Chapter 268

Alcohol and Drug Abuse

John C. M. Brust

Introduction

Worldwide, a variety of drugs are used recreationally, and they differ in their ability to produce either psychic dependence (compulsive drug-seeking behavior, "craving," "addiction") or physical dependence (an adaptive state in which cessation of drug use or administration of an antagonist produces physical withdrawal signs).[5] Many of these agents, by either indirect or direct mechanisms, increase the risk of seizures. This chapter addresses those drugs most often used recreationally in North America and Europe, exclusive of tobacco and caffeine (Table 1). Although agents are discussed individually, it is important to recognize that polydrug use (including ethanol) is common and, in fact, a person may be simultaneously overdosed on one drug while withdrawing from another.

Indirect Mechanisms

Drug users are frequent victims of cerebral trauma: in alcoholics usually associated with intoxication and in illicit drug users with lawlessness and violence. Post-traumatic seizures can be early or late in onset, and, depending on the agent, intoxication or withdrawal can further reduce seizure threshold.

Parenteral drug abusers are subject to systemic and central nervous system (CNS) infection. Endocarditis causes meningitis, brain abscess, and infected ("mycotic") aneurysm. Seizures in patients with AIDS may reflect opportunistic CNS infection or neoplasm, or direct infection of the brain by human immunodeficiency virus (HIV). Illicit drug users and alcoholics are often immunocompromised in the absence of HIV infection.

Independent of endocarditis, illicit drug users are at risk for ischemic and hemorrhagic stroke; mechanisms include embolization of foreign material, vasculitis, coagulopathy, and, with psychostimulants (especially cocaine), hypertensive crisis and direct cerebral vasoconstriction. Although mild-to-moderate doses of ethanol are protective against ischemic stroke, high doses increase risk, and any dose of ethanol is a risk factor for hemorrhagic stroke.[51]

Metabolic derangements are frequently encountered in drug users, including hyponatremia, hypocalcemia, and renal failure. In particular, hypoglycemic seizures, which in alcoholics tend to occur during binges, are often mistakenly attributed to ethanol withdrawal.

Direct Mechanisms: Toxicity, Withdrawal, and Individual Agents

Opioids

Opioid drugs include a large number of agonists, antagonists, and mixed agonists/antagonists (Table 2). Heroin, the most commonly abused opioid, can be injected, snorted, or smoked. Commercial street heroin contains a variety of pharmacologically active and inactive adulterants.

Heroin overdose, with coma, pinpoint pupils, and respiratory depression, is sometimes associated with seizures, but their occurrence in that setting is so unusual that other possible causes such as concomitant cocaine use, ethanol withdrawal, or CNS infection should be sought. In a case-control study, heroin use, either past or current, was a risk factor for new-onset seizures independent of head trauma, infection, stroke, ethanol, or other drugs.[45] For provoked seizures (i.e., caused by an underlying precipitant such as infection or trauma) the odds ratio (OR) was 3.65; for unprovoked seizures it was 2.57. The risk was greatest if heroin had been used on the same day as the seizure, but in no patient was there clinical evidence of overdose, and the risk persisted after a year of abstinence.

The pharmacologic basis of this risk is unclear. In animals, opioids are variably proconvulsant or anticonvulsant depending on species, seizure model, rate of administration, and particular agent (e.g., μ-, δ-, or κ-agonist). In some models, effects are blocked by the antagonist naloxone; in others they are not.[4,55]

Seizures or myoclonus are a well-recognized feature of meperidine toxicity, attributable to its active metabolite normeperidine.[29] Seizures are also anecdotally described as a toxic effect of fentanyl, pentazocine, and propoxyphene.

Except in neonates seizures are not a feature of opioid withdrawal, which produces flu-like symptoms and intense craving. In newborns of opioid-dependent mothers, withdrawal causes tremor, screaming, fever, tachypnea, tachycardia, vomiting, explosive diarrhea, and sometimes death.[21] Seizures and myoclonus are described, but can be difficult to distinguish from jitteriness. The diagnosis requires exclusion of hypoglycemia, hypocalcemia, intracranial hemorrhage, CNS infection, and withdrawal from other drugs or ethanol.

Table 1 Categories of recreational drugs

Opioids
Psychostimulants
Sedatives/hypnotics
Cannabis
Hallucinogens
Inhalants
Phencyclidine
Anticholinergics
Ethanol
Tobacco

Table 2 Major opioids

Agonist
Camphorated tincture of opium (paregoric)
Morphine
Heroin
Methadone
Fentanyl
Meperidine
Oxymorphone
Hydromorphone

Codeine
Oxycodone
Hydrocodone
Levorphanol
Antagonist
Naloxone
Naltrexone
Mixed agonist-antagonist
Pentazocine
Butorphanol
Buprenorphine

Table 3 Major psychostimulants

Dextroamphetamine
Methamphetamine
Methylphenidate
Pemoline
Ephedrine
Pseudoephedrine
Phenmetrazine
Diethylpropion
Benzphetamine
Phenylpropanolamine
Methylenedioxymethamphetamine (ecstasy)
Cocaine

Psychostimulants

Psychostimulant drugs include amphetamine-like agents, whose principal action is to release monoamines at synaptic nerve endings, and cocaine, which blocks monoamine synaptic reuptake (Table 3). Cocaine is the only recreationally used psychostimulant with local anesthetic properties, which probably contributes to its epileptogenicity. Amphetamine-like drugs are taken parenterally or orally, and methamphetamine is often smoked. Cocaine hydrochloride is taken parenterally or intranasally; alkaloidal cocaine ("crack") is smoked.[5]

Amphetamine-like drugs tend to cause seizures in the setting of obvious overdose (fever, hypertension, cardiac arrhythmia, delirium, or coma).[3] With cocaine, seizures more often occur in the absence of other signs of toxicity; they can appear immediately or several hours after use, perhaps attributable to pharmacologically active metabolites.[25,34,43] A focal signature to seizures suggests a structural lesion such as cocaine-related

P.2684

intracerebral hemorrhage. Status epilepticus (SE) following cocaine use is often refractory to conventional anticonvulsant therapy.

In different reports, the prevalence of seizures among cocaine-intoxicated patients ranged from 1% to 9.3%.[8,34,48,52] Seizures are more likely to occur after smoking crack than after snorting cocaine hydrochloride, probably a dosage effect. A seizure can be new onset with no other contributing factor than cocaine, or it can be triggered by cocaine in a known epileptic.[48] In animals (and probably humans), repeated administration of cocaine progressively lowers seizure threshold until seizures occur at doses that were originally subthreshold ("kindling," "reverse tolerance").[13,41]

Methylenedioxymethamphetamine ("ecstasy") has pharmacological properties of both amphetamine-like psychostimulants and hallucinogenic agents such as mescaline. Popular on college campuses, it is usually taken orally in groups, including "rave" parties (dancing to loud fast music for hours at a time). Overdose can cause seizures, delirium, coma, and death.[30,59]

Phenylpropanolamine, available over-the-counter as a decongestant or appetite suppressant, and sold by mail order as a "legal stimulant," was banned by the U.S. Food and Drug Administration (FDA) after it was shown to increase the risk of stroke. Seizures are described at recommended doses.[42]

"Dietary supplements" containing ephedra alkaloids ("ma huang") became popular in North America and Europe during the 1990s, and both seizures and stroke were described in users. In 2003, the FDA banned these products.[24]

Sedatives and Hypnotics

Sedative/hypnotic agents include barbiturates, benzodiaze- pines, and nonbarbiturate/nonbenzodiazepine agents. Recreational barbiturate use is either parenteral or oral; short-acting agents are most popular. Although available as street drugs, benzodiazepines have much less abuse potential. Other sedative drugs vary in their addiction liability. Glutethimide, for example, is a well-recognized street drug, often combined with codeine ("hits," "loads"). Buspirone, by contrast, does not appear to be abused.[5]

Barbiturates and benzodiazepines potentiate γ-amin- obutyric acid (GABA) neurotransmission through stereospecific receptors on the GABA receptor–chloride channel complex. GABA receptor downregulation is probably a major mechanism of seizures during barbiturate or benzodiazepine withdrawal.

Short-acting barbiturates are most likely to produce seizures on the second or third day of abstinence; full-blown delirium tremens sometimes follows. In a study of human volunteers, abrupt withdrawal from secobarbital or pentobarbital after several months of a daily dose of 400 mg produced paroxysmal EEG changes without symptoms in one-third of the subjects. Withdrawal from 600 mg daily produced minor symptoms in half the subjects and a seizure in 10%. Withdrawal from 900 mg daily produced seizures in three-fourths and delirium tremens in two-thirds.[20]

Following withdrawal from benzodiazepines, anxiety and tremor are common but can be difficult to distinguish from the symptoms for which the drug was being taken in the first place. Seizures and delirium tremens do occur, however, usually within 24 hours of stopping a short-acting agent and within several days of stopping a long-acting agent.[18] As with barbiturates, seizures are dose-related and unlikely in patients taking recommended therapeutic doses.[6]

Withdrawal seizures have been described with a number of nonbarbiturate/nonbenzodiazepine sedatives, including meprobamate and chloral hydrate. Tolerance and physical dependence are infrequent among users of zolpidem, America's most popular sleeping pill, but tremor, agitation, and seizures are described during withdrawal.[35] Glutethimide-induced

P.2685

seizures were reported as an acute toxic effect, possibly related to the drug's anticholinergic properties.[44] Seizures are also a feature of acute toxicity in recreational users of antihistamines. During the 1980s, parenteral administration of tripelennamine combined with pentazocine was a popular fad ("Ts and blues"), and seizures were a frequent complication.[7]

γ-Hydroxybutyrate, or its precursors γ-butyrolactone or 1,4-butanediol, is popular at "rave" parties and as a "date rape" drug. Acting at its own receptors as well as at GABA receptors, it produces ethanol-like effects, including a life-threatening abstinence syndrome. Myoclonus and seizures can be features of intoxication, however.[38,54]

Marijuana

Marijuana, made from cut tops and leaves of the hemp plant, *Cannabis sativa,* contains many cannabinoid compounds, of which Δ-9-tetrahydrocannabinol (Δ-9-THC) is the principal psychoactive ingredient. A more potent preparation, hashish, is made from resin covering the leaves. Marijuana can be smoked or eaten. In the brain, Δ-9-THC acts at stereospecific cannabinoid receptors (called CB-1) on synaptic terminals containing either excitatory or inhibitory neurotransmitters.[5]

A case-control study found marijuana use protective against new-onset seizures in men (OR = 0.42); for women there was a trend toward risk reduction that did not achieve statistical significance.[45]

In animal studies, cannabinoid compounds are variably proconvulsant or anticonvulsant depending on species and seizure model.[50] The nonpsychoactive compound, cannabidiol, is more consistently anticonvulsant.[9,49]

Anecdotal reports describe either improved or worsened seizure control temporally associated with marijuana use.[10,16,17,23] In a placebo-controlled study of 16 epileptics refractory to other drugs, cannabidiol acutely exacerbated EEG abnormalities but not behavioral seizures; after several months, however, seven of eight patients receiving cannabidiol were seizure-free compared to one of eight controls.[11]

Hallucinogens

Worldwide, dozens of hallucinogenic plants are used ritualistically or recreationally for their hallucinogenic properties. In North America and Europe, the most popular agents are peyote cactus containing mescaline, mushrooms containing psilocybin and psilocin, and the synthetic ergot compound D-lysergic acid diethylamide (LSD). The visual illusions and hallucinations produced by these agents—including those that spontaneously recur days or weeks after last use ("flashbacks")—are not considered epileptiform.[1] True seizures can follow very high doses, however.[19]

Inhalants

The recreational inhalation of volatile substances is a popular form of drug abuse, especially among children and adolescents. Products include solvents, cleaning fluids, glues, aerosols, bottled fuel gas, deodorizers, marker pens, petroleum, anesthetics, and nitrites, and the intoxicating compounds include hydrocarbons, esters, and ketones. Despite the variety of agents, the effects they produce resemble ethanol intoxication. A difference is that hallucinations and seizures can occur with overdose and are not features of inhalant withdrawal.[39,53]

Phencyclidine

Phencyclidine ("PCP", "angel dust") and the related compound, ketamine, are classified as "dissociative anesthetics." Their principal pharmacologic action—inhibition at glutamate receptors—is anticonvulsant, yet myoclonus and seizures including SE occur with overdose. Additional signs of intoxication—fever, tachycardia, hypertension, nystagmus, psychosis, delirium, dystonia, and stupor or coma with a blank stare—are likely to precede or accompany the seizures.[31,37]

Anticholinergics

Plants containing scopolamine and atropine are used recreationally worldwide. In North America and Europe, *Datura stramonium* (jimsonweed) is especially popular among adolescents, who ingest the seeds, leaves, or roots. Drugs with anticholinergic properties (e.g., amitriptyline) are also abused. The syndrome of anticholinergic poisoning—hallucinations, delirium, dilated unreactive pupils, hot dry skin—may include myoclonus or seizures.[40]

Ethanol

As with other drugs, seizures associated with ethanol may be the consequence of acute or remote head injury, CNS infection, stroke, or toxic/metabolic derangement. In many heavy drinkers, seizures are a direct effect of the ethanol ("alcohol-related seizures"), especially as a withdrawal phenomenon.

In a study of alcoholics presenting to an emergency room with either incident (new onset) or prevalent seizures, 78% of seizures occurred between 7 and 30 hours after the last drink. Excepting three subjects whose seizures occurred after 2 or more weeks, 99% of seizures occurred within 72 hours. A few seizures happened during active drinking. Forty-one percent of subjects had a single seizure; 21% had more than three, usually within a few hours after the first. SE occurred in 3%. Seizures were generalized in 95%; 5% had a focal onset. These seizures could occur alone or accompanied by other withdrawal signs. One-third of the patients subsequently developed delirium tremens. (Seizures, however, are not commonly present during delirium tremens.) The authors concluded that alcohol-related seizures were a withdrawal phenomenon, and that subjects whose seizures occurred beyond the withdrawal period or had focal signature probably had underlying structural pathology such as a remote cerebral contusion.[57]

In a study of volunteers, six subjects drank ethanol every few hours (including a 3:00AM dose) for at least 48 days. Withdrawal produced seizures in two subjects and delirium tremens in two.[28] The pattern of drinking in this study would be unusual for most alcoholics, who do not customarily awaken themselves in the middle of the night to have a drink. Moreover, the high percentage of subjects who experienced seizures was not encountered in other studies. For example, of over a thousand alcoholics who were detoxified without pharmacologic support, only 1% developed seizures.[58]

Consistent with the view that withdrawal might not be the sole mechanism for alcohol-related seizures is a case-control study of incident seizures, in which chronic daily ingestion of 50 g absolute ethanol raised the odds ratio (OR) above one, and 200 g daily increased the OR to 20. The minimal duration of drinking necessary to increase seizure risk could not be determined. In that study, many seizures occurred either during active drinking or more than a week after stopping, and statistical analysis failed to demonstrate a clear-cut temporal relationship between seizures and early abstinence. Moreover, those who had recently increased their ethanol consumption tended to have seizures earlier during abstinence than those who had decreased their consumption.[46]

Another case-control study found similar dose relationships for ethanol and incident seizures, with an increased risk appearing at 50 g daily absolute ethanol for men and 25 g for women, but that study did not address temporal relationships between seizures and active drinking.[33]

Animal studies demonstrate the existence of ethanol withdrawal seizures, and selective breeding can produce genetic susceptibility.[22] Alcohol-related seizures in animals, however,

often occur with low doses of ethanol, and their variable time courses and semiology suggest multiple mechanisms. In both animals and humans, repeated bouts of ethanol withdrawal increase the risk of eventual alcohol-related seizures.[32]

A common neuropharmacologic mechanism to explain both withdrawal and nonwithdrawal alcohol-related seizures might be glutamate toxicity. Acutely, ethanol blocks glutamate neurotransmission, with receptor upregulation.[14,56] Abrupt abstinence would then produce a hyperglutaminergic state, resulting in withdrawal symptoms, including seizures. Repeated bouts of withdrawal might result in more lasting excitotoxicity, thus lowering the threshold for seizures independent of acute withdrawal.

Should brain imaging be performed in patients with alcohol-related seizures? In a study of 259 patients with incident alcohol-related seizures and no obvious explanation other than ethanol withdrawal, computerized tomography (CT) identified intracranial lesions in 16 (6.2%).[15] Four had subdural hematomas, four subdural hygromas, two vascular malformations, two cysticercosis, and one each aneurysm, possible neoplasm, skull fracture with subarachnoid hemorrhage, and cerebral infarction. Seven (44%) of the 16 patients were alert and had no focal signs or evidence of trauma. In 10 patients, the identified lesions altered management. The answer to the above question is therefore, yes, as far as new-onset seizures are concerned. More problematic is the patient with repeated alcohol-related seizures. Although imaging may not be necessary in every instance, the clinician must consider the possibility of underlying new treatable pathology in such patients.

Should alcohol-related seizures be treated acutely? Because ethanol withdrawal seizures tend to occur singly or in a brief cluster, the likelihood of recurrence has often passed by the time a decision is made whether to treat. In a controlled trial, either intravenous lorazepam 2 mg or placebo was given to alcoholic patients following a single generalized seizure. Over the next 6 hours, 3% of those receiving lorazepam had a second seizure, compared with 24 % of those receiving placebo (OR = 10.4). Of those not admitted, one receiving lorazepam and seven receiving placebo had a second seizure within 48 hours.

Should alcohol-related seizures be treated prophylactically? Anticonvulsants for seizure prevention are usually not indicated in alcoholics. Abstainers do not need them, and drinkers do not take them. Phenytoin, carbamazepine, and valproate, moreover, are probably ineffective in preventing withdrawal seizures.[2,26,36] For those whose seizures are not temporally associated with drinking, who have an additional lesion that by itself could account for seizures, or who have epileptiform electroencephalographic (EEG) abnormalities, prophylactic anticonvulsants may be required even though patient compliance is unlikely.

Can epileptics safely drink ethanol? In one report, one or two drinks daily appeared to precipitate seizures in 5% of epileptic patients; five or six drinks daily precipitated seizures in 85%.[36] In another study, however, epileptics given one to three glasses of vodka over a 2-hour period daily for 16 weeks were no more likely to have a seizure than those given orangeade; there was no change in seizure frequency or in EEG epileptiform activity.[27] Although these observations are reassuring, it is probably advisable to discourage ethanol use by an epileptic.

Management Strategies in Substance Abusers with Seizures

Medical or surgical conditions that might be causing or contributing to seizures—trauma, infection, stroke, metabolic derangement—must be identified and treated. For example, cocaine intoxication might entirely explain fever, delirium, and seizures, but not until an image and a spinal tap have excluded meningoencephalitis or intracranial hemorrhage.

Seizures accompanied by other signs of drug toxicity tend to be refractory to treatment. SE in such patients is nonetheless managed in the usual fashion. Other than naloxone for opioid overdose, flumazenil for benzodiazepine overdose, and physostigmine for anticholinergic poisoning, there are no available pharmacologic agents that specifically reverse the signs of recreational drug overdose, including ethanol.

The treatment of drug withdrawal should include an agent from the same pharmacologic class (e.g., methadone for heroin withdrawal) or with a degree of cross-tolerance (e.g., a benzodiazepine for ethanol withdrawal). Seizures observed during neonatal opioid withdrawal respond more predictably to opioid substitution therapy (e.g., methadone or paregoric) than to anticonvulsants.[47] Phenytoin is an inappropriate agent for either preventing or treating seizures during sedative or ethanol withdrawal, and neuroleptics given for anxiety or agitation in such patients may do nothing more than lower seizure threshold. Ethanol itself is a direct neurotoxin and therefore also an inappropriate agent to use in the prevention or treatment of ethanol withdrawal, including seizures.

As with ethanol, prophylactic anticonvulsants are seldom indicated when drug toxicity or withdrawal is the sole explanation for single or even multiple seizures.

Summary and Conclusions

Alcohol and recreational drugs can cause seizures by indirect mechanisms such as trauma, stroke, CNS infection, or metabolic derangement. Depending on the agent, seizures can also be the result of either direct toxicity or withdrawal. Such patients should be thoroughly assessed for underlying cerebral pathology, but if toxicity or withdrawal is then considered the sole cause of a seizure, anticonvulsant prophylaxis is usually not indicated.

Chapter 269

Disorders of Pregnancy

Martha J. Morrell

Maurice L. Druzin

Introduction

Few conditions occurring during pregnancy give rise to epilepsy, but some pregnancy-associated conditions give rise to seizures. Seizures developing during pregnancy may herald an acute central nervous system (CNS) event, such as cerebrovascular disease, neoplasia, or infection. Fortunately, these occurrences are rare. Most commonly, new-onset seizures in later pregnancy are associated with eclampsia. This chapter reviews the pregnancy-related disorders that may present with seizures; the clinical presentation of each is described, along with a suggested diagnostic evaluation and treatment approach. Because of their frequent occurrence and the controversy regarding the treatment of seizures associated with pre-eclampsia and eclampsia, much of the chapter is devoted to a discussion of the approach to these seizures.

Pregnancy and Epilepsy: Approach to the First Seizure

Seizures may first appear during pregnancy in women who later are given a diagnosis of epilepsy. How often this occurs is not known, although Suter (as described by Lennox and Lennox[33]), in a study of 200 women with epilepsy, found that seizures had begun during pregnancy in 40. It is not clear how many of these women actually experienced eclampsia. Some women with epilepsy have seizures only during pregnancy (gestational epilepsy), but the frequency with which this occurs also is not known. Sleep deprivation and the physiologic stresses associated with pregnancy may lower the seizure threshold and precipitate the first seizure in women with an underlying epileptogenic lesion or genetic predisposition to epilepsy. The hormonal changes of pregnancy may also provoke seizures. The pregnant woman experiences a dramatic increase in the production of estrogens and progestogens. The population of sex steroid hormones also changes during pregnancy; whereas estradiol is the principal sex steroid hormone in women who are not pregnant, estriol is the most prevalent hormone of pregnancy. Some women may be susceptible to changes in cortical excitability triggered by these endocrine changes.[43]

Recommended Evaluation Strategy for the Pregnant Woman With a First Seizure

The appropriate neurologic evaluation for a pregnant woman with a first seizure does not substantially differ from the evaluation indicated for any patient with a first-time seizure. A careful neurologic history is taken and an examination performed to detect any neurologic symptoms or signs that would indicate increased intracranial pressure, a CNS infection or hemorrhage, or a focal CNS lesion. The history is explored for risk factors for seizures and for epilepsy. The basic evaluation should include a complete blood cell count, measurement of electrolytes, liver and renal function tests, and a toxicology screen—particularly to detect cocaine or alcohol, which are the most common substances of abuse associated with seizures.[42] The obstetric history includes determination of dates and an evaluation for hypertension, proteinuria, and edema to exclude pre-eclampsia and eclampsia.

Electroencephalogram (EEG) and neuroimaging are indicated in any woman seen with a seizure in the absence of eclampsia. If it has been determined that the seizure arose from pre-eclampsia/eclampsia and the presentation is otherwise not complicated, then EEG and neuroimaging are not usually required. However, if the patient with pre-eclampsia/eclampsia has focal neurologic symptoms or signs and partial seizures, EEG and neuroimaging should be obtained. Magnetic resonance imaging (MRI) is generally preferred to computed tomography (CT). Magnetic resonance imaging is the most sensitive technology for detecting CNS pathology and is safer for the pregnant woman. There is no known risk to humans from MRI scans using <2.0tesla.[56] The remainder of the evaluation is guided by the differential diagnosis.

When an antiepileptic drug is used in pregnant women, a dosage adjustment may be required from what is customary in the nonpregnant woman. Because of a reduction in protein binding during pregnancy, highly protein-bound antiepileptic drugs may have higher free, or non–protein-bound, fractions than would usually be anticipated. This translates into a higher CNS concentration. For example, during pregnancy the non–protein-bound fraction of phenytoin may represent 15% of the total fraction, in contrast to 10% in the nongravid state. The standard load of phenytoin (20 mg/kg) may prove excessive for the pregnant woman. A suggested regimen for pregnant women is to give 10 mg/kg and repeat with 5 mg/kg in 2 to 6 hours.[54]

Disorders of Pregnancy Associated with Seizures

Cerebral Ischemia

Seizures may be a sign of cerebral ischemia. The risk that a pregnant woman will experience a cerebral infarction varies from 1/481 in India to 1/26,099 in Rochester, Minnesota.[68] In one retrospective and prospective study of strokes associated with pregnancy and the puerperium in women delivering in public hospitals in Ile de France, 31 cases of stroke were identified among 348,295deliveries.[57] Arterial occlusion represents 50% to 80% of all cerebral infarctions occurring during pregnancy, with central venous thrombosis next most common. Arterial infarctions tend to occur in the second and third trimesters,

P.2690

whereas venous infarctions are more likely to occur in the first trimester. In the Ile de France study, nonhemorrhagic strokes (47%) and intracranial hemorrhage (44%) were most likely to occur in association with eclampsia.[57]

Stroke during pregnancy resulting from an arterial thrombosis usually arises in individuals with an identifiable risk factor for stroke. Most arterial infarctions are a consequence of arteropathy associated with premature atherosclerosis, moyamoya disease, Takayasu arteritis, fibromuscular dysplasia, and, rarely, isolated CNS vasculitis. Stroke and seizures may also be the initial manifestation of hematologic disorders, such as hemoglobinopathy (sickle cell disease), antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura, and deficiencies in antithrombin III and proteins C and S. The factor V Leiden mutation is a hereditary abnormality of the coagulation system that appears to enhance resistance to activated protein C, which inhibits coagulation. Up to 5% of the population exhibits resistance to activated protein C, and about 20% of patients with venous thromboembolism carry the factor V Leiden mutation.[30,71] Evaluation of a patient with stroke and seizures would also consider cardioembolism and paradoxic embolism from a patent foramen ovale, deep venous thrombosis, thrombosis of the pelvic or ovarian vein, or fat embolism. During labor and delivery, amniotic fluid and air embolism are considered in the differential diagnosis.

The clinical syndrome of cerebral venous thrombosis is characterized by headache, nausea and vomiting, visual symptoms, encephalopathy, lateralized neurologic deficits, and focal or generalized seizures.[21] Unlike arterial thrombosis, cerebral venous thrombosis develops in pregnant women who have no other specific risk for stroke. Cerebral venous thrombosis appears to be caused by the combination of the hypercoagulable state of pregnancy and the decrease in cerebral blood flow consequent to blood loss during labor and delivery. Other conditions associated with cerebral venous thrombosis include infection; hyperviscosity syndromes; sickle cell anemia; leukemia; antiphospholipid antibody syndrome; protein C, S, and antithrombin III deficiency; and factor V Leiden mutation. Malignancies and arteriovenous malformations should also be considered.[68] Although cerebral venous thrombosis may require acute treatment for seizures, the long-term prognosis is good. In one series of 77 patients with cerebral venous thrombosis, of 28 patients who experienced seizures acutely, seizures recurred in only four.[45]

Cerebral Hemorrhage

Cerebral hemorrhage occurs in between 1 and 5 pregnancies per 10,000. Associated mortality is 30% to 40%.[69] The risk for intracranial hemorrhage appears to be increased in pregnant women,[57,70] although data from Rochester, Minnesota, found no evidence of a gestational increase.[67] Pregnant women are likely to experience conditions that increase the risk for hemorrhage, however, such as eclampsia, metastatic choriocarcinoma, cerebral emboli, and coagulopathies. In addition, physiologic changes occur in pregnancy that predispose to intracranial hemorrhage, such as hypertension and increases in cardiac output, blood volume, and venous pressure. High concentrations of circulating estrogens may cause arterial dilation and be an additional risk factor for cerebral hemorrhage.[69]

Subarachnoid hemorrhage in the pregnant woman is most likely to be caused by cerebral aneurysms and arteriovenous malformations. Other causes of subarachnoid hemorrhage are eclampsia, cocaine abuse, coagulopathy, subacute bacterial endocarditis, and choriocarcinoma.[69] Aneurysmal bleeding is most likely to occur in older patients (25–35 years of age) and in the second and third trimesters of gestation. Bleeding is unlikely to occur in the postpartum period. In contrast, hemorrhages from arteriovenous malformations are more likely to occur in younger women (18–25 years) and are uniformly distributed throughout gestation, with a higher risk during labor and the puerperium.

Subarachnoid hemorrhage in a pregnant woman, as in a patient who is not pregnant, may be associated with severe headache, nausea, vomiting, focal neurologic signs, and seizures. Transient hypertension and proteinuria are often present and must be differentiated from pre-eclampsia/ eclampsia. Diagnosis is established based on the clinical presentation and CT of the brain. If the brain CT findings are negative and intracranial hemorrhage is still suspected, then a lumbar puncture to detect hemorrhage is indicated. If hemorrhage is detected, the patient requires either an MR angiogram or four-vessel angiography, depending on the institution's technical capabilities and experience, and a brain MRI to evaluate for aneurysms and arteriovenous malformations.

Intracerebral hemorrhage in pregnancy is most often attributable to hypertension occurring in the setting of eclampsia. Other causes include bleeding from an arteriovenous malformation, hemorrhagic transformation of an ischemic stroke, cocaine or alcohol abuse, and coagulopathies. The presenting symptoms of intracerebral hemorrhage are usually focal neurologic deficits, headache, nausea, vomiting, and seizures. A noncontrast CT of the head is generally the imaging test of first choice, followed by MRI to detect any structural lesion underlying the hemorrhage.

Treatment of seizures in the setting of subarachnoid or intracranial hemorrhage does not differ in pregnant and nonpregnant patients. The risk for teratogenic effects of antiepileptic drugs is far outweighed by the risk for repeated hemorrhage following a major motor seizure.

Rheumatologic Disease

Patients with immunologic and rheumatologic diseases, such as systemic lupus erythematosus (SLE), may experience an exacerbation of CNS disease during pregnancy.[41] Unlike most rheumatologic disorders, which spare the CNS, SLE involves the CNS in as many as one half of patients.[12] Neurologic disease is the second-leading cause of death in SLE[53] and frequently causes neuropsychiatric disturbances such as seizures, encephalopathies, psychosis, and lateralized motor deficits.[20] The risk for development of pre-eclampsia, hypercoagulability, and antiphospholipid antibodies is also increased in SLE. The CNS lesion in SLE is principally a small-vessel vasculitis with vascular hyalinization, endothelial proliferation, thrombosis, and capillary wall thickening.[1] Low-dose corticosteroids are the preferred treatment for SLE, with or without aspirin or heparin. Lupus of the CNS may require treatment with higher doses of corticosteroids. Antiepileptic drugs for seizures may be required only during acute flares.

Antiphospholipid antibodies may be associated with neurologic disease, either in the context of SLE (30% of patients) or within the primary antiphospholipid antibody syndrome.[35] The syndrome is characterized by deep venous and arterial thrombosis and stroke, repeated miscarriages, and thrombocytopenia. Seizures may occur. Cerebral events during pregnancy associated with anticardiolipin antibodies are generally treated with heparin anticoagulation. Seizures usually require antiepileptic treatment.

Thrombotic thrombocytopenic purpura is a rare disorder that may occur more frequently during pregnancy. Presenting features are thrombocytopenic purpura, microangiopathic hemolytic anemia, renal disease, and neurologic symptoms, which may include headache, encephalopathy, paresis, visual disturbance, and paresthesias. Seizures occur

in 20% of patients and are treated acutely with antiepileptic drugs.[48] The outcome of thrombotic thrombocytopenic purpura has substantially improved with plasmapheresis and plasma exchange.[55]

Neoplasia

The types of brain tumors that occur in pregnant women are not different from those in nonpregnant women—most commonly gliomas, then meningiomas and acoustic neuromas.[11] Pregnancy does not appear to be a risk for development of a specific neoplasm, but it can exacerbate tumor growth. Symptoms associated with increased intracranial pressure, such as nausea and vomiting, may be confused with "morning sickness," especially during the first trimester. However, persistent headache and neurologic deficits should raise concern for neoplasia. Seizures are a common presenting symptom of cranial neoplasms and may be partial or generalized. Any patient who has a seizure and in whom neurologic signs and symptoms are present warrants evaluation with an MRI.

Infections

Seizures may be the presenting symptom of infections of the CNS during pregnancy. The frequency of viral meningitis and encephalitis is not increased during pregnancy. However, pregnant women are at higher risk for infections caused by intracellular organisms because specific immune responses are altered to permit maternal adaptation to fetal and placental antigens.[23] The agents most likely to cause CNS infections and seizures during pregnancy include bacteria (*Mycobacterium tuberculosis*, *Listeria monocytogenes*), fungi (*Coccidioides immitus*), protozoa (*Toxoplasma*, *Plasmodium*), and viruses (influenza, varicella-zoster [chicken pox only], and polio).[27] The increased incidence of HIV seropositivity and AIDS in pregnancy should prompt consideration of this entity in any pregnant patient with opportunistic infections of the CNS. Treatment of these infections is the same as for nonpregnant women, with choice of antibiotic guided by information regarding the relative teratogenicity. Seizures are treated with antiepileptic drugs as required during the acute illness.

Pre-eclampsia and Eclampsia

Pre-eclampsia and eclampsia are diseases of pregnancy that occur most often in nulliparous women. Most seizures occurring during pregnancy are a sign of eclampsia. Eclampsia is defined as the development of convulsions and/or unexplained coma during pregnancy or postpartum in patients with signs or symptoms of pre-eclampsia. Pre-eclampsia is a multisystem disorder associated with hypertension, proteinuria, edema, hemoconcentration, hypoalbuminemia, abnormalities of hepatic function or coagulation, and increased urate levels.[32] In a recent study, 3.9% of 467 women with untreated pre-eclampsia progressed to seizures (eclampsia).[7]

Eclampsia is associated with seizures, cerebral bleeding, and death. The diagnosis of eclampsia is made when an antepartum or postpartum woman presents with generalized edema, hypertension, proteinuria, and convulsions. The spectrum of presentation, however, includes severe to minimal or even no hypertension, proteinuria, or edema.

Eclampsia most commonly occurs at or beyond week 28 of pregnancy. However, some cases occur between weeks 21 and 27 (7.5%) or at 20 weeks' or earlier (1.5%). Eclampsia occurring before 20 weeks' gestation is usually associated with molar or hydropic degeneration of the placenta. Eclampsia may also present within 48 hours postpartum and even as late as 4 weeks postpartum.

The incidence of eclampsia in Europe and other developed countries is 1/2,000 deliveries. In developing countries, estimates vary from 1/100 to 1/1,700. Maternal mortality ranges from 1.8% to 5%.[10,16] Eclampsia accounts for approximately 50,000 maternal deaths and is a leading cause of maternal deaths in the United States, Scandinavia, Iceland, Finland, and the United Kingdom.[50]

In the classification scheme of hypertension in pregnancy of the National Institutes of Health, pre-eclampsia and eclampsia are diagnosed according to the following criteria: increase in blood pressure to 140/90 mm Hg or greater in late pregnancy if no early reading is available, plus proteinuria (>300 mg/24 h), edema, or both.[32] Pathologic changes in pre-eclampsia and eclampsia involve multiple organ systems and arise because of vasospasm caused by exaggerated vascular responsiveness to circulating angiotensin II and catecholamines. Cardiac output, intravascular volume, and renal hemodynamics may be decreased. Uteroplacental perfusion may be compromised, leading to fetal growth retardation. A subset of pre-eclampsia is designated the HELLP syndrome: H for hemolysis, EL for elevated liver enzymes, and LP for low platelets.[61]

Neurologic abnormalities associated with eclampsia are usually acute and transient. These may include cortical blindness, focal motor deficits, and coma, although there is usually no permanent neurologic deficit. Seizures are most often generalized, but they may be partial.

During an eclamptic convulsion, the EEG shows spike-and-wave discharges. In one series of 65 patients with eclampsia,[60] a transient neurologic deficit was the presenting symptom in 5% of cases, and another 5% had transient cortical blindness. Electroencephalographic abnormalities were present acutely in 75% of cases, consisting primarily of excessive diffuse slow activity (67%), focal slow activity (33%), and paroxysmal spike activity (10%). These abnormalities were evident during administration of therapeutic doses of magnesium. The EEG abnormalities resolved at follow-up between 1 week and 6 months in all the patients. Other authors have described similar transient EEG abnormalities.[64]

Brain imaging in eclampsia shows vasogenic cerebral edema in 93% to 100% of women.[36,71] Extensive bilateral abnormalities of white matter are described in the posterior regions of the cerebral hemispheres as well as cerebellum and brainstem.[25] In addition, foci of infarction may be present. Angiography has shown spasm in large and medium-caliber arteries.[15] Results of CT are usually normal, but scans may show regions of decreased density corresponding to areas of cerebral edema.[15] The findings are similar to results with imaging in hypertensive encephalopathy. MRI abnormalities can persist for 6 to 8 weeks after resolution of symptoms.[36,71]

Pathologic examination of eclamptic brains usually reveals multiple petechial hemorrhages in cortical patches or subcortical hematomas. Areas predisposed to hemorrhages are the parietooccipital regions and the occipital lobes. Microscopically, these lesions correspond to ring hemorrhages about capillaries that are occluded by fibrinoid material.[15]

The treatment of eclamptic seizures associated with maternal hypertension has been controversial. There is wide consensus that the therapy for pre-eclampsia is delivery if the pregnancy is appropriately advanced. Hypertension is treated as necessary with antihypertensive drugs. The prevention of and treatment of seizures associated with pre-eclampsia and eclampsia has varied across countries and medical centers. The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy[32] recommends the use of magnesium sulfate for women with pregnancy-induced hypertension to prevent eclamptic seizures during labor and the immediate puerperium. Although most obstetricians in the

P.2692

United States have traditionally used magnesium sulfate to prevent eclamptic seizures in pregnant women with hypertension, obstetricians in the United Kingdom have favored diazepam and phenytoin.[18,26,47] A number of clinical studies have found magnesium sulfate treatment to be efficacious in preventing recurrent seizures in women with eclampsia.[24,46,58]

A randomized, placebo-controlled trial was performed in women from 33 countries diagnosed with preeclampsia and randomized to receive magnesium (5,071) or placebo (5,070).[2] Primary outcomes were eclampsia and, for women randomized before delivery, death of the infants. A total of 1,201 of 4,999 (24%) women given magnesium sulfate reported side effects versus 228 of 4,993 (5%) given placebo. Women allocated magnesium sulfate had a 58% lower risk of eclampsia (95% confidence interval [CI] 40–71) than those allocated placebo (40, 0.8%, vs. 96, 1.9%; 11 fewer women with eclampsia per 1,000 women). Maternal mortality was also lower among women allocated magnesium sulfate (relative risk 0.55, 0.26–1.14). For women randomized before delivery, there was no clear difference in the risk of the infant dying (576, 12.7%, vs. 558, 12.4%; relative risk 1.02, 99% CI 0.92–1.14). This trial established that magnesium sulfate halves the risk of eclampsia and probably reduces the risk of maternal death. There do not appear to be substantive harmful effects to mother or infant in the short term.

Whether antiepileptic drugs are appropriate to use in the treatment of seizures in this population has been debated. Arguments in favor of using antiepileptic drugs have stressed that magnesium is not antiepileptic, and it affects only the overt manifestations of seizures through neuromuscular blockade without altering the epileptic discharge.[14,28,29] Magnesium may have some unwanted obstetric effects as well. Inhibition of labor and impairment of postpartum hemostasis as a consequence of uterine smooth muscle relaxation have been described,[22] although others have not found that use of magnesium (or phenytoin) is associated with prolonged labor or an increased number of cesarean deliveries.[4]

A number of small trials have evaluated obstetric and seizure outcomes after phenytoin treatment in pre-eclamptic and eclamptic patients. Phenytoin was associated with more rapid cervical dilation and a smaller fall in hemocrit compared with magnesium in 105 pre-eclamptic and eclamptic women.[22] Slater et al.[62] treated 26 women who had eclampsia or pre-eclampsia with intravenous phenytoin and reported no convulsions. Robson et al.[52] treated 5 women who had eclampsia and 67 women who had severe pre-eclampsia with a phenytoin dose of 15 mg/kg or a loading dose of 17.5 mg/kg and found that some women had seizures despite therapeutic levels. Dommisse[13] assigned 22 women with eclampsia to receive either intravenous phenytoin or magnesium. Four of the women on phenytoin (levels of 10–25 mg/mL) had seizures, but none of the women on magnesium had seizures. Appleton et al.[3] randomized 50 patients with pre-eclampsia to phenytoin or magnesium for seizure prophylaxis. No differences were found in patient tolerance, adverse reactions, or neonatal outcomes between groups. No patient in either group had seizures.

