of altered protein binding and renal excretion of drugs; dialysis may also result in removal of anticonvulsant agents from the circulation. The situation is exemplified by phenytoin. This anticonvulsant is normally 90% protein bound, but in advanced renal failure, protein binding of phenytoin declines by as much as 20%, resulting in a greater volume of distribution and lower serum concentrations.[12,142] Nevertheless, the benefit of a given dose is maintained because the proportion of unbound (active) phenytoin increases. Consequently, in advanced renal disease, the optimal therapeutic range of phenytoin in the blood decreases from 10 to 20 μg/mL to approximately 5 to 10 μg/mL.[107] Therapy is best monitored in uremic patients by measurement of free phenytoin levels; the therapeutic range is 1 to 2 μg/mL. The total daily dose need not be reduced because phenytoin is unlikely to accumulate unless hepatic function is impaired. Because the half-life of phenytoin may diminish in uremia,[112] it may be appropriate to divide the daily dose rather than to take it all at one time.[12] Phenytoin is not removed to any significant extent by dialysis, and, therefore, the daily dose does not require adjustment.[107]

Valproic acid is especially helpful for myoclonic and generalized tonic–clonic seizures in uremic patients.[12] In renal insufficiency, plasma protein binding decreases, but the free fraction remains constant.[107] Careful clinical and laboratory monitoring is important when patients have severe renal failure. Dialysis does not necessitate additional doses.

Plasma phenobarbital levels are unaffected by uremia. The drug may accumulate,[107] however, and lower maintenance doses are used when it is given on a long-term basis to patients with severe renal failure.[12] Because it is 40% to 60% protein bound, phenobarbital may be partially removed by hemodialysis; some patients therefore require supplemental doses after dialysis.[107] Primidone and its metabolites may also accumulate and lead to toxicity in patients with renal failure.[12] Serum carbamazepine levels are unchanged by uremia, and doses do not need adjustment.[107] Ethosuximide levels are significantly reduced by hemodialysis, and supplementation may therefore be necessary.[107]

P.2008

Many of the newer antiepileptic drugs show decreased clearance when renal function is impaired. These agents include felbamate,[68] gabapentin,[20] topiramate,[104] levetiracetam,[45] vigabatrin,[75] pregabalin,[16] and oxcarbazepine and its active metabolite monohydroxycarbazepine.[168] Gabapentin and pregabalin are excreted almost exclusively by the kidney with negligible metabolism,[16,20,156] and these drugs should be used with extreme caution and at reduced doses in patients with renal insufficiency. Topiramate also is eliminated mainly in the urine, although the percentage decreases somewhat in the presence of hepatic enzyme–inducing medications[11,104]; doses must be reduced in patients with kidney disease as with gabapentin and pregabalin. In patients on hemodialysis, supplemental doses of levetiracetam, typically 250 to 500 mg, are required.[45] Topiramate[104] and pregabalin[156] concentrations also decrease significantly after hemodialysis, and additional doses may be required. Gabapentin should be administered as a single 200- to 300-mg dose after each dialysis session.

Zonisamide is 40% to 50% protein bound and undergoes both hepatic metabolism and renal clearance.[11,110] Dose reduction may be necessary in patients with moderate or severe renal insufficiency. Protein binding may be lower in patients undergoing hemodialysis, and about 50% is removed during each dialysis session; however, supplemental doses often are not required if zonisamide is administered as a single daily dose after dialysis sessions, given the markedly reduced clearance in end-stage renal disease.[87] Tiagabine and lamotrigine pharmacokinetics appear largely to be unaltered even when renal function is severely impaired, and dose adjustment is usually unnecessary.[30,210] Occasionally, the half-life of lamotrigine is prolonged with severe renal insufficiency, however, and its elimination is more rapid in patients undergoing hemodialysis.[56]

Seizures and Liver Disease

Although early reports suggested that convulsions occurred in up to one third of patients with acute hepatic encephalopathy, Plum and Posner[152] found a smaller incidence and attributed many of the seizures in earlier reports to alcohol withdrawal rather than liver disease. Seizures may be generalized or partial and typically occur in stage III hepatic encephalopathy.[167] Treatment is directed at the underlying hepatic disorder and at relieving the hepatic encephalopathy with protein restriction and agents such as lactulose. Anticonvulsant therapy may not be required unless there is an underlying cause for the seizures, such as intracranial hemorrhage.