Small trials have also evaluated the efficacy of prophylactic benzodiazepine treatment. Fifty-one women with eclampsia were randomized to magnesium or diazepam as an anticonvulsant.[9] Convulsions occurred in about one fourth of the women in each group, and there was no statistically significant difference in maternal morbidity, although significantly fewer infants in the magnesium group had low Apgar scores compared with those in the diazepam group.

Recently, several randomized, large-scale trials have permitted objective comparison of the efficacy of alternative medical treatments for pre-eclampsia/eclampsia. These represent the best information concerning the relative efficacy of magnesium and phenytoin for seizure prophylaxis and improving maternal and fetal outcome.

The Eclampsia Trial Collaborative Group[19] was an international multicenter, randomized trial that compared magnesium sulfate, diazepam, and phenytoin as treatment for eclampsia. This trial included 1,687 women with eclampsia from South Africa, Argentina, Colombia, Zimbabwe, Uganda, Brazil, Ghana, India, and Venezuela. Women were randomized to receive either magnesium or diazepam, or magnesium or phenytoin. Each center chose the comparison pair. Women receiving magnesium had a 54% lower risk of recurrent convulsions than did those receiving diazepam. There was no difference in maternal morbidity or perinatal morbidity and mortality. Women receiving magnesium had a 67% lower risk of recurrent convulsions than did women receiving phenytoin. Maternal mortality was not significantly lower in the women receiving magnesium. However, women on magnesium were less likely to be ventilated, contract pneumonia, and be admitted to an intensive care unit than were those receiving phenytoin. The infants of the mothers on magnesium were less likely to be intubated and to require admission to a special care nursery. Infant mortality remained high in the trial. Overall, 27% of infants died, with a mortality rate of 49% to 58% for those delivered before 34 weeks' gestation. This high infant mortality rate may be a reflection of the multinational nature of the trial. In the United States, mortality rates at 28 weeks or more are 10% or less.[51]

A second trial,[37] based in the United States, evaluated magnesium and phenytoin as prophylaxis for eclampsia in hypertensive pregnant women. Women admitted to labor and delivery with hypertension received either magnesium or phenytoin. Magnesium was administered as 4 g intravenously, followed by 10 g intramuscularly and 5 g intramuscularly every 4 hours thereafter as needed and as tolerated by protocol. Phenytoin was given as 1,000 mg intravenously, then at a maintenance dose 10 hours later of 500 mg orally. In this intention-to-treat analysis, 178 women randomized to the phenytoin group were given no phenytoin or received only partial loading doses. None of these women experienced an eclamptic seizure. Although there were no significant differences in any risk factors for eclampsia between the two groups or in maternal and fetal outcomes, 10 of 1,089 women receiving phenytoin had convulsions, compared with none of the 1,049 women receiving magnesium sulfate. These women had a number of peripartum complications: 5 had cesarean sections, 6 had infants with low birth weight, 1 had abruptio placentae, and 2 required transfusions. Several women who underwent neuroimaging had areas of low density, a finding that has been previously described with eclampsia,[8] but otherwise showed no structural abnormalities. Phenytoin levels in the women who had seizures ranged from 5.8 to 24 mg/mL; 9 of the 10 women with seizures had phenytoin levels of at least 10 mg/mL. The past experience of this center[37] predicted that the incidence of eclampsia after admission for hypertension and during magnesium sulfate prophylaxis would be 1/750 women. In this study, the observed incidence in the magnesium-treated group was 1/1,384, whereas the phenytoin failure rate was 1/100. This can also be compared with an incidence of 1/78 in one study in which women with proteinuric hypertension received no treatment.[8]

Magnesium sulfate may have other beneficial effects in high-risk infants and after neuronal injury in other patient populations. Magnesium is associated with improved survival in infants weighing <1,000 g.[6] Magnesium also appears to protect against hemorrhage into the germinal matrix or ventricles in infants of very low birth weight.[31] In an experimental model of birth asphyxia, magnesium was associated with less evidence of brain injury.[39,65] In one observational study, in utero exposure to magnesium sulfate appeared to be associated with a protective effect against cerebral palsy in infants of very low

P.2693

birth weight.[44] Magnesium administration also decreases secondary neuronal damage after experimental traumatic brain injury.[40,66]

What are the mechanisms by which magnesium effectively treats seizures in these patient populations? Seizures are an expression of dysfunctional cortical excitability and arise in a variety of pathophysiologic conditions. Magnesium may be most effective against seizures and brain injury that arise as a result of increased excitatory neurotransmitters.[34] Magnesium suppresses activity at the *N*-methyl-D-aspartate (NMDA) receptor, blocks calcium influx at the NMDA receptor, and reduces calcium-dependent presynaptic neurotransmitter release. Phenytoin blocks sodium channels but has no significant effect on calcium channels. Although there is no accepted animal model for eclampsia, stimulation at the NMDA receptor may reproduce some of the neurochemical events responsible for the eclamptic seizure. In one experimental model of eclamptic seizures, rats were cannulated in the lateral cerebral ventricle and given NMDA to elicit seizures. Magnesium sulfate was more effective in terminating these seizures than was phenytoin.[38] Seizures in amygdala-kindled rats, however, representing a model more typical of human localization-related epilepsy, responded to phenytoin but not to magnesium in terms of seizure duration, duration of postictal depression, and behavioral seizure stage.[63] Sibai et al.[59] also found that magnesium did not suppress epileptiform potentials as recorded on the EEG.

Seizures in pre-eclampsia and eclampsia may also occur in response to intense vasospasm. Magnesium sulfate is a potent vasodilator and increases cerebral blood flow as measured by Doppler ultrasonography of intracranial vessels.[5] Vasodilation appears to be greatest in the smaller-diameter intracranial vessels distal to the middle cerebral artery. This effect would be anticipated to relieve cerebral ischemia. The vasospasm in pre-eclampsia and eclampsia is thought to be partly related to endothelial dysfunction. Magnesium increases the production of prostacyclin, an endothelial vasodilator, and also protects against endothelial injury mediated by free radicals—perhaps by substituting for calcium and preventing the influx of calcium that is induced by free radicals.[49]

Magnesium has been the standard treatment for pre-eclampsia and eclampsia, reducing maternal and neonatal morbidity and mortality.[49] The largest number of fetal deaths occur as a consequence of maternal hypertension, which is associated with retardation of intrauterine growth, low birth weight, and prematurity as well as a significant rise in fetal death rate.[17] Magnesium addresses the maternal hypertension and improves fetal outcome. It appears that in most cases, magnesium also effectively treats eclamptic seizures. This should not be surprising. The optimal treatment of any seizure corrects the specific neurochemical events triggering the epileptic discharge. The events in seizures arising with pre-eclampsia/eclampsia appear to differ from those in seizures arising with epilepsy. Whether treating eclamptic seizures with magnesium and an antiepileptic drug confers additional benefit has not been directly evaluated. Further understanding of the pathophysiology of seizures associated with pre-eclampsia/eclampsia will better define the best therapy.

Summary and Conclusions

The diagnostic and treatment approach to the pregnant woman with seizures follows the same basic principles as the approach to any patient with a first seizure, although the diagnostic differential must be expanded. The need for emergent antiepileptic treatment is assessed. Results of the medical and neurologic history and the physical and neurologic examination are combined with findings of a comprehensive obstetric history and examination. Laboratory examinations include urinalysis for proteinuria, complete blood cell count with platelets to exclude infection and evaluate for a hematologic disorder or HELLP syndrome, determination of electrolytes, liver function tests, and a toxicology screen for cocaine and alcohol. Except in situations in which the diagnosis is clearly pre-eclampsia/eclampsia, EEG and MRI are indicated. In cases of complicated eclampsia or in the setting of focal neurologic deficits, neuroimaging should also be obtained.

Seizures occurring in the later part of gestation in a hypertensive woman are most likely a manifestation of pre-eclampsia/eclampsia. Other potential causes of seizures during pregnancy include acute cerebrovascular disease, infection, exacerbation of a neoplastic lesion or SLE, or hematologic disorders.

In a pregnant woman with seizures in whom the diagnosis of pre-eclampsia/eclampsia has been excluded, treatment of seizures proceeds as would be appropriate for a nonpregnant woman. Although antiepileptic drugs are teratogenic, seizures—particularly convulsive or prolonged seizures—pose a greater risk to the well-being of both mother and fetus. Care should be taken in figuring the doses of highly protein-bound drugs because the non–protein-bound fraction active in the CNS is relatively higher in a pregnant woman.

In the pre-eclamptic patient, magnesium sulfate is indicated for both prophylaxis and treatment of seizures. The question of whether an antiepileptic drug should be administered as well must be answered by future research. In the meantime, it appears prudent to obtain an EEG (or EEG monitoring) in any woman in whom seizures recur after treatment with magnesium sulfate or in any woman whose mental status is not normal. The EEG permits persistent electrographic seizures to be detected; these may be difficult to diagnose clinically in a patient with obtundation and neuromuscular blockade. Patients with clinical or electrographic seizures who are receiving magnesium should be treated with an antiepileptic drug as well. Phenytoin or a benzodiazepine appears to be an acceptable choice because of the relatively good safety profile in both mother and fetus.

Chapter 270

Overview: Disorders That Can Be Confused with Epilepsy

Frédérick Andermann

Introduction

The history is crucial in suggesting a diagnosis of epilepsy. The value of the interview hinges largely on the availability of an accurate history from both the patient and a witness to the event. In the absence of either of these essential features, the information is usually incomplete or inadequate, and every effort should be made to obtain a complete and detailed account before attempting to formulate a diagnosis.[2]

The last quarter-century has witnessed a great increase in the number of neurologists sophisticated in the treatment of epilepsy, and such neurologists are now available in many practice groups and academic departments. Many neurologists developed sophisticated monitoring units, to which patients with unexplained paroxysmal events are often referred. It soon became obvious that many of these individuals did not have epileptic seizures, and this led epileptologists and other neurologists to focus on the wide range of disorders presenting for differential diagnosis. More recently this increased awareness and accuracy in diagnosis by referring physicians has led to a reduction in the number of patients with clinically recognizable nonepileptic paroxysmal events who are referred to epilepsy centers.

Nonepileptic seizures present the most common problem in differential diagnosis (see Chapter 282). Increasingly available information and sophistication coupled with ready access to medical literature and the Internet, along with the individual's ability to learn from previous interviewers and examiners, has led to the appearance of complex accounts of what might be called "pseudoepileptic nonepileptic seizures." Thus, such patients often provide a history that contains many features of temporal lobe epilepsy or of other specific epileptic disorders. They may have a background of study in a field related to epilepsy, which obviously makes diagnosis difficult. The patients' social and cultural backgrounds are important determinants not only of the pattern of nonepileptic seizures, but also of their response to treatment. In many settings and localities the majority of patients respond to appropriate psychiatric treatment with remission of the attacks. In other environments with different levels of psychiatric sophistication and social problems, the disorder is much more refractory and the percentage of patients who cannot be relieved of their nonepileptic attacks is higher.[43]

Systemic Disturbances

Anoxic convulsions, or "ischemic convulsions" as they are sometimes termed, continue to present a diagnostic problem. They occur most often as a sequel to syncope and are related usually to the person being kept in an upright or standing position. Sometimes, however, syncope may occur in individuals who are recumbent. The circumstances of the event and the family history will provide clues to the diagnosis.[18,21,29,43] Not only might patients with asthma during an acute attack have cerebral ischemia, but they also might present with tonic episodes, whose mechanism is analogous to that of anoxic convulsions.[27] When there is some lateralization, the differential diagnosis is, of course, more difficult. However, lateralization of clinical features is not uncommon and has long been recognized in generalized processes such as idiopathic epilepsy.[24] It may be erroneously inferred by the observer, depending on the patient's position during the attack. It is important to distinguish between persistent or habitual lateralization and less significant and inconstant asymmetries in body and limb postures and movements.

Many individuals with migraine present features that make diagnosis difficult (Chapter 274). Acephalgic migraine occurring in older individuals is often not accompanied by headache, and these patients are not infrequently referred for diagnosis because of the suspicion of intermittent cerebral ischemic attacks or an epileptic etiology. Acephalgic migraine, however, does also occur in younger individuals and children.[45]

The march of the migrainous aura has a time course that frequently is different from that of the recruitment of symptoms in epilepsy, and in a majority of individuals distinguishing between the two is not difficult.[12,38,45] After the migrainous aura, however, the patient may have convulsive seizures, so-called intercalated attacks.[3,47] These are most likely related to spreading depression crossing the central sulcus, but proof of the specific mechanism is lacking. Whether these attacks require treatment with antiepileptic medication is not clear. Patients with a habitual tendency to develop such epileptic manifestations in the course of their migraine attacks eventually may develop seizures, usually temporal in pattern, which no longer occur in relation to clear-cut migrainous events. The mechanism of this form of secondary epileptogenesis is not clear.[1] Confusional migraine may also result in an epileptic seizure occurring during the acute event.[1,19] Here, too, the possibility of eventual development of independent epileptic attacks exists.

Patients with basilar migraine not infrequently present difficult diagnostic problems. It is usually the sequence of symptoms pointing to brainstem involvement, such as diplopia and ataxia, that provides clues to the diagnosis.[9,39,46] Neuro-otologic investigation during an attack documenting the very prominent nystagmus is also helpful.

Patients with basilar migraine also may have epileptic events or in rare instances status epilepticus. Here, too, the account of symptoms preceding the seizure will lead to clarification.[14]

The unresponsiveness that is not uncommon during basilar migraine attacks may be interpreted as loss of consciousness; however, the patients generally can be aroused by vigorous stimulation, only to relapse into stupor when stimulation ceases.[9]

P.2696

In addition to the clinical problems, the recognition that the migraine aura may be manifested by electroencephalographic (EEG) spike discharge (usually over posterior head regions) may lead to diagnostic difficulty.[6,33,44]

Migraine is an extraordinarily common disorder, and despite the efforts of the International Migraine Society, there is still considerable disparity in deciding on its prevalence. It seems fairly clear that migraine and epilepsy have different mechanisms but that relationships between the two conditions, at times of a causal nature, exist. An interesting example is the association between benign rolandic epilepsy or benign occipital epilepsy and migraine.[10] Surprisingly, there is no unanimity among pediatric neurologists and epileptologists about the high and probably consistent association of these two disorders. Clarification must await advances in molecular genetics, which, it is hoped, will provide markers for these conditions.

Recent advances in molecular biology have shed some light on the nature of hemiplegic migraine with coma; it is notable that these patients do not have clear epileptic events. The hallucinations that occur as they recover from the coma are similar to those of peduncular hallucinosis.[26,36,50]

Patients with peduncular hallucinations are often considered to have epilepsy and are so treated. The hallucinations are usually vivid, stereotyped, prolonged, and not associated with overt epileptic manifestations. They are caused by mesencephalic lesions or abnormalities and do not respond to antiepileptic drugs.[15,25,37] The hallucinations of patients with parkinsonism are probably similar to if not identical to those of peduncular hallucinosis and also may raise questions as to their nature.[16,20] The auditory hallucinations of the deaf or the visual hallucinations of the blind are occasionally misinterpreted as epileptic in nature.

Neurologic Disturbances

Patients with episodic hypothalamic dysfunction or the Kleine-Levin syndrome have varied behavioral abnormalities, including hallucinations and excessive sleep. The patients often have some disturbance of awareness and memory, although they remain fully conscious.[11,42] An epileptic twilight state is at times suspected, but when the examiner is aware of the condition, a detailed history stressing associated features such as excessive eating and inappropriate sexual behavior should lead to the diagnosis.

Paroxysmal events occurring exclusively during sleep have led to diagnostic difficulties for some time (see

Chapter 276).[22,35] The identification of nocturnal paroxysmal dystonia as a specific entity arose at a time when there was little awareness of the various patterns found in frontal lobe epilepsy. It now appears that paroxysmal nocturnal dystonia is not an entity that can be distinguished from partial epilepsy of frontal origin. The recent recognition of familial frontal epilepsy has further helped to clarify the diagnosis in a number of individuals.[41] It is not a homogeneous condition, however, and although in some families the attacks are always nocturnal and easily controlled by antiepileptic medication, in others there is variation in the occurrence of attacks in relation to the sleep/waking cycle, and medical control is difficult to achieve. This disorder, or rather this group of disorders, occurs in the absence of visible lesions and most likely is related to regional disorders of channel function or other, unidentified molecular abnormalities.[32,41]

Rapid-eye-movement (REM)–related sleep disorder may be mistaken for epileptic or postepileptic confusion and aggression but has become increasingly recognized as a consequence of the development of sleep medicine.[22] Hypnagogic and hypnapompic myoclonus is often misinterpreted as epileptic by patients with epilepsy and their families. The nature of myoclonus occurring during sleep is often difficult to interpret and to relate to a patient's known epileptic disorder.

Myoclonus has recently been intensively studied by epileptologists and movement disorder specialists, and its neurophysiologic basis is much better understood, but gaps still exist (see Chapter 277). Although the myoclonic component of idiopathic generalized epilepsy is usually easy to recognize, the diagnosis is often missed until generalized tonic–clonic or clonic–tonic–clonic seizures supervene.

The progressive myoclonic epilepsies subsume a number of disorders that share an association with generalized seizures, photosensitivity, and sometimes occipital epileptic discharge, ataxia, and some degree of neurologic deterioration (see Chapter 252). The most common disorders are Lafora disease, Unverricht-Lundborg disease, neuronal ceroid lipofuscinosis, myoclonus epilepsy with ragged red fibers (MERRF), and sialidosis. There are also several other entities that may present in this way.[8,13,30,40,49] Despite recent progress, particularly in the area of molecular biology, the neuronal networks in brainstem and cerebellar structures leading to these manifestations have not been identified. This is surprising considering the great disparity in their biochemical and neuropathologic abnormalities.

Myoclonic ataxia as defined by Marsden et al.[34] implies that these patients do not have overt epileptic seizures. It is likely that at least a percentage of these individuals suffer from MERRF or a related mitochondrial disorder (Chapter 262). Patients presenting in this way should have a detailed investigation of mitochondrial function.[34]

Benign essential myoclonus is an ill-defined disorder. Affected family members may have an occasional seizure, which casts doubt on the nonepileptic nature of the syndrome.[17]

The nature of some of the paroxysmal movement disorders has been intensely debated recently. Benign paroxysmal kinesigenic choreoathetosis (PKC), perhaps the most common of these, is easily recognized if one is aware of the clinical symptomatology. Attacks are classically induced by initiation of movement, are brief, and are not associated with any impairment of awareness. The disorder gradually improves with age. The episodes respond remarkably to low levels of antiepileptic medications such as carbamazepine and phenytoin. However, stopping the small dose of medication usually leads to recurrence.[28] This disorder is clearly not epileptic in the classical sense. Until its mechanism is more clearly understood, the relationship to epilepsy will remain uncertain (see Chapter 278).[7,31]

Symptomatic choreoathetosis may well have a different pathophysiologic basis.[23] The symptoms are more varied than in PKC, triggers are less obvious and not stereotyped, and an epileptic etiology is more frequently assumed. Examination with depth electrode recording in one patient showed spike discharges, which prompted the investigator to assume a relationship of the disorder to epilepsy, at least in the patient so studied.[7] Certainly the presence of such spiking in subcortical structures may be related in some way to the effectiveness of antiepileptic drugs in low doses in some of the individuals with paroxysmal movement disorders.

Alternating hemiplegia of childhood is almost invariably still diagnosed initially as an epileptic disorder. The progressive deterioration and the lack of response to antiepileptic drugs eventually lead to the diagnosis. Perhaps as many as half the children later develop epileptic seizures as well, and in most instances these are easily controlled. This disorder is probably also migraine related, although its cause remains a mystery. The attacks of hemiplegia are associated with only mild or no definite slow-wave electroencephalographic changes during the event. This pattern of alternating hemiplegia is not limited to the classical syndrome, and several disorders may manifest in this way. Benign nocturnal alternating hemiplegia is not associated with mental deterioration and is even more clearly

migraine related. Pyruvate dehydrogenase deficiency, undiagnosed basal ganglia disorders, and episodic dystonic attacks in infancy also may present with similar motor symptoms and share what seems to be a common subcortical or brainstem mechanism.[4]

Shuddering attacks are not uncommon in children and are often considered to be myoclonic or epileptic. They may be related to a family history of essential or familial tremor, and this has again been suggested in the recent literature.[5,48] Benign nocturnal myoclonus recently was recognized in infants who continue to develop normally (see Chapter 280).

Summary and Conclusions

The clinical features of the epilepsies and of epileptic seizures and epileptic syndromes have been well delineated in recent years. This has led in turn to more accurate diagnosis and increasing recognition of a variety of paroxysmal events of a nonepileptic nature. The progress reported in this overview and in the following chapters is not merely an idle theoretical exercise; rather, it has prevented the needless use of antiepileptic drugs with their known side effects in situations in which these agents cannot be expected to be helpful.

Chapter 271

Syncope

Mark S. Quigg

Thomas P. Bleck

Introduction

The term *syncope*, from the Greek for "cutting short," refers to an abrupt and transient loss of consciousness accompanied by loss of muscular tone. It is usually caused by a sudden, global reduction in cerebral perfusion, and clinical recovery occurs with restoration of normal cerebral blood flow. The very transience of this syndrome and the variety of medical disorders that can cause or mimic it are at the core of the diagnostic problems that the neurologist faces.

Definitions

Patients and physicians alike use a variety of terms to describe an occurrence of syncope. The term *fainting* is often used synonymously with syncope and captures the essential criteria— loss of consciousness and muscle tone. If the symptoms differ only in degree, so that there is partial loss of consciousness with a near fall, the term *presyncope* is often used. Less specific terms, such as *passing out*, *blackout*, or *dizziness*, need further clarification to become diagnostically useful. Some clinicians restrict the meaning of *drop attacks* to episodes of transient loss of tone with preservation of consciousness, a definition that carries a different burden of etiologies than does syncope.

Incidence and Prognosis

When measured in studies of consecutive emergency room visits, syncope prompts about 3% of emergency room evaluations, a proportion that has changed little over the last 25 years.[9,14,56] Multicenter surveys estimate that of 865 million emergency room visits between 1992 and 2000, 6.7 million (0.77%) were related to syncope.[78]

Although no age is spared, the incidence of syncope is highest among the elderly. A study of 711 elderly patients revealed a 10-year prevalence of 23% and a yearly incidence of 7%.[52] Of those who are admitted to hospital, 59.9% are age 70 years or older.[79] In addition to increasing age, other factors leading to higher rates of hospitalization are female gender and white race.[78]

The incidence of syncope among children and adolescents is 1.25%, peaking in the 15- to 19-year-old group.[20] Young athletes at a mean age of 16 years report that 6.2% had syncope within the last 5 years.[10]

Diagnosis is important because the mortality of syncope varies widely with the underlying etiology. Kapoor determined the 5-year outcome of 433 patients evaluated for syncope.[41] Mortality is >50% in patients with a cardiac cause of syncope, compared to 30% in patients with a noncardiac cause and 22% with an unknown cause.

Data from the Framingham Heart Study emphasize that syncope from cardiac causes is often a harbinger of significant coronary disease.[76] In this study, 822/7,814 (10.5%) individuals reported syncope over a 24-year period, for an overall incidence of first report of syncope of 6.2/1,000 person-yr. The relative hazard rate experienced by those with syncope from any cause compared to those without syncope is 1.31. Cardiac syncope has the highest relative risk of death than any other cause of syncope at 2.01 and an especially high risk of death related to coronary artery disease (relative risk 2.66). The Framingham study also emphasizes that those whose etiology of syncope remains unknown do not necessarily experience a benign course, having a relative risk of death from any cause of 1.32.

Older age appears to increase the risk of mortality in cardiac syncope. Another study by Kapoor that compared mortality rates of patients <60 and >60 years of age found that although the 2-year mortality rate was 27% in the older and 8% in the younger group, cardiovascular causes remained the most significant risk factor for mortality in either.[43] In the elderly, syncope carries a greater mortality despite etiology. In elderly patients hospitalized for syncope, the 4-year mortality was 41%, with the relative risk of cardiac syncope not varying significantly from that of noncardiac syncope.[30]

Morbidity associated with trauma from syncopal falls also contributes to the costs related to syncope. Between 16% and 36% of patients presenting with syncope experience a range of injuries from minor lacerations and bruises to fractures of the hip, face, or limbs.[14,41]

The morbidity of syncope goes beyond the physical. Assessments of the functional status of patients with chronic syncope show degrees of psychosocial impairment similar to those experienced by patients suffering from other disabling diseases such as rheumatoid arthritis or low back pain.[51]

The frequency of recurrence of syncope is not especially helpful in characterizing patients by etiology or prognosis,[41] although each syncopal episode increases the probability of serious injury. In Kapoor's study of 433 syncopal patients followed for 5 years, 153 had one or more recurrences, and the mean number of recurrences was greater than six.[41] Whether the diagnosis was cardiac, noncardiac, or unknown, recurrences were common in every category.

The 2000 Healthcare and Utilization Project estimates the annual cost of syncope-related hospital admissions in the United States at $2.4 billion, placing syncope on par with asthma ($2.8 billion) and human immunodeficiency virus ($2.2 billion).[78] The estimated cost per patient is $5,400. The high cost reflects the difficulties in establishing a diagnosis of a syndrome having both a wide range of possible etiologies and a high rate of studies returning nondiagnostic results. These problems have led to the publication of guidelines on evaluation and hospitalization of syncope, the adherence to which, some report, leads to higher yields in diagnostic accuracy but to no clear reductions in cost.[16,26] Other clinicians, however, report success in cost reduction, test reduction, and health benefits in the use of specialized syncope units and protocols of risk stratification and evaluation.[45,74]

Clinical Description

Classic Symptoms

The prodromal symptoms of classic syncope are familiar to most physicians and consist of nausea, “clammy” sweating, visual blurring and “graying out,” tinnitus, lightheadedness, and dizziness. The patient appears ashen or pale and becomes diaphoretic. Mydriasis may occur with tachypnea and bradycardia. Witnesses frequently note that the victim's “eyes rolled back into the head,” reflecting fading extraocular muscle tone. The patient becomes diffusely weak and hypotonic and, as consciousness is lost, falls to the ground with lack of protective reflexes if unsupported. Within seconds to minutes, once the patient is horizontal, color, pulse, and consciousness return. During the anoxic phase, before the patient recovers consciousness, a few myoclonic jerks or even more rhythmic, clonic movements may appear. Such a syncopal convulsion is common and often leads to erroneous reports of epileptic seizures. Sequelae include continued nausea and generalized malaise, but drowsiness, confusion, and amnesia are limited.

Syncopal Myoclonus

These common clinical features have been confirmed by video analysis of syncope induced in healthy volunteers through ocular pressure, hyperventilation, and Valsalva maneuver.[49] Typical prodromal symptoms were blurred vision, dizziness, vertigo, and nausea. Average duration of loss of consciousness was about 12 seconds, and myoclonic activity (syncopal convulsions) occurred in 38/42 syncopal episodes. Automatisms were observed in nearly 80%. Opened eyes and upward eye deviation were also common. Auditory and visual hallucinations, not usually elicited in previous studies, were reported in 60%. Postictally, transient amnesia occurred in 1 of 42 individuals, but cognitive sequelae were otherwise unremarkable. In none of these normal individuals nor in other studies of induced syncopal convulsions in patients did incontinence occur.[2,34,49]

Of the manifestations of syncope, convulsive movements are potentially the most confounding because they raise the question of epileptic seizures. Studies of syncopal convulsions induced in patients during cardiac electrophysiology studies,[2] positive tilt-table studies,[34] and in healthy volunteers[49] describe a prevalence of 45% to 90%.

Myoclonic activity during a syncopal convulsion is usually multifocal and arrhythmic, but generalized, rhythmic myoclonus is also common.[36,49] In our experience, biased by patients admitted for diagnosis in epilepsy monitoring units, dystonic posturing similar to that of a complex partial seizure is not unusual and adds further difficulty in the purely visual distinction between syncopal and epileptic motor activity. This opinion is supported by a large study (694 individuals) of symptoms provoked by tilt-table testing; 8% of participants with positive results (n = 222) had “neurologic events” consistent with the clinical behaviors of tonic–clonic seizures, focal seizures, or dysarthria or aphasia.[63]

Electroencephalographic Appearance

Electroencephalographic recordings document the electrophysiologic correlates of syncopal convulsions. In patients with vasovagal syncope who have attacks induced by tilt-table, the electroencephalogram (EEG) demonstrates gradual development of high-amplitude 3- to 5-Hz slowing during prodromal symptoms. Slow-wave frequency decreases to 1- to 3-Hz activity with loss of consciousness.[36] In recordings of cardiac syncope caused by ventricular arrhythmias,[2] electrographic findings are more variable and sometimes feature marked attenuation of cortical activity with loss of consciousness, although in most cases, rhythmic slowing occurs before voltage attenuation. The changes in EEG occur about 10 to 15 seconds after development of arrhythmia. It is of interest that brain-slice preparations deprived of oxygen show a time of onset to isoelectric activity of about 7 minutes,[64] which implies that corticothalamic activity comprising scalp EEG is more susceptible to hypoxia than individual cortical neurons. Normal background activity returns quickly with restoration of circulation and return of consciousness. Myoclonic activity has no consistent relationship with the EEG changes, and could occur either before or after EEG attenuation.[2] In neither study were epileptiform or ictal discharges observed.[2,36] Both the duration of loss of consciousness and postsyncopal confusion are linearly related to the duration of cardiac dysfunction.[2] Figures 1 and 2 demonstrate typical EEG accompaniments in syncope induced by cardiac asystole and in reflex bradycardia induced by breath-holding.

Differential Diagnosis

Because neurologists and epileptologists can be expected to see a more selected patient group than cardiologists, general practitioners, and emergency room physicians, the bulk of this discussion focuses on the separation of neurologic causes of syncope from other etiologies. However, because neurologic causes are relatively infrequent, a discussion of the differential diagnosis of syncope is undertaken first.

As Table 1 shows, even a brief listing of causes of syncope can be daunting. A more concise method is to group the myriad causes onto five main categories: (a) disorders of orthostatic intolerance; (b) primary cardiac dysfunction; (c) transient neurologic dysfunction; (d) metabolic derangement; and (e) psychiatric syndromes. The relative frequency of these diagnostic groups as they present in emergency rooms and other primary care facilities is shown in Table 2.

Disorders of Orthostatic Intolerance

Disorders of the homeostatic mechanisms of blood pressure maintenance comprise a large portion of syncope seen by physicians. In these disorders, the unifying pathophysiology is the abnormal or insufficient response of the peripheral vascular system and in reflex cardiac mechanisms to internal or external stimuli.

To briefly review, on standing, about 300 to 800 mL (about 25% of total blood volume) is displaced downward from the thorax. Reduced pressure is detected by receptors in the carotid sinus and aortic arch and within cardiac and pulmonary tissues. Tonic central sympathetic inhibition decreases, which allows an increase in peripheral vascular resistance and an increase in heart rate as mediated by medullary cardiovascular control centers.[81] Defects in this regulatory system lead to orthostatic hypotension, which can be due to degeneration of the autonomic nervous system either centrally, as in Shy-Drager syndrome, or peripherally as the result of acquired or hereditary neuropathies. An intact autonomic nervous system, on the other hand, may be unable to compensate for conditions causing hypovolemia, such as anemia or dehydration. Elderly patients have particular problems with compensatory cardiovascular regulation and are vulnerable to orthostasis whatever the cause.[43]

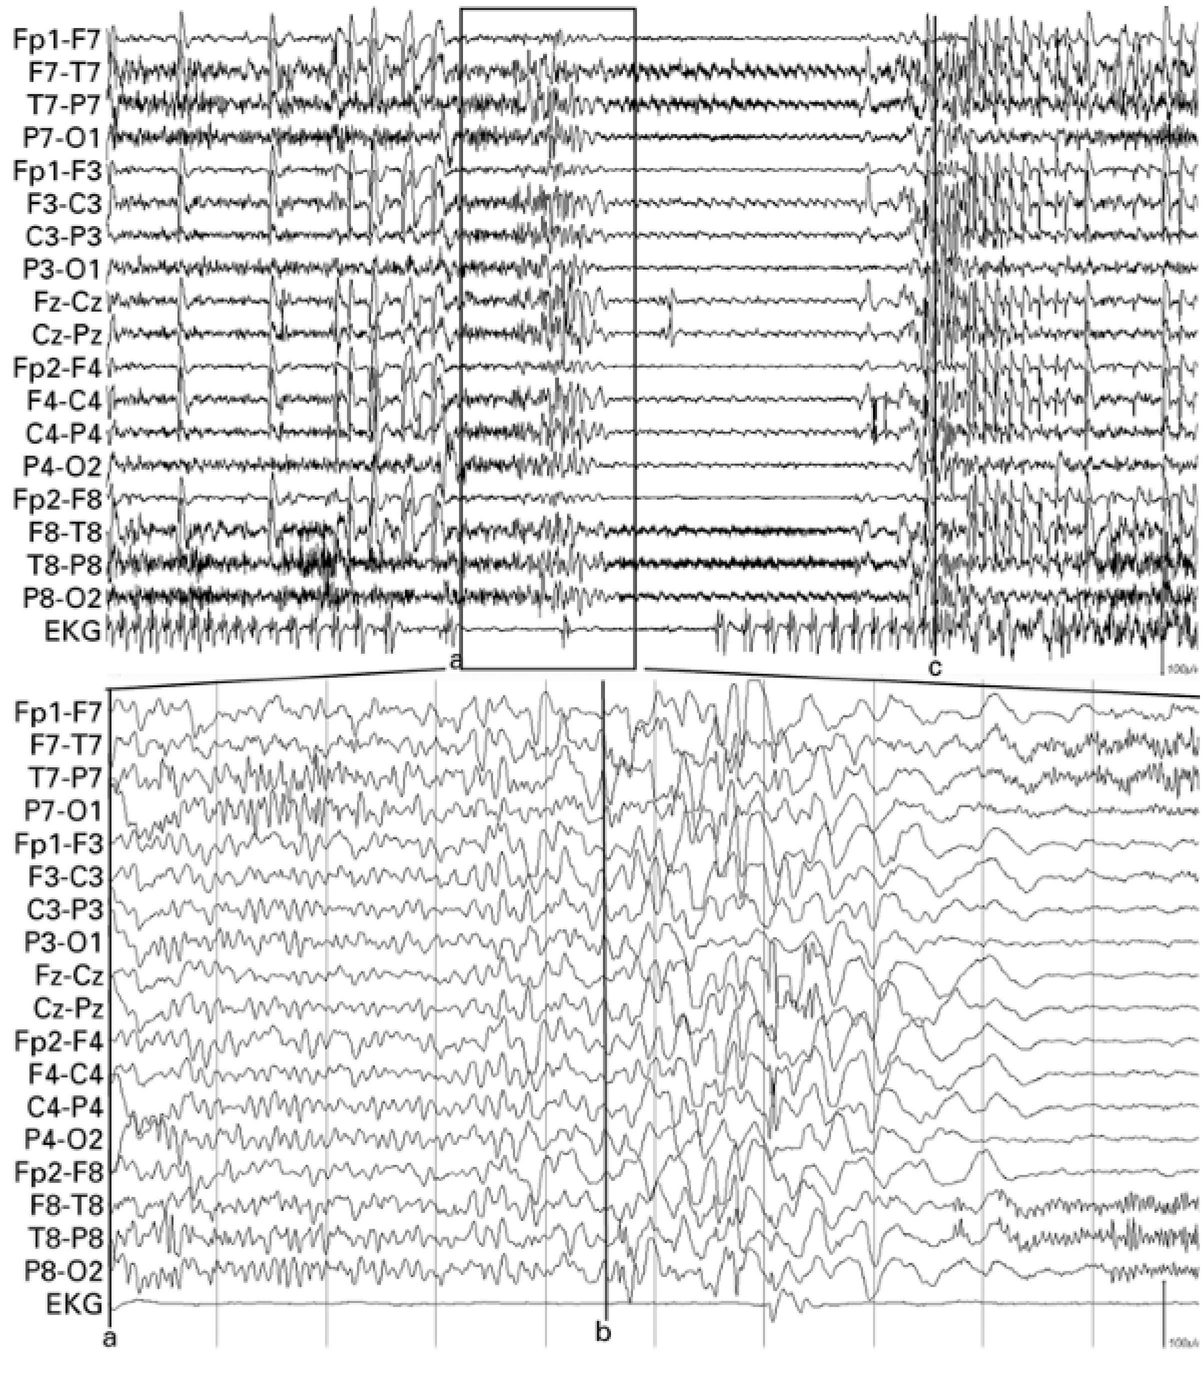

FIGURE 1. Electroencephalographic (EEG) excerpts from intensive video-EEG diagnosis of syncopal convulsion following spontaneous asystole in a patient who had undergone treatment for 1 year for presumptive epileptic seizures. The top panel shows a 60-second page with the box indicating the 10-second page excerpt in the bottom panel. The EEG starts with the patient in her normal, awake state while lying in bed. At time point a, the ECG channel shows the onset of asystole. The patient experiences clinical onset at point b marked by behavioral arrest and bilateral, dystonic posturing. The EEG, typical in response to cerebral hypoperfusion, develops abrupt, generalized slowing approximately 5 seconds after the last heartbeat, followed by generalized attenuation. Note the lack of epileptiform discharges despite the apparent motor activities of a complex partial seizure. Symptoms resolve at point c about 10 seconds following the return of normal sinus

rhythm. The lags from ECG to EEG and clinical changes are typical for syncope and represent a combination of cardiac output and cerebral perfusion volume.

FIGURE 2. Breath-holding spell in a 15-month-old resulting in asystole, syncope, and brief convulsion recorded with continuous-telemetry electroencephalogram and simultaneous video recording. **A:** Patient, held in mother's arms, is crying while the technician re-gels the electrodes. **B:** Crying abruptly stops, and several seconds later, the technician notes that the patient is not breathing. **C:** The patient becomes limp and is unresponsive. **D:** A single axial myoclonic jerk is seen. **E:** The patient abruptly resumes crying. **F:** Normal tone returns. The tracing demonstrates that breath-holding precedes bradycardia/asystole by approximately 6 seconds. Generalized rhythmic delta activity gradually builds up during the event and, after ECG activity and crying resume, gradually resolves. (Adapted from figures provided courtesy of Ted Burns, M.D., Neuromuscular/Autonomic Testing Division, Department of Neurology, University of Virginia.)

One of the more important causes of syncope in older people is orthostatic hypotension induced by drugs. In a study of elderly, institutionalized patients, hypotensive adverse effects

P.2701

P.2702

of drugs caused 8 of 32 cases of noncardiogenic syncope.[52] Nitrates, levodopa, and thioridazine were cited this study, but any new medication, especially one that antagonizes the alpha-1 receptor such as amitriptyline or chlorpromazine, should be suspect in any elderly patient with syncope.

Current consensus divides disorders of orthostatic intolerance into three groups, as follows.[3]

Reflex Syncope

Reflex syncope is a group of disorders that occur because of a sudden failure of the cardioregulatory system to maintain adequate vascular tone during orthostatic stress, resulting in hypotension that is frequently associated with bradycardia.

Neurocardiogenic syncope (or vasovagal syncope) is a reflex syncope believed to result from an inappropriately hypercontractile response of the heart to abrupt venous pooling. The resulting state mimics hypertension and causes a compensatory but pathologic bradycardia, initiating syncope.[35] In susceptible individuals, neurocardiogenic syncope is triggered by strong emotions such as fear or follows painful stimuli such as venipuncture, dental procedures,[22] or prostate exams.[5] Sometimes the precipitating event is merely a prolonged upright stance, as is frequently required of soldiers standing at attention. In this situation, there is also the confounding variable of venous pooling in the legs because gastrocnemius and soleus muscle contraction ceases. Soldiers who are taught to keep their knees slightly flexed and to intermittently contract their leg muscles are at much lower risk of syncope.

Hypersensitivity of peripheral visceral afferents, whether idiopathic or the result of trauma or tumor, is another mechanism of reflex syncope. Asystole after carotid massage is the hallmark of carotid sinus hypersensitivity. Neuralgic syncope is associated with tumors or other pathology of the

P.2703

glossopharyngeal nerve, and there are rare cases of syncope associated with trigeminal neuralgia well.[40]

A variety of seemingly prosaic activities such as coughing, micturition, defecation, and breath-holding are all subsumed under the term situational syncope. Each stimulus, as in the Valsalva maneuver, leads to syncope through neurally mediated vasodepression analogous to vasovagal syncope. Micturition syncope may in addition reflect the relief of pressure exerted by the bladder on the inferior vena cava producing a transient decrease in venous return.

Autonomic Failure

Autonomic failure, either from primary degeneration of the autonomic nervous system, as in Shy-Drager syndrome (multiple-system atrophy) or that secondary to peripheral neuropathies, is the second major category of disorders of orthostatic intolerance.

Pure autonomic failure syndrome[27] is a chronic, insidious-onset disease with syncope as one major symptom accompanied by other failures of the autonomic nervous system (anhydrosis, impotence, etc.) that, unlike multiple-system atrophy, is not accompanied by a movement disorder or cognitive deficits.[27]

Other autonomic failure syndromes are usually attributable to small-fiber peripheral neuropathies resulting from such diseases as diabetes mellitus or paraneoplastic syndromes. In the case of diabetes mellitus, autonomic neuropathies can present quite early and severely coincident with other evidence of the disease.[72]

Postural Orthostatic Tachycardia Syndrome

Postural orthostatic tachycardia syndrome (POTS) is the third major category of orthostatic intolerance and consists of excessive increases in heart rate in the upright position.[35] The

P.2704

partial dysautonomic form is believed to be due to insufficient increases in peripheral vascular resistance on standing and may be a precursor to more severe primary autonomic failure. The second form consists of an initially appropriate tachycardic response to standing that does not “turn off,” thus causing symptoms of presyncope and palpitations along with postural hypertension and tachycardia. The latter is often called beta-hypersensitivity syndrome because isoproterenol infusion causes a marked increase in heart rate. Investigation is underway to confirm a genetically mediated basis for these disorders.[73]

Primary Cardiac Dysfunction

Cardiac causes comprise disorders of pump failure caused by obstructed outflow, impaired cardiac filling, shunting, myocardial ischemia, or arrhythmias. The large but not all-inclusive list shown in Table 1 includes typical primary and secondary causes of episodic pump failure. Most of these disorders are distinguished from epilepsy by standard and invasive electrophysiologic tests or by specific aspects of the history or physical examination.[41]

The long-QT syndrome of Romano-Ward is an autosomal-dominant disorder of cardiac repolarization that results in ventricular tachycardias leading to palpitations, syncope, and sudden death. It is a channelopathy of cardiac hERG potassium or voltage-gated sodium channels[71] that is easily confused with epilepsy because patients are often young and usually have had unprovoked syncopal convulsions and the family history reveals similarly affected relatives. Other genetic long-QT syndromes, such as the Jervell-Lange-Nielsen syndrome, have different modes of inheritance and different channel abnormalities.[1] The electrocardiogram (ECG) is diagnostic, demonstrating a long, corrected QT interval. A large number of drugs and other precipitants have more recently been associated with acquired prolonged-QT syndromes.[69] These latter patients may not have prolongation of repolarization at

P.2705

baseline. One should also consider the Brugada syndrome, an autosomal-dominant disorder consisting of syncope, sudden death, ECG with ST-segment elevation, and an appearance similar to a right-bundle-branch block in the anterior leads.[80]

Especially in adolescents and young adults, one should also consider arrhythmogenic right ventricular dysplasia as a cause of syncope.[12]

Metabolic Disorders

Metabolic disorders usually cause loss or alteration of consciousness that is more indolent and longer lasting than the relatively abrupt, transient impairment with rapid, spontaneous resolution that characterizes typical syncope. As a correlate of this observation, brain-slice preparations take five times longer to reach isoelectric potentials when deprived of glucose as opposed to oxygen.[64] Thus, most metabolic disorders are more suited to a discussion of delirium or coma. For example, although hypoglycemia is frequently cited as a cause of syncope, reports of proved hypoglycemic syncope are rare.[7] Glucose tolerance tests were not positive in any of 121 patients tested in one study.[42] More common in the modern emergency room is intoxication due to alcohol or other drugs presenting as syncope.[1,21,41]

Table 2 Causes of syncope by frequency as seen in emergency rooms

	Kapoor 1990[41]	Eagle et al. 1985[21]	Day et al. 1982[14]	Total	Percent
Cardiovascular volume/tone					
Vasovagal	35	64	57	156	19.3

Total	433	176	198	807	100.0

Psychiatric Disorders

Psychiatric disorders, especially depression and panic disorder, were the cause of syncope in 24% of patients referred to a specialized syncope clinic.[50] Conversion reaction and somatization

P.2706

are other psychiatric causes of syncope.[14,21,41] In contrast to patients with physiologic syncope, psychiatric patients are said to be relatively younger, have a higher recurrence rate, and are more often disabled by attacks.[50] Vertigo, rather than lightheadedness and disequilibrium, is more frequent in younger patients with psychiatric syncope.[75]

Table 1 Causes of syncope by etiology

Disorders of orthostatic intolerance

- Reflex syncope
  - Neurocardiogenic/vasovagal
  - Carotid hypersensitivity syndrome
  - Neuralgic
  - Situational
    - Micturation
    - Deglutation
    - Tussive
    - Breath-holding
    - Postexercise/postprandial
- Autonomic failure
  - Shy-Drager/multiple-system atrophy
  - Parkinson disease
  - Pure autonomic failure
  - Peripheral and autonomic neuropathies
  - Postural orthostatic tachycardia syndrome
  - Partial dysautonomia
  - Primary beta-hypersensitivity
  - Hypovolemia
  - Drug induced

Disorders of cardiac function
- Impaired outflow
  - Idiopathic hypertrophic subaortic stenosis
  - Atrial myxoma
  - Aortic stenosis/dissection
  - Pulmonary hypertension
- Impaired filling
  - Pericardial effusion
  - Pulmonary embolus
- Shunt
  - R to L Shunt (tetrology of Fallot)
- Ischemia
- Bradyarrhythmias
  - Sick sinus
  - Second-degree heart block
  - Atrioventricular heart block

Panic disorder

Epilepsy and Other Neurologic Disorders

Epileptic Seizures That Mimic Syncope

Transient neurologic causes of syncope, especially epileptic seizures, are relatively infrequent. In a study of cost-effectiveness, tests of neurologic function in 121 occurrences of syncope were not diagnostic in any.[42] Nevertheless, the more unusual neurologic causes of syncope must be differentiated from the more common nonneurologic etiologies.

Complicating the differential diagnosis is the fact that convulsions following syncope are commonplace.[2,36,49] Syncopal convulsions are briefer than generalized tonic–clonic seizures, do not have extended rhythmic clonic jerking, recover rapidly, and lack postictal symptoms.[36] Normal orientation immediately or shortly after the event is a helpful clue to the diagnosis of syncope,[37] although recovery after atonic or frontal lobe seizures may be rapid. Conversely, if hypoxia produced by syncope is more severe or prolonged than usual, recovery may be slower than anticipated.

A variety of epileptic seizures may mimic the loss of tone and consciousness that are salient features of syncope. Some seizure types are more frequently confused with syncope than others. A subset of complex partial seizures, misleadingly termed temporal lobe syncope, can present with sudden drops or falls with or without prodromal symptoms but are followed by confusion, amnesia, and gradual recovery.[15] Scalp recordings suggest that temporal lobe syncope may have an extratemporal localization despite the name.[15] For example, six of seven epilepsy surgery patients who experienced drop attacks and who also suffered from focal motor seizures of the face and arm had seizures localized to the sensorimotor facial area.[48] On the other hand, temporal localization has been described in patients with temporal lobe epilepsy who developed drops and falls late in the course of previously manageable complex partial seizures.[28,67] The development of epileptic drop attacks is a poor prognostic sign, not only of the morbidity from fall-related injuries, but in its implication for future seizure control in the face of loss of inhibitory mechanisms that mediate rapid secondary propagation of seizure activity. Studies of volumetric magnetic resonance imaging (MRI) in patients with mesial atrophy demonstrate that extensive mesial atrophy, especially amygdalar atrophy, correlate with secondary generalization and temporal lobe syncope.[32]

Patients with the Lennox-Gastaut syndrome and other epileptic encephalopathies commonly have atonic seizures. These are frequently the source of greatest morbidity and are usually refractory to antiepileptic drug treatment. They can take the form of brief head nods or of sudden myoclonic jerks followed by atonia (myoclonic–astatic seizures).[19] EEG/video recordings of epileptic drop attacks reveal that the majority take the form of tonic "axial spasms," analogous to an adult version of infantile spasms, with rapid, moderate flexion axially followed by a tonic phase during the fall. The anatomic substrate for these events may be the lower brainstem.[23] Care must be taken in evaluating an exacerbation of epileptic drop attacks because drug intoxication or vasovagal syncope and other form of syncope can coexist.

Table 3 Emergency room risk stratification of syncope based on history, physical examination, and electrocardiogram findings

High-risk group
Chest pain compatible with acute myocardial infarction
Signs of congestive heart failure
Valvular disease

History of ventricular arrhythmias
Electrocardiogram findings of ischemia
Prolonged QTc (>500 ms)
Trifascicular block
Persistent sinus bradycardia between 40 and 60 bpm
Atrial fibrillation and nonsustained ventricular tachycardia without symptoms
Cardiac devices (pacemaker or defibrillator) with dysfunction

Intermediate-risk group
Age ≥50 yr
With previous history of:
  Coronary artery disease
  Myocardial infarction
  Congestive heart failure
  Stable cardiomyopathy
Bundle-branch block or Q wave without acute changes on electrocardiogram
Family history of unexplained sudden death
Symptoms not consistent with a vasovagal cause
Cardiac devices without evidence of dysfunction
Physician's judgment that suspicion of cardiac syncope is reasonable

Low-risk group
Age <50 yr
With no previous history of:
  Cardiovascular disease
  Symptoms consistent with reflex-mediated or vasovagal syncope
  Normal cardiovascular examination
  Normal electrocardiogram findings

Seizure-induced Asystole, Bradyarythmias, or Ventricular Tachycardias

A rare cause of syncope is a seizure-induced cardiac asystole or arrhythmia. Simultaneous EEG/ECG recordings have documented cases of asystole following photic-stimulation–induced spike-wave[60] and asystole, supraventricular tachycardia, and bradyarrhythmias following temporal lobe ictal discharges,[11,31,66,68,70] to give a few examples. Asystole

during seizures is probably more frequent with left hemispheric foci.[68]

The pathophysiology of ictal arrhythmias is not well understood but may involve cardiac efferents that are stimulated by insular, limbic, and midbrain cardiopedal pathways.[58] Autonomic instability and subsequent cardiac arrest induced by an ictal discharge has been invoked as a mechanism of sudden unexpected death in epilepsy,[46] a finding supported by animal studies that show that epileptic triggering of hypothalamic and mesencephalic cardiovascular control centers by focal application of penicillin G causes cardiovascular instability and bradyarrhythmias.[53]

Ambulatory EEG/ECG monitoring of patients with epilepsy, however, has demonstrated that cardiac dysrhythmias do not occur at an increased rate compared to the general population.[44] The frequency of ictal and interictal discharges has little relation to the generation of cardiac rhythm abnormalities.[44] The usual cardiac response to a seizure is sinus tachycardia that seems to be more dependent on the volume of brain involved in the ictal discharge than on the location of seizure onset.[25] Thus, despite well-documented "epileptic syncope," such cases appear to be more like unlucky exceptions rather than useful models for sudden epileptic death.

One epileptic syndrome in which syncope is a frequent complication is Panayiotopoulos syndrome.[61] In this idiopathic, childhood epilepsy, autonomic seizures start with emesis and may proceed to ictal syncope. Because symptoms may last >30 minutes (thus qualifying as autonomic status epilepticus),[61] the prolonged course and prominent parasympathetic involvement are helpful in differentiating it from the shorter course of typical syncope. It is not clear whether syncope in Panayiotopoulos syndrome results from bradycardia, decreases in peripheral resistance, or both.

Hypoperfusion-induced Seizures

The inverse problem to seizure-induced arrhythmias is the occasional seizure that is provoked by a cardiac arrhythmia,[39,57] presumably from the triggering of a latent seizure focus by decreased cerebral perfusion. Review of both confirmed and suspected cases of hypoperfusion-induced seizures in children shows that rare cases of prolonged bilateral clonus following syncope can be epileptic in origin rather than strictly limited to more typical, brief nonepileptic convulsions.[39] Because nonepileptic syncopal convulsions often mimic epileptic seizures,[63] simultaneous EEG/ECG recordings are the only way reliably to make these diagnoses.

Cerebrovascular Attacks

Neurologic syndromes other than epilepsy can be confused with syncope. Cerebrovascular disease and, specifically, transient ischemic attacks of vertebral-basilar origin can cause abrupt and transient loss of consciousness following interruption of blood flow to the brainstem. Concurrent symptoms helpful in diagnosis are vertigo, ataxia, and parasthesias. Although the posterior circulation is often the site for such symptomatic ischemic disease, bilateral carotid atherosclerosis has also been described.[13] As in cortical stroke syndromes, such patients have a high incidence of hypertension and heart disease.[13]

Basilar migraine is a syndrome that is most common in adolescents and young adults. Some patients have syncope before a severe occipital or vertex headache, but they usually have a variety of associated symptoms, including dizziness, visual phenomena, nausea, disequilibrium, and ataxia. The EEG occasionally shows occipital spikes or intermittent rhythmic delta activity.[17] Patients with basilar migraine can be confused with those with Panayiotopoulos syndrome[61] or other forms of benign occipital epilepsy.[29]

Cataplexy

Finally, cataplexy may occasionally be confused with syncope. As with vasovagal syncope, an emotional trigger sets off a typical attack. Unlike syncope, however, the loss of tone in cataplexy is not clearly accompanied by loss of consciousness. The other hallmarks of narcolepsy—daytime somnolence, hypnogogic hallucinations, and sleep paralysis—help to identify cataplexy as well.

Diagnostic Evaluation

History

Because of the significant morbidity and mortality of cardiac syncope, the acute, emergency room evaluation of syncope centers on the distinction between cardiac and noncardiac causes. Risk stratification and protocols have come to bear on syncope evaluation. Table 3 divides syncope into high-, intermediate-, and low-risk groups based on history, physical, and baseline ECG findings used in prospective studies of the efficacy and cost–benefit relation of syncope protocols and specialized syncope units.[74]

Eliciting the critical elements of loss of consciousness and tone of a putative syncopal spell are important during

P.2708

tertiary evaluation. Certain clinical characteristics indicate particular syndromes. In a comparison of historical features that distinguished among ventricular tachycardia, atrioventricular block, and vasovagal syncope,[8] cardiac etiologies were suggested by male gender, old age, infrequent recurrence, and short or no prodromal symptoms. On the other hand, vasovagal syncope was more likely when prodromal symptoms were complex, including palpitations. Symptoms from vasovagal syncope tended to persist longer than those from cardiac syncope.

A key to distinguishing reflex syncope from other disorders is a "trigger," that is, an event such as sudden standing, fright, or pain that can initiate an abnormal or insufficient response of the autonomic nervous system. Other triggers may be elusive, and diagnosis may hinge on uncovering subtle signs such as grunting before episodes, as occasionally happens with children who have breath-holding spells.

The timing of certain triggers, specifically exercise, in relationship to syncope is a particularly important historical feature. In a study of 474 young athletes who were surveyed on aspects of syncope, syncope was nonexertional in 87%, postexertional in 12%, and exertional in 1.3%. Two of the 6 athletes with exertional syncope had structural cardiac disease, and the remaining 4 had positive tilt-table tests. In contrast, no adverse events occurred in nonexertional or postexertional syncope despite recurrence rates of ~20 events per 1,000 person-years.[10]

One confounding factor is that patients often cannot provide important historical details and witnesses may be lacking. Retrograde amnesia for the event, especially in the elderly, may be severe enough to have the patient present with falling with no memory of loss of consciousness.[62] In one study of carotid hypersensitivity syndrome, 95% of patients who presented with falling rather than syncope could not recall loss of consciousness following symptomatic carotid massage. In comparison, 12% of patients who presented with syncope recalled loss of consciousness. Similarly, in the evaluation of 65 patients in a specialty syncope clinic, 15% denied loss of consciousness despite subsequent typical syncopal episodes induced by a tilt table. Furthermore, only 58% of patients could recall events immediately before the attack, suggesting that retrograde amnesia may be frequent,[55] although postictal confusion is either brief or absent following syncope in contrast to an epileptic seizure.[36,49]

The presence and quality of prodromal symptoms can be confounding. Falls, lightheadedness, and vertigo often overlap in the presenting symptoms.[55,75] "Dizziness," for example, is a confusing term both linguistically and diagnostically, and patients mean different things by them, as do physicians.[55,75] Up to two thirds of patients with syncope say that their main problem is "dizziness."[75] When prompted by a standard questionnaire, 68% of patients with proved syncope had presyncopal lightheadedness, 55% reported disequilibrium, and 35% had vertigo, with some patients having more than one symptom.[75] Patients who complained solely of vertigo tended to be young and have a psychiatric cause for their symptoms.[75]

Some clinicians emphasize that the predictive value of prodromal symptoms are too low to usefully distinguish cardiac from other causes. Instead, they emphasize event triggers. Of note, no prospective assessment of the predictive value of history has been performed.

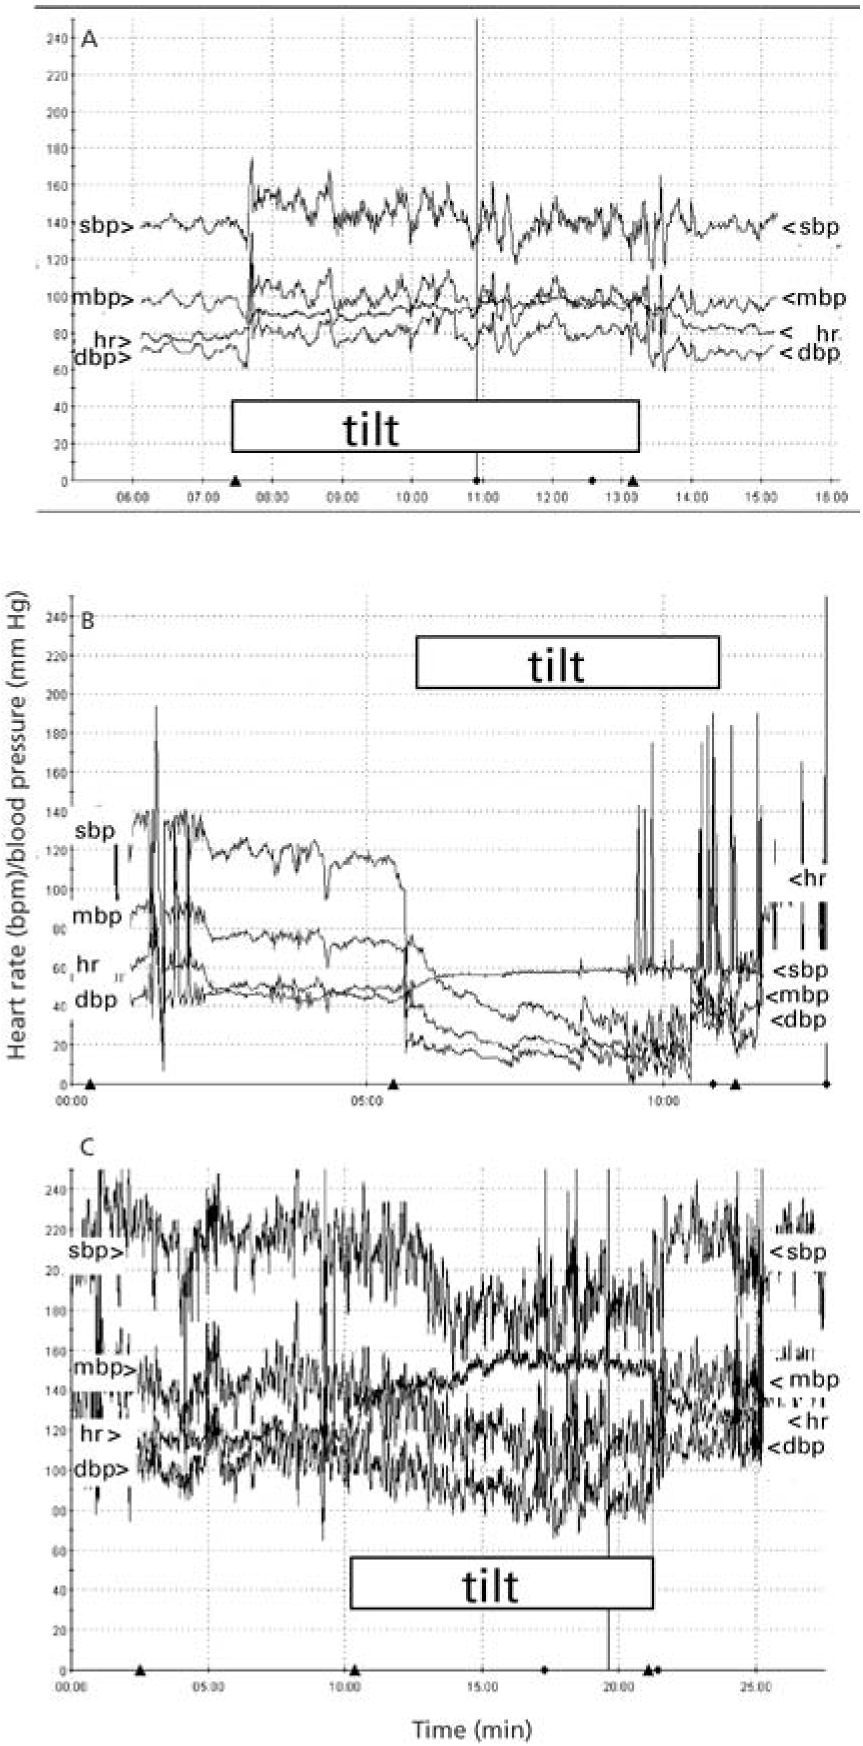

FIGURE 3. Findings in tilt-table testing. **A:** Normal tilt-table response. In response to abrupt vertical positioning of the tilt table, heart rate (hr) increases are limited to 15% to 30% of the horizontal rate because of the appropriate compensatory increase of peripheral vascular resistance, as denoted by the

~10% increase in diastolic blood pressure (dbp). **B:** A patient with Parkinsonism demonstrates central and peripheral postural hypotension marked by a severe drop in peripheral vascular resistance (with corresponding drops in systolic [sbp], mean [mbp], and diastolic blood pressures) accompanied by insufficient compensatory tachycardic response. **C:** A woman with small-cell breast cancer demonstrates positional tachycardia syndrome (POTS) marked by baseline hypertension, a relative hypotension with tilt, and an excessive tachycardic response. (Adapted from figures provided courtesy of Ted Burns, M.D., Neuromuscular/Autonomic Testing Division, Department of Neurology, University of Virginia.)

Physical Examination

Findings on physical examination help to diagnose some cases of syncope. Orthostatic hypotension is defined as a 20-mm Hg drop in systolic pressure or sinus bradycardia when standing.[55] Carotid massage followed by 3 or more seconds of asystole or a 50-mm Hg drop in blood pressure suggests carotid hypersensitivity.[55] Although one should be cautious in the patient with carotid bruits or at a high risk for carotid atherosclerosis, carotid massage is generally a safe procedure under supervised circumstances with appropriate monitoring. Bárány or Hallpike maneuvers can help to identify patients with vestibular dysfunction and vertigo. Nystagmus may suggest drugs or indicate central or peripheral vesicular dysfunction, depending on the direction, latency, and reproducibility.

The ECG is the significant helpful screening electrophysiologic test for cardiac causes of syncope.[41] Although one half of 433 patients with syncope had ECG abnormalities, these were diagnostic in only a small number of cases. In patients with arrhythmias, the routine ECG was diagnostic in 30% of cases.

Prolonged ECG monitoring using a Holter monitor, event recorder, or loop recorder is another common diagnostic test. Although <5% of patients have symptomatic arrhythmias during extended ECG, Kapoor[41] reported a diagnostic yield of 22% when screening for arrhythmias.

Implantable loop recorders have recently become available and marketed to neurologists. These devices have a battery life of approximately 14 months and record and store a

single-lead ECG when activated by a patient event button at the time of symptoms. Some clinicians recommend early use of implantable loop recorders when cardiac syncope is suspected and when events are rare rather than withholding it until other modes of testing have been exhausted. In early use, implantable recorders yield positive diagnoses in >50% of cases after a 1-year recording duration and in >80% after 2 years.[54]

Invasive electrophysiologic testing has been advocated in the subset of syncopal patients with heart disease[41] because these patients are most likely to have a positive test and the worst

prognosis if untreated. With any of the electrophysiologic tests, the diagnostic value of an arrhythmia that does not reproduce symptoms is debatable.

Echocardiography, although frequently used in the diagnostic evaluation of patients with syncope, is best reserved for patients found to have cardiac abnormalities on physical examination or in the course of other studies.[65]

Head-up tilt-table testing, with or without augmentation using isoproterenol, has gained favor because of its usefulness in diagnosing vasovagal syncope.[36] Tilt-table testing (Fig. 3), performed in combination with testing of vagal function, allows localization of orthostatic insufficiency into sympathetic or parasympathetic systems. Although controversies sur- round its specificity and sensitivity, tilt-table testing is safe in experienced hands. Guidelines for its application have been published.[4]

In most cases, routine EEG has a low diagnostic yield, especially in initial screening.[41] In those patients in whom a seizure is suspected, however, the EEG is of course a useful tool. In one study, the EEG provided useful information in only 12% of patients with suspected nonneurologic causes. On the other hand, the EEG yielded diagnostically helpful findings in 41% of patients suspected of having neurologic disease.[14] A comparison of patients with either epilepsy or syncope demonstrated that findings of focal epileptiform discharges, generalized epileptiform discharges, or focal slowing offered a sensitivity of 40% and a specificity of 95% in distinguishing between these two groups.[38]

The utility of routine brain imaging is also limited. Most studies evaluating the emergent diagnosis of syncope[14,21,41] have found that head computed tomography, when not guided by clinical data, had a poor diagnostic yield. Information is not available, however, regarding MRI, MR angiography, and functional MR.

If the clinical event occurred within 1 hour, elevated serum prolactin levels have been proposed to aid in the distinction between seizure and syncope,[18,82] but the most recent studies give conflicting results, suggesting that this assay may not reliably aid in differential diagnosis.[59]

Finally, as mentioned earlier, intensive telemetry with simultaneous EEG/ECG recording may establish a definitive diagnosis if the events are frequent and confounding enough to merit the costs incurred in such a study. Of note, most cases in which unusual cardioarrhythmic seizures have been documented were captured fortuitously, not through purposeful prolonged monitoring. With the development of implantable electrocortigraphy devices, perhaps long-term monitoring analogous to that of implantable ECG loop recorders will fill this clinical need.

Treatment

Treatment of syncope is as varied as the range of possible etiologies. A few statements regarding the treatment of autonomic insufficiency, such as found in the Shy-Drager syndrome, severe polyneuropathy, or idiopathic orthostatic hypotension, deserve mention. Measures to expand volume, such as increased fluid intake and salt ingestion, are often sufficient to ameliorate mild cases. The addition of compression stockings or, with more severe cases, of leg-to-waist customized support garments may be necessary. Fludrocortisone, a mineralocorticoid, will aid in volume expansion provided that due caution is allowed for possible congestive heart failure or recumbent hypertension. Biofeedback training may occasionally be a useful adjunct to more traditional measures.[6]

The development of the tilt-table test has led to a variety of pharmacologic treatments for refractory vasovagal syncope.[77] Beta-blockade is usually tried first, although the use of a beta-blocker for syncope seems at first counterintuitive. Nonetheless, the strategy works in a majority of patients with tilt-table–positive vasovagal syncope,[77] although the mechanism of efficacy is not clearly understood. Beta-blockade may attenuate the hyperactive response of cardiac mechanoreceptors thought to be in part responsible for vasovagal syncope.[36,77] Disopyramide has combined inotropic, anticholinergic, and vasoconstrictive effects and is occasionally used.[77] Anticholinergic drugs such as scopolamine are sometimes efficacious but are poorly tolerated by the elderly as a rule. A double-blind clinical trial failed to show efficacy of transdermal scopolamine.[47] Cardiac pacing is sometimes performed for severe and refractory cases but is often ineffective.[77] Methylphenidate is occasionally worth trying.[33]

When syncope is unpredictable, the patient and other people may be placed at risk by common activities such as driving. A position statement on this issue is available.[24]

Summary and Conclusions

In conclusion, syncope consists of loss of consciousness and muscle tone that is abrupt in onset, of short duration, and followed by rapid recovery. Syncope occurs in response to transient impairment of cerebral perfusion. Typical prodromal symptoms often herald onset of syncope, and postictal symptoms are minimal. Syncopal convulsions, resulting from cerebral anoxia, are common but are not a form of epilepsy, nor are there any accompanying EEG ictal discharges. Diagnosis is based on the history, physical, examination, and ECG findings. A major emphasis should be on distinguishing cardiac from noncardiac causes of syncope because of excess mortality of the former. Despite intensive study, one third of all syncope cases remain undiagnosed.

Chapter 272

Metabolic and Endocrine Disorders Resembling Seizures

Peter W. Kaplan

Shehzad Basaria

Introduction

Patients frequently consult a physician because of alarming "spells." These may consist of symptoms such as sudden malaise, a feeling of faintness, flushing, a perceptibly irregular or rapid heart beat, dizziness, sweating, confusion, as well as myriad other alarming complaints. The physician's task is to differentiate psychological from organic complaints and potentially dangerous from benign symptoms and to localize the symptoms to a particular system of the body—cerebrovascular, neurologic, endocrine, or other. When patients are seen with lip smacking, loss of consciousness, prolonged jerking movements, and tongue biting, the diagnosis of a tonic–clonic seizure is straightforward. More difficult diagnostic problems occur when the complaints are subjective, as with symptoms of autonomic or sensory origin, because objective confirmation of disease may be lacking, and the subjective perceptions (e.g., feelings of dissociation, anxiety, or panic) are often difficult to put into words.

Among the many entities considered in the differential diagnosis of "spells" are those associated with metabolic and endocrine disturbances, some of which have proved to be among the "great imitators" of other diseases, including hysteria. Endocrine or metabolic disturbances may in themselves cause seizures, or they may exacerbate epilepsies by lowering seizure thresholds. The primary emphasis of this chapter is on metabolic and endocrine disturbances that result in symptoms that may be mistaken for seizures.

General Comments Regarding Patient History

Spells associated with many endocrine disturbances are characteristically accompanied by other features of the endocrine disease. For example, patients with spells caused by thyrotoxicosis usually have tremulousness, weight loss, and sweating in addition to palpitations and anxiety attacks. In other endocrine or metabolic disturbances, however, few clinical signs may be present. In such cases, attention must be paid to the particular precipitating factors, pattern, course, duration, and resolution of the spell in the context of the patient's medical history. For example, in a patient who has undergone gastric surgery, the malaise, sweating, and light-headedness occurring at fixed intervals after meals should alert the physician to the possibility of reactive hypoglycemia with "dumping syndrome." Similarly, patients with diabetes who are taking oral hypoglycemic agents or insulin may have the same symptomatology resulting from episodic hypoglycemia. Typical settings would be a lower-than-usual caloric intake, or unanticipated exercise without appropriate changes in insulin. In these cases, symptomatic hypoglycemia may supervene over the ensuing hours. Conversely, hyperglycemia may appear with intercurrent illness and decreased insulin dosage.

Particular inquiry into dietary habits, medications, and prior medical problems or surgery, therefore, is essential in making the appropriate diagnosis.

With some diseases, the constellation of signs and symptoms may provide the physician with a diagnosis through "pattern recognition." For example, intermittent severe abdominal pain and episodes of limb paralysis, delirium, and "port wine"–colored urine are typical features of an acute intermittent porphyric crisis. A history of previous similar attacks, possibly triggered by drugs, should be sought. In a similar vein, the simultaneous occurrence of paroxysmal headache, facial flushing, and hypertension will evoke the diagnosis of pheochromocytoma.

Specific Metabolic and Endocrine Disorders

Hypoglycemia

Because the central nervous system requires a constant supply of glucose, hypoglycemia may produce transient neurologic dysfunction[51] that can be mistaken for or even precipitate seizures. When delivery of glucose to the central nervous system is insufficient, a number of signs and symptoms may appear (Table 1). The particular array of clinical features may vary with the rapidity of development of hypoglycemia and the depth of hypoglycemia, as may the degree of impairment and level of consciousness. The symptoms of hypoglycemia are generally divided into adrenergic symptoms and neuroglycopenic symptoms. The former include anxiety, nervousness, palpitations, diaphoresis, and tremors. Neuroglycopenic symptoms include lethargy, disorientation, confusion, blurry vision, stupor, and in severe cases seizures and coma. In rare cases, focal weakness may also be seen.

Table 1 Symptoms of hypoglycemia in insulin-dependent diabetes mellitus

Sweating	Tremor
Blurred/double vision	Weakness
Confusion	Vertigo
Odd behavior	Anxiety
Perioral paresthesias	Hunger
Sensation of cold	Ataxia
Slurred speech	Palpitations

The symptoms of falling levels of blood glucose usually occur episodically, and the diagnosis rests on demonstrating subnormal levels of blood sugar in the symptomatic patient. Some patients may lose the warning symptoms[17] and adapt to the sensations that accompany hypoglycemia. This is known as "hypoglycemia unawareness." Patients particularly at risk are the elderly,[70] those taking adrenergic blocking agents,[47] and patients who have a history of frequent hypoglycemic attacks. The variability in the threshold at which particular patients experience symptoms is marked. Normal individuals when fasting may have a blood glucose concentration that falls below 45 mg/dL and remain asymptomatic; in contrast, some patients who have insulin-dependent diabetes mellitus and certain elderly patients become symptomatic when blood glucose

levels descend toward 45 mg/dL.[50,51] Diagnosis of symptomatic hypoglycemia, therefore, lies in determining a low plasma glucose level in the symptomatic patient, with relief effected when blood glucose concentrations are normalized (Whipple's triad).[73] It is important to appreciate that some poorly controlled diabetics (who have marked hyperglycemia) experience hypoglycemic symptoms (mostly adrenergic symptoms) even when their glucose levels are lowered toward normal. It is interesting that with better glycemic control, these symptoms resolve.

Causes of Hypoglycemia

The differential diagnosis of hypoglycemia includes the array of causes leading to the condition (Table 2). Because plasma glucose concentrations are affected by a number of agents, imbalance in these dynamic forces may cause hypoglycemia. In humans, there is a dynamic and often delicate balance between factors that increase blood glucose levels, such as epinephrine, cortisol, growth hormone, and glucagon, and factors that decrease glucose levels, including oral hypoglycemic agents, exogenous or endogenous insulin, and concurrent he- patic or renal disease. An excess of glucose-lowering agents or insufficiency of gluconeogenic mechanisms may result in symptomatic hypoglycemia. Common causes are oral hypoglycemic agents, excess exogenous or endogenous insulin, he- patic or renal disease, heavy alcohol use, a decrease in food intake, or unanticipated exercise in an insulin-dependent diabetic patient.[45] A number of drugs when taken concurrently may enhance or prolong the hypoglycemic effect of oral hypoglycemic agents or inhibit compensatory mechanisms of hepatic glucose release.[2] These include anticoagulants, beta-blockers, clofibrate, isoniazid, phenylbutazone, salicylates, and sulfonamides. Other drugs may precipitate hypoglycemia, including colchicine, disopyramide, haloperidol, paracetamol, pentamidine, perhexiline, and quinine. Insulin-treated patients may have hypoglycemic attacks as a result of missed meals, excess insulin dose, and exercise not compensated for by an increase in food intake or adjustment in insulin dose.

Of the oral hypoglycemic agents, the sulfonylureas are the most notorious in causing hypoglycemia. The elderly and the patients with renal disease are particularly sensitive to sulfonylurea-induced hypoglycemia (due to decreased clearance of the drug). They are also the most common cause of factitious hypoglycemia. This surreptitious use is most commonly seen in medical personnel and persons with family members on these agents.[15]

Excessive long-term alcohol intake, resulting in chronic disease of the liver, also predisposes to hypoglycemia because glycogen stores are depleted.[42] Similarly, patients who have not eaten for several days and who have a binge of moderate to heavy drinking may also experience transient or even prolonged hypoglycemia up to 1 day after the end of the binge.

Hypoglycemia may occur in patients after gastric surgery, later than the symptoms of “dumping syndrome.” Overactivity of the “enteroinsular axis” is thought to result in excessive release of glucose-dependent insulinotropic peptide (GIP) and other hormones, which in turn increase insulin secretion after ingestion of glucose.[66]

Other rare causes of hypoglycemia include endogenous hyperinsulinism caused by insulin-secreting tumors (insulinomas) of the pancreas.[34] Of such tumors, 10% are malignant, 10% are of questionable malignancy, and the rest are benign.[53] Patients with multiple endocrine neoplasia type I may have multiple tumors that secrete a variety of hormones, including pancreatic polypeptide, glucagon, gastrin, and somatostatin. Symptoms typically include blurred vision, double vision, sweating, palpitations, weakness, confusion, behavioral changes, obtundation, and tonic–clonic seizures. Patients with adrenal insufficiency and growth hormone deficiency may also present with hypoglycemia. Finally, tumor (nonislet)-induced hypoglycemia is seen in rare retroperitoneal mesenchymal tumors that elaborate insulin-like growth factor II (IGF-II). Surgical resection is the treatment of choice in these patients.

Diagnostic Investigation

When the diagnosis of symptomatic hypoglycemia has been made, determination of the particular cause depends largely on the medical and surgical history, evaluation of medications that are known to impair glucose regulation, and a physical examination.

In insulin-treated patients, the query is directed at the dose, timing, method, and location of subcutaneous administration (e.g., thigh, which has greater absorption, especially if the patient exercises). A frequent cause of inappropriate dosing is self-administration of insulin by patients with impaired vision. Syringes with larger writing are now available. Attention should

P.2715

also be directed at patients taking oral hypoglycemic agents or other newly introduced drugs that may interfere with glucose regulation. Surreptitious injection of insulin may be deduced by a high plasma insulin level with a low plasma C-peptide concentration. This contrasts with excessive endogenous insulin production, in which a high plasma insulin level is accompanied by an appropriately high C-peptide level. Both sulfo- nylureas and insulinomas result in elevated levels of plasma insulin and C-peptide levels. Hence, measurement of serum levels of sulfonylureas is an important part of the workup of hypoglycemia. If insulinoma is suspected, endoscopic ultrasound, magnetic resonance imaging of the abdomen, and arteriography are the main imaging modalities. Octreotide scan is not very sensitive. Percutaneous transhepatic portal venous sampling may be needed in some cases.