Chronic liver disease rarely causes seizures.[116] Seizures that occur in alcoholics with hepatic cirrhosis usually result from previous trauma, intracranial hemorrhage, or alcohol withdrawal. Seizures are common in Reye syndrome[151] and infrequent in Wilson disease.[167] When convulsions occur in patients with acute hepatic necrosis, they frequently relate to severe hypoglycemia.

Many anticonvulsant agents are metabolized by the liver and may cause hepatic toxicity. This is discussed elsewhere in this book and is not considered further here.

The effect of hepatic disease on anticonvulsant pharmacokinetics is usually clinically insignificant until the liver disease is advanced. The management of anticonvulsant drug regimens in patients with liver disease may be problematic. There is reduced protein binding of phenytoin and valproic acid, correlating with levels of serum albumin and bilirubin.[12,107] However, clearance is usually unaltered, and toxicity from drug accumulation is unlikely unless the liver disease is severe. In this latter circumstance, reduction in dose of phenytoin and valproic acid may be necessary, depending on serum drug concentrations. Free serum levels should be monitored closely. The hepatotoxicity of valproic acid mandates that it be used with caution in patients with preexisting liver disease.[12]

Hepatic encephalopathy may be precipitated by phenobarbital, benzodiazepines, and other sedatives in patients with otherwise compensated liver disease.[151] These agents, therefore, are best avoided or used very cautiously in patients with hepatic dysfunction; daily doses may have to be reduced to avoid their accumulation as a result of decreased hepatic metabolism.[107] The slightly decreased protein binding of carbamazepine that occurs in patients with liver disease is clinically insignificant, and serum carbamazepine concentrations are unaltered.[12]

Liver dysfunction alters the clearance of some newer antiepileptic agents. The elimination of lamotrigine decreases in the setting of significant hepatic insufficiency, and dose reduction therefore may be necessary.[123] Lamotrigine clearance also decreases by about one third in patients with Gilbert syndrome, or unconjugated hyperbilirubinemia, requiring the use of lower doses of the drug.[154] Tiagabine undergoes extensive hepatic metabolism, and its clearance is reduced by hepatic dysfunction; the dose should be lowered or the dosing interval increased in this situation.[106] The elimination of topiramate[104] and levetiracetam[45] is reduced only modestly with liver impairment, and the effect is usually clinically insignificant in the absence of concurrent renal dysfunction. Gabapentin[11] and pregabalin[16] undergo only minimal hepatic metabolism, and dose reductions are unnecessary in patients with hepatic insufficiency but preserved kidney function. Liver disease may increase the risk of felbamate-induced hepatic failure, and this medication should not be used in patients with liver disease under most circumstances.

Hepatic Porphyrias

The hepatic porphyrias are characterized by a partial defect in the heme biosynthetic pathway in the liver. The three autosomal-dominant forms with neurologic manifestations are acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria. In acute intermittent porphyria, there is a partial deficiency of porphobilinogen deaminase, and this leads to the buildup of δ-aminolevulinic acid and porphobilinogen, which are excreted in the urine. Hereditary coproporphyria is caused by a partial deficiency of coproporphyrinogen oxidase, and variegate porphyria by a partial deficiency of protoporphyrinogen oxidase.

The neurologic features of these disorders are similar and include peripheral neuropathy, autonomic dysfunction, and behavioral disturbances. Seizures occur in 10% to 20% of patients with acute intermittent porphyria and may be its presenting feature.[93] They may be partial or generalized.[22,170] Status epilepticus may occur but is rare.[170] Cerebral dysfunction in porphyria may relate to γ-aminobutyric acid (GABA) receptor binding by δ-aminolevulinic acid,[14,136] which causes seizures when infused directly into rat brain.[93] In addition, defects in hepatic heme synthesis can affect levels of neurotransmitter substrates, such as tryptophan, in the CNS.[93] Patients with acute porphyric attacks may also have seizures as a result of fluid and electrolyte disturbances, usually from excessive vomiting and inappropriate secretion of antidiuretic hormone. Moreover, idiopathic or symptomatic epilepsy may coexist with porphyria,[64,81,105,118,192] so that anticonvulsant treatment may be required in both acute and chronic settings.

Unfortunately, many antiepileptic agents have been implicated in exacerbating hepatic porphyria by stimulating hepatic δ-aminolevulinic acid synthase activity in humans, in animal models, or in assays in vitro. The anticonvulsants implicated include phenobarbital, phenytoin, primidone, carbamazepine, valproic acid, succinimides, oxazolidones, and benzodiazepines.[22,64,81,105,118,130,160,161,170,176,192] The positions