Treatment

Treatment of episodic hypoglycemia is based on treatment of the underlying cause. In patients treated with insulin and hypoglycemic agents, careful attention to modification of the regimen may prevent hypoglycemic dips. The aid of a specialist in diabetes should be sought. After gastric surgery, “dumping syndrome” may be avoided by more frequent and smaller meals containing complex carbohydrates. Insulin-secreting tumors are usually resected; if they are inoperable, octreotide, a long-acting somatostatin analog, may be used. If hypoglycemia is a manifestation of adrenal insufficiency, physiologic glucocorticoid replacement results in the resolution of hypoglycemia.

Association with Epileptic Seizures

Hypoglycemia itself may be the cause of seizures. In infants, these usually occur on the second postnatal day in newborns who are small for gestational age. Occasionally, hypoglycemia may be seen in infants of diabetic mothers and in cases of syndromes associated with defects of gluconeogenesis, defects of organic or amino acid metabolism, and mitochondrial dysfunction. Hypoglycemia may trigger tonic–clonic seizures and cause paroxysmal electroencephalographic (EEG) activity that can be confused with seizure activity.

Hyperglycemia

Hyperglycemia is a state that develops gradually, typically during a period of days to weeks. Because changes are gradual and usually progressive, these events are not often mistaken for an epileptic disturbance. Hyperglycemia in the absence of ketosis, however, may be associated with a number of abnormal movements, including asterixis, paroxysmal choreoathetosis, hemiplegia, and partial epileptic seizures.[38,56] Such partial seizures are typically motor, often exhibit a jacksonian march, and may be reflex seizures or effort induced. The seizures are resistant to antiepileptic drugs, but they usually regress on treatment of the hyperglycemia within a few hours to a few days.[7] Occasionally, partial seizures may continue for long periods in the state of epilepsia partialis continua.[22,56] Ketotic hyperglycemia is much less frequently associated with seizures, possibly because of the antiepileptic effect of ketosis.

Hypocalcemia

The predominant clinical features of hypocalcemia are the consequence of a decrease in ionized serum calcium, which in turn leads to an increase in neuromuscular excitability. This may be accompanied by numbness and tingling in the fingers, paresthesias, stiffness, muscle cramps, carpopedal spasm, and perioral numbness. Associated clinical features include papilledema, cataracts, developmental defects, and mental retardation in the congenital forms of the disease and calcification of the basal ganglia with dyskinesias. The electrocardiogram may show prolonged QT_c intervals and T-wave changes.

Several conditions may be accompanied by hypocalcemia, each with its own constellation of clinical features. Well-described causes include thyroid and parathyroid surgery, chronic renal failure, renal tubular acidosis, malabsorption, hypomagnesemia, blood transfusion, acute pancreatitis, osteomalacia or rickets, vitamin D deficiency, intake of chelating agents, and pseudohypoparathyroidism.

Bedside diagnostic features include the Chvostek sign (twitching of the lips or nasal alae, or even of the entire half of the face, produced by tapping the branches of the facial nerve as it passes through the parotid gland above the angle of the jaw). The diagnostic indicator is a low level of ionized serum calcium. The underlying cause of hypocalcemia should be sought.

Tetany is characterized by flexor spasms in the arms and extensor spasms in the legs; it may resemble tonic–clonic seizures and can be induced by hyperventilation. Both tetany and partial or tonic–clonic seizures may supervene.[18] Tonic–clonic seizures can be treated by administering a slow intravenous infusion of 15 mL of 10% calcium gluconate under cardiac monitoring.

Hypercalcemia

The most common cause of hypercalcemia is primary hyperparathyroidism. In this condition, hypercalcemia is generally mild and typically develops over a period of months to years; in most cases, patients are asymptomatic. In contrast, malignancy-induced hypercalcemia usually develops rapidly and can be severe and is accompanied variably by anorexia, nausea, vomiting, weight loss, and constipation. Neurologic symptoms are general fatigue, muscular weakness, and proximal myopathy, with mental status changes that include personality changes, depression, stupor, coma, and tonic–clonic seizures. The major causes of hypercalcemia are primary or tertiary hyperparathyroidism, humoral hypercalcemia of malignancy, multiple myeloma, paraneoplastic disorders, bone metastases, thyrotoxicosis, milk-alkali syndrome, vitamin D intoxication, immobilization, and rarely Paget disease of bone. Adrenal insufficiency and acromegaly are other rare endocrine causes of hypercalcemia.

Occasionally, a more acute hypercalcemia is characterized by paroxysmal headache, nausea, vomiting, abdominal pain, and constipation. Muscle weakness, lethargy, and coma may supervene. There may be visual impairment, tonic–clonic seizures, and spike-and-wave discharges over the occipital regions.[26]

The diagnosis of hypercalcemia is based on the finding of a raised level of ionized calcium. The next step is to measure serum levels of intact parathyroid hormone (iPTH). This test is fundamental to differentiating between parathyroid and nonparathyroid causes of hypercalcemia. An electrocardiogram may show a shortened QT_c duration.

The underlying cause should be sought and treated. Acute management of hypercalcemia includes hydration with saline, subcutaneous calcitonin, and intravenous bisphosphonates.

Excess of Growth Hormone

Paroxysmal attacks of sweating that occur with excess levels of growth hormone may be mistaken for autonomic seizures.[25] Sweating occurs due to increased concentration of sweat glands as a result of growth hormone excess. In contrast to autonomic

P.2716

seizures, paroxysms are not associated with other ictal manifestations.

Hyperthyroidism

The acute malaise, anxiety, sweating, tremulousness, and tachycardia of hyperthyroidism may mimic partial seizures,[52] as may choreiform movements and encephalopathy.[1,24] Features of the illness that suggest thyrotoxicosis include heat intolerance, weight loss despite a healthy appetite, hyperdefecation, goiter, exophthalmos, palpitations, atrial fibrillation, and muscle wasting and weakness. Proximal myopathy is the classical presentation of Graves disease. Patients with severe thyrotoxicosis (thyroid storm) may present with fever, stupor or coma, pyramidal and bulbar dysfunction, and convulsions.[31,41] It is important to appreciate that many elderly patients may not have any of the typical clinical features of hyperthyroidism (apathetic hyperthyroidism). Cardiac arrhythmias, like atrial fibrillation, may be the initial presentation in these subjects.

The most common causes of hyperthyroidism include Graves disease, solitary toxic adenoma, and toxic multinodular goiter (Plummer disease) Other etiologies of thyrotoxicosis include iodine-induced thyrotoxicosis, various thyroiditides, factitious thyrotoxicosis, and central hyperthyroidism (TSHomas). Large metastases of follicular thyroid cancer are a rare cause of thyrotoxicosis. The diagnosis is based on finding an undetectable or suppressed thyroid-stimulating hormone (TSH and increased T_3 or free T_4 levels. Imaging with radioactive iodine is the gold standard in determining the etiology of thyrotoxicosis.

Occasionally, choreiform movements and encephalopathies occur. Clinical seizures may rarely supervene, and partial motor, adversive, and tonic–clonic seizures are reported. A rare manifestation of hyperthyroidism is hypokalemic periodic paralysis, which may be confused with a seizure. This entity is predominantly seen in individuals of Asian decent, and Graves disease is the most common underlying etiology. The attacks may last for minutes to hours. Ingestion of a carbohydrate meal is a well-known trigger (the release of insulin being responsible for shifts in potassium).

Hypothyroidism

Hashimoto thyroiditis is the most common cause of primary hypothyroidism. Other causes include history of thyroid surgery, neck radiation, lithium therapy, and central hypothyroidism. General symptoms include dry skin, constipation, cold intolerance, sallow skin discoloration, ovulatory dysfunction, and minimal weight gain. Hypothyroidism may be accompanied by neurologic complaints, including neuropathy, myopathy, choreoathetosis, dementia, or even coma.[10,37,57] Sudden falls from arrhythmias secondary to hypothyroidism rarely occur.[40] There may be nocturnal jerking movements from obstructive sleep apnea and, more rarely, central sleep apnea. Comatose, hypothyroid patients may have tonic–clonic seizures. In severe hypothyroidism, patients may develop psychosis with hallucinations (myxedema madness). Myxedema coma remains the dreaded complication of severe hypothyroidism. It usually occurs in the elderly and has a high mortality rate. Intravenous thyroxine therapy is indicated in these cases.

Diagnosis rests on finding elevated TSH and low T_3 or free T_4 levels in cases of primary hypothyroidism. In secondary hypothyroidism due to pituitary dysfunction, TSH levels are low or inappropriately normal. Imaging of the pituitary with magnetic resonance imaging (MRI) is mandatory in such cases to rule out mass lesions. Treatment involves replacement of thyroid hormone.

Hashimoto Encephalopathy

Very few entities in neurology and endocrinology have puzzled and at the same time fascinated clinicians (more neurologists than endocrinologists). Hashimoto encephalopathy is one such entity. The story began in 1966 when Lord Brain, a famous English neurologist, described a case of a man with confusion, disorientation, and seizures.[6] The patient also had transient episodes of fluctuating hemiparesis of different extremities and aphasia, which completely resolved. Investigations revealed abnormalities in EEG, and cerebrospinal fluid (CSF) showed elevated levels of protein. Brain antibodies were not detected in the serum. This patient had known Hashimoto thyroiditis with positive antithyroid antibodies and was on optimal thyroxine therapy during these episodes. According to Lord Brain, “the apparent onset of Hashimoto's disease—was followed by an extraordinary and puzzling neurological illness which waxed and waned for over a year.” He concluded, “antibody studies in future cases of unexplained encephalopathy should show whether we have described a syndrome or a coincidence.”

Hashimoto encephalopathy remains a diagnosis of exclusion, which is usually entertained by a neurologist when a case of acute or subacute encephalopathy is seen in a patient with no evidence of other etiologies (infectious and metabolic causes excluded), positive antithyroid antibodies, and good clinical response to steroids. It is important, however, to appreciate that positive antithyroid antibodies are present in 10% of the U.S. population.[23] Hence, it is debatable whether Hashimoto encephalopathy is a distinct clinical entity or a coincidence of a rare encephalopathy that occurs in an individual with a common endocrinologic condition and a not uncommon circulating antibody. Furthermore, there is no evidence that antithyroid antibodies are directly responsible for the encephalopathy. As a result, some have suggested that this entity should be called “steroid-responsive encephalopathy associated with Hashimoto thyroiditis.”

Three fourths of the cases of Hashimoto encephalopathy occur in women. Although many cases have mild hypothyroidism, many patients with encephalopathy are adequately treated with thyroxine. Furthermore, there is no correlation between the degree of hypothyroidism and the severity of encephalopathy. Clinical manifestations include headaches, fatigue, memory loss, confusion, and transient aphasia. Movement disorders like tremors, myoclonus, ataxia, and chorei- form movements may be seen. Some patients experience auditory hallucinations. It is important that, as described by Lord Brain, many patients have signs and symptoms suggestive of stroke. The majority of these symptoms are episodic, with most of them resolving either spontaneously or with glucocorticoid therapy. Approximately 80% of the patients have elevated levels of protein in the CSF; however, pleocytosis is only seen rarely.[9] Abnormalities in the EEG are present almost universally and include diffuse slowing of the waves or epileptiform abnormality. The findings on MRI are nonspecific and include white matter changes. In some cases, cerebral angiography shows perfusion abnormalities of the cortex and basal ganglia.[16] The majority of the cases respond to steroids, an important aspect of this condition.

Carcinoid Tumors

The carcinoid syndrome is characterized by paroxysmal flushing, gastrointestinal hypermobility, bronchoconstriction, and

P.2717

right-sided cardiac valvular disease.[63] The paroxysmal flushing typically involves the face, neck, and upper trunk, producing a transient erythema and sensation of warmth, occasionally with palpitations. With more severe paroxysms, dizziness and rarely syncope can occur.[12] Other associated symptoms of gastrointestinal origin include diarrhea and abdominal cramps. This syndrome is produced by the release of serotonin from carcinoid tumors located in structures of the embryonic foregut (bronchus, pancreas, and stomach), midgut (duodenum and transverse colon), or hindgut (descending colon and rectum).[74] Rarely, carcinoid tumors only produce histamine, in which case, pruritis is the most common manifestation.

Carcinoid attacks may be induced by exertion, eating, emotional upset, and alcohol. The diagnosis is made by the finding of elevated levels of 5-hydroxyindoleacetic acid (5-HIAA), a serotonin metabolite, in the urine.[43] Recently, assays have been developed that measure serotonin levels in blood. Differentiation from simple partial seizures or auras in patients who experience flushing or heat sensation is made by the absence of subsequent confusion, automatisms, and convulsions that typify the progression of simple partial seizures to complex partial seizures; further distinguishing characteristics are the absence of bronchoconstriction, cardiac disease, diarrhea, and abdominal cramps. Nonetheless, ill-defined flushing or sensations of heat with upper gastrointestinal discomfort are seen with epileptic auras, and diagnostic confusion may occur.

Spiral computerized tomography (CT) of the chest and abdomen and an octreotide scan are the imaging modalities available. Treatment involves excision of the carcinoid tumors, when possible. Medical treatment, which is disappointing, involves blockade of the effects of secreted 5-hydroxyindoles with serotonin antagonists such as methysergide, α-methyldopa reduction of 5-hydroxytryptophan, or chemotherapy.

Pheochromocytomas

Pheochromocytomas are tumors that produce catecholamines, including norepinephrine, epinephrine, l-dopa, and dopamine. Ninety percent of these tumors arise in the adrenal medulla; the remaining 10% arise from extramedullary chromaffin tissue and are known as paragangliomas. In 10% of the cases the tumors occur bilaterally and may be malignant. Some are inherited as part of a multiglandular neoplastic syndrome (multiple endocrine neoplasia type II [MEN II]), von Hippel-Lindau disease, and von Recklinghausen disease.

Clinical presentation is typified by sudden headache, blurring of vision, hypertension, pallor, sweating, and malaise (Table 3).[59]

Poorly definable symptoms of sudden onset are suggestive of autonomic partial seizures or anxiety or panic attacks. The absence of confusional states, automatisms, and tonic–clonic seizures differentiates the spells from complex partial seizures and secondarily generalized tonic–clonic seizures. The clinical manifestations of pheochromocytoma, caused by tumor secretion of catecholamine,[32,54] which in turn stimulates adrenergic receptors, depend on the catecholamine or vasoactive neuropeptide produced: vasoactive intestinal peptide (VIP), calcitonin gene–related peptide (CGRP) and endothelin, neuropeptide Y, angiotensin II, and rarely corticotropin-releasing factor (CRF) and corticotropin (ACTH). Headaches occur in 80% of patients and are often accompanied by a sense of apprehension, tightness in the chest and abdomen, palpitations, and sweating.[62] Less frequently, nausea, vomiting, and generalized paresthesias occur. During the paroxysms, pallor or flushing and a sensation of warmth may occur with changes in heart rate. In rare cases in which the tumor preferentially secretes epinephrine or dopamine, the patients are normotensive and may even experience episodes of hypotension.

Table 3 Symptom complex in pheochromocytoma

Headache	Sweating
Palpitations	Pallor
Tremor/trembling	Feeling of exhaustion
Anxiety	Epigastric and chest discomfort

Dyspnea	Flushing/warm feeling
Paresthesias	Tightness of throat
Convulsions	Nonspecific dizziness
Syncope	Faintness

Source: From Bouloux P, Kaplan PW. *Imitators of Epilepsy.* New York: Demos; 1994:205, with permission.

With their sudden brief onset (typically 15–20 minutes), often associated with a sensation of impending doom, these spells may resemble complex partial seizures, but the absence of true confusional states and the more frequent occurrence of sudden headache, hypertension, visual dysfunction, and vomiting differentiate the symptoms of pheochromocytoma from those of complex partial seizures.

The diagnosis of pheochromocytoma is based on the demonstration of inappropriate catecholamine secretion in blood and urine or abnormal secretion of urinary metabolites. Computed tomography or magnetic resonance imaging may localize tumors, as may the chromaffin-seeking radioactive nuclide ^{131}I-metaiodobenzyl guanidine.[55]

Paroxysms may occur spontaneously or with movement that induces release of vasoactive peptides/catecholamine from the tumors. Movements that displace abdominal contents including straining, lifting, and bending forward, and any strenuous exercise may precipitate spells.

Treatment is by surgical excision of the tumors after complete pharmacologic alpha- and beta-blockade.

Menopausal Vasomotor Flushes

Menopause is frequently accompanied by agitation, anxiety, depression, and hot flushes, associated with increases in levels of gonadotropins.[8] Flushes are not accompanied by impaired consciousness or other features of complex partial seizures. Autonomic seizures, for which they may be mistaken, are usually accompanied by sweating, dilated pupils, salivation, and changes in heart rate, respiration rate, and blood pressure, and they rarely occur without other seizure manifestations. Symptoms may be alleviated by estrogen replacement therapy.

Porphyrias

Porphyrias are disorders of porphyrin metabolism and heme biosynthesis caused by inherited enzyme defects.[5,35] The absence of particular enzymes in heme synthesis leads to the accumulation of psychoactive and neurotoxic metabolites that produce a wide spectrum of acute, subacute, and chronic neurologic changes. The manifestations of subacute changes may resemble seizures.

P.2718

Table 4 Clinical features of acute intermittent porphyria: comparison of percentage incidence before puberty, in adolescence, and in adulthood

	Adult cases				Pediatric cases	
	Waldenström[68] (321 cases)	Markovitz[33] (69 cases)	Goldberg[19] (50 cases)	Stein and Tschudy[58] (46 cases)	0–14 yr (37 cases)	15–19 yr (35 cases)

Acute Intermittent Porphyria

Acute intermittent porphyria (AIP), the porphyric syndrome most frequently confused with seizures, is most commonly seen in Sweden.[68,69] Inherited as a mendelian dominant trait, the syndrome can occur with a number of mutations that result in defectiveness of the enzyme porphobilinogen deaminase (PBGD). Although it was originally described in young adults after the onset of puberty, it has been increasingly recognized in children. Among adults, it affects women twice as often as men, whereas in children, it affects both sexes equally.[27] The incidence of clinical features and seizures in pediatric and adult patients undergoing medical treatment is given in Table 4.

Acute attacks may be heralded for years by "nervousness" and tiredness. Attacks may last for days to weeks and are characterized by symptoms that can be referred to psychic, autonomic, and peripheral nerve dysfunction.[68] Dominating the clinical picture are abdominal pain, constipation, and tachycardia. Other clinical features are optic atrophy, ocular palsies, hoarseness, general malaise, lethargy, and coma. During the attack, there may be an agitated delirium with hallucinations and psychosis. Isolated neuropathies, with wrist or foot drop progressing to a flaccid limb paralysis, may supervene and take months to regress.

In the early stages of the crisis, the psychosis and encephalopathy may dominate in the absence of the other typical features of porphyria, although the classic "port wine"-colored urine may appear.[35,65,71]

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT), caused by a deficiency of uroporphyrinogen decarboxylase in the liver, is characterized by the presence of urocarboxylic and heptacarboxylic porphyrins in the urine and isocoproporphyrin in the feces. It usually does not occur with acute neuropsychiatric symptoms, but it may be associated with hallucinations and dysphoria and, occasionally, seizures.[29,30] Seizures may be precipitated in patients with epilepsy from other causes who are being treated with porphyrinogenic antiepileptic drugs. It is differentiated clinically from AIP by the presence of skin lesions. Exposed areas of the skin, face, and hands are photosensitive, resulting in ulcerative vesicular eruptions. Coexisting liver disease and diabetes further complicate the diagnosis, which is based on a urinary porphyrin screen. Valproate and gabapentin have been safely used to treat seizures in PCT,[11,29] but valproate has precipitated attacks in AIP.

Variegate Porphyria

Variegate porphyria is the term used by Dean and Barnes[13] to denote the condition of patients from South Africa, who have a mixed clinical picture of photosensitivity, as in PCT, and neurologic episodes, as in AIP. Variegate porphyria is associated with urinary porphobilinogen and D-aminolevulinic acid (D-ALA) and fecal protoporphyrin and coproporphyrin. Episodes can result in sudden hallucinosis, psychosis, and catatonic states, as well as seizures.[13,44] It may be precipitated by oral contraceptives.

Hereditary Coproporphyria

Hereditary coproporphyria (HC), the rarest of the hepatic porphyrias, is characterized by fecal and urinary excretion of coproporphyrin. It may start in childhood, be precipitated by barbiturates and sulfonamides, and be manifested in crises with hypertension, abdominal pain, tachycardia, constipation, confusion, and delirium.[4] Subacute and acute neuropathies may lead to limb paralysis. Epileptic seizures frequently occur, often predating the first diagnosed porphyric crisis.[20]

P.2719

Treatment

There are three aspects to the treatment of porphyria: (a) avoidance of all drugs known to be porphyrinogenic;

(b) interruption of an attack by preventing induction of D-ALA synthetase with a high intake of carbohydrate or administration of intravenous glucose and reducing porphyrin production by the administration of intravenous hematin, and (c) symptomatic management of autonomic symptoms and pain with propranolol, chlorpromazine, meperidine, and morphine.

Porphyric crises can be precipitated by many drugs, including most antiepileptic drugs (AEDs), estrogens, alcohol, and oral contraceptives.[65] Some AEDs without porphygenic effect in a rodent model are levetiracetam, gabapentin, zonisamide, and possibly low doses of oxcarbazepine. The diagnosis is made with the Watson-Schwartz test and enzyme assays that reveal decreased activity of PBGD.

Problems in Diagnosis of Seizures and Management

Although porphyric crises may resemble simple partial sensory seizures, simple partial psychic seizures, and complex partial seizures, the prominence of abdominal pain, tachycardia, constipation, and paralysis distinguish them from ictal syndromes. The porphyric crisis itself, however, may precipitate partial or tonic–clonic seizures. In children, AIP and HC may be associated with mental retardation, itself a risk factor for epilepsy.[27,68] The cause of the psychic and epileptogenic manifestations is unknown, but some investigators have suggested that toxicity is a consequence of the structural similarity of porphobilinogen and D-ALA to γ-aminobutyric acid (GABA) and glutamate.[39] Some authors suggest that porphyrins are endogenous ligands for mitochondrial benzodiazepine receptors.[67]

The management of patients with porphyria who are in or between crises is complicated by the frequently marked porphyrinogenic qualities of most antiepileptic drugs. Barbiturates, carbamazepine, clonazepam, diazepam, ethosuximide, the hydantoins, primidone, paraldehyde, and valproate may all induce crises and are porphyrinogenic in chick embryo hepatocyte cultures.[46,49,60,61] Triggering of the first porphyric crisis around puberty derives from the fact that steroids, including estradiol, containing a 5-ß configuration induce D-ALA synthetase, thus precipitating the porphyric crisis.[28,72] Oral contraceptives also increase urinary enzyme excretion in normal patients, and asymptomatic relatives of patients with porphyria should avoid contraceptive pills.[14] The cyclic nature of AIP attacks of varying severity, usually late in the luteal phase or during ovulation, may simulate the catamenial exacerbation of seizure disorders.[65] As with catamenial seizures, attempts to suppress ovarian cycling by oral contraception to reduce porphyric crises have met with variable success.[3]

The chick embryo hepatic cell culture has been used to test the potential of antiepileptic drugs to induce porphyria.[21,46] Reynolds and Miska[46] found that phenytoin, phenobarbital, carbamazepine, clonazepam, and valproate may all increase porphyrin levels. Benzodiazepines (diazepam), bromides, magnesium sulfate, and gabapentin have been suggested as alternatives in the treatment of porphyria based on single case reports and small reviews of the literature.[27,46,49,60,61]

Table 5 Safe drugs for patients with porphyria

Analgesics
Codeine
Narcotic analgesics
Antibiotics
Penicillins
Streptomycin
Tetracycline
Antiemetics
Chlorpromazine
Prochlorperazine
Promethazine
Diphenhydramine

Trifluoperazine
Anticonvulsants
Bromides
Clonazepam
Diazepam
Gabapentin
Levetiracetam
Zonisamide
Vigabatrin
Others
Chloral hydrate
Corticosteroids
Propranolol

Independent of the acute porphyric attack per se, partial or generalized seizures in children[27] or adults may supervene in about 1% to 30% of hospitalized patients or patients brought to medical attention. In genetically susceptible individuals, the incidental intake of one of the many drugs thought to precipitate porphyria may induce a porphyric crisis, which may, in turn, be associated acutely with partial or generalized seizures. However, seizure onset may appear after the original crisis or even between crises. Some patients may have both conditions, apparently occurring independently, with the onset of epilepsy preceding the first porphyric attack. Common drugs and antiepileptic agents that can usually be safely used in porphyria are listed in Table 5.

Idiopathic Recurring Stupor

Idiopathic recurring stupor (IRS) is a rare disease that has only recently been elucidated. It is a syndrome of recurring obtundation or coma unassociated with a known toxic, metabolic, or structural abnormality.[48,64] Events in the few cases described occur in early middle age or in older male patients who are light drinkers. Characteristics are drowsiness that is not associated with alcohol intake, slurred speech, drunken gait, and aggressiveness upon challenge. Lethargy deepens to sleep, from which the patient can be briefly aroused only with vigorous stimuli. Spells, which may occur weekly but are usually infrequent, can last up to 3 days, after which the patient may appear stunned and be amnestic.

During stupor, there may be up to a 300-fold increase in levels of endozepine-4, an endogenous ligand for benzodiazepine recognition sites on $GABA_A$ central nervous system receptors, with normalization of levels between attacks.[48] Ictal EEGs reveal a fast (14- to 16-Hz) unreactive background activity without apparent epileptiform activity.[64]

The stuporous state can be reversed by the pure benzodiazepine antagonist flumazenil.

Table 6 Metabolic and Endocrine imitators of epilepsy

Hypoglycemia	Relation to meals or fasting Hunger Characteristic prodrome Hypoglycemia correlated with symptoms Response to glucose
Hyperglycemia	Elevated blood glucose and osmolarity Prolonged confusion

	Movement disorder syndromes Epilepsia partialis continua
Hypocalcemia	Acral and perioral paresthesias Tetanic spasms and Chvostek sign Low serum calcium Response to calcium
Hyperthyroidism	Anxiety, tremor, sweating, weight loss, tachycardia Choreiform movements Rare periodic paralysis Suppressed thyroid-stimulating hormone, elevated serum T_4, T_3
Hypothyroidism	Choreoathetoid movements Confusion, stupor, or coma Sleep apnea Decreased serum T_4, elevated thyroid-stimulating hormone
Pheochromocytoma	Hypertension, headache, malaise, pallor Episodes resembling panic attacks Secretion of catecholamines Computed tomography, magnetic resonance imaging, or radionuclide tumor identification
Carcinoid	Flushing with transient erythema Bronchoconstriction, diarrhea Increased serotonin metabolites in urine Radiologic localization of gastro- intestinal or bronchial tumor
Porphyria	Paroxysmal hyperautonomic symptoms Abdominal pain, delirium, neuropathy Generalized seizures, provoked by drugs Porphyrins in the urine
Hyponatremia	Fluctuating confusion or stupor Generalized seizures Low serum sodium and osmolarity Syndrome of inappropriate antidiuretic hormone

Movement Disorders

A marked tremor may be confused with an epileptic seizure. Several metabolic and endocrine disorders include tremor, such as hypoglycemia and pheochromocytoma. Choreiform movements may be seen with hypocalcemia, hypoglycemia, hyperglycemia, hyperthyroidism, and porphyria. Hypoglycemia and hyperglycemia may induce myoclonus.

Acute Confusional States

Acute confusional states or delirium may also resemble complex partial seizures. Many metabolic and endocrine disorders, including hyponatremia and hypernatremia, hypocalcemia and hypercalcemia, hypothyroidism and hyperthyroidism, hypocortisolemia and hypercortisolemia, hypoparathyroidism and hyperparathyroidism, hepatic insufficiency, and porphyria, may cause delirium.

Summary and Conclusions

Many metabolic, endocrine, and vasoactive/autonomic disturbances share clinical features with simple partial and some complex partial seizures. Differentiating them from myoclonic or tonic–clonic seizures usually poses little difficulty. The key to differentiating partial seizures from metabolic, endocrine, and vasoactive/autonomic dysfunctions is usually the constellation of signs and symptoms associated with the two respective categories. Although rare, simple psychic, autonomic, or sensory seizures not infrequently progress to complex partial seizures or secondarily generalized tonic–clonic seizures. Metabolic or endocrine conditions may lower seizure thresholds, but typically they cause generalized tonic–clonic seizures that are not preceded by partial symptomatology. Similarly, most endocrine and metabolic dysfunctions are associated with other clinical features that distinguish them from partial seizures. Prominent malaise, sweating, anxiety and palpitations, diarrhea or constipation, and abdominal pain or cramping occur relatively infrequently with partial seizures.

Hypoglycemia is one of the most important mimics of epilepsy. The temporal relationship of the cardinal features of hypoglycemia to fasting, food intake, or intake of hypoglycemic drugs should alert the physician to the correct diagnosis, despite the fact that the symptoms of anxiety, clamminess, tachycardia, sweating, and confusion are also associated with anxiety states, hyperventilation, and rare conditions such as pheochromocytoma and carcinoid syndrome. Differentiation rests on demonstration of hypoglycemia and the symptomatic relief provided by reestablishment of normal glucose levels. Rarer causes, including carcinoid syndrome, pheochromocytoma, and porphyria, may be tested for on an individual basis, with a higher diagnostic probability during an attack. Typically, the array of multisystem features, including sudden headache, hypertension, and marked sweating (pheochromocytomas), diarrhea and abdominal cramps (carcinoid syndrome), and abdominal pain, constipation, and paralysis (acute porphyrias), helps to differentiate these conditions.

A more complex issue is the coincidence of epileptic seizures. Carcinoid tumors and pheochromocytomas are rarely associated with seizures. Tonic–clonic seizures, however, are seen with hypoglycemia, as are characteristic partial motor seizures and epilepsia partialis continua in nonketotic hyperglycemia. Similarly, the porphyric syndromes, in addition to resembling certain seizure types, may be associated with epileptic seizures or be precipitated by antiepileptic drugs. The management of these conditions, therefore, involves not only diagnostic differentiation, but also the appropriate management of metabolic and endocrine disorders on the one hand and intercurrent seizures on the other.

Blanket testing for rare endocrine or metabolic disorders is neither justified nor cost-effective. The tests are frequently invasive. It is only with justifiable suspicion of the rare entities that costly and morbid investigation should be undertaken. Table 6 summarizes the characteristic presentations of endocrine and metabolic disorders.

Chapter 273

Systemic Nonepileptic Paroxysmal Disorders From Neonatal to Childhood Periods

Mark S. Scher

Federico Vigevano

Introduction

Paroxysmal phenomena during neonatal and childhood periods cause intermittent or recurrent motor or behavioral signs or symptoms that must be distinguished from epileptic disorders. The clinician's diagnostic acumen can be especially challenged by specific behaviors. Nonepileptic paroxysmal disorders can be on either a neurologic or a systemic basis. The clinical context may help to distinguish paroxysmal nonepileptic disorders from epileptic seizures. Before committing to a specific pharmacologic intervention with medications, which may both be unnecessary and place the child at risk for adverse effects, alternative etiologies first must be considered. Home videography of the suspicious event can be pivotal for the clinician to reach a prompt and correct diagnosis with minimal investment in time and resources. Synchronous video-neurophysiologic monitoring either in the inpatient or outpatient setting[1,65,70] may also be necessary more definitively to categorize the event as epileptic or nonepileptic.

The child's age, state of arousal, and organ system involvement and an accurate description of the event by a witness will lead, in most cases, to the correct diagnosis. One must always be alert to nonepileptic disorders that occur in the context of a child who also has epilepsy. An early classification by Prensky[53] utilized functional categories to subdivide disorders: Disease-related behaviors, altered tone or consciousness, respiratory disturbances, perceptual disturbances, behavioral disorders, and unusual movements (see Table 1). Recent reviews further highlight selected disorders in young children.[18,19,22,48] Discussion of specific epileptic and nonepileptic paroxysmal events of neurologic origin such as nocturnal frontal lobe epilepsy, migraine, tic disorders, sleep disorders, psychogenic seizures, and cerebrovascular events are reviewed elsewhere in this book.

Relative to maturation, these paroxysmal disorders can be referred to as transient, paroxysmal, and/or chronic in presentation.[19] The proportion of transient events is highest during childhood, with the preponderance occurring during the first year of life. Many disorders remain idiopathic and unassociated with other neurologic diseases. When investigations are performed, test results are often normal. The clinician must therefore rely on clinical experience and consider a functional mechanism without known pathophysiologic explanations. Knowledge of these conditions is essential for the pediatric neurologist to avoid unnecessary tests and treatment while alleviating family anxiety (Table 1).

Disease-Related Behaviors

Various systemic disease states present with recurrent signs and symptoms during infancy and childhood that may be misdiagnosed as epilepsy. Alteration of consciousness or muscle tone, focal neurologic deficits, and diffuse weakness may be clinical signs of systemic nonepileptic paroxysmal disorders.

Tetralogy Spells

This phenomenon is characterized by episodes of cyanosis, dyspnea, and unconsciousness and can present during the first several years. The repertoire of events occurs in 10% to 20% of children with congenital heart disease and may result in seizures. Anoxia-induced seizures occur in such individuals who suffer chronic and significant hypoxemia. Such episodes are labeled “tet spells” because young children with the especially cyanotic congenital heart lesions (such as tetralogy of Fallot) usually present in this manner. The pathogenesis for “tet spells” is the sudden increase in right-to-left shunting of blood through the heart with sudden oxygen desaturation. On careful history taking, attacks of hyperpnea and cyanosis are seldom misinterpreted as epileptic seizures. Loss of consciousness may result from anoxia or hypoxia, however, which then may precipitate seizures in certain children and, therefore, may be confusing to the clinician. For those children old enough to be ambulatory, taking a squatting position and then remaining nearly motionless is a maneuver for recovering cardiac reserve.[49]

Table 1 Systemic NonEpileptic Paroxysmal Disorders

Disease-related behaviors	**Behavioral disorders**
Tetrology spells	Head banging or nodding
Cardiac arrhythmias	Rumination
Poststreptococcal autoimmune disorders	Nightmares
Hypoglycemia	Night terrors
Hypocalcemia	Sleepwalking
Hydrocephalic spells	Confusional states
Hyperthyroidism	Panic attacks
Periodic paralysis	Dyscontrol syndrome or rage attacks
Gastroesophageal reflux	Munchausen syndrome by proxy
Drug poisoning (e.g., neuroleptics)	Psychotic states (i.e., fugue spells, hallucinations)
Cerebrovascular events	Stereotypic behavior
Loss of tone or consciousness	**Unusual movements**
Syncope	Jitteriness or tremulousness

Drop attacks	Shuddering
Narcolepsy/cataplexy	Benign sleep myoclonus (neonate or infant)
Attention-deficit hyperactivity syndrome	Exaggerated startle responses (i.e., hyperekplexia)
Respiratory disturbances	**Other unusual self-stimulator behaviors**
Infant apnea	Paroxysmal torticollis
Apparent life-threatening events	Masturbation
Breath-holding (including vagotomy)	Withholding, constipation
Hyperventilation	Transient dystonia, choreoathetosis
Perceptual Disturbances	Paroxysmal choreoathetosis or dystonic spasms
Headache (i.e., migraine)	Kinesigenic or nonkinesigenic
Abdominal pain	Tic disorder or Tourette syndrome
Vertigo, dizziness	Paroxysmal tonic up gaze

Cardiac Arrhythmias

Children with recurrent episodes of loss of consciousness or alterations in arousal may suffer from cardiac arrhythmias. Disturbances of cardiac conduction of either intracardiac or extracardiac origin include sick sinus syndrome,[60] Jervell-Lange-Nelson syndrome, which is genetically determined and includes an associated deafness,[29] and Ward-Romano syndrome.[51] Therefore, careful history taking and examination may reveal characteristic features such as hair hypopigmentation, hearing loss, or dysmorphea. Syncope may frequently include convulsive movements similar to an Adams-Stokes attack. The prolonged-QT syndrome should be suspected in children particularly with underlying cardiac disease on a genetic basis such as the velocardiofacial syndrome (i.e., chromosomal 22q 11.2 deletion).[31] Prolonged-QT syndrome may be benign and transient or prolonged with risk for sudden death.[67] Prognosis is guarded because sudden unexpected death may occur at any time. True epileptic seizures may ensue in affected children as a result of asphyxia-induced brain injury incurred during prolonged episodes of hypoxemia during cardiac arrest. A cardiologic evaluation, including a prolonged electrocardiographic (ECG) recording and/or ECG during exercise may be required.

In a recent study of adults, 20% of patients referred to a neurologic department with possible idiopathic epilepsy were subsequently found to have cardiac arrhythmias that caused or significantly contributed to their symptoms.[60] Pediatric populations referred to neurology or epilepsy clinics may reflect comparable percentages, but few studies are available for comparisons with older populations. A report of sudden death in the young presenting with presumed cardiac arrhythmias was the most common cause of mortality in people 5 to 35 years of age. The two most common noncardiac causes of sudden death were epilepsy (23.8%) and intracerebral hemorrhage (23.8%).[55] In another study of adult epileptic patients, one third showed ictal bradycardia, with greater than one half experiencing serious cardiac events meriting pacemaker placement.[58] In general, sinus tachycardia accompanies approximately 90% and bradycardia or asystole 0.5% of all seizures.[72]

Metabolic Abnormalities: Hypoglycemia and Hypocalcemia

Hypoglycemia may occasionally challenge the clinician because of its association with unusual symptomatology. Both seizures and nonepileptic behaviors occur with hypoglycemia at any age, including the neonatal period. Neonates with hypoglycemia may present with tremulous behavior. Rare metabolic disorders can present early in life with hypoglycemia associated with, for example, hyperammonemic states, leucine intolerance, and hereditary fructose intolerance. Particularly after 1 year of age, unusual episodes of unconsciousness, stupor, or even seizures may occur during the early morning hours after an all-night fast. Postevent confusion or stupor can be prolonged after hypoglycemia-induced seizures. Such events may occur after episodes of vomiting, diarrhea, or transient reduced food intake, sometimes in the setting of a transient illness. The combination of symptoms associated with the condition of ketotic hypoglycemia[8] accounts for approximately 50% of cases of hypoglycemia that occur during early childhood. The child appears grossly ketotic during the attack and may exhibit marked hyperventilation. Acetonuria is an essential feature, which is rapidly corrected by administration of glucose. Hospitalization with carefully controlled provocation tests are suggested to induce hypoglycemia, such as with the administration of a ketogenic diet. Treatment consists primarily in preventing ketosis by adhering to regular mealtimes, particularly during times of illness, together with glucose supplementation. Of course, hypoglycemia and seizures may coexist; children may have epileptiform discharges on electroencephalogram (EEG), which may support a seizure diagnosis but not be interpreted in the context of the patient's clinical history. For example, neonatal hypoglycemia can result in injury to parietal-occipital cortical regions, which may later present as one form of focal epilepsy, involving posterior pathways.

Hypocalcemic stress usually results in seizures and can be secondary to primary or secondary hypoparathyroidism (with or without genetic cardiac syndromes). Severe nutritional deficiencies may be associated with poor feeding practices, starvation, or chronic diseases such as malabsorption syndromes or rickets.[2] A rare genetic disease of familial hypomagnesemia may be associated with hypocalcemia.[68] Rarely, profound hypocalcemia can result in nonepileptic tetanic spells,

P.2725

including generalized clonic activity, jaw rigors, and tremulousness.

Gastroesophageal Reflux

Infants may demonstrate episodic extension and lateral flexion of the head, usually in association with feeding. This syndrome was first described by Kinsbourne[34] and is sometimes termed “Sandifer syndrome” because the first patient described by Kinsbourne was under the care of Dr. Paul Sandifer. Although these seizure-like episodes suggest epilepsy, gastroesophageal reflux disorder (GERD) should be suspected after a careful history is obtained. In a retrospective review of 342 infants presenting with symptoms suggestive of GERD, all were <1 year of age; they presented with regurgitation, choking, irritability, failure to thrive, an apparent life-threatening event (ALTE), or wheezing.[64] In a study of 69 infants with ALTE, GERD was diagnosed in 38 cases and gastric volvulus in 21.[45]

Gastrointestinal radiographs, such as barium swallow study, document reflux with or without hiatal hernia or other morphologic abnormalities of the upper airway or gastrointestinal tract. Surgical correction is sometimes required to correct such attacks. The age range for these events is wide, beginning during the neonatal period and extending into adolescence. For infants, choking, apnea, laryngospasm, and opisthotonos also commonly occur,[25] whereas other gastrointestinal complaints, weight loss, or sleep disturbances are noted for older children.

Altered Muscle Tone or Consciousness

The following discussion of syncope does not include neurologic conditions, such as cataplexy associated with the sleep disturbance of narcolepsy, or the inattention associated with attention-deficit hyperactivity disorder.

Syncope

Syncope is a common occurrence for adults and older children and is usually distinguished from true epileptic seizures by the historical description of a witness (see Chapter 271).[5] Patients describe warning signs of lightheadedness, dizziness, or visual dimming, such as graying out or browning out. Nausea may also be described after the event. Subjective feelings of temperature change and profuse sweating are also described. Sometimes a specific stimulus such as the sight of blood, minor trauma, or enclosure in a confined space may precipitate an attack. Orthostatic syncope may follow after prolonged standing or sudden change in posture. A careful review of a family history may document similar events in other relatives.[6]

Reflex syncope may also be described with certain physiologic maneuvers such as coughing, swallowing, or micturition.[32] Table 2 lists some causes of syncope, some of which are described elsewhere in this chapter, such as cardiac arrhythmias.

Table 2 Causes of Syncope

Menstruation in females	Decreased blood volume
Anemia	
Vasovagal	Fear Pain Unpleasant sights
Reflex	Cough Micturition Swallowing Carotid sinus pressure
Decreased venous return	Orthostatic with Valsalva maneuver
Disease states Cardiac Cerebrovascular insufficiency	Arrhythmia, obstructive outflow
Familial undetermined causes	

Syncopal events in the neonate, infant, or preverbal children have unique diagnostic challenges. Events may occur precipitously following surprise, pain, or prolonged crying. Breath-holding spells are discussed later, given the prominent respiratory component to this event. Underlying illnesses such as cardiorespiratory or metabolic-genetic causes may suggest a pathophysiologic mechanism. Neurocardiogenic syncope and neurologic disorders (80% and 9%, respectively) are the most common diagnoses for pediatric patients presenting to an emergency department.[41] Cardiogenic studies such as prolonged ECG monitoring, ultrasonography of the heart, or a tilt-table test may help to document associated abnormalities or capture events. Serum studies during an attack may document metabolic disturbances, such as hypoglycemia. Rarely, syncope triggers epileptic seizures, requiring both cardiologic treatment such as antiarrhythmic medication or cardiac pacing, as well as antiepileptic medications.[28] Patients with syncope, however, may have a few clonic jerks or even incontinence during or following the syncopal event[52] without evolving to seizures.

The physical examination of syncopal patients yields normal results. Blood pressure changes from supine to standing positions, however, may demonstrate a substantial drop in the diastolic component, supporting the diagnosis of orthostatic syncope. A tilt-table test may also be helpful. If one documents a blood pressure reduction of more than 15 points or the presence of a sinus bradycardia on standing, orthostatic hypotension should be suspected. A cardiologic evaluation including investigation for a heart murmur or dysrhythmia should be considered. Exceptional cases of congenital heart block have been associated in children with chronic myopathy, ophthalmoplegia, deafness, and ataxia, termed the Kearne-Sayne syndrome.[3]

If an attack is prolonged, a tonic motor seizure may occur. In a review of 77 patients appearing in an emergency room, 40 had syncope, 17 had near-syncope, and 20 did not have a syncopal episode. Vasovagal (50%) and orthostatic hypertension (20%) were the most common causes of syncope. Near-syncopal episodes occurred with lightheadedness (29%), seizures (18%), tension headaches (12%), and migraine (6%).[52] Adolescents, particularly those who lift weights or perform gymnastics, may induce syncope by stretching or straining the musculature, including inducing a neck-hyperextended position.

Children with recurrent symptoms should be evaluated by a cardiologist. Autonomic functioning of patients with beta-adrenergic hypersensitivity should be tested. A tilt-table test is particularly useful, sometimes with administration of isoprotosenol infusion as a provocative agent to induce blood pressure changes.[23]

Respiratory Disturbances

Primary respiratory disorders most commonly occur without associated seizures. These symptoms, however, may be

confused with seizures. At times, clonic jerks or isolated seizures may follow primary apnea.[69] An electroencephalogram or polysomnogram during such events will help to distinguish a respiratory disorder from a true seizure.

Infant Apnea or Apparent Life-threatening Events

Apnea usually occurs during sleep and may be associated with centrally mediated hypoventilation, airway obstruction, or aspiration. Paroxysmal events are sometimes commonly referred to as apparent life-threatening events (ALTEs). On polysomnography, central apnea is defined as the absence of both chest and abdominal movements, as well as a cessation of airflow at the nares. Obstructive apnea usually involves movement of the chest and abdomen without airflow at the nares. Clonic or myoclonic jerks may occur during the apnea episode but do not represent true epileptic seizures. Most do not define apnea until it reaches durations of 15 to 20 seconds. Apnea associated with preterm infants is the most common presentation, but it also may occur in older infants.

If apnea occurs while a child is fully awake, this may be associated with gastroesophageal reflux.[26,63] Such an event is common usually when the infant is laid supine after a feeding, and aspiration may result following the reflux event.

Apparent life-threatening events predominantly affect children younger <1 year of age. This syndrome is characterized by a frightening constellation of symptoms in which the child exhibits some combination of apnea, color change, change in muscle tone, coughing, or gagging.[24] Recent studies highlight that a diagnostic testing strategy should depend on the outcome of the initial clinical assessment.[4,42] Together the two studies found that 50% to 70% of patients were correctly diagnosed based on the history and examination. Suggested algorithms follow a stepwise approach, with investigations initially directed by historical and clinical findings. The first step is consideration of child abuse. Based on information from six studies, baseline studies were suggested as follows: (a) basic blood tests, (b) infection screens, (c) metabolic workup, (d) cardiologic evaluations or ancillary organ system monitoring such as EEG, (e) polysomnography, and (f) pH probe studies.[42] It has also been recently emphasized that there are clear differences in epidemiology and risk factors between ALTE and sudden infant death syndrome (SIDS).[33]

Breath-holding Spells

This phenomenon is common between 6 months and 6 years and is often confused with tonic seizures. The child is described as falling, followed by tremulousness or convulsive, clonic-like movements. Two forms—cyanotic and pallid spells—have been reported, both resulting from reflex vagal changes that produce bradycardia and decrease cerebral blood flow. The cyanotic form of breath-holding spell is typically more common, beginning during the second or third year of life in response to anger, fear, excitement, or minor injury. The child will cry and suddenly stop breathing, often during expiration. Cyanosis ensues within seconds, followed by a loss of consciousness, limpness, and loss of postural tone. After 1 to 2 minutes of unresponsiveness, consciousness rapidly returns with the resumption of normal activities without postictal alterations in arousal.

The pallid form of breath-holding spells (BHS) often follows minor trauma or surprise, but crying is minimal or absent. There is rapid loss of consciousness or limpness as with the cyanotic form. Attacks may be longer, however, and frequently involve clonic movements associated with cerebral hypoxia.[39] Children with the pallid form may have more profound bradycardia or even asystole. Both cyanotic and pallid forms of BHS can be associated with autonomic nervous system dysregulation,[14] and children with myelodysplasia and Arnold-Chiari malformations exhibit various brainstem abnormalities manifesting in abnormal control of breathing, upper airway dysfunction, aspiration, pneumonia, and cor pulmonale. Severe and sudden bradyarrhythmia or asystole may also result, necessitating treatment with beta-adrenergic antagonists such as atropine.

Unwitnessed attacks may be difficult to distinguish from seizures, but observers often describe an association between precipitating causes as the historical key to the diagnosis. Electroencephalographic recordings do not demonstrate epileptiform discharges, but may show paroxysmal slowing of background EEG activities during an induced syncopal episode.

The optimal treatment is usually behavioral modification without the need for medication, although atropine may be rarely recommended for frequent pallid spells and a trial of iron supplementation is usually recommended for children with BHS and hematologic evidence of iron-deficiency anemia.[9,47]

The presumed pathogenesis of breath-holding spells involves an acute reduction of cerebral blood flow because of increased intrathoracic pressure. This mechanism is analogous to syncope induced by the Valsalva maneuver, which occurs in addition to acute oxygen desaturation caused by respiratory arrest. Some clinicians describe the pallid form as “vagotonia,” which may reveal genetic transmission after obtaining a family history. Children with posterior fossa malformations, such as the Arnold-Chiari anomaly, have also been described as having this physiologic abnormality.[46]

For a typical pediatric population who present with breath-holding spells, 76% of the attacks occur between 6 and 18 months of age.[38] Eighty-five percent of affected children are free from attacks by the age of 5 years. There is generally no relationship with mental retardation and later epilepsy, but it can occur in children with developmental disorders, in whom such attacks are repetitive and stereotypic.

Hyperventilation Syndrome

This phenomenon is most commonly noted in older children, particularly during adolescence. Children with the complete clinical presentation breathe rapidly with shallow, irregular breathing, whereas others complain of an inability to obtain satisfying deep breaths. The initial complaints are commonly dyspnea, chest pain, and lightheadedness. Syncope or pseudoabsence seizures have been described and may be mistaken for true epileptic events. The clinician must have a high index of suspicion in the presence of the typical symptoms, which often include thoracic pain, shortness of breath, and muscle pain. Having the patient rebreathe in a paper bag permits the clinician quickly to control the symptoms of the impending attack. Such a syndrome, however, should alert the clinician to the presence of an anxiety disorder or other significant psychological disturbance. For recurring or chronicity of events, antianxiety medications may help; long-term psychiatric intervention may also be required.

Behavioral Disorders

Rumination

These attacks involve hyperextension of the neck, repetitive swallowing, and protrusion of the tongue and may overlap with the syndrome of gastroesophageal reflux. Although some situations may be due to abnormalities of esophageal peristalsis

P.2727

on an anatomic basis, other patients manifest this behavior as a developmental disturbance because of a dysfunctional relationship between the caretaker and child. The child is usually described as alert but sometimes appears under stress and uncomfortable. Variable feeding techniques are helpful to correct this disorder, depending on the etiologic possibilities. Intensive psychotherapy with both the caretaker and child may be required before long-term benefits result.

Panic Attacks

Panic attacks occur as acute events associated with a chronic anxiety disorder (see Chapter 285). Patients suffering from depression, schizophrenia, or hyperthyroidism may present with these events. The possibility of substance abuse should also be considered. Attacks last from minutes to hours and are accompanied by palpitations, sweating, dizziness or vertigo, and feelings of unreality. Other symptoms have also been described such as dyspnea or a smothering sensation, unsteadiness or faintness, palpitations or tachycardia, trembling or shaking, choking, nausea or abdominal distress, depersonalization or derealization, numbness or tingling, flushes or chills, chest pain or discomfort, and fears of dying, aura, going crazy, or losing control.[50] Specific situational experiences may bring on panic attacks, such as agoraphobia. Children with developmental disturbances, such as those with pervasive developmental disorders with autistic signs, may also manifest stereotypic behaviors that suggest seizures.[12]

Episodic Dyscontrol Syndrome (Rage Attacks)

Episodic dyscontrol syndrome is characterized by recurrent attacks of uncontrollable rage. Such attacks occur despite minimal or absent provocation, often totally out of context with the personality of the patient or the situation.[17] Although this can be seen in younger children, this is more often noted in teenagers and young adults. Younger children with specific language delay or developmental disorders in multiple domains may present with rages. Many patients may have impaired mental status and other neurologic abnormalities on examination, but the history provided by a family or witnesses document that such attacks occur suddenly, are explosive, and are characterized by uncontrollable behavior. Behavior may include primitive physical violence such as kicking, striking, or biting, or even verbal abuse with profanity. Patients display uncharacteristic strength and speed and appear to be psychotic, claiming amnesia, fatigue, or remorse following the episode. At times, such attacks may be difficult to distinguish from complex partial seizures; however, directed violence is very unusual during a true epileptic seizure. Patients rarely describe an aura, and their EEG examination is noncontributory. Some authors indicate that patients with complex partial seizures also have a higher-than-expected incidence of rage attacks.[36,54]

Munchausen Syndrome by Proxy

Clinicians must be cognizant of children with false events or illnesses invented or induced by a relative or caretaker. Meadow[43,44] described children whose mothers fabricated signs and symptoms of illness; a false history of seizures ranging from 1 month to 20 years with an average of 4 years was described. These “seizures” are reported to occur as generalized events at night during sleep, poorly controlled by a wide variety of antiepileptic medications, leading to repeated hospitalizations and multiple diagnostic studies.

The physical examination of these children is usually completely normal. In addition to the commitment and expense of diagnostic studies and prolonged hospitalizations, emotional trauma, prolonged absence from school, and unnecessary restrictions in sports and recreational activities are the consequences to the child of this condition.

The mothers of children with Munchausen syndrome by proxy are medically sophisticated and spend long hours in hospital settings. Knowledge about medical procedures and other factual minutiae allows these individuals to be conversant in sophisticated discussions involving different diagnoses. Fathers, on the other hand, keep a low profile, rarely visit the child in the hospital, and are quite passive by description.[20]

It is essential to diagnose this condition promptly because it is considered a form of child neglect or abuse. The clinician must maintain a high index of suspicion and conduct a methodical review of all medical records with a case conference with as many health care providers as possible.[59] Covert video surveillance of infants in pediatric hospitals is now more widely recommended, although ethical and legal dilemmas have been discussed.[21] Some children are at risk of being asphyxiated or poisoned to induce spells, and mortality is estimated at 10%. Prompt psychiatric intervention for the caretaker is required.

Unusual Movements

Tremulousness or Jitteriness

Neonates and young infants commonly present with rapid generalized tremulousness. Infants appear alert, and gentle flexion of the affected body part will extinguish or diminish these movements. The movement is a to-and-fro movement of the limb, which is contrasted with the fast and slow movement phases characterized by clonic activity. Tremors or jitteriness may persist up to 4 to 6 weeks postconceptional age but usually resolve after this time. This movement is a benign pattern during infancy, with a high rate of normal neurodevelopmental outcome.[62] The movements may occur spontaneously or be provoked by stimulation. Older children may also exhibit tremors. In the absence of cerebellar or motor neuron signs, dystonia, family history of cerebellar disease, or a history of hyperthyroidism, childhood essential tremor can be considered. Other entities such as drugs with tremor-inducing properties must be considered. One in 20 essential tremor cases arise during childhood, with an age range at onset of 1 to 14 years.[40] Neonates who are small for gestational age, hypoglycemic infants, infants of diabetic mothers, and infants withdrawing from prenatal substance exposure may present with jitteriness.

Shuddering, Myoclonus, Hyperekplexia, Dyskinesias

Shuddering is an exaggerated movement resembling shivering. Events occur both during waking and sleep states. Video-EEG monitoring may be required to capture the events.[30] There is a rapid tremor involved in the head, arms, and trunk or even the lower extremities. Such episodes have been described as early as 3 to 4 months of age but decrease gradually in frequency and intensity by 10 to 11 months of age. Essential tremor may be more common in families of children with shuddering spells.[27,66] Young children show an abrupt onset of shuddering movements with flexion of the head, elbows, trunk, and knees and abduction of the elbows and knees. Some describe provocation with excitement, fear, anger, or an urge to void.

A more frequent nonepileptic condition described in infants is benign neonatal myoclonus (BNM)[56] or benign myoclonus

of early infancy (BMEI),[18] which may include shuddering of the upper limbs in approximately 50% of children. Fejerman[18] suggested that shuddering attacks are a variant of BMEI. Children with BNM resolve by 6 months of age. Myoclonic jerks are only present during sleep and mainly during non–rapid-eye-movement sleep. Arousal always terminates the jerks. By definition, the neurologic examination and electroencephalogram are normal.

Hyperexplexia or hyperekplexia is a relatively benign disorder consisting of exaggerated startle responses and hypertonicity that may occur during the first year of life, and in severe cases presents during the neonatal period. As a relatively uncommon disorder, it is usually sporadic, but familial inheritance has been reported. Thirty-nine patients were recently reported[61] with an average age at onset of 3.3 months. Children usually present with marked irritability and recurrent startles in response to handling or sounds. Severely affected infants had severe jerks and stiffening, sometimes with breath-holding spells. Symptoms gradually resolved by 2 years of age with normal neurodevelopment.

Paroxysmal dyskinesia is a general descriptive term that encompasses a number of clinical phenomena of adults and children.[10] Abnormal movements may be induced by sudden voluntary movements (i.e., paroxysmal kinesigenic choreo-athetosis). Some movements may be dystonic, choreic, ballistic, or choreoathetotic. Three other dyskinesias are nonkinesigenic, exertion induced, or hypnogenic. Seven children were recently described, with the earliest onset at 18 months.[35] Most cases are idiopathic with a benign course, diminishing in frequency and severity with age. Video-EEG monitoring may be required to exclude epilepsy, but antiepileptic medications may be required for the specific child.

Paroxysmal Eye Movements: Spasm Nutans, Benign Paroxysmal Tonic Upward Gaze, Eye Fluttering

Spasm nutans is a syndrome occurring in early childhood. It consists of a triad of symptoms: (a) head nodding,

(b) ocular oscillations, and (c) anomalous head position. Ophthalmologic and neurologic findings are otherwise normal. This syndrome is benign and has spontaneous resolution.[16] Age of onset ranges from 1 to 15 months, with both head nodding and nystagmus, which most of the time are intermittent. Neuroimaging is required for the rare association of brainstem masses or malformations.

Benign paroxysmal tonic upgaze is an ill-defined neuro-ophthalmologic disorder with onset in infancy.[11] It consists of sudden ocular movements with sustained upward deviation of the eyes. Episodes disappear with time with normal neurodevelopment,[57] although ataxia has been reported in a child.[37]

Although eye fluttering may be part of typical childhood absence epilepsy, nonepileptic eyelid movements have been described in 19 children and adults with well-controlled generalized epilepsy.[7] Eye movements in children began 2 to 4 years before epilepsy was noted and did not resolve with age. Twelve patients had a family history of the eyelid disorder without epilepsy.

Self-stimulatory Behavior

Some behaviors may be mistaken for seizures, especially in neurologically impaired children. Donat and Wright[15] described head shaking and nodding, lateral and vertical nystagmus, staring, tongue thrusting, chewing movements, periodic hyperventilation, tonic postures, ticks, and excessive startle reactions in some children. Self-stimulatory behavior, such as rhythmic hand shaking, body rocking, and head swaying performed during a time of apparent unawareness of the surroundings, are commonly noted in children with mental deficits, as well as those with pervasive developmental disorders such as autism. The clinical syndrome Rett syndrome should be suspected in young girls who are delayed in development and exhibit “hand washing” movements. Deaf and blind children frequently resort to self-stimulatory behavior, such as hitting their ears or eyes. Developmentally normal children with constipation or refusal to urinate may present with unusual behaviors that may appear to be seizure-like or self-stimulatory but instead reflect the child's discomfort and distraction because of his or her resistance to voiding or defecating.

Finally, masturbatory behavior, even in the very young, may give the appearance of seizures. Referrals for neurologic consultation may have requested evaluations for seizures or movement disorders. Infantile masturbation may mimic pain, inattention, or fear. Infants of either gender, for instance, may be found in a sitting position with their legs held tight together or straddling bars of the crib or playpen and rocking back and forth.[71] Direct observation is crucial, and video-monitoring at home or by the neurology team can be diagnostic.

Diagnostic Methods and Differential Diagnosis

The paroxysmal events discussed here represent, for the most part, transitory functional disorders not associated with any particular disease. As already mentioned, specific investigations should be performed only for organ-specific clues by history and examination, such as cardiopathies causing syncope or gastrointestinal pathologies causing gastroesophageal reflux. In other situations, there are no particular examinations that can lead to an etiologic diagnosis.

The cardinal element for diagnosis is a precise history of the event. It is important to investigate favoring or triggering factors that preceded the event and the patient's subjective sensations, motor manifestations, and postictal state. Differential diagnosis with tonic–clonic generalized epileptic seizures can be particularly difficult in a syncope that can present a tonic contraction of the entire body and sometimes arrhythmic myoclonic limb jerks. Family history must be reviewed for the presence of nonepileptic paroxysmal disorders, such as syncopes or other paroxysmal events. Careful attention must paid to discover any family history of sudden death. The objective examination will be normal, except in cases with cardiopathy, as will the neurologic examination.

The clinician must consider that patients with a suspected convulsive seizure should undergo an EEG or video-EEG study that can provide additional information. Home videography can also prove helpful.

The EEG will characteristically show an absence of interictal epileptogenic abnormalities or the presence of abnormalities not relevant to the symptomatology, for example, rolandic spike discharges in children with episodes of loss of consciousness.

An optimal routine should always include a recording of cardiac activity, by which it is sometimes possible to detect cardiac arrhythmias, especially during a hyperventilation test. There should be an increase in heart rate during the hyperventilation test that can favor the triggering of arrhythmias (Fig. 1).

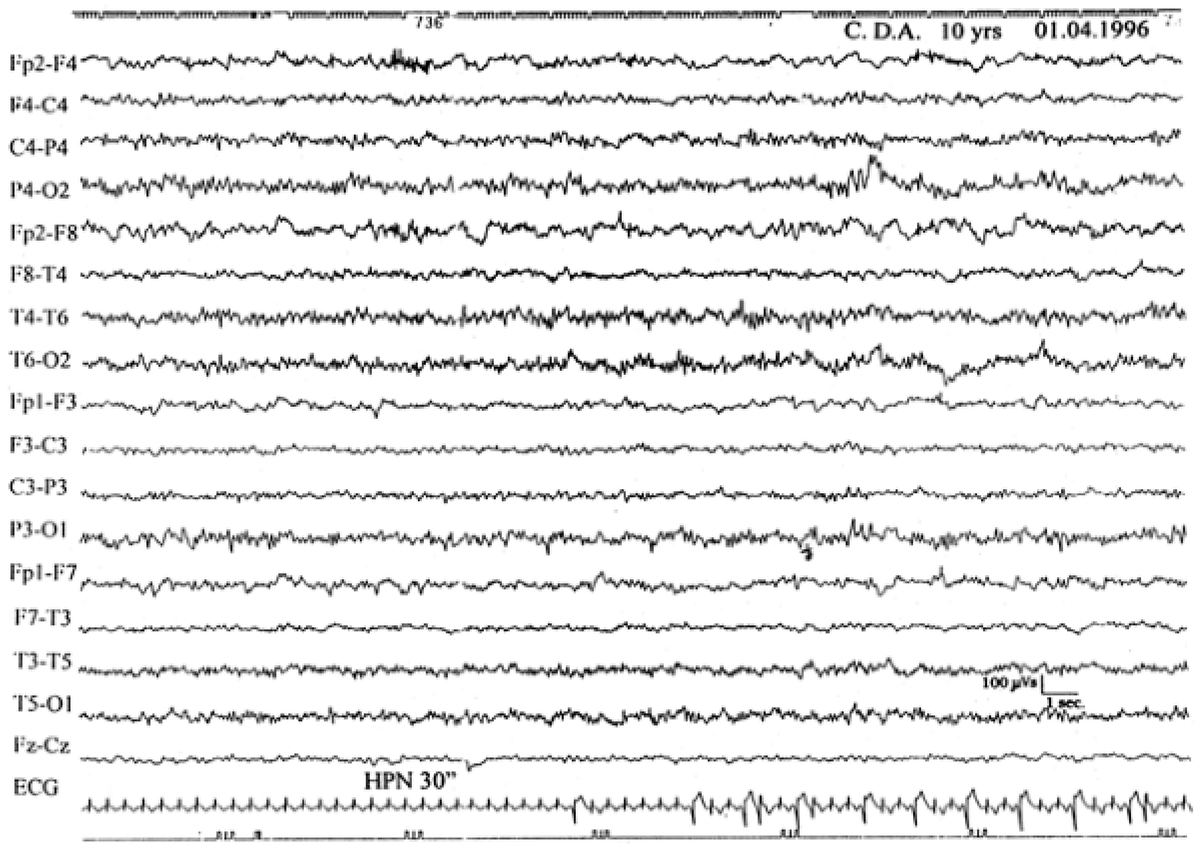

FIGURE 1. A 10-year-old girl who presented with a seizure with loss of consciousness and diffuse tonic contraction. A sister died suddenly at age 13 years. The electroencephalogram is normal; extra systoles appear after 30 seconds of hyperventilation (HPN). Diagnosis: exercise-induced ventricular tachycardia.

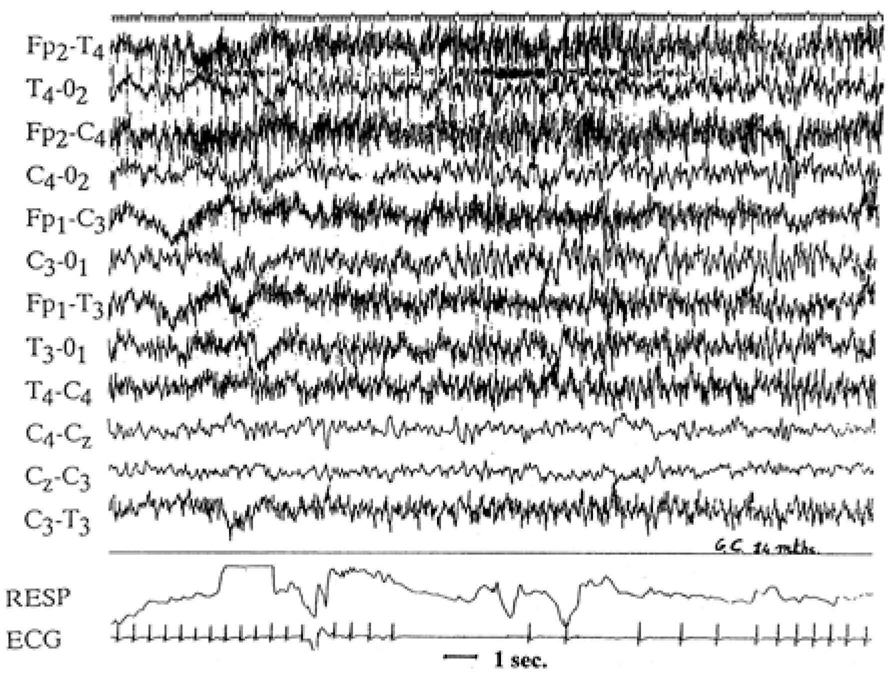

FIGURE 2. A 14-year-old boy with pallid form of breath-holding spells, triggered by emotion or fear. His brother presented with the same phenomenon. A strong emotion (the father leaving the recording room) provoked crying and, after a few seconds, bradycardia to a cardiac pause of 7 seconds. This type of reaction is an expression of "vagotonia."

Even more useful is the polysomnographic study with recording of EEG, ECG, and nasal, oral, and chest breathing, in addition to other parameters. In cases of ALTE, this test is mandatory while the patient is awake and asleep because it helps to identify any central or obstructive apnea.

P.2729

The best diagnostic method is undoubtedly the documentation of the paroxysmal manifestation. In cases of frequent and unprovoked paroxysmal manifestations, it could be useful to ask the parent to try to record the phenomenon with a video camera at home.

One can try to provoke the event in the neurophysiology laboratory. Use of the tilt table can provoke syncopes caused by orthostatic hypotension; crying can provoke either a cyanotic or pallid type of breath-holding spell (Fig. 2); contraction of the scapular girdle muscles can provoke a stretching syncope.

When it is possible to record the event, EEG generally does not evidence any change or only nonepileptic changes (Fig. 3).

The first observation during the syncope is a slowing in background activity, then a diffuse synchronization with appearance of diffuse, wide-amplitude 1- to 2-c/s waves. Clinical manifestations include dizziness and visual dimming, pallor with cold sweating, and loss of consciousness. If the syncope is

P.2730

P.2731

prolonged and there is significant decrease in arterial pressure or severe bradycardia, electrical activity decreases abruptly until an isoelectric pattern is reached. In this phase, the patient is unconscious and can have a diffuse tonic contraction, generally in extension with cyanosis and sometimes even clonic jerks. Subsequently, with the return to baseline cardiac activity and arterial pressure, slow electrical activity with wide amplitude reappears and progressively desynchronizes until normal characteristics are resumed. From a clinical point of view, the patient returns to normal respiration and coloring and regains consciousness (Fig. 4). Epileptic-type abnormalities should not be noted in any phase.

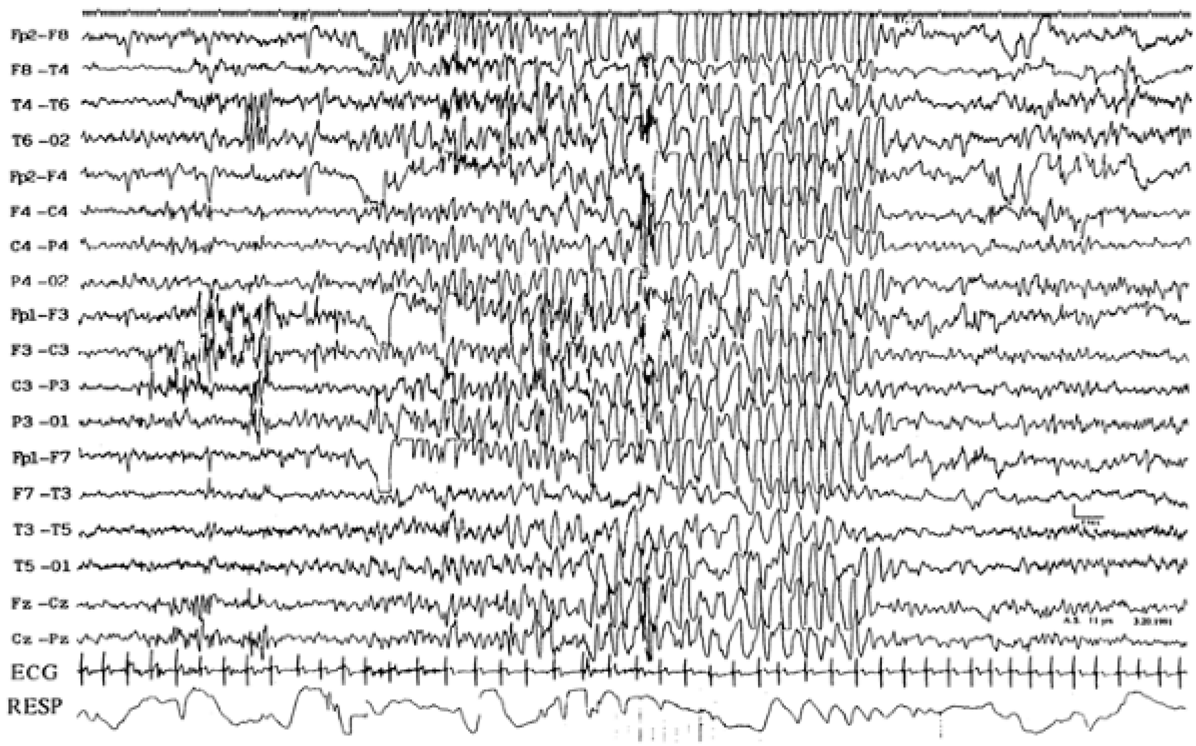

FIGURE 3. An 11-year-old girl with a history of loss of consciousness. The electroencephalogram is performed standing. The patient presented a syncope caused by orthostatic hypotension. Cerebral electrical activity synchronized progressively to 1 to 2 c/s, then progressively desynchronized as symptoms disappeared.

FIGURE 4. An 8-month-old boy with tetralogy of Fallot and frequent cyanotic spells. **A:** After crying briefly, the child stops breathing and rapidly becomes cyanotic. Polygraphic recording shows progressive synchronization of background activity and bradycardia. **B:** The child shows diffuse tonic contraction with apnea and cyanosis. The electroencephalogram (EEG) shows an isoelectric-type pattern; bradycardia is always very significant. There are some artefacts on the EEG due to resuscitation maneuver. **C:** Respiratory and cardiac activities slowly return to normal and the child regains consciousness. The EEG shows slow, wide-amplitude electrical activity that progressively desynchronizes.

Summary and Conclusions

This overview describes nonepileptic systemic paroxysmal disorders during neonatal and childhood periods. Some of these nonepileptic phenomena may be challenging to the clinician. In most situations, however, a careful history by a reliable observer leads the clinician to a successful diagnosis. Home video recordings, synchronous video-neurophysiologic monitoring, or cardiologic testing in the hospital or clinic may document the episodes in question for the clinician, who can then make an accurate diagnosis.

Chapter 274

Migraine

Stephen D. Silberstein

Richard B. Lipton

Sheryl Haut

Introduction

Migraine and epilepsy are the most common of the chronic neurologic disorders with episodic manifestations. Each group includes a highly variable family of clinical features, natural histories, and patterns of treatment response.[6,99] Therefore, there are many types of migraine, as there are many types of epilepsy. Both disorders are characterized by episodes of neurologic dysfunction that are sometimes accompanied by headache, as well as gastrointestinal, autonomic, and psychologic features.

This chapter focuses on the relationship between migraine and epilepsy for several reasons. First, abundant clinical and epidemiologic data demonstrate that migraine and epilepsy are highly comorbid, in that individuals with one disorder are at least twice as likely to have the other.[5,6,7,60,61,67] Secondly, the clinical presentation of migraine and epilepsy may overlap, creating a challenge in differential diagnosis. Finally, the disorders share overlapping risk factors, brain mechanisms, and treatments.[61] We will begin by describing the migraine attack, dividing it into four traditional stages—the premonitory phase, the aura, the headache phase, and the resolution phase[31]—and contrast the seizure using this framework. We will then review the diagnosis of migraine using the International Classification of Headache Disorders (ICHD)-2 criteria, emphasizing the variants of migraine most frequently mistaken for epilepsy. Finally, we will summarize the epidemiologic evidence that migraine and epilepsy are associated, and provide treatment considerations.

Classification

Each family of disorders has an internationally recognized classification system. The classification system for headache, developed by international consensus, was updated in 2004, and will be referred to herein as the ICHD-2.[40] The classification system utilized in epilepsy was developed by the International League Against Epilepsy (ILAE).

The ICHD-2 criteria divide headache disorders into two broad groups: Primary headache disorders and secondary headache disorders.[40] In a somewhat similar manner, epilepsies are regarded as idiopathic, symptomatic, or cryptogenic by ILAE criteria. In the secondary headache disorders, the headache is symptomatic of an underlying condition, such as a stroke or a mass lesion. This group is analogous to the symptomatic epilepsies in that an underlying cause has been identified. In the primary headache disorders, the headache does not have an identifiable underlying cause. Primary headaches are divided into four major categories: Migraine; tension-type headache; the trigeminal autonomic cephalgias, including cluster headache; and a group of headache disorders analogous to the idiopathic epilepsies. There is no group of headache disorders akin to cryptogenic epilepsies. Furthermore, there is no classification of headache types analogous to the classification of seizure types.

Migraine

Migraine is an extremely common disorder. Recent population-based studies have yielded remarkably consistent

1-year period prevalence estimates of about 6% in men and 15% to 18% in women.[87,62,97] Most studies find that migraine is about three times more common in women than in men.[62,64,97]

Headache diagnosis is usually based on the retrospective reporting of attack characteristics. The results of general medical and neurologic examinations, as well as laboratory studies, are usually normal and serve to exclude other, more ominous, causes of headache. The ICHD-2 classification of migraine subtypes is presented in Table 1. The most important International Headache Society (IHS) subtypes of migraine are “migraine without aura” (formerly common migraine) (Table 2) and “migraine with aura” (formerly classic migraine) (Table 3). In migraine, the aura is a complex of focal neurologic symptoms that precedes or accompanies an attack.[116] About 20% to 30% of migraineurs have migraine with aura.[63] The same patient may have headache without aura, headache with aura, and aura without headache.

The migraine attack can be divided into four phases: The premonitory phase, which occurs hours or days before the headache; the aura, which comes immediately before the headache; the headache itself; and the postdrome. Although most people experience more than one phase, no one phase is absolutely required for a diagnosis of migraine, and most people do not experience all four phases.[17] The epilepsy attack may also have a premonitory, aura, attack, and postictal phase. The similarity in terminology does not imply similarity in mechanisms.

Premonitory, or prodromal, phenomena occur in approximately 60% of migraineurs, often hours to days before the onset of headache.[3,4,17] The phenomena of the premonitory phase has been elucidated using an electronic diary.[33] Features include constitutional, autonomic, psychological (depression, euphoria, irritability, restlessness, mental slowness, hyperactivity, fatigue, and drowsiness), and neurologic (photophobia, phonophobia, and hyperosmia) features. Some patients report a poorly characterized feeling that a migraine attack is coming. Although features vary widely among individuals, they are often consistent within an individual. The most common premonitory symptoms were feeling tired/weary (72%), difficulty concentrating (51%), and stiff neck (50%). Poor functioning commonly predicted headache.[35] Migraineurs who reported premonitory symptoms accurately predicted their full-blown headaches 72% of the time. Among patients who were almost certain that attacks would occur, 93% had attacks.

Table 1 International Classification of Headache Disorders (ICHD)-2 Migraine Classification

1. Migraine
  - 1.1 Migraine without aura
  - 1.2 Migraine with aura
    - 1.2.1 Typical aura with migraine headache
    - 1.2.2 Typical aura with nonmigraine headache
    - 1.2.3 Typical aura without headache
    - 1.2.4 Familial hemiplegic migraine
    - 1.2.5 Sporadic hemiplegic migraine
    - 1.2.6 Basilar-type migraine
  - 1.3 Childhood periodic syndromes that are commonly precursors of migraine
    - 1.3.1 Cyclical vomiting
    - 1.3.2 Abdominal migraine
    - 1.3.3 Benign paroxysmal vertigo of childhood
  - 1.4 Retinal migraine
  - 1.5 Complications of migraine
    - 1.5.1 Chronic migraine
    - 1.5.2 Status migrainosus
    - 1.5.3 Persistent aura without infarction
    - 1.5.4 Migrainous infarction

- 1.5.5 Migraine-triggered seizures
- 1.6 Probable migraine
  - 1.6.1 Probable migraine without aura
  - 1.6.2 Probable migraine with aura
  - 1.6.3 Probable chronic migraine

Table 2 Migraine without Aura

Diagnostic Criteria

A. At least five attacks[87] fulfilling criteria B–D
B. Headache attacks lasting 4–72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate or severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
D. During headache at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia and phonophobia
E. Not attributed to another disorder

From Headache Classification Committee. The International Classification of Headache Disorders. 2nd ed. *Cephalalgia.* 2004;24:1–160.

Table 3 Migraine with Aura (41)

Diagnostic Criteria

A. At least two attacks fulfilling criterion B
B. Migraine aura fulfilling criteria B and C for one of the subforms 1.2.1–1.2.6
C. Not attributed to another disorder

Typical aura with migraine headache
Diagnostic Criteria

A. At least two attacks fulfilling criteria B–D
B. Aura consisting of at least one of the following, but no motor weakness:
    1. Fully reversible visual symptoms including positive features (e.g., flickering lights, spots, or lines) and/or negative features (i.e., loss of vision)
    2. Fully reversible sensory symptoms including positive features (i.e., pins and needles) and/or negative features (i.e., numbness)
    3. Fully reversible dysphasic speech disturbance
C. At least two of the following:
    1. Homonymous visual symptoms and/or unilateral sensory symptoms
    2. At least one aura symptom develops gradually over ≥5 minutes and/or different aura symptoms occur in succession over ≥5 minutes
    3. Each symptom lasts ≥5 and ≤60 minutes
D. Headache fulfilling criteria B–D for 1.1 *Migraine without aura* begins during the aura or follows aura within 60 minutes
E. Not attributed to another disorder

From Headache Classification Committee. The International Classification of Headache Disorders. 2nd ed. *Cephalalgia.* 2004;24:1–160.

Premonitory symptoms have also been reported prior to seizure onset.[30] Although less commonly present than in migraine, patients with epilepsy often report a constellation of symptoms prior to a seizure, including irritability, gastrointestinal upset, heaviness, or depression.

P.2734

Aura

The migraine aura consists of focal neurologic symptoms that precede or accompany an attack. Approximately 20% to 30% of migraineurs experience auras. Most aura symptoms develop slowly over 5 to 20 minutes and usually last for <60 minutes. The aura almost always includes visual features but somatosensory, motor, language, and brainstem disturbances are not rare.

The visual aura often has a hemianoptic distribution and includes both positive (scintillations, fortification spectra, photopsia) and negative (scotoma) features. Elementary visual disturbances include colorless scotoma, photopsia, or phosphenes. Simple flashes, specks, or hallucinations of geometric forms (points, stars, lines, curves, circles, sparks, flashes, or flames) occur and may be single or number in the hundreds. More complicated hallucinations include teichopsia, or fortification spectrum, which is the most characteristic visual aura and is almost diagnostic of migraine. An arc of scintillating lights classically begins near the point of fixation and may form a herringbone-like pattern that expands to encompass an increasing portion of a visual hemifield. It migrates across the visual field with a scintillating edge of zigzag or flashing lights that are often black and white; on occasion colored dots appear at the end of the white stripe. A scotoma is a negative phenomenon consisting of a blanking or graying out of vision. Scotomas are usually accompanied by a positive visual display, but may occur independently. Complex disorders of visual perception include metamorphopsia, micropsia, macropsia, zoom vision, and mosaic vision.[99,100]

Numbness or tingling (paresthesia) over one side of the face and in the ipsilateral hand or arm is the most common somatosensory phenomena. Hemiparesis and dysphasia or aphasia may develop. Olfactory hallucinations are rare, unpleasant, and short lived (5 minutes to 24 hours). Anxiety, déjà vu, and jamais vu have been reported as migraine auras and are presumably of temporal lobe origin.[90] One type of aura may follow

P.2735

another: Sensory phenomena may occur as visual phenomena fade, or motor phenomena may develop as sensory phenomena dissipate. Although visual auras are relatively specific for migraine, related phenomena may occur in cerebrovascular disease, including carotid dissection, and in epilepsy, especially of the occipital lobes.

Nonvisual association cortex symptoms also occur; these include complex difficulties in the perception and use of the body (apraxia and agnosia), speech and language disturbances, states of double or multiple consciousness associated with déjà vu or jamais vu, and elaborate, dreamy, nightmarish, trance-like or delirious states.[38,51,59,90,95]

In epilepsy, the aura, representing an actual seizure discharge, is typically rapid in development and brief. In contrast to the common visual auras of migraine, epileptic auras are often associated with more unusual symptoms. Auras are estimated to precede up to 80% of temporal lobe seizures; in this setting, autonomic and psychic phenomena, such as a rising abdominal sensation, nausea, fear, or déjà vu, are common.[103]

Mechanisms of Aura

Cortical spreading depression (CSD) is believed to underlie the migraine aura. CSD consists of a wave of excitation followed by a wave of inhibition that moves across the cortical mantle at a rate of 3 mm/min. Best studied as an animal phenomenon, it can be induced by pricking the cerebral cortex with a pin, by applying potassium chloride, and in other ways.[56] CSD is characterized by transient increases in metabolic and electrical activity and transient increases in cerebral blood flow (CBF), followed by sustained decreases.[75] The aura is associated with an initial hyperemic phase followed by reduced CBF, which moves across the cortex (spreading oligemia).[76]

Several lines of evidence in humans suggest that CSD is a mechanistic substrate of migraine aura. Olesen and Lauritzen[74,76] found 17% to 35% reductions in posterior CBF, which spread anteriorly at 2 to 3 mm/min. It crossed brain areas supplied by separate vessels and is, thus, not due to segmental vasoconstriction.[74] Reduced CBF persisted from 30 minutes to 6 hours, then slowly returned to baseline or even increased. The rates of progression of spreading oligemia could account for the rate of expansion of the scotoma in migraine, suggesting that they are related.[55,56,69,77]

Magnetoencephalographic studies show similar profiles in humans during migraine aura and in experimental animals during CSD,[101] implying that spreading depression may be the mechanism that produces the aura.[18,53,86,87,111] Subjects with spontaneous migraine visual auras have also been studied with functional magnetic resonance imaging (fMRI).[23] Interictally, using perfusion-weighted imaging, CBF, cerebral blood volume, and mean transit time were normal and symmetric. During visual auras, CBF decreased 15% to 53%, cerebral blood volume decreased 6% to 33%, and mean transit time increased 10% to 54% in the occipital cortex gray matter contralateral to the affected visual hemifield. When multiple perfusion images were obtained during the same aura, the margin of the perfusion defect moved anteriorly. The absence of diffusion abnormalities in these patients suggests that ischemia does not occur during the migraine aura.[22]

Blood oxygenation level–dependent (BOLD) fMRI reflects the relative concentration of deoxyhemoglobin in venous blood. Visual stimulation was used to trigger headache in migraineurs.[20] A wave of increased (hyperoxygenated blood) and then decreased (possibly reflecting neuronal metabolic-flow coupling) BOLD signals propagated into the contiguous occipital cortex at 3 to 6 mm/min. When visual stimulation was used to test the visual cortex response, the BOLD signal and the BOLD response to visual activation diminished following progression of the visual aura.[39]

Using transcranial magnetic stimulation–applied magnetic fields of increasing intensity to evaluate occipital cortex excitability, Aurora et al.[9] and Young et al.,[115] but not Afra et al.,[1] found that phosphenes were generated in migraineurs at lower thresholds than controls, and that it was easier to visually trigger headaches in those with lower thresholds. Other evidence of increased central nervous system (CNS) excitability comes from studies of visual and brainstem auditory-evoked potentials.[93] Migraine with aura may be due to neuronal hyperexcitability, perhaps due to cortical disinhibition.

The aura of epilepsy is a simple partial nonmotor seizure that typically precedes an observable seizure, but may occur alone. The patient experiences the aura prior to loss of consciousness, and memory of it may be retained. The aura is associated with the electroencephalographic correlate of the seizure type in which it occurs[27]; however, the EEG pattern is often not evident on surface recording until the seizure has progressed to involve a larger area of cortex.

Headache Phase

The typical migraine headache is unilateral and described as throbbing by 85% of patients. Headache severity ranges from moderate to marked and is aggravated by head movement or physical activity. The onset is usually gradual and the attack usually lasts 4 to 72 hours in adults and 2 to 48 hours in children.[99] Anorexia is common, although food cravings can occur. Nausea occurs in up to 90% of patients, and vomiting occurs in about one third of migraineurs.[63] Many patients experience sensory hyperexcitability manifested by photophobia, phonophobia, and osmophobia, and seek a dark, quiet room.[28,95] To make a diagnosis of migraine, the pain must be accompanied by other features. The ICHD-2 selects particular associated features as cardinal manifestations for diagnosis (Table 2).[98]

Postdrome or Postictal Phase

With migraine, the patient may feel tired, washed out, irritable, and listless and may have impaired concentration. Many patients report scalp tenderness. Some people feel unusually refreshed or euphoric after an attack, whereas others note depression and malaise. In epilepsy, during the postictal phase, there may be a depressed level of awareness or focal neurologic deficits that sometimes provide clues to the site of seizure onset.

Formal International Classification of Headache Disorders-2 Classification

Migraine without Aura (Common Migraine) **(Table 2)**

To establish a diagnosis of ICHD-2 migraine without aura (1.1), five attacks lasting from 4 to 72 hours are required. The attacks must have two of the following four pain characteristics: Unilateral location, pulsating quality, moderate to

P.2736

severe intensity, and aggravation by or causing avoidance of routine physical activity. In addition, the attacks must be associated with at least one of the following: Nausea or vomiting or photophobia and phonophobia. No single characteristic is mandatory for a diagnosis of migraine. A patient who has photophobia, phonophobia, and severe pain aggravated by routine activity meets these criteria, as does the more typical patient with unilateral throbbing pain and nausea.[98] Attacks that persist for more than 3 days define status migrainosus. Although the frequency of attacks varies widely, the average migraineur experiences one to three headaches a month. Like epilepsy, migraine is, by definition, a recurrent phenomenon. The requirement for at least five attacks is imposed because headaches simulating migraine may be caused by such organic diseases as brain tumors, sinusitis, or glaucoma.[98]

Migraine with Aura (Classic Migraine) **(Table 3)**

Descriptively, auras are focal neurologic symptoms that usually develop gradually over 5 to 20 minutes and last for <60 minutes. The diagnosis of migraine with aura (1.2) requires at least two attacks meeting the criteria of one of the subforms. In addition, it cannot be attributed to another disorder. Migraine with aura is subclassified into typical aura with migraine headache (1.2.1) (homonymous visual disturbance, unilateral numbness or aphasia); typical aura with nonmigraine headache (1.2.2); typical aura without headache (1.2.3); familial hemiplegic migraine (FHM) (1.2.4); sporadic hemiplegic migraine (1.2.5) (see Table 6); and basilar-type migraine (1.2.5). Some of these variants will be discussed in detail since they may be confused with epilepsy.

Typical aura with migraine headache (1.2.1) requires at least two attacks with the aura consisting of at least one of the following (but no motor weakness): Fully reversible visual symptoms including positive; fully reversible sensory symptoms including positive; and fully reversible dysphasic speech disturbance. Additionally, it requires at least two of the following: Homonymous visual symptoms and/or unilateral sensory symptoms; at least one aura symptom developing gradually over ≥5 minutes and/or different aura symptoms occurring in succession over ≥5 minutes; and each symptom lasting ≥5 and ≤60 minutes. Fewer attacks are required to make a diagnosis of migraine with aura because a typical aura is highly specific for migraine. Headache with the features of migraine without aura usually follows the aura symptoms. Less commonly, headache lacks migrainous features or is completely absent.[40,98]

If the aura includes motor weakness, it is coded as 1.2.4 *Familial hemiplegic migraine* or 1.2.5 *Sporadic hemiplegic migraine*.

The headache and associated symptoms of migraine with aura are similar to those of migraine without aura but may be less severe and/or of shorter duration. Most people who have migraine with aura also have migraine without aura. The aura usually lasts 20 to 30 minutes and typically precedes the headache, but occasionally it occurs only during the headache.

Migraine Variants

The variants of migraine as classified by the ICHD-2 have been discussed in detail elsewhere.[40] In this section we will describe the migraine variants that are most commonly confused with epilepsy, using ICHD-2 terminology when possible.

Basilar-type Migraine

Originally called basilar or basilar artery migraine,[40] the term *Bickerstaff syndrome* has also been applied to this disorder.[13] It affects all age groups and both sexes, with the usual female predominance. The aura often lasts <1 hour and is usually followed by a headache. In basilar-type migraine, the visual aura is usually followed by at least one of the following: Ataxia, vertigo, tinnitus, diplopia, nystagmus, dysarthria, bilateral paresthesia, or a change in the levels of consciousness and cognition. If marked, these alterations in consciousness define confusional migraine.

The aura symptoms described above are often, but not always, followed by a severe, throbbing occipital headache and vomiting. Although attacks are usually infrequent, they can last for 1 to 3 days. These headaches can be very frightening and difficult to diagnose. On occasion, the attacks can lead to cardiac arrhythmias and brainstem stroke. A diagnosis of basilar migraine should be considered in patients with paroxysmal brainstem disturbances. Basilar migraine may be difficult to differentiate from simple or complex partial seizures and the postictal state following a primary or secondary generalized seizure. The differential diagnosis, besides occipital lobe epilepsy, includes posterior fossa tumor or malformation, urea cycle defects, and mitochondrial disorders.[84]

Confusional Migraine[40,43]

No longer part of the ICHD-2 classification, confusional migraine is probably a form of basilar-type migraine or hemiplegic migraine. It is characterized by a typical migraine aura, a headache (which may be insignificant), and confusion, which may precede or follow the headache. During the confused period the patient is inattentive, is distracted, and has difficulty maintaining speech and other motor activities. The electroencephalogram (EEG) may be abnormal during the attack. Agitation, memory disturbances, obscene utterances, and violent behavior have been reported. Single attacks are most common; multiple attacks rare. Attacks may be triggered by mild head trauma. A more profoundly disturbed level of consciousness may lead to migraine stupor, which can last from hours up to 5 days. The confusional state is usually followed by sleep, resembling postictal depression of mental status. Confusional migraine may be difficult to diagnose. The differential diagnosis includes drug ingestion, metabolic encephalopathies (Reye syndrome, hypoglycemia), viral encephalitis, and acute psychosis. Acute confusional states also occur during complex partial seizures and in the postictal state. The patient may be delirious, hyperactive, restless, and, on occasion, combative. Acute migraine confusional states may recur over a period of days or months and then evolve into typical migraine episodes. A history of typical migraine aura supports a diagnosis of migraine.[52]

Benign Paroxysmal Vertigo of Childhood

Now classified as one of the “childhood periodic syndromes,” this condition is a precursor of migraine (1.3.3). This disorder is characterized by recurrent, brief episodic attacks of vertigo. Attacks occur without warning and resolve spontaneously in otherwise healthy children. Children with this disorder cannot stand, and lie silently on the floor or wish to be held during attacks. Attacks last a few minutes and tend to recur at irregular intervals over a period of 6 to 12 months. While headache may not be present at the onset, as the disorder evolves the vertigo may be replaced by attacks of headache and vomiting,

P.2737

facilitating diagnosis. When simple partial seizures give rise to vertigo, the vertigo is usually less prominent than it is in migraine.

Aura without Headache

Migraine aura can occur without headache,[112] although diagnosis is more difficult in this setting. These periodic neurologic phenomena (scintillating scotomata or recurrent sensory, motor, or mental phenomena) should be accepted as migraine only after a full investigation. Headache occurring in association with some attacks will help confirm the diagnosis.[88] Ziegler and Hassanein[116] reported that 44% of their patients who had headache with aura had aura without headache at some time.

Late-life migrainous accompaniments are characterized by attacks of aura without headache beginning in late life.[31,32] Many patients have a history of migraine in early or midlife, often with an attack-free hiatus. Because focal neurologic defects occur without headache, they can be confused with transient ischemic attacks (TIAs) or seizures. Late-life migrainous accompaniment remains a diagnosis of exclusion.

Migraine-triggered Seizure

New to the ICHD-2 is a seizure triggered by a migraine aura (1.5.5). This diagnosis requires migraine that fulfills the criteria for 1.2 Migraine with aura and a seizure fulfilling diagnostic criteria for one type of epileptic attack that occurs during or within 1 hour after a migraine aura. This phenomenon is sometimes referred to as *migralepsy*.

Epidemiologic Connections between Migraine and Epilepsy

Andermann and Andermann[5] summarized a number of studies that examined the association between migraine and epilepsy. The prevalence of epilepsy in persons with migraine ranged from 1% to 17% with a median of 5.9%, substantially higher than epilepsy's population prevalence of 0.5%. Migraine prevalence in patients with epilepsy ranged from 8% to 15%. Many of these studies were limited by the method of patient identification, the lack of appropriate control groups, and poorly specified definitions of migraine and epilepsy. Nonetheless, these studies powerfully argue that migraine and epilepsy are associated.

Ottman and Lipton[79] examined the association between migraine and epilepsy using data from Columbia University's Epilepsy Family Study. Subjects with epilepsy (probands) who were over 18 years of age were identified and recruited from voluntary organizations for persons with epilepsy. Among the probands with epilepsy, migraine prevalence was 24%. Migraine prevalence was 26% in the relatives with epilepsy. In the control group of relatives without epilepsy, only 15% had migraine. The gender-adjusted rate ratio for migraine in probands with epilepsy compared with relatives without epilepsy was 2.4 (95% confidence interval [CI]: 2.0 to 2.9). For relatives with epilepsy compared with relatives without epilepsy the rate ratio was also 2.4 (95% CI: 1.6 to 3.8). These statistics indicate that the incidence of migraine is 2.4 times higher in persons with epilepsy than in persons without epilepsy.

Risk of migraine was not associated with the age of onset of epilepsy. The risk of migraine was elevated in both partial and generalized seizures, although the risk was higher for probands with partial-onset versus those with generalized-onset seizures (relative risk [RR] = 1.3; 95% CI: 1.00 to 1.86). The risk of migraine was elevated in both idiopathic and symptomatic epilepsy. Probands with epilepsy caused by head trauma had a higher risk of migraine than probands with idiopathic/cryptogenic epilepsy (RR = 1.8, 95% CI: 1.32 to 2.43). Nonetheless, migraine risk was elevated in every subgroup of epilepsy defined by seizure type, age of onset, and etiology of epilepsy.[70]

Although migraine and epilepsy are associated, the mechanisms of the association are complex and may be multifactorial. One possibility is a simple unidirectional causal explanation. For example, migraine may cause epilepsy by inducing brain ischemia and injury. Under this hypothesis, we would expect the incidence of migraine to be elevated before, but not after, the onset of epilepsy. Alternatively, epilepsy may cause migraine by activating the trigeminovascular system. This hypothesis leads us to expect an excess risk of migraine after, but not before, the onset of epilepsy. The data show that there is an excess risk of migraine both before and after seizure onset, leading to the rejection of both unidirectional causal models.

Marks and Ehrenberg[67] explored the timing and features of headache in patients with epilepsy. They found that of 79 of 395 patients with epilepsy, 20% also had IHS migraine. In 84% of patients with both migraine and epilepsy (66 of 79), the attacks were completely independent. In 16% of patients (13 of 79), a seizure immediately followed the migraine aura (migralepsy); 11 of 13 were women, seven of whom had a catamenial pattern. Migralepsy was also seen in refractory patients with both migraine and epilepsy in Andermann's series,[6] although this phenomenon does not account for the majority of the comorbidity.

Velioglu and Ozmenoglu[109] studied the relationship between migraine and epilepsy in 412 adults with epilepsy. Fourteen percent of adults with seizures had IHS migraine. Migraine-induced epilepsy (migralepsy) was found in seven patients (1.7%); all had migraine with aura. The authors at times found it difficult clinically to distinguish the aura of migraine from the aura of epilepsy. Patients were at increased risk for both conditions if they had migraine with aura and catamenial epilepsy. Three of the patients with refractory seizures had improved control with the combination of antimigraine and antiepilepsy drugs.

Lenaerts[57] evaluated the degree of comorbidity and tried to establish the pattern of temporal relationship between migraine and epilepsy in 201 patients from tertiary care clinics. He systematically reviewed charts, obtained additional information by telephone interviews where necessary, and applied IHS and ILAE diagnostic criteria. Two-tier grouping according to reason for referral (migraine or epilepsy) was done. Adequate information was obtained from 185 patients (113 females, 72 males). In the epilepsy-referred patient group (n = 103), 23% had migraine, a risk ratio of 1.9 (p = 0.01). In the migraine-referred group (n = 82), 11% had epilepsy, a risk ratio of 21 (p = 0.05). Of the 33 comorbid cases, 21 had their attacks in close temporal relation. The migraine attack preceded the seizure in 12 patients (nine migraine with aura) (57%) and followed it in nine (six migraine with aura) (43%). Migraine attacks equally precede or follow seizures, but migraine aura more often precedes the seizure (migralepsy).

Shared environmental risk factors may contribute to comorbidity. The risk of migraine is higher in subjects with epilepsy caused by head injury. Since head injury is also a risk factor for migraine,[8] comorbidity may result, in part, from an effect of head injury on the risk of both disorders. Because risk is also significantly increased in persons with idiopathic/cryptogenic epilepsy, known environmental risk factors cannot account for all of the comorbidity.

Table 4 Migraine and Epilepsy Relationships

1. Coexisting epilepsy and migraine Both disorders occur together at an increased prevalence, but attacks occur independently
2. Migraine-induced epilepsy (migralepsy) Seizures are triggered by migraine aura
3. Epilepsy-induced headache (ictal or postictal) Headache occurs as part of seizure or postictal state
4. Primary epilepsy–migraine syndromes Syndromes with features of both migraine and epilepsy without a specific underlying cause
   –Occipital epilepsies (e.g., benign occipital epilepsy)
   –Benign rolandic epilepsy
5. Secondary epilepsy–migraine syndromes Both migraine and epilepsy occur in the same individual with a common underlying cause
   –Mitochondrial disorders (MELAS)
   –Symptomatic (e.g., arteriovenous malformation of occipital lobe)
   - Neurofibromatosis
   - stürge-Weber

Modified from Andermann F. Migraine and epilepsy: an overview. In: Andermann F, Lugaresi E, eds. *Migraine and Epilepsy*. Boston: Butterworths, 1987:405–421; and Welch KM, Lewis D. Migraine and epilepsy. *Neurol Clin.* 1997;15:107–114.

Ottman and Lipton[79] tested the alternative hypothesis, that shared genetic risk factors might account for comorbidity. They

argued that the risk of migraine should be higher in families with genetic versus nongenetic forms of epilepsy if genetic factors account for comorbidity. They further argued that the risk of epilepsy should be greater in the relatives of probands with migraine and epilepsy versus the relatives of probands with epilepsy alone. In a series of analyses, they adjusted for a number of potentially confounding factors including age, gender, the familial aggregation of migraine, and the comorbidity of migraine and epilepsy. The analyses failed to confirm either of the authors' hypotheses, leading them to reject the idea that genetic susceptibility accounts for comorbidity.[79]

Having rejected the unidirectional model, the environmental model, and the genetic hypothesis, they proposed that an altered brain state (increased excitability) might increase the risk of both migraine and epilepsy and account for comorbidity. Enhanced neuronal hyperexcitability and a reduced threshold to attacks figure prominently in the pathophysiologic models of migraine and epilepsy. Reduction in brain magnesium or perturbations in neurotransmitter systems may provide a basis for these alterations in brain excitability. In theory, genetic or environmental factors could produce these alterations. Regardless of mechanisms, these findings are important for clinical practice.

Interrelationships between Headache and Epilepsy

Apart from the causal epidemiologic issues discussed above, there are many possible clinical interrelationships between headache and epilepsy (Table 4). The disorders may exist independently. Migraine may trigger epilepsy (migralepsy) or epilepsy may initiate headache. Seizure and headache seem to be associated in certain syndromes, such as benign occipital epilepsy of childhood with occipital paroxysms (BOEP). In addition, both disorders may have a common underlying cause such as head trauma, an arteriovenous malformation,[66] or neurofibromatosis.[21,85] Finally, migraine may be a predictor of poor outcome in persons with epilepsy. We will now consider some of these interrelationships.

Headache as a Consequence of Seizures

Although headache is commonly associated with seizures as a preictal, ictal, or postictal phenomenon, it is often neglected because of the dramatic neurologic manifestations of the seizure. Patients with migraine-triggered epilepsy seek medical attention because of seizures, which may overshadow the migraine and be overlooked by the patient and physician.

Preictal and Ictal Headache

Palmini and Gloor[80] presented a descriptive study of auras in partial seizures. Cephalic auras, defined by the symptoms of nonvertiginous dizziness, lightheadedness, or head pressure, occurred in 22 of 196 patients. In Blume and Young's epilepsy unit, 2.8% of 858 patients had brief ictal pain and 1.3% (11 patients) had headache. Only two patients described the pain as throbbing; the others described it as sharp or steady. Headache preceded the seizure in eight patients and accompanied the other ictal symptoms in three; all three of these patients had partial seizures, although the nature and location of EEG abnormalities varied considerably from patient to patient.

Isler et al.[47] found that hemicranial attacks of pain coincided with seizure activity and lasted for seconds to minutes (hemicrania epileptica). Two exceptions were noted: One a case of complex partial status in which the headache lasted for hours and another in which the headache lasted most of the 20 minutes of a recorded seizure. Overall, 20% of this group of drug-resistant epileptics had cephalic symptoms.

In a more recent study,[114] nearly half of patients undergoing continuous EEG monitoring for intractable epilepsy experienced peri-ictal headache, the majority being postictal. Interestingly, preictal headache lateralized to the side of seizure focus in 9 of 10 patients.

Headache can also be the sole or most predominant clinical manifestation of epileptic seizures, although this is a relatively rare situation.[54] Headache was noted to be a true ictal manifestation during intracranial monitoring, in two cases relieved by resective epilepsy surgery.[54]

Postictal Headache

In a telephone interview of 372 patients attending an epilepsy clinic, 45% had experienced postictal headache (PIH) and 21% always had PIH. Of those who always had PIH, headache was severe 39% of the time; in contrast, it was severe in only 10% of patients with occasional PIH. Twenty-seven percent of patients had independent headaches that were usually similar to their seizure-related headache. Headaches lasted <6 hours in 81% of patients, 12 to 24 hours in 11%, and >24 hours in 8%.[92] The headache was throbbing in over two thirds.

Schön and Blau[94] reported on 100 epileptic patients, 51 of whom had PIH either always (*n* = 35), usually (*n* = 5), or 25% to 50% of the time (*n* = 11). PIH was more commonly associated with generalized tonic–clonic seizures than with focal seizures; 9% of the patients with PIH also had independent migraine attacks. The headaches were either bilateral or unilateral. They were associated with photophobia and phonophobia, throbbing pain, vomiting, nausea, and visual aura, and lasted 6 to 72 hours. Epileptic migraineurs recognized these headaches as being similar to their migraine. Postictal headaches with migraine features respond to triptans.[49]

Ito et al. reported that 40% of 364 patients with partial epilepsies had PIH and that 26% had postictal migraine.

Migraine-like PIH was more likely in temporal and occipital lobe epilepsy and less likely in frontal lobe epilepsy.[48]

The mechanism of ictal and postictal headaches is uncertain. In recent years, the theory of migraine pathogenesis has focused on the trigeminovascular system; activation of this system gives rise to neurogenic inflammation of cranial blood vessels and pain.[70] In animal models, Moskowitz et al. have shown that seizures activate the trigeminovascular system, providing a potential mechanism for the associated headaches. This mechanism would account for the triptan response in postictal headache.[46] Velioglu et al. examined the effect of migraine on the prognosis of epilepsy in a prospective study of 59 patients with both disorders and a control group of 56 patients with epilepsy but not migraine. The group with migraine and epilepsy was less likely to become seizure free and more likely to have intractable seizures and medication problems than patients with epilepsy alone. Thus, comorbid migraine may be a predictor of poor outcome in epilepsy.[108]

In summary, preictal and ictal headaches are relatively rare and short lived. The seizure itself may limit the patient's ability to observe or recall the manifestations of these headaches. In contrast, PIH is common and can impact the quality of life of the person with epilepsy. It is most common with generalized tonic–clonic seizures, but is also common in complex partial seizures; it is less common with simple partial seizures.[92]

Migraine–epilepsy Syndromes

Benign Epilepsy of Childhood with Occipital Paroxysms

BEOP is a clinical syndrome characterized by a partial seizure with visual symptoms, followed by postictal migraine and occipital spikes on EEG. A rare disorder, it accounts for <5% of epilepsy in children (mean age of onset 7.5 years).[24,33,82] BEOP has features of both epilepsy and migraine.[33,35,105] The visual symptoms may include amaurosis, elementary visual hallucinations (phosphenes), complex visual hallucinations, or visual illusions, including micropsia, metamorphopsia, or palinopsia.[11,33,73] The visual symptoms are often followed by hemiclonic, complex partial, or secondarily generalized tonic–clonic seizures. Following the seizure, approximately 25% to 40% of the patients develop migraine-like headaches.[105]

The interictal EEG is characterized by normal background activity and distinct occipital discharges. The occipital spikes typically have a high voltage (200 to 300 μV), diphasic morphology, and a unilateral or bilateral occipital and posterior temporal distribution. The spikes disappear with eye opening and reappear 1 to 20 seconds after eye closure.

Gastaut reviewed the clinical and EEG features of 53 patients with BOEP. Only 55% had the “complete” syndrome of occipital spikes, ictal visual symptoms followed by a partial seizure, and postictal migraine. In patients with nocturnal seizures, motor symptoms predominated; in those with daytime seizures, visual symptoms were more common. Nocturnal seizures are more common in younger children and bear a good prognosis.[33,82] Seizures starting after 8 years of age are more likely to be frequent, diurnal, and persistent,[33,82] although overall, complete seizure control is achievable in about 60% of patients.

Occipital spikes are not specific for BOEP. They have been reported in people with migraine, and in children under 4 they may not be associated with epilepsy or any other defined disorders.[41,58,102] Occipital spikes can also be seen in other disorders, including myoclonic, absence, and photosensitive epilepsies, as well as celiac disease.[19,33]

Benign Rolandic Epilepsy

Benign rolandic epilepsy is characterized by unilateral somatosensory or motor seizures and centrotemporal spikes; both clinical and electrographic features can shift from side to side. Speech arrest, pooling of saliva, and (usually) preservation of consciousness are also typical, although secondary generalization may occur. Most patients respond well to anticonvulsant medication. In one series, 75% of patients were seizure free after 5 years.[10] The seizures almost invariably disappear by age 15. An association with migraine has been reported in some, but not all, studies.[15,16] Rossi et al.[89] found that migraine prevalence in male controls (11.1%) was much higher than one would expect in boys between the age of 6 and 15 years. Giroud et al.,[36] in a control study, found that epilepsy with rolandic paroxysms and migraine were associated. Migraine incidence was studied in four groups of patients: Patients with centrotemporal epilepsy, patients with absence epilepsy, patients with partial epilepsy, and nonepileptic patients with a history of cranial trauma. Migraine was present in 62% of the patients with centrotemporal epilepsy, 34% of the patients with absence epilepsy, 8% of the patients with partial epilepsy, and 6% of the patients with cranial trauma. These results suggest that centrotemporal epilepsy and, to a lesser degree, absence epilepsy are associated with migraine.[36] The association between benign rolandic epilepsy and migraine may be part of the comorbidity of migraine with all forms of epilepsy.[85]

Differential Diagnosis and Concomitant Diagnosis of Migraine and Epilepsy: Clinical and Electroencephalographic Features

The most important tool in differentiating between migraine without aura and epilepsy is the history.[82] Table 5 illustrates high levels of symptomatic overlap between migraine and epilepsy. Tables 6 and 7 present the features most useful in distinguishing them. In general, in comparison with epilepsy, attacks of migraine are more gradual in onset and of longer duration. Nausea and vomiting are more commonly associated with migraine, while prolonged confusion or lethargy after the attack favors epilepsy.

Table 5 Symptoms Common to Both Migraine and Epilepsy

Symptom	Migraine	Epilepsy
Systemic		
Vomiting	+	+/-
Nausea	+	+/-
Diarrhea	+/-	-
Headache	+	+/-
Visual disturbances		

Colored circles	-	+
Black and white lines	+	-
Blindness	+/-	+/-
Blurred vision	+	+
Visual triggering factors	+	+
Other neurologic		
Olfactory	+/-	+
Vertigo	+	+/-
Confusion	+/-	+
Loss of consciousness	+/-*	+
Impaired consciousness	+/-	+
Loss of memory	+/-	+
Postevent lethargy	+	+
Depersonalization	+/-	+
Paresthesias	+	+
Hemiparesis	+/-**	+
Hemisensory loss	+/-**	+
Aphasia	+/-**	+

*More complex.
**Hemiplegic migraine.

At times, differentiating migraine with aura from epilepsy can be difficult, particularly when motor manifestations such as tonic or clonic movements are absent. The characteristics of the aura may help[29]: The migraine aura is longer (5+ minutes) and the aura of epilepsy is brief (usually <1 minute).[5] In addition, the aura symptom profiles differ. Autonomic, psychic, or somatosensory features favor epileptic auras, while a mix of positive and negative visual features, such as a scintillating scotoma, favors migraine.[81]

Table 6 Prodrome and Aura in Migraine and Epilepsy

Symptom	Migraine	Epilepsy
Premonitory	Common	Often
Duration of aura	15–60 min	Brief, often <1 min
Automatisms	Unusual	Absent in aura, present in complex partial seizures
Gastrointestinal aura	Abdominal pain (rare); nausea (common)	"Butterflies"—rising epigastric sensation
Visual disturbances	Positive/negative	Complicated visual phenomenon
Paresthesias	Common (5–60 min)	Common (seconds to minutes)
Altered consciousness	Usually responsive	Responsive during aura, altered responsiveness during complex partial seizure
Olfactory	Very uncommon	More common
Aphasia	Common	Common
Déjàvu	Rare	Common

The characteristics of the visual features present in migraine and epilepsy bear further discussion. Colorless glittering scotomata are typical of migraine, as are black-and-white zigzag patterns that appear concentrically around the point of fixation, usually unilaterally. (These are also termed fortification spectra.) The phenomenon of a geometric pattern with expansion from the center to the periphery of the visual field (rarely in the reverse direction) and a simultaneous increase in size over a period of several minutes suggests CSD and migraine. The regular angular patterns in the photopsias that accompany migraine correspond to the cortical structures that generate them.[44,45,46] Photopsias in migraine may evolve into a scotoma or a temporary homonymous hemianopia. Resolution of the visual field

P.2740

defect typically occurs without any positive visual phenomena. Colors may be seen as well, or spots, circles, and beads with or without colors. When these occur, they are usually part of the scintillating scotoma or teichopsia and not a predominant independent feature of the migrainous visual hallucination.

In contrast, visual epileptic auras are predominantly multicolored, with a circular or spherical pattern, as opposed to the predominantly black-and-white zigzag pattern of migraine.[83] During a seizure, hallucinations that begin unilaterally may later encompass the whole visual field, and simple hallucinations may develop into complex forms. In contrast to migraine, epileptic visual auras last for only seconds (with the rare exception of persistent visual auras),[113] thus limiting the patient's opportunity to observe and describe the hallucinations. The auras are often associated with head or eye movement and alteration of consciousness. Formed visual hallucinations are rare in migraine; when present in epilepsy, this manifestation may localize the seizure onset to the temporal or temporo-occipital region.[14]

The sensory auras of migraine and epilepsy also differ. In migraine, the auras are paresthesias (pins and needles) that typically begin in the hand, move up the arm, skip the shoulder, and move into the face and tongue over a period of 10 to 15 minutes. They are often associated with a visual aura.[92] The sensory aura of epilepsy is typically briefer and is often described as burning, cramping, stinging, aching, electric, or throbbing.

Correctly diagnosing and separating epilepsy and migraine can be more difficult in children than in adults. Young children may give incomplete descriptions of their symptoms; features useful in diagnosing epilepsy or migraine in adults may be absent or difficult to elicit in children. Hemicranial pain and visual auras occur less often in children with migraine than in adults. In children, the first symptoms of migraine may not even be associated with headaches.[42] Children are also less likely to experience feelings of déjà vu or to have olfactory hallucinations as part of a simple partial seizure or temporal lobe epilepsy. Furthermore, the epilepsies most commonly mistaken for migraine are childhood syndromes, as discussed above.

While the EEG is extraordinarily useful in diagnosing epilepsy and differentiating subtypes, it is less valuable in diagnosing migraine. EEGs recorded during an attack of migraine with aura, unlike those recorded during a clinical seizure, are usually normal. Focal slowing sometimes occurs during migraine auras, although this is not a consistent finding. Previously recommended EEG markers of migraine, such as robust photic driving at high flash frequencies and slowing with hyperventilation, can be seen in children without a history of migraine and are not very specific.[37]

Table 7 Features of Epilepsy and Migraine

Clinical features	Migraine	Epilepsy
Consciousness	Usually clear	Usually clouded
Duration	Hours	Minutes
Family history	Often positive for migraine	Sometimes positive for epilepsy
Onset	Gradual	Sudden
Electroencephalogram	Nonspecific abnormalities	Spikes and sharp waves, ictal patterns

The incidence of epileptiform activity in patients with migraine appears to be higher than that of the general population. In a large multicenter study, the incidences of spikes and paroxysmal rhythmic events in 10-hour overnight EEGs of normal adult volunteers (*n* = 135) was 0.7%, as compared to 12.5% for subjects with a history of migraine and 13.3% for subjects with a family history of epilepsy.[86] However, this finding does

P. 2741

not contribute to the diagnosis of patients with migraine, and may in fact confuse the issue. Currently, the Quality Standards Subcommittee of the American Academy of Neurology has concluded that the EEG is not useful in the routine assessment of headache patients.[2] It does not identify headache subtypes or effectively screen for structural causes of headache. The EEG is useful if headache patients have symptoms that suggest a seizure disorder, such as atypical migrainous aura or episodic loss of consciousness. Assuming head-imaging capabilities are readily available, EEG is not recommended to exclude a structural cause for headache.[2,91]

There is, however, clearly a role for 24-hour closed-circuit television EEG recording; when differentiating migraine aura from epileptic aura is difficult on clinical grounds, these procedures can also facilitate the diagnosis of comorbid epilepsy and migraine as well as the migralepsy syndrome. Marks and Ehrenberg[29] studied patients with migralepsy using multiple 24-hour video EEG telemetry recordings. The entire migraine–epilepsy sequence of two patients was captured, showing changes during the clinical migraine aura that were atypical for electrographic epilepsy. During migraine aura, bursts of spike activity may resemble the ictal EEG during an epileptic seizure. In most reported cases, however, the EEG does not show the usual temporal evolution with progressive increases and declines in the frequency and amplitude of rhythmic, repetitive epileptiform activity typical of ictal EEGs in epilepsy. In addition, the EEG during migraine aura may show “waxing and waning” patterns, separated by completely normal EEG activity despite the persistence of clinical symptoms.

Manzoni et al.[65] and Terzano et al.[106,107] coined the term intercalated seizures to denote epileptic seizures occurring between the migrainous aura and the headache phase of migraine. They found that 16 of 450 patients with migraine (3.6%) also had seizures. The two conditions appeared to be coincidental in 4 of the 16 patients. In another five patients, the two types of attacks were quite distinct, but often an epileptic seizure was followed by a migraine attack and vice versa. The remaining seven patients had intercalated seizures. All had a family history of migraine and two also had relatives with epilepsy. All had visual seizures consisting of highly stylized contours of plain figures, or single or multicolored spots that often rotated. The seizures lasted for 1 to 2 minutes and came out of a scintillating scotoma, slowly developing in the visual field and evolving into unilateral or bilateral hemianopia. DeRomanis et al.[25,26] studied patients who had brief ictal visual hallucinations of “colored dots or discs” and interictal occipital paroxysms on EEG. EEG during a seizure showed that they had occipital epilepsy and not migraine with aura.[85]

Striking EEG patterns have been described in specific subtypes of migraine.[12] The brain regions most often involved in the published EEG samples in basilar-type migraine include the posterior temporal, parietal, and occipital regions. The posterior electrographic localization may not pertain to other forms of migraine.[71] Paroxysmal lateralized epileptiform discharges (PLEDs) or PLED-like activity has been associated with hemiplegic migraine, prolonged migraine aura, or incipient migrainous infarction. Those patients with PLED-like activity did not have any of the usual entities associated with PLEDs, such as stroke, brain abscess, glioblastoma, or viral encephalitis; their PLEDs usually resolved within 24 hours. Certain migralepsy patients had clinical seizures when PLEDs were present on their EEGs.[67]

Treatment Considerations

Because migraine and epilepsy are associated, clinicians should be sensitive to the issue of concomitant diagnoses. When diseases are comorbid, the principle of diagnostic parsimony does not apply. Individuals with one disorder are more likely, not less likely, to have the other. In the Epilepsy Family Study, only 44% of probands with epilepsy who were classified as having migraine on the basis of their self-reported symptoms reported physician-diagnosed migraine.[78] In the general population, 29% of men and 40% of women with migraine reported a medical diagnosis.[63] The proportion of probands reporting a physician's diagnosis of migraine was surprisingly low, given that all were already being treated for epilepsy.

Why is the comorbidity of migraine and epilepsy not recognized? Epilepsy may be viewed as a more serious disorder than migraine. As a result, the migrainous symptoms of patients with a diagnosis of epilepsy may have been overlooked or attributed to the seizure disorder. In addition, the diagnosis of atypical migraine symptoms can be quite difficult, and a number of epileptic and nonepileptic syndromes may mimic migraine. Some patients with epilepsy and migraine may not report their headaches because the headaches are being effectively treated with an antiepileptic drug without a diagnosis of migraine. Finally, the interview used in the Epilepsy Family Study may lead to overdiagnosing migraine in some patients.

When planning treatment strategies for epilepsy and migraine, the possibility of comorbid disease should be considered. Although tricyclic antidepressants and neuroleptic drugs are often used to treat migraine in patients with comorbid epilepsy, caution is advisable, as these medications may lower seizure thresholds. When selecting drugs for migraine prophylaxis, it is sometimes advantageous to treat comorbid conditions with a single agent; for example, when migraine and hypertension occur concomitantly, a beta-blocker or calcium channel blocker is commonly used.[97] In the same way, anticonvulsants with efficacy for both migraine and epilepsy (divalproex sodium and topiramate) should be considered in patients with both disorders.

Divalproex sodium is a Food and Drug Administration (FDA)-approved anticonvulsant for migraine prophylaxis. The efficacy of divalproex has been supported by recent open and double-blind, placebo-controlled studies.[50,68,96,104] The doses that are effective in migraine are generally lower than those used for epilepsy; 500 mg/day is often sufficient. Topiramate is a second FDA-approved anticonvulsant for migraine prophylaxis. In both open and small, placebo-controlled, double-blind trials, doses of 50 to 100 mg/day have been shown to be effective for migraine.[99] Other antiepileptic drugs that have been shown to be superior to placebo for migraine include gabapentin, levetiracetam, tiagabine, and zonisamide, but large-scale studies are needed. Lamotrigine may be effective for migraine aura, but not headache.

An advantage to the use of anticonvulsants as migraine prophylactic agents is that they can be administered to patients with depression, Raynaud disease, asthma, and diabetes, circumventing the contraindications to beta-blockers.[98]

In addition, the recognition of potentially similar mechanisms and response to therapy between the disorders has led to crossover of other treatment modalities. For example, the vagal nerve stimulator, an FDA-approved device for the add-on treatment of intractable partial epilepsy, is under investigation for migraine.[72] Similar efforts are likely to continue.

Summary and Conclusions

In summary, migraine and epilepsy are comorbid conditions, and the presence of one disorder increases the likelihood of the other. Because of its greater prevalence, migraine is very common in persons with epilepsy, while epilepsy is rare in migraineurs. The comorbidity of migraine and epilepsy presents both pitfalls and opportunities, and the diagnosis and treatment of each disorder must take into account the potential presence of the other.

Chapter 275

Cerebrovascular Disorders

Clinton B. Wright

Joan T. Moroney

Ralph L. Sacco

Introduction

The relationship between cerebrovascular disease and epilepsy has long been appreciated since Hughlings Jackson first reported partial seizures in the setting of acute stroke.[7] Indeed, cerebrovascular disease has been found to be the most common cause of secondary epilepsy. In a population-based study from Rochester, Minnesota, cerebrovascular disease accounted for 11% of cases.[37] This chapter will review the limited data on the epidemiology and treatment of poststroke seizures and epilepsy. Because the differentiation between cerebrovascular disorders and seizures is sometimes difficult, the chapter will also aim to make the clinical distinction between epileptic syndromes, transient ischemic attacks (TIAs), and other minor ischemic stroke syndromes. The nosology and natural history of TIAs, the more common TIA syndromes, and some less common clinical syndromes of TIAs and minor strokes that might be confused with paroxysmal epileptic syndromes will be discussed.

Epidemiology

Seizures can be a complication of an acute stroke. Traditionally, poststroke seizures have been divided into early and late based on presumed differences in pathophysiology.[41] Early seizures are thought to result from acute biochemical disturbances and may result in part from the damaging effects of the excitatory neurotransmitter glutamate in response to ischemia.[14,17,58] In contrast, late seizures are attributed to gliosis and cortical scarring with resulting selective neuronal loss and hyperexcitability of the surrounding tissue.[39,58] Some authors have argued that early seizures are not reliably related to the strokes themselves because of other concurrent metabolic problems.[38,57] The International League Against Epilepsy (ILAE) defines early poststroke seizures as those that occur before 1 week, but studies have used widely varying definitions, from under 24 hours up to 1 month after stroke.[46,49] Despite varying definitions of what constitutes an early poststroke seizure, several studies have found that the risk of epilepsy is significantly increased among those patients who have seizures within 2 weeks of the onset of a stroke.[71] Late poststroke seizures have also been associated with an increased risk of epilepsy.[10,15,48,71]

Data from five prospective studies have shown that the rate of epilepsy after ischemic stroke ranges from about 2% to 4%.[10,15,48,57,71] However, the reported incidence of epilepsy varies between studies with the definition. Using the ILAE definition of two or more unprovoked seizures more than 1 week after stroke, a study from Rochester, Minnesota, found an overall rate of poststroke epilepsy of 3.3%, and 66% of those that developed an initial late seizure after ischemic stroke went on to develop epilepsy by 4.5 years.[71] In a study from Norway, the overall incidence of poststroke epilepsy was 3.1%, while 11 of 28 subjects with poststroke seizures developed epilepsy (55%).[57]

Limited data are available regarding risk factors for poststroke seizures and more is known about those that occur early than late. Involvement of the cortex is the most well-recognized predictor of early seizure occurrence, having been found to be an independent risk factor in several prospective studies.[8,10,15,47,48,71] Stroke severity and infarct size have also been found to be independent risk factors.[10,48,57,65] Few studies have examined independent predictors of late poststroke seizures or epilepsy.[17] Early seizures appear to be a risk factor for late seizures and possibly epilepsy, and a few studies have found that infarct size, cortical involvement, and recurrent stroke have been independent predictors.[10,48,71] However, in a large prospective study from Norway, stroke severity was an independent risk factor for epilepsy while cortical location was not.[57] Thus, further data are needed to clarify the relative importance of these modifying factors.

Treatment

Treatment of poststroke seizures and epilepsy is complicated by a lack of clinical trial data to support the use of a particular antiepileptic drug on the one hand, and evidence that some commonly used drugs may be detrimental to stroke recovery on the other. For example, treatment with antihypertensive drugs that block the adrenergic system, such as prazosin and clonidine, or those that stimulate γ-aminobutyric acid (GABA) receptors, such as benzodiazepines, have been shown to impair recovery after brain injury in the rat, and the antiepileptic drugs phenytoin and phenobarbital have been implicated as well.[33] Less is known about the effect of these drugs on recovery in humans. One study examining the control group of an acute ischemic stroke treatment trial found that subjects administered any of a group of "detrimental drugs" including benzodiazepines, dopamine receptor antagonists, α-1 blockers, α-2 agonists, phenobarbital, or phenytoin had worse motor recovery and less independence in activities of daily living than those that did not receive any of these drugs.[33] Recovery after subarachnoid hemorrhage may also be impeded by such treatment. In a prospective case series, greater phenytoin exposure was associated with worse functional outcome at 14 days and worse cognitive outcome at 3 months.[60] However, treatment after experimental ischemia in rodents has shown that many antiepileptics may be neuroprotective if given very early.[17] For example, phenytoin when given 30 minutes after experimental occlusion of the rat middle cerebral artery was neuroprotective, but not if given after 2 hours.[22] Separately, diazepam given 30 and 90 minutes after induced forebrain ischemia in the gerbil resulted in protection of hippocampal neurons.[69] Neuroprotective properties have also been reported for lamotrigine,

P.2746

topiramate, levetiracetam, and zonisamide.[17] Thus, further data are needed to clarify the importance after stroke of the doses, timing, and length of treatment with antiepileptic drugs that may be helpful or harmful to patients.

Nosology of Transient Ischemic Attacks

The term *stroke* generally describes a group of vascular disorders diverse in etiology and includes ischemic brain infarction, intracerebral hemorrhage, and subarachnoid hemorrhage.[4] The term *transient ischemic attack* has been limited to the description of a brief episode of neurologic dysfunction resulting from ischemia and was introduced in 1957 by C. Miller Fisher. TIA is formally defined as "an abrupt onset of focal loss of brain function lasting less than 24 hours that localizes to a portion of the brain supplied by one vascular system and for which no other cause can be found."[2] The arbitrary 24-hour time limit was selected on the basis of prospective studies in the 1970s prior to the widespread use of brain imaging.[3] It was thought that focal deficits lasting beyond 24 hours would be expected to result from a focus of ischemic infarction. This definition now requires revision, based upon recent brain imaging evidence of infarction in a substantial proportion of episodes classified by the 24-hour time limit as TIAs.[11,24] The term *reversible ischemic neurologic deficit* (RIND) was created to define those patients with neurologic dysfunction lasting longer than 24 hours but resolving completely within 1 to 3 weeks.[4] Neurologic deficits in the minor ischemic stroke syndromes conversely persist beyond these arbitrary time periods. Ischemic stroke may be more appropriately viewed as a continuum that encompasses TIA, RIND, and minor ischemic stroke.[18] As similar risk factors and vascular pathologies underlie these diagnostic subgroups, their continued separate distinction from each other is employed primarily for the purposes of differential diagnosis and prognostic risk strati- fication.[23]

Prevalence and Incidence of Transient Ischemic Attacks

Differing methods and ambiguities of definition have resulted in a wide disparity in reported prevalence and incidence rates of TIAs.[13] Estimated prevalence has varied from 1.1 to 77 per 1,000 persons, but three recent studies have dealt more effectively with the ascertainment bias inherent in capturing transient episodes, and data have shown incidence rates that are more consistent. Population-based data from Rochester, Minnesota, for the period 1985 to 1989 led to a calculated annual age- and sex-adjusted incidence rate of 68 per 100,000 population.[13] The incidence rate was somewhat higher in the Greater Cincinnati/Northern Kentucky Stroke Study at 83 per 100,000, but 15% of the sample is of black race and may be at higher risk of cerebrovascular disease.[42] Similar rates were seen in the United Kingdom. In the Oxfordshire study the overall age- and sex-adjusted incidence rate for TIA was 51 per 100,000.[66] In addition, annual incidence rates for TIA appear to be reasonably stable over time, taking into account lower ascertainment in earlier studies. The incidence rate did not change appreciably in Rochester between the periods 1960 and 1972 and 1985 and 1989, although the rate increased slightly in Oxfordshire, U.K., between 1981 and 2004 (relative incidence 1.27).[13,66] The incidence of TIA was strongly related to age in all three studies.

Natural History of Transient Ischemic Attacks

Transient ischemic attacks precede 11% to 50% of strokes, depending on the specific stroke subtype.[3] They have been reported most frequently in association with large artery atherothrombotic disease and less commonly with small vessel disease.[30,59] Approximately 50% to 75% of patients who experience a stroke from extracranial carotid atheromatous disease have a prior TIA.[59] Perhaps the most important finding in recent studies has been the very high rate of stroke following TIA. Data from a large health maintenance organization in California found that roughly 10% of those presenting with TIA went on to have an ischemic stroke within 90 days and half of these occurred within the first 48 hours after the index event.[40] Similarly, data from the Greater Cincinnati/Northern Kentucky Stroke Study found a 17% ischemic stroke rate within 6 months after TIA, 65% of which occurred within the first month.[42] The results from the North American Symptomatic Carotid Endarterectomy Trial (NASCET) helped clarify the outcomes for TIA patients.[1] Patients with TIAs and symptomatic extracranial carotid stenosis exceeding 70% were followed prospectively over a period of 18 months. During this time period, 24% of the medically treated group had a stroke or died, compared with a 7% rate in the endarterectomy-treated group. This striking difference proved that surgery was effective in reducing the risk of stroke after TIA and that TIAs should be regarded as a marker of significantly increased stroke risk. Certain subgroups of TIAs carry a higher stroke risk than do others. Data from NASCET showed that hemispheric TIAs with known high-grade ipsilateral carotid stenosis had a stroke risk exceeding 40% over 2 years.[75] Early stroke risk is probably greater in those patients with “crescendo” TIAs (multiple and frequent) and in the subgroup with ventricular thrombi.[2]

Clinical discrimination between TIAs and nonvascular causes of transient neurologic dysfunction is crucial as the occurrence of a TIA is a reliable warning signal of an impending stroke. An episode consistent with a TIA should be rapidly evaluated to determine the cause. Prompt clinical recognition of TIAs and timely institution of appropriate therapy can help prevent stroke. Furthermore, the possibility of occult coronary artery pathology should be considered in the workup of these patients as the occurrence of TIAs may indicate generalized atherosclerosis; ischemic heart disease is the leading cause of death in elderly TIA patients.[2,25]

Diagnostic Difficulty

Less than one in ten TIAs are witnessed by a physician; therefore, accurate diagnosis usually depends on a careful interpretation of the patient's history.[26] Health care professionals tend to formulate a preliminary diagnosis within the first few minutes of history taking, which works well when the symptoms follow classic textbook descriptions.[68] However, many patients cannot offer a clear, concise account of abrupt onset of focal neurologic dysfunction, as required for the diagnosis of TIA. Details are often forgotten or unappreciated regarding time, mode of onset, and subsequent course of symptomatology. Historical reliability becomes more questionable when patients consult a physician weeks or months following the event. Nondominant hemispheric TIAs are particularly susceptible to misclassification because the event may be ignored or misinterpreted by the patient.[78] The lack of uniform diagnostic criteria for TIA is reflected in significant interobserver disagreement. The Cooperative Group for the study of TIA found that 30% of patients hospitalized with a diagnosis of TIA had been misclassified.[16]

P.2747

This finding has been confirmed in other series.[43] Questionnaires on TIA symptomatology have documented a high positive response rate, both in the elderly and in a group of young adults.[56,81] These surveys indicate that episodes of transient central nervous system dysfunction are common. Follow-up of those patients whose transient symptoms were considered too vague to represent TIA has revealed a stroke rate comparable to the TIA group, suggesting that current empiric criteria for TIA are too narrow.[82] Standardized checklists using nonmedical terminology and computer-based diagnostic algorithms offer useful alternatives to enhance diagnostic consistency.[44,63] There is a need for improved diagnostic guidelines for TIAs with enhanced reliability, sensitivity, and specificity.

Table 1 Frequency and Type of Symptoms[a] in Carotid Transient Ischemic Attacks

Frequency left carotid[b]		Frequency right carotid[c]	
67%	Sensorimotor (arm)	70%	Sensorimotor (arm)
56%	Weakness (face, arm, or leg)	50%	Weakness (face, arm, or leg)
45%	Aphasia	N/A	
44%	Sensory (arm)	53%	Sensory (arm)
21%	Dysarthria	24%	Dysarthria
20%	TMB	27%	TMB

N/A, not applicable; TMB, transient monocular blindness.

[b]n = 171.

[c]n = 142.

Data derived from Futty DE, Conneally M, Dyken ML, et al. Cooperative study of hospital frequency and character of transient ischemic attacks. V. Symptom analysis. *JAMA.* 1977;238(22):2386– 2390.

Typical Transient Ischemic Attack Symptoms

Traditionally, TIAs have been classified according to the vascular territory involved: Carotid or vertebrobasilar. This differentiation is important for management and prognosis.[55] Carotid territory TIAs occur more frequently and may result in the following: Weakness, paralysis, or clumsiness of one side of the body or face; numbness or paresthesias affecting one side of the face or body; loss of vision affecting one eye or, less frequently, one visual field; language disturbance (aphasia); and dysarthria.[4] Analysis of a large series of carotid TIAs has proved helpful in determining the relative frequencies of various symptoms typical of TIAs (Table 1).[31]

Mixed sensorimotor disturbances of the distal arm and hand were the most frequent carotid TIA symptoms, followed by motor weakness variably affecting the face, arm, or leg; aphasia with left carotid territory syndromes; and isolated sensory dysfunction of the arm. Transient monocular blindness (TMB) or amaurosis fugax and dysarthria were less frequent manifestations. Neurologic evaluations during the occurrence of TIAs confirmed the presence of motor or language disturbance. Sensory complaints were found to have less objective associated signs on examination, and reflex asymmetry or Babinski signs were found infrequently. Patients with visual field deficits were often unaware of their deficit, and the examiner found evidence for deficits in addition to the presenting symptom.

Table 2 Frequency and Type of Symptoms[a] in 97 Vertebrobasilar Transient Ischemic Attacks

60%	Ataxia (appendicular or gait)
43%	Vertigo
39%	Diplopia
37%	Blurry vision
27%	Dysarthria

[a]Only symptoms reported by at least 20% of patients are tabulated.
Data derived from Futty DE, Conneally M, Dyken ML, et al. Cooperative study of hospital frequency and character of transient ischemic attacks. V. Symptom analysis. *JAMA.* 1977;238(22):2386– 2390.

Table 3 Atypical Transient Ischemic Attack Syndromes That May Mimic Epileptic Activity

Syndrome	Vascular territory	Localization
Limb shaking	Carotid	Hemisphere
Asterixis	Vertebrobasilar	Diencephalon
Dyskinesia	Carotid Vertebrobasilar	Hemisphere Diencephalon
Pure sensory	Vertebrobasilar Carotid	Diencephalon Hemisphere
Speech arrest	Carotid	Hemisphere
Visual inversion	Vertebrobasilar	Brainstem

Auditory hallucinosis	Vertebrobasilar	Brainstem
Anosognosia	Carotid	Hemisphere
Akinetic mutism	Carotid	Hemisphere
Drop attacks	Vertebrobasilar	Brainstem

Vertebrobasilar TIAs may cause the following symptoms: Weakness, paralysis, or clumsiness with or without sensory deficit affecting the face or limbs; gait imbalance; vertigo; diplopia; dysarthria; or dysphagia.[4] Complaints may alternate from side to side, be bilateral from onset, or affect one side of the face and the opposite body (crossed syndromes). Symptom analysis from a large series of vertebrobasilar TIA patients is presented in Table 2.[31] Vertigo, diplopia, dysarthria, dysphagia, and disequilibrium occurring alone were considered less likely to be a TIA. Whether nonrotatory dizziness may have a vascular etiology remains unclear.

These large clinical series have demonstrated that motor symptoms accompany most TIAs, that typical TIA symptoms are "negative" (loss of function), and that dysarthria can result from either anterior or posterior circulation dysfunction. Symptoms considered unlikely to represent TIAs include loss of consciousness without other vertebrobasilar signs, tonic or clonic activity, light-headedness, syncope, incontinence, and focal symptomatology with migraine headache (e.g., "march" of a sensory deficit, scintillating scotomata). Less typical TIA symptoms that include positive clinical manifestations and can cause diagnostic confusion will be discussed further (Table 3).

Typical Time Course of Transient Ischemic Attacks

Eliciting historical information regarding the temporal course of the TIA symptoms is as important as the nature of the actual

symptoms in making an accurate diagnosis. There is now general acceptance that the arbitrarily defined time period of 24 hours for the definition of TIAs is too long.[55] Most TIAs are rapid in onset and extremely brief, with one series reporting that 24% resolved within 5 minutes, 39% within 15 minutes, and 50% within 30 minutes.[56] Only 40% of TIAs in this series lasted longer than 1 hour. The Cooperative Group for the study of TIAs found that carotid TIAs lasted, on average, 14 minutes, whereas vertebrobasilar events lasted approximately 8 minutes.[5] The prognosis of those patients with longer-lasting TIAs may differ from the subset with brief spells, with reports suggesting that longer-duration TIAs are more likely to exhibit ischemic infarction on more sensitive brain imaging.[11,24] The term *cerebral infarction with transient signs* (CITS) has been developed to describe this subgroup.[79]

Atypical Transient Ischemic Attack Presentations

Limb-shaking Carotid Transient Ischemic Attacks

It is generally assumed by physicians that motor TIAs cause limb weakness, whereas focal motor seizures produce convulsive limb movements; however, focal limb shaking resembling a partial motor seizure has been described in association with carotid occlusive disease. Fisher first recognized this unusual manifestation in his observations on carotid TIAs.[27] He noted that the patients described the involved limb as "trembling, shaking, twisting, drawing up, or moving irregularly." His observations have since been corroborated by several investigators.[9,36,84] Russell and Page reported one patient who had involuntary jerking movements affecting the left arm and leg in association with carotid occlusive disease.[66a] Yanagihara and Klass described six patients with involuntary limb jerking, all in association with high-grade stenosis or occlusion of the contralateral carotid artery.[84] They concluded that cerebral ischemia due to diminished cerebral perfusion was the underlying pathogenic mechanism. All of their patients benefited from cerebral revascularization, either carotid endarterectomy (CEA) or extracerebral-intracerebral (EC-IC) bypass grafting. Eight patients were described by Baquis et al. in whom involuntary repetitive movements affected the arm/hand alone or arm and leg opposite to a diseased carotid.[9] The movements had a coarse, wavering, nonrhythmic character with a frequency of 3 to 12 Hz, and seven of the patients had additionally experienced more typical carotid TIAs. In one of their patients, the episodic limb shaking was temporarily related to postural changes in the absence of documented orthostatic hypotension. Cerebral revascularization procedures performed in six of eight patients produced resolution or reduction in the episodic limb-shaking spells. The authors suggested that ischemia affecting the distal field of the atheromatous carotid artery and resulting in perfusion insufficiency was the pathogenic mechanism.

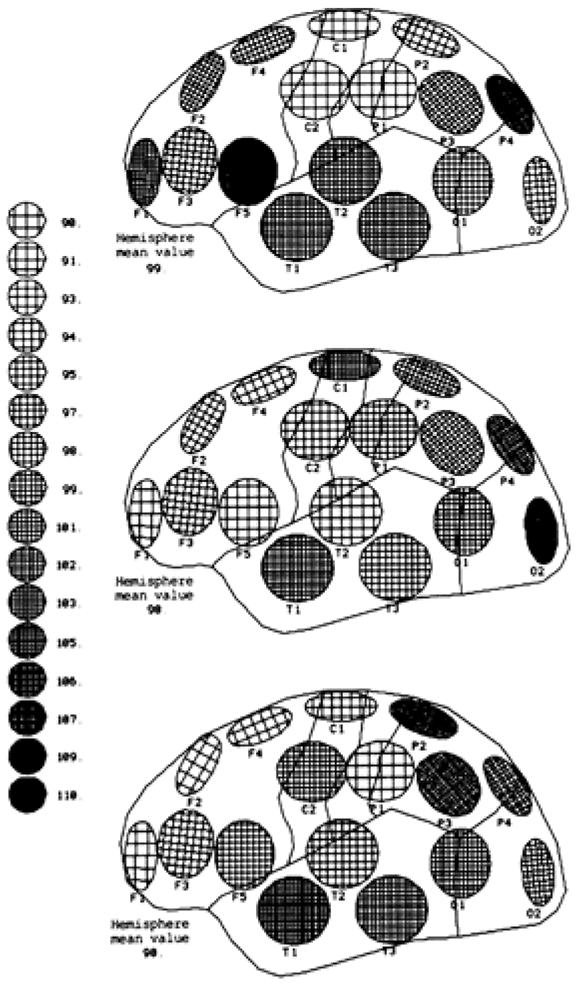

FIGURE 1. Map of cerebral blood flow asymmetry (right initial slope index ([ISI] ÷ left ISI × 100) before carotid endarterectomy under normocapnic (**upper**), hypercapnic (**middle**), and hypotensive (**lower**) conditions. Asymmetry is indicated by intensity of shading, quantified by scale (**left**), given as a percentage. Under normocapnic conditions, there was hypofrontality and reduced perfusion focally in right dorsofrontal and upper rolandic regions (detectors *C1, C2, P1,* and *P2*). With hypercapnia, more extensive zone in right dorsofrontal region was apparent, extending to superior and inferior frontal regions (detectors *F4, F2, F1, F3, F5,* and *T2*). During hypotension, blood flow deficit in right dorsofrontal and prerolandic regions (detectors *C1, P1, F4, F2, F1,* and *F3*) was further accentuated. (From Tatemichi TK, Young WL, Prohovnik I, et al. Perfusion insufficiency in limb-shaking transient ischemic attacks. *Stroke.* 1990;21(2):341–347.)

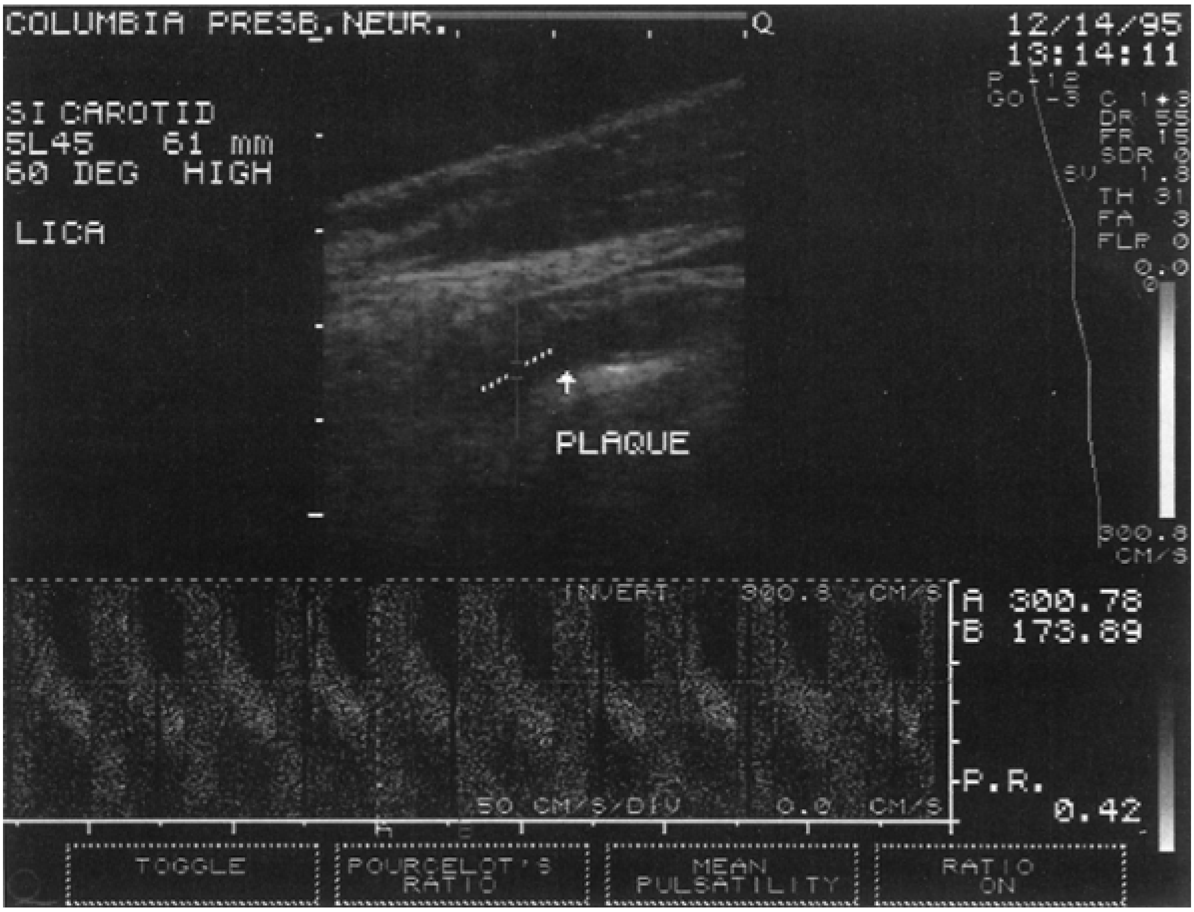

FIGURE 2. Duplex Doppler of the left internal carotid artery showing severe stenosis with plaque obstructing the lumen (*arrow,* **upper**). The Doppler wave form spectra confirm the hemodynamically significant stenosis (**lower**).

Subsequent investigators have confirmed the mechanism of perfusion insufficiency as the probable cause of focal limb shaking. Levine et al. studied cerebral blood flow (CBF) reactivity to induced hypercapnia using fluoromethane positron emission tomography (PET) scanning in 32 patients with carotid TIAs.[54] Reactivity was found to be significantly diminished in a hemodynamic subset of eight patients whose clinical manifestations included orthostatic limb shaking. Tatemichi et al. reported on a patient whose limb-shaking episodes occurred repeatedly on standing up. Cerebral blood flow was measured using inhaled Xenon-133, and a focal decrease was observed in the right frontal convexity, representing the distal fields between the anterior cerebral artery and the middle cerebral artery.[77] Impaired reactivity was demonstrated in response to hypercapnic challenge using CBF and transcranial Doppler (TCD). A circumscribed loss of cerebral autoregulation was also demonstrated in the same patient, with exacerbation of the perfusion deficit in the right frontal region during hypotension (Fig. 1). The abnormal CBF response to both hypercapnia and hypotension was felt to reflect maximum vasodilation in the distal fields or watershed territory of the involved hemisphere with poor hemodynamic reserve.

These cases illustrate that limb shaking as the first manifestation of a carotid TIA correlates with hemodynamically significant carotid artery disease, with perfusion failure being the most likely mechanism. The patients typically have risk factors for cerebrovascular disease, and the spells are often triggered by postural change or exertion. The movements tend to be coarse and irregular, lasting minutes, and occurring from once a week to several times a day. Other neurologic deficits

P.2749

rarely occur during the spells, and the interepisode examination is usually normal. A seizure mechanism is not supported in these patients, based on the following observations: No associated clinical seizure phenomena (e.g., impairment of consciousness, rhythmic tonic–clonic jerking, head or eye deviation); no epileptiform activity recorded on electroencephalograms (EEGs) between and during such attacks; a lack of response to trials of antiepileptic medication when such a mechanism was entertained; and, finally, the prompt and favorable response to cerebral revascularization. It remains unclear how ischemia produces the positive motor symptoms, with release of subcortical motor pathways proposed as a possible explanation. Failure to recognize that focal limb shaking can occur secondary to ischemia could lead to delay in diagnosis of the associated severe carotid atheromatous disease (Fig. 2).

The converse situation, where focal seizure activity may cause limb weakness and be misdiagnosed as a TIA, has also been described.[53,64] Fisher referred to this situation as "nonconvulsive seizure paralysis," and noted that it may give rise to diagnostic confusion.[29] Lee and Lerner reported on a 70-year-old diabetic man who presented with recurrent episodes of short-lived right arm weakness and numbness.[53] These spells lasted from 3 to 5 minutes and occurred without warning or other obvious precipitating factors. The patient also noted some speech difficulty during these spells. Neurologic evaluation at the time of admission revealed only a mild right pronator drift, and a computed tomography (CT) scan of the brain was normal. An initial diagnosis of crescendo left carotid TIAs was made, and the patient was anticoagulated with intravenous heparin. Despite therapeutic heparin, the patient continued to have spells at a frequency of three or four hourly. During a typical attack, the patient was noted to first complain of vague right arm discomfort, followed by right arm paralysis; he was described as alert throughout the episode, but with mild word-finding difficulty. An EEG obtained during one such episode demonstrated intermixed spike-and-sharp-wave activity in the left parietal region, which resolved after return of motor function to the affected arm. The presence of these EEG abnormalities was confirmed during subsequent spells. The patient was treated with phe- nytoin, and the spells decreased in frequency and resolved completely over several days. The authors proposed that a seizure discharge involving the motor region of the left parietal lobe was responsible for the limb paralysis in their patient.

Primavera et al. described a 56-year-old woman with multiple vascular risk factors who presented with recurrent bouts of weakness affecting the right face and arm.[64] Neurologic examination disclosed a right pronator drift, and a CT scan showed multiple old lacunar infarcts. Anticoagulation was begun for a presumptive diagnosis of carotid TIAs, but the intermittent attacks of limb weakness continued. An EEG obtained during a typical attack revealed intermittent high-amplitude slow-wave activity of 2 to 3 Hz intermixed with spikes and sharp waves in the left frontotemporal regions. The attacks decreased in frequency and eventually ceased after treatment with phenobarbital.

These case reports emphasize that the differential diagnosis between TIA and seizure is not always straightforward, even in the presence of vascular risk factors and established ischemic

P.2750

cerebrovascular disease. High-grade carotid stenosis may produce limb shaking, mimicking a focal motor seizure, whereas somatic inhibitory seizures can result in motor weakness, simulating an ischemic TIA.

Unilateral Asterixis

Asterixis is the sudden failure in maintenance of posture, characterized by transient electrical silence in muscles activated to maintain the posture.[80] Clinically it is manifested by asynchronous jerky or flapping movements of the outstretched hands. It was first described by Adams and Foley in a group of patients with hepatic encephalopathy.[6] However, unilateral intermittent asterixis may occur in association with focal cerebral ischemia and be confused with partial motor epilepsy.

Lazzarino and Nicolai described a 56-year-old man who presented 5 months after a left posterior cerebral artery stroke with sudden onset of involuntary movements of the right hand:

> The right hand, when outstretched, showed a movement characterized by sudden flexion of the wrist with loss of position, followed by its sudden restoration. This movement was repeated intermittently at regular intervals, but brief periods of sustained posture between the flaps were present. Active movements abolished these involuntary movements.[52]

Another report described the onset of unilateral asterixis in a 73-year-old man during his recovery from a right ventral thalamic infarct, where the unusual nature of the movements led to a misdiagnosis of epilepsia partialis continua:

> In the left arm, involuntary semi-rhythmic abduction and flexion movements of the fingers and flexion of the wrist were present regardless of the posture of the limb. In contrast, with the left wrist held in extension and the arms pronated, rhythmic loss of posture resulted in wrist flexion movements typical of those seen in asterixis.[74]

The precise mechanism for the asterixis due to ischemia remains uncertain, but it is thought to be related to lapses of sustained muscular contraction secondary to episodic disturbances in the responsible neuronal circuits.[80] The movements may appear at rest, but gravity is the most effective stimulus to elicit asterixis. Failure to consider ischemia as a diagnostic possibility in the evaluation of episodic unilateral involuntary movements may result in the unwarranted administration of anticonvulsant medication.

Episodic Dyskinesia

Acute hemiballism or choreoathetosis is known to occur from infarcts of the subthalamic nucleus of Luys, striatal and thalamic nuclei.[55] The involuntary movements are usually of sudden onset, without accompanying deficits. The following case report serves to illustrate the clinical presentation:

> An 81-year-old, right-handed woman suddenly developed involuntary movements of the left limbs…. On neurologic examination, she showed choreic and ballistic movements of the left limbs. There was almost constant, small-amplitude, proximal and distal choreic movements, with superimposed brisk, large-amplitude proximal movements, primarily related to action. Magnetic resonance imaging (MRI) revealed a small area of hypointense T1 signal in the right thalamus.[45]

Episodic dyskinesias, while less frequently reported, have been described in association with both vertebrobasilar and carotid occlusive disease. Margolin and Marsden reported on four patients with episodic abnormal involuntary movements affecting the limbs opposite to carotid atheromatous disease.[58a] The clinical spectrum included both choreoathetoid and ballistic involuntary movements, lasting from minutes to 1 hour. The patients used the terms *writhing, wild gyrations*, and *snakelike* to describe the involuntary movements. Cerebral revascularization with carotid endarterectomy resulted in resolution of the movements. Stark described recurrent brief attacks of snakelike movements affecting the left arm in a 53-year-old woman with high-grade stenosis of the right internal carotid artery that responded to endarterectomy:

> She had three attacks within 1 month; each was characterized as sudden inability to "control my left arm." When she was asked to demonstrate the attacks, she raised her left arm and made snakelike movements, proximally and distally, characteristic of choreoathetosis.[72]

Unilateral dyskinetic movements may be mistaken for convulsive phenomena unless a vascular etiology is given careful consideration. Witnessed accounts of such episodic involuntary movements may not be available, and if the nondominant hemisphere is involved, the patient may ignore or trivialize the episode. The presence of vascular risk factors and evidence for infarction on brain imaging should be specifically sought. Both the carotid and vertebrobasilar circulation have been implicated in previous reports, and ultrasound examination using duplex Doppler may reveal abnormalities.

Pure Sensory Spells

Sensory disturbances affecting part or all of the contralateral body are frequent manifestations of hemispheric TIAs. Although TIAs are usually considered to result from large-artery atherothrombotic disease, they may also occur from small penetrating vessel disease. Awareness of these so-called lacunar TIAs is critical to any discussion of pure sensory phenomena. The Stroke Data Bank (SDB) found that lacunar syndromes had a preceding TIA in 13% of the cases versus 40% for large-artery syndromes.[30] Thus, both large- and small-vessel pathology need to be considered in the differential of focal sensory complaints. Isolated fleeting sensory dysfunction can also be the result of a partial seizure syndrome, and it is a diagnostic challenge to separate an ischemic from an ictal mechanism.

Pure sensory symptoms involving the arm occurred in approximately 50% of the cases from a large series of carotid TIAs.[31] The distal arm and hand were the sites most frequently affected in the attacks, with the sensory deficit thought to result from ischemia of the sensory cortex in the distal field of the diseased carotid territory. To confidently attribute pure sensory disturbances in the individual patient to a hemispheric TIA, a search using duplex and transcranial Doppler to find an appropriate carotid lesion should be performed. Failure to document hemodynamically significant stenosis of the extracranial carotid artery or its intracranial branches suggests that large-vessel stenosis is less likely to account for the sensory spells.[55]

Pure sensory stroke (PSS) is a well-recognized vascular syndrome resulting from lacunar infarction of the ventral tier thalamic nuclei. Fisher's case 9 in his original collection of PSS cases was characterized by transient attacks of sensory disturbance affecting the fingers of the right hand; the right side of the lips along with the right side of the tongue were affected, in addition to the fingers, during subsequent spells. At autopsy, a lacune in the ventral posterior thalamic nucleus, measuring 7 mm in diameter, was found. Another case in his collection had intermittent sensory spells affecting the left lower lip, fingers of the left hand, and sole of the left foot. Other patterns of sensory involvement described in PSS cases by Fisher were as follows: Face, arm, and leg; head, cheek, lips, and hand; face,

P.2751

fingers, and foot; shoulder tip and lower jaw; distal forearm alone; fingers alone; and leg alone.[28]

The peculiar nature of sensory complaints in thalamic ischemia may lead the unsuspecting to fail to consider a vascular etiology. The patients may describe the affected body part as feeling stretched, hot, swollen, sunburnt, larger, smaller, or heavier. Eyeglasses, jewelry, and clothing may feel heavier on the affected part, and contact may transiently exacerbate the dysesthetic sensations. Thalamic-origin TIAs can give rise to either a sensory disturbance restricted to a few digits or an extensive abnormality splitting the entire body, including the scalp, neck, trunk, and genitalia.[55] It may not be readily appreciated that such midline splitting can be produced by an ischemic mechanism unless the unique somatosensory organization of the thalamus and the thalamocortical connections is considered in the approach to differential diagnosis.

Speech Arrest

Isolated episodes of language disturbance due to left carotid TIAs must be distinguished from those secondary to seizure activity. Cascino et al. described three patients in whom transient episodes of speech arrest were initially attributed to TIAs, but in which subsequent EEG recordings demonstrated bifrontal seizure activity.[20]

Case 1 was a 66-year-old woman with end-stage renal disease admitted for shunt placement. During her hospitalization, she experienced spells in which she would abruptly stop talking and stare aimlessly. She remained alert throughout the episodes and followed verbal commands.

Case 2 was a 72-year-old hypertensive male admitted with a diagnosis of TIAs. Multiple spells lasting minutes were observed, during which he said he could understand speech but “could not get the words out.”

The final case they described involved an 87-year-old man on long-term warfarin therapy for an artificial heart valve admitted with abdominal complaints. He was noted to experience several spells of “expressive aphasia,” where he could not speak but would follow commands. In all of the cases, the episodes resolved following treatment with anticonvulsants.

Peled et al. provide a further insightful case description of a 65-year-old man with multiple stroke risk factors (smoking, diabetes, hypercholesterolemia) evaluated for transient episodes of sudden inability to talk.[62] These spells lasted from 2 to 5 minutes and occurred up to four times daily. Clinical observation of the spells during the patient's period of hospitalization was remarkable for sudden onset of mutism with preserved comprehension and absence of any forced head, gaze deviation, or focal motor activity. EEG obtained between the episodes proved normal, and a seizure diagnosis was not entertained until the patient was noted to raise his right hand and turn his head to the right during one of his characteristic spells. Closer observation revealed involuntary gaze deviation and clonic motor activity affecting the right face and limbs during some of his spells. Brain imaging demonstrated a probable metastatic lesion in the medial dominant frontal lobe corresponding to supplementary motor area (SMA). Treatment with phenytoin was begun, and the spells resolved.

This case material helps to emphasize that although cerebral ischemia commonly underlies the sudden onset of language disturbances in the elderly, infrequently seizures may be the cause.

Penfield and Roberts have reported that electrical stimulation of the SMA region anterior to the leg representation can produce speech arrest in humans.[63] Proposed pathogenetic mechanisms include interference with the motor pathway subserving vocalization or a true ictal "aphasic" speech arrest from a primary language disorder. Certainly, when dominant SMA lesions produce this latter type of aphasic speech arrest without accompanying eye–head deviation or tonic posturing, the epileptic nature of the spells may be missed, and an incorrect diagnosis of dominant carotid territory TIA may result. Such a misdiagnosis may lead to inappropriate investigations and a decision to commence long-term anticoagulation, with its attendant risks.

Visual Inversion

Momentary vertical inversion of images has been described in Wallenberg syndrome and vertebrobasilar TIAs and can sometimes be confused with the visual phenomena of seizures.[67,73] Patients present with the unusual complaint of acute "upside-down" vision, their world appearing 180 degrees reversed. The entire visual field is affected, with color and shape perception generally preserved, which helps distinguish it from the visual phenomena (e.g., macro- or micropsia, visual hallucinations) that can be associated with temporal or occipital lobe epilepsy. The following case report of an 83-year-old man serves to illustrate the features of this novel visual illusion:

> He was awakened by severe nausea and vertigo. When he switched on the light next to his bed… the telephone and bedside table appeared 180 degrees reversed, hanging down from the ceiling. This visual experience lasted only a few minutes. Neurologic exam 5 hours later was normal. The inversion of vision recurred several hours later and the patient again graphically described the experience: people surrounding his bed appeared inverted, with their legs up and heads down, the floor became the ceiling.[73]

This unique visual symptomatology may occur in isolation or be accompanied by nausea, vertigo, gait instability, and examination findings (Horner syndrome, limb ataxia, hemihypalgesia) consistent with lateral medullary infarction (Fig. 3).[67] The 180-degree reversal of vision has been attributed to transient ischemia of central vestibulo-ocular integrative control mechanisms, particularly dysfunction of vestibular inflow, which may disturb visual space orientation and result in aberrant egocentric orientation.[73] Such visual field complaints occur infrequently with vertebrobasilar ischemia but, when present, should alert the physician to the possibility of brainstem ischemia.

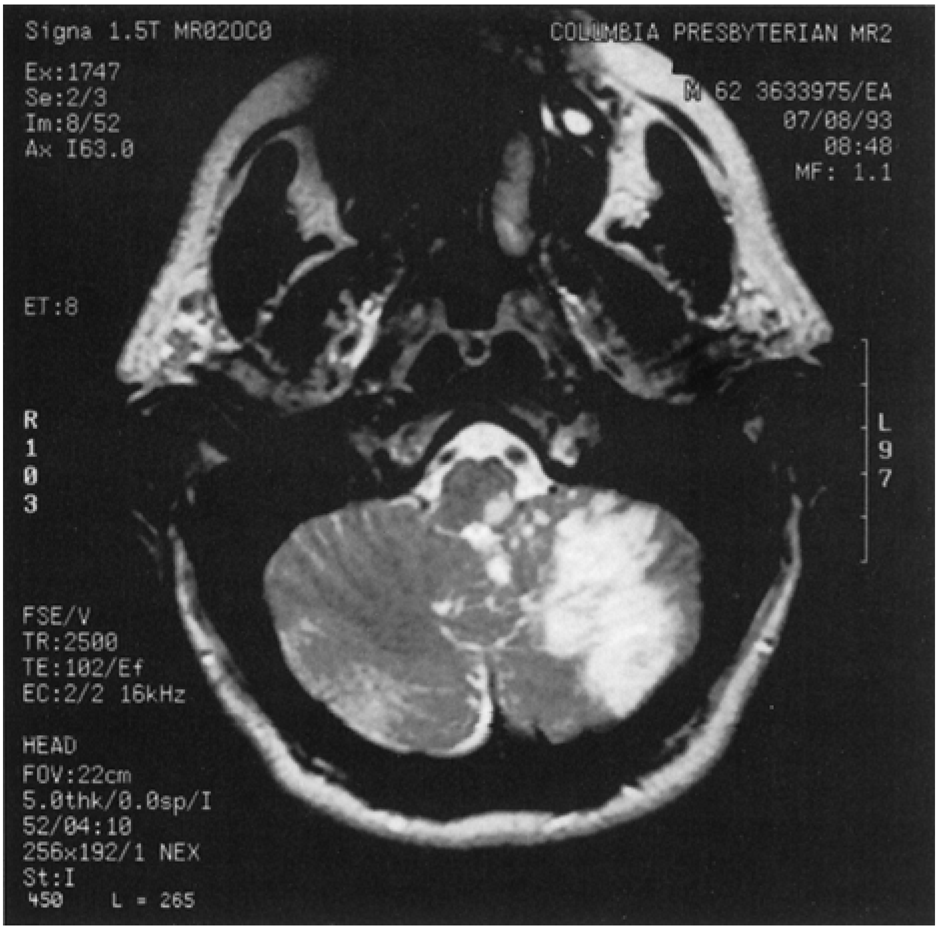

FIGURE 3. Axial (1.5-T) T2-weighted magnetic resonance image in a patient with lateral medullary syndrome showing infarction of the left inferior cerebellar hemisphere and the left lateral medulla.

Brainstem Auditory Hallucinosis

Intermittent auditory hallucinations, which can raise the suspicion of epileptic activity, have been reported in patients with radiologic evidence of vascular lesions affecting the pontine tegmentum.[19,50] The phenomenon is illustrated by the following case description:

> A 55-year-old hypertensive man… complained of hearing low-pitched musical sounds in both ears. The sounds were localized externally but were not associated with any auditory stimuli. He recognized these sounds as abnormal. Examination demonstrated a left Horner's syndrome, nystagmus, and long tract signs. Over the following several days… the auditory hallucinations became like people talking and later like the sound of rain falling on a roof.[50]

There was no alteration in consciousness or other positive motor or sensory phenomena, and an EEG had mild slowing but no epileptiform activity. Audiometry found moderate bilateral sensorineural hearing loss with poor speech discrimination affecting the left ear. Magnetic resonance imaging of the brain demonstrated a left caudal pontine tegmental hemorrhage involving the superior olivary nucleus, the trapezoid body, and the dorsal and intermediate acoustic striae. The

P.2752

authors postulated a "release" mechanism for the hallucinations from hearing loss caused by dysfunction of the central auditory pathways.[50] Although rare, the occurrence of auditory hallucinosis, accompanied by other brainstem findings, should prompt an investigation for a vascular etiology.

Auditory Aprosodia

Episodic loss of pitch perception is another auditory aberration that could be attributed to epileptic phenomena and has been described in right hemisphere cerebral ischemia. The following case illustrates the syndrome:

> A 52-year-old man was well until he experienced the first of two episodes of transient loss of pitch perception. The patient was at a party when he noticed that all of the voices that he heard sounded as if they were spoken in a monotone. He recalled no confusion at that time, nor did he recall experiencing any difficulty comprehending the content of what was said. This episode reportedly lasted less than 20 minutes, and was regarded as a curiosity by the patient. Several days later, a second 20-minute episode occurred while the patient was at home in his kitchen…. The patient noted that the music on the radio lost its melodic quality, sounding flat and monotonous. The patient indicated that the loudness and rhythm sounded normal…. Approximately two weeks after… the patient suffered transient spells of left facial droop, slurred speech, and left-sided weakness. Finally, he experienced the sudden onset of left hemiparesis, and a left hemianopsia. CT scan revealed a right middle cerebral artery territory infarct and angiography revealed a total occlusion at the origin of the right internal carotid artery.[70]

These recurrent spells, during which the patient was unable to perceive normal variations in pitch of conversation and music, were thought to represent transient ischemia affecting the auditory cortex of the nondominant hemisphere.

Transient Anosognosia

Transient anosognosia or failure to appreciate neurologic deficits, which may be confused with postictal behavioral disturbances, have been reported in six patients in association with transitory hemiparesis, paresthesias, and visual field cuts.[34] This unusual behavioral syndrome is illustrated by the following case description:

> A 68-year-old man came out of his room unaware of being improperly dressed with his buttons and belt undone, and his shirt-tail hanging out. He nevertheless declared himself ready to attend a planned choir practice at church. Upon inquiry, he denied being sloppily dressed despite confrontation before a mirror. Intrigued at first, his wife became alarmed after noticing, a few minutes later, an obvious dysarthria and left-sided weakness. Pointing out these deficits to him met with emphatic denial once more. Upon arrival at the hospital he had completely recovered from this initial one-hour episode. An identical 30-minute episode was later witnessed the same evening in our Emergency Room. A head computed tomography (CT) scan was normal. Angiography revealed bilateral internal carotid fibromuscular dysplasia. He remained asymptomatic under anticoagulants, and was discharged 7 days after admission.[34]

The authors concluded that a nondominant hemispheric syndrome from carotid occlusive disease accounted for the change in behavior observed in their patient. Although behavior disturbance can be seen with epileptic phenomena, a vascular etiology should be strongly considered in patients who present with abrupt changes in behavior or personality.

P.2753

Akinetic Mutism

Akinetic mutism describes patients who appear awake and alert, yet remain mute and motionless, despite intact motor and sensory pathways.[7] This behavioral syndrome may resemble nonconvulsive or absence status, but the differential also includes a vascular etiology.

The disturbance has been described with bilateral frontal lobe lesions and has been attributed to an impaired psychic drive (abulia). Gugliotta et al. described a patient who experienced abrupt onset of akinetic mutism in association with spontaneous bilateral anterior cerebral artery (ACA) occlusion:

> A 65-year-old male had been suffering from sudden mild headache, followed by gait difficulty and limb paresthesia. The day of admission he was found unconscious in bed, with eyes open and rotated upward; he was unable to speak or follow commands. On admission the patient had an alert appearance but was unresponsive to any auditory or visual command. His eyes were open and moved spontaneously as though he was looking around the room, without however following a moving object or person. CT scan of the brain revealed the presence of low density foci, which were localized in the mesial frontal region bilaterally.[35]

Unilateral ACA territory infarction can also present with severe apathy, abulia, and mutism or acute confusional states, and must be considered when the clinical presentation involves transient confusion or stuporous states.[12]

Drop Attacks

Typical drop attacks are characterized by a sudden falling spell that occurs without warning and without loss of consciousness. Drop attacks must be distinguished from akinetic seizures.[7] The patient suddenly falls to the ground while walking or standing and is usually able to get up immediately. The falling spells may recur over a period of years, EEGs obtained are usually normal, and an identifiable mechanism is difficult to find. Such attacks in isolation are not considered typical vertebrobasilar TIAs; however, when associated with other symptomatology, they may suggest brainstem ischemia. The following case illustrates an example:

> A married woman of 52 had a drop attack; she suddenly fell to the ground, hit her face, picking herself up immediately and saying she was all right. There was no loss of consciousness, no warning and no sequels. Since that time there have been repeated attacks of vertigo, some of intense severity, with ataxia. These are associated with occipital headaches, and pains in the neck, which may last up to half an hour. There are intermittent sensory disturbances unrelated to these attacks of vertigo, of a cold sensation and pins and needles over the scalp and upper neck on either side independently. There are also episodes of dysaesthesiae in either arm independently or together.[83]

Carotid occlusive disease may rarely result in spells of transient paraparesis simulating drop attacks. Ho et al. reported a patient with recurrent episodes of transient paraparesis in the setting of a high-grade right internal carotid stenosis and a hypoplastic A1 segment of the left anterior cerebral artery.[51] This vascular anatomy meant that both anterior cerebral artery territories subserving motor control of both legs suffered ischemia from perfusion failure due to the right-sided carotid occlusive disease. In another case reported by the author, a bihemispheric anterior cerebral artery above a left carotid stenosis of 90% led to drop attacks. Shaking of the right arm on reaching for objects provided a clue to the perfusion failure in this case.[32] The spells in both these patients were abolished by revascularization with carotid endarterectomy.

Moyamoya Disease

Moyamoya disease is characterized by chronic progressive multiple stenoses or occlusions of the intracranial arteries of the carotid system.[78] The angiographic hallmark of the condition is the presence of abnormal anastomotic vessels at the base of the brain. It is a form of cerebrovascular disease that predominantly affects children and young adults, where its clinical manifestations may be mistaken for paroxysmal epileptic events. Accurate diagnosis of intermittent spells in this population is hindered by the observation that moyamoya disease may also present with seizures.

The Cooperative Group for the study of moyamoya disease in Japan has described the clinical features of the disease in children and adults. Among 155 children (<15 years), TIAs (39%) and strokes (39%) were the most common presentations, followed by seizures (14%) and hemorrhage (7%).[61] Conversely, the clinical presentation in adults (<15 years) was dominated by hemorrhage (65%), with TIAs (6%) and seizures (6%) occurring less commonly. The recurring ischemic attacks seen in children have certain characteristic features. Hemiplegia and monoplegia are common manifestations at the onset, though sensory, speech, or visual disturbances may also occur. The attacks are typically triggered by crying, coughing, or straining—circumstances that may not immediately suggest an ischemic basis to those unfamiliar with this condition. The hyperventilation associated with these activities results in CBF reductions that are sufficient to induce cerebral ischemia. This observation is consistent with the theory that marginal hemodynamic reserve and perfusion failure affecting the watershed or distal field territory is the underlying mechanism for the ischemic attacks.[76]

Summary and Conclusions

TIAs are a powerful marker of increased stroke risk, myocardial infarction, and death. Accurate clinical identification of TIAs depends on recognizing typical, as well as less typical, symptoms and an awareness of mimicking conditions. A reliable history may prove difficult to obtain because the episodes are usually unwitnessed and tend to be brief and frightening, and nondominant hemisphere ischemic attacks may be ignored by the patient. The neurologic examination is generally not helpful, as it is often normal by the time the physician has the opportunity to assess the patient. The proven value of antiplatelet therapy and carotid endarterectomy and the rapid proliferation of hyperacute stroke protocols emphasize the need for the rapid detection of TIAs. The diagnostic evaluation in the individual patient needs to consider that small-vessel disease may also produce ischemic attacks, in addition to the more accepted large-artery atherothrombotic mechanism. The currently accepted definition of TIA regarding time course and the assumption of no persistent cerebral injury have been proven incorrect and will require revision.

The differential diagnosis of patients presenting with focal neurologic disturbances is broad and includes TIAs, seizures, migraine, syncope, and brain tumors. Each requires specific diagnosis and management. Wider use of event detection questionnaires that have been validated in epidemiologic studies is an attractive option that may improve interobserver reliability in the diagnosis of TIAs. Data from large TIA series have helped to identify particular symptoms that are not typical of ischemic attacks, such as isolated dizziness, unconsciousness or drop attacks without accompanying vertebrobasilar symptoms, scintillating scotomata, and "march" of symptoms over body parts. The occurrence of these symptoms should encourage physicians to consider alternative diagnoses. Atypical TIA symptoms such as limb shaking, other adventitious

movements, visual phenomena, and behavioral change pose a particular dilemma for the physician faced with discriminating TIA from epileptic phenomena. Physician and public awareness that these less frequent clinical features may have an ischemic etiology should enhance diagnostic accuracy and improve selection of the proper therapy.

Chapter 276

Sleep Disorders

Mark W. Mahowald

Carlos H. Schenck

Introduction

Since sleep and epilepsy are common bedfellows, it stands to reason that sleep disorders may mimic, cause, or even be triggered by epileptic phenomena, and vice versa. It is known that, in some individuals, sleep promotes seizures, as does sleep deprivation.[25,86] Conversely, seizure disorders can affect the wake–sleep cycle.[114] As discussed in Chapter 188, in most cases, epilepsy is highly state-dependent: Non–rapid eye movement (NRM) sleep promotes seizures, while rapid eye movement (REM) sleep is a relatively antiepileptic state.[132,134] This fact reflects the dramatic reorganization of the entire central nervous system (CNS) as it moves across the three states of being: Wakefulness, NREM sleep, and REM sleep.

There are certain predisposing factors in NREM sleep that facilitate epileptic discharges. There may be a relationship between sleep spindles and spike-and-wave bursts in human epilepsy.[57] There may also be a relationship between the cyclic alternating pattern (CAP) of "fluctuating cortical excitability" with both sleep-related epilepsy and a number of other sleep disorders.[136,145]

In simpler times, it was felt that sleep was a unitary phenomenon—the passive absence of wakefulness. In the first half of this century, it was discovered that sleep was an active state. Then, in 1953, it was discovered that sleep was actually composed of two completely different states of being: NREM and REM sleep. We, as humans, as most mammals, spend our lives in three completely different states of being: Wakefulness, REM sleep, and NREM sleep. Each of these states has its unique neuroanatomic, neurophysiologic, neurochemical, and neuropharmacologic correlates and substrates.[55,135] It took centuries to determine that sleep is actually a bimodal process because (a) superficially and from a distance, REM and NREM sleep look similar, and (b) these two states cycle back to back, giving the illusion of homogeneity.

There are five primary determinants of the quality of nighttime sleep and of daytime alertness[117]:

1. Homeostatic (duration of prior wakefulness)
2. Circadian (biologic clock influence)
3. Age
4. Drugs
5. CNS pathology

These factors determine the overall wake–sleep pattern, upon which the parasomnias are superimposed. These same factors also play an integral role in epileptic events.

With the advent of neurophysiologic monitoring techniques, it has become obvious that state determination is a very complex and dynamic phenomenon, involving multiple neural networks, neurotransmitters, neuropeptides, neurohormones, and myriad sleep-promoting substances. Given these complexities, it has become clear that the determination of state may be inexact, with components of two or all three states occurring simultaneously or oscillating rapidly. This concept of state dissociation in animals and humans has been extensively reviewed.[73,74,76]

Parasomnia is the term given to undesirable motor, verbal, or experiential phenomena that occur during the sleep period. It is these sleep disorders that are most commonly confused with epileptic phenomena. Parasomnias may be conveniently categorized as primary (disorders of sleep states per se) and secondary (disorders of other organ systems manifesting themselves during sleep). The primary sleep parasomnias can be classified according to the sleep state of origin: REM sleep, NREM sleep, or miscellaneous (those not respecting sleep state). The secondary sleep parasomnias can be further classified by the organ system involved.[72] Many parasomnias are manifestations of state dissociation. These mixed states result in fascinating and perplexing clinical phenomena that may easily be confused with epileptic events, and conversely, these sleep disorders may be perfectly imitated by epileptic events. Furthermore, other primary sleep disorders may trigger seizures, and, conversely, seizures may trigger abnormal sleep phenomena. In addition to the parasomnias, there is impressive overlap among epileptic, sleep, and psychiatric phenomena (Table 1).

Clinical Description

The following is a listing of various areas of overlap and confusion between sleep disorders and seizures ranging from normal events to hypersomnia, insomnia, and parasomnias.

Normal Sleep Phenomena

Sleep Starts

Sleep starts (hypnic jerks) are experienced by many normal individuals during the transition from wake to sleep. The most common is the motor sleep start, a sudden jerk of all or part of the body, occasionally awakening the victim or bed partner.[106] Variations on this theme include the visual (flashes of light, fragmentary visual hallucinations), auditory (loud bangs, snapping noises), or somesthetic (pain, floating, something flowing through the body) sleep start, occurring without the body jerk.[20,42,70,101,122] Sleep starts represent a normal (although not understood) physiologic event, and should not be confused with seizures or other neurologic conditions. It is likely that the “exploding head syndrome,” characterized by a sensation of a loud sound like an explosion or a sensation of “bursting” of the head, and “explosive tinnitus” are variants of sensory sleep starts.[22,108,121,144,152] Similar phenomena may represent the sole manifestation of a seizure.[37]

Table 1 Overlap among epileptic, sleep, and psychiatric phenomena

Symptom	Sleep disorder	Seizure
Normal sleep phenomena	Sleep starts (hypnic jerks) Nightmares	Seizures manifesting as sleep-onset sensory/motor phenomena or nightmares
Hypersomnia	Sleep deprivation Idiopathic CNS hyperinsomnia	Hypersomnia as a manifestation of having frequent nocturnal seizures resulting in recurrent arousals or hypersomnia as an accompaniment of epilepsy
	Narcolepsy	Akinetic

	Cataplexy	Fugue states
	Sleep paralysis	Partial complex seizures
	Hypnagogic hallucinations	Subclinical status
	Automatic behavior	Poriomania
	Recurrent hypersomnia Kleine-Levin Menstruation-related	Recurrent seizures resulting in prolonged periods of "sleepiness"
	Sleep apnea triggering seizures	Seizures resulting in apnea
Insomnia	Medical Psychiatric Psychological Constitutional	Seizures whose sole manifestation is recurrent arousals
Parasomnias	Disorders of arousal Confusional arousals Sleepwalking Sleep terrors Sleep-eating RBD Dreams/nightmares Enuresis Rhythmic movement disorder Periodic limb movement disorder Posttraumatic stress disorder Cardiopulmonary Cardiac arrhythmias Respiratory dyskinesias Gastrointestinal-paroxysmal choking Panic disorder Psychogenic dissociative disorders	Mesial frontal, temporal lobe seizures presenting with complex, bizarre behaviors, hypnogenic (nocturnal) paroxysmal dystonia, or autonomic (diencephalic) seizures

CNS, central nervous system; RBD, rapid-eye-movement sleep behavior disorder.

Nightmares

Nightmares are frightening dreams that usually awaken the sleeper from REM sleep. Unlike disorders of arousal (see below), they are not usually associated with prominent motor or vocal behavior or autonomic excitation, and the arousal

P.2758

results in immediate full wakefulness, with memory for the dream sequence of events that caused the awakening.[72] Seizures manifest as recurrent dreams, nightmares, or disorders of arousal such as sleepwalking, and sleep terrors have been well described in both adults and children. The diagnosis of seizure-related dreams and nightmares may be overlooked, as the symptom is misinterpreted as a primary sleep phenomenon.[12,28,29,39,138] Autosomal dominant frontal epilepsy may also present as recurrent "nightmares."[124,125]

Hypersomnia

Epilepsy

Nocturnal seizures may cause severe sleep fragmentation, if the sole manifestation is arousal (which may not be appreciated by the patient). The end result is excessive daytime sleepiness.[130] Some patients with seizures are hypersomnolent during the day—even after antiepileptic medication discontinuation. Seizure-free preadolescent children with epilepsy are sleepier than healthy controls. In one study, there was no difference in objective sleepiness in children with epilepsy on or off medication, suggesting that use of antiepileptic drugs does not necessarily result in daytime sleepiness.[103] The complaint of daytime sleepiness in patients with epilepsy may be due to a number of different conditions (sleep deprivation, sleep-related seizure-induced arousals, coexisting sleep disorders such as sleep apnea or narcolepsy, or medication effect). Thoughtful evaluation of this complaint is encouraged; hypersomnia in patients with epilepsy should not summarily be attributed to the effect of antiepileptic medications.[7,35]

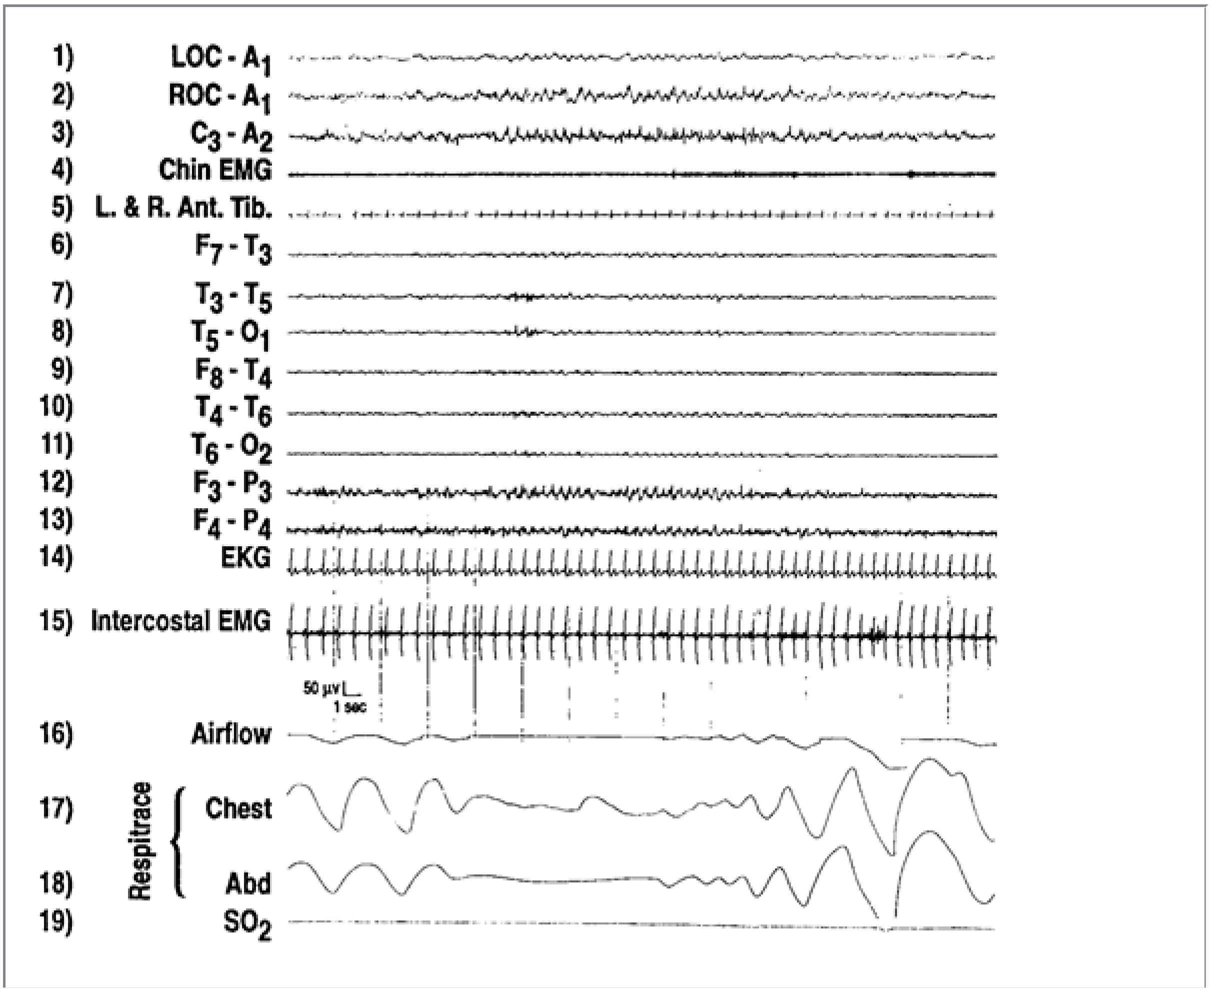

FIGURE 1. Polysomnographic tracing of a 56-year-old male with a long-standing history of well-controlled generalized seizures who developed severe progressive excessive daytime sleepiness. The polysomnogram revealed 22 central apneas per hour as the sole manifestation of seizures. Aggressive medical management was unsuccessful. There was marked improvement in his excessive daytime sleepiness following a right frontal lobectomy.

Narcolepsy

Narcolepsy is a genetically determined disorder characterized by excessive daytime sleepiness, cataplexy (the sudden loss of muscle tone triggered by emotionally laden events), sleep paralysis, hypnagogic hallucinations, and automatic behavior during which prolonged, complex activities may be performed without conscious awareness or recall.[1] The "spell-like" nature of some sleep attacks, cataplexy, and sleep paralysis may be mistaken for seizures. Conversely, atonic or inhibitory seizures may mimic cataplexy,[3,41,45,56,66,139] and the periods of

automatic behavior are often misdiagnosed as partial complex seizures, postictal confusion, or poriomania.[32,60,80] The incomplete and waxing and waning nature of cataplexy can imitate tonic–clonic seizure activity.

Periodic Hypersomnia (Kleine-Levin Syndrome)

The Kleine-Levin syndrome is a poorly understood condition characterized by recurrent periods of hypersomnia. The often-cited association with adolescent males and unusual behaviors such as hypersexuality and megaphagia has been overrated.[6,137] Menstruation-related periodic hypersomnia may represent a variant of the Kleine-Levin syndrome.[11] Similar recurrent episodes of hypersomnia may be caused by "ictal sleep" lasting 1 to 3 days at 10- to 60-day intervals.[94,156]

Sleep-disordered Breathing

There is an interesting and important relationship between sleep-disordered breathing and seizures. Nocturnal seizures, probably triggered by periods of hypoxemia, may be the presenting symptom in some individuals with obstructive sleep apnea or sleep-related hypoventilation.[62] Furthermore, sleep apnea may exacerbate seizures in patients with epilepsy due to sleep disruption, sleep deprivation, hypoxemia, or decreased cerebral blood flow. As would be expected, patients who have both epilepsy and sleep-disordered breathing may have better control of their seizures following effective treatment for the sleep-disordered breathing.[79,148] Not all "spells" associated with sleep apnea are epileptic manifestations. They may be due to episodes of cerebral anoxia.[16]

In yet other cases, seizures may cause apnea, often repetitive, and may closely mimic the conditions of obstructive or central sleep apnea.[17,90,146,151,153] FIGURE 1 shows repetitive apneas as the sole manifestation of seizures.

Insomnia

Paroxysmal, otherwise unexplained awakenings may be the sole manifestation of nocturnal seizures, and will result in the complaint of insomnia.[8,30,31,97,110] Some patients with occasional paroxysmal periodic motor attacks during sleep have very frequent (every 20 to 60 seconds) subclinical arousals resulting in severe sleep fragmentation.[130] These paroxysmal arousals may be due to deep epileptic foci.[92] The arousal preceding nocturnal seizures may be the initial manifestation of the seizure.[78] Animal studies support the concept of frequent arousals as the manifestation of seizures.[133] This may explain the fact that some patients with epilepsy report frequent, otherwise unexplained, nocturnal awakenings and excessive daytime sleepiness.[50]

Parasomnias

Disorders of Arousal

Disorders of arousal are the most common and impressive of the NREM sleep parasomnias, and may readily be confused with epileptic phenomena. These occur on a continuum ranging from confusional arousals to sleepwalking to sleep terrors. The disorders of arousal share common features: A positive family history, suggesting a genetic component; they tend to arise from slow-wave sleep (stages 3 and 4 of NREM sleep), therefore usually occurring in the first third of the sleep cycle (and rarely during naps); and they are common in childhood, usually decreasing in frequency with increasing age.[77] Although they most frequently occur during slow-wave sleep, they may occur during any stage of NREM sleep, and may occur late in the sleep period. Contrary to popular opinion, the

appearance or persistence of these events into adulthood is usually not associated with significant psychiatric disease. Specialized forms of arousal disorders may manifest as sleep-related eating or sleep-related sexual activity.[126,131]

The disorders of arousal may be difficult to differentiate from nocturnal seizures, and vice versa.[68,109] Preservation of consciousness during seizures may lead to confusion with disorders of arousal or psychogenic conditions.[26] Crying (dacrystic) or laughing (gelastic) seizures may be misinterpreted as confusional arousals or sleep terrors.[5,69] Both disorders of arousal and seizures may be menstrual related.[52,96,127]

The disorders of arousal may be triggered by arousals induced by other sleep disorders such as sleep apnea or seizures, so the clinical event of a sleepwalking or sleep terror episode may, in fact, represent an epiphenomenon of yet a different underlying sleep disorder.[46] It is common clinical experience to see an improvement in disorders of arousal following effective treatment of obstructive sleep apnea (OSA). Conversely, effective treatment of OSA with nasal continuous positive airway pressure (CPAP) may result in disorders of arousal, presumably associated with deep NREM sleep rebound.[34,89] Sleep terrors and seizures can coexist in the same individual.[143]

Rapid Eye Movement Sleep Behavior Disorder

REM sleep behavior disorder (RBD) is a recently described condition in which the anticipated atonia of REM sleep is absent, hypothetically allowing patients to “act out their dreams,” often with violent or injurious results. It typically is a disorder of older males, and is frequently misdiagnosed as a nocturnal seizure or psychogenic event. RBD is readily diagnosable by formal sleep studies, which reveal the absence of somatic muscle atonia that normally accompanies REM sleep. RBD responds exquisitely to clonazepam.[128] Nocturnal seizures or obstructive sleep apnea may mimic RBD.[19,53]

Dream/Nightmare Disturbances

As mentioned above, recurrent dreams or nightmares as the primary manifestation of nocturnal seizures have been well documented.

Enuresis

Enuresis was formerly classified as a “disorder of arousal,” implying a relationship with NREM or slow-wave sleep.[13] However, enuresis does not respect sleep stage, and may occur during either NREM or REM sleep.[44,88] Enuresis may be the sole manifestation of nocturnal seizures.[4,33,46]

Bruxism

Rarely, bruxism may be the manifestation of a seizure.[84]

Rhythmic Movement Disorder

Rhythmic movement disorder (RMD) refers to a number of behaviors characterized by stereotyped movements (rhythmic oscillation of the head or limbs, head banging or body rocking during sleep) seen most frequently in childhood and, rarely, in adults. RMD may arise from any stage of sleep, may be familial, and is usually not associated with underlying psychiatric or psychological conditions.[118] Rarely, it may be the sole manifestation of a seizure.[46]

Periodic Limb Movements of Sleep

Periodic limb movement of sleep (PLM) is a polysomnographically determined diagnosis. It is characterized by periodic (every 20 to 30 seconds) dorsiflexion of the great toe, foot, or even flexion of the entire leg. These movements are not perceived by the patient, and may be associated with the complaint of excessive daytime sleepiness or insomnia. These movements may also be asymptomatic.[93] When prominent, these movements may be confused with myoclonic seizure activity, or may actually represent epileptic phenomena.[71] These movements may be particularly dramatic in patients with underlying renal failure.[58,111]

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is often associated with subjective sleep complaints including "nightmares" and sleep terrorlike experiences.[2] PTSD may be confused with nocturnal panic or seizures manifesting solely as arousals with fearful affect.

Seizures

The behaviors associated with nocturnal seizures are often bizarre, and masquerade as primary sleep parasomnias, secondary sleep parasomnias, or psychiatric conditions.[141] The following are particularly apt to result in diagnostic dilemmas:

1. *Conventional seizures* occur frequently during sleep. In many individuals with epilepsy, seizures occur exclusively during sleep, increasing the likelihood of a misdiagnosis of a primary sleep disorder. Approximately 10% of patients with seizures experience seizures exclusively or predominantly during sleep.[157]
2. *Nocturnal frontal lobe epilepsy* (NFLE), sometimes autosomal dominant, presents a broad spectrum of behaviors, including frequent isolated paroxysmal arousals, episodic nocturnal wanderings, and nocturnal paroxysmal dystonia.[99,112,113,124] NFLE may present as other sleep disorders, particularly disorders of arousal or sleep apnea.[100,125] Nocturnal and diurnal paroxysmal dystonia may exist in the same patient, as can reflex and hypnogenic paroxysmal dystonia. There is considerable overlap among the different clinical categories of paroxysmal dyskinesias.[23,67,91,149] NFLE may be posttraumatic[9] and may coexist with panic disorder.[142] Temporal lobe seizures may also result in hyperkinetic behaviors.[98] Vigilance level-dependent tonic seizures[115] and familial paroxysmal hypnogenic dystonia[65] likely represent variants of this condition. Carbamazepine is often very effective in eliminating these spells.
3. *Pure tonic seizures with arousal* (or paroxysmal polyspike activity with arousal) were mentioned above as seizures presenting as insomnia or hypersomnia due to seizure-induced arousals or sleep fragmentation. An interesting subtype of hypnic tonic postural seizures has been described in ten children, many with a positive family history. This may be a benign epilepsy syndrome similar to benign childhood epilepsy with centrotemporal spikes,[51] and childhood epilepsy with occipital paroxysms.[61,104,105]
4. *Autonomic/diencephalic seizures* are rare, and could present from sleep with such manifestations as intermittent or paroxysmal apnea,[123,151] stridor,[81] coughing,[155] laryngospasm,[116] chest pain and arrhythmias,[24,43,49,59] paroxysmal flushing, localized hyperhidrosis,[63,87] and piloerection,[120] which are easily confused with other primary or secondary sleep parasomnias. Isolated autonomic symptoms are a well-documented manifestation of seizures, and are probably much more common than generally suspected.
5. *Electrical status epilepticus of sleep* (ESES) may be detected during a polysomnogram (PSG) performed for other reasons, and is characterized by continuous spike-and-wave activity during NREM sleep. ESES is seen in

children who usually, but not always, have a history of seizures or neurologic dysfunction. The prognosis is variable inasmuch as it may be an asymptomatic finding. This pattern occurs on a broad spectrum including the Landau-Kleffner syndrome and benign childhood epilepsy with centrotemporal spikes.[40]

Cardiopulmonary

1. *Cardiac arrhythmias* may be a manifestation of seizures, masquerading as nocturnal cardiac abnormalities and possibly playing a role in sudden unexplained death in epilepsy.[54,95] Ictal cardiorespiratory arrest in Panayiotopoulos syndrome has recently been reported.[150] Seizures may also result in stunned myo-cardium and pulmonary edema.[15,36] Conversely, primary cardiac (prolonged QT interval) or respiratory events (REM sleep-related hypoventilation) may present as seizures.[62,102]
2. *Respiratory dyskinesias* may occur or persist during the sleep period. These include (a) segmental myoclonus such as palatal myoclonus or diaphragmatic flutter and (b) paroxysmal dystonia. Respiratory dyskinesias may also be the manifestation of neuroleptic-induced dyskinesias, and may or may not persist during sleep.[64] These should be differentiated from unusual nocturnal seizures that present with primarily or exclusively respiratory symptoms.[146,151,154]

Gastrointestinal

The sole manifestation of nocturnal seizures may be paroxysmal choking.[14]

Nocturnal Panic Attacks

Nocturnal panic attacks (NPAs) may occur in patients with diurnal panic, or, rarely, may precede the appearance of diurnal panic, or may be exclusively nocturnal in nature.[18,85,119] The striking similarity of the symptoms of dream anxiety attack, sleep terror, nocturnal seizures, and nighttime panic urges caution in diagnosis. Obstructive sleep apnea can also cause symptoms of NPAs.[27] The common association of the affect of "fear" as an accompaniment of nocturnal seizures intensifies their confusion with nocturnal panic.[21,47,48,82] It must be remembered that seizures and panic may co-exist.[83,140]

Psychogenic Dissociative States

Complex and potentially injurious behaviors, occasionally confined to the sleep period, may be the manifestation of a psychogenic dissociative state. A history of childhood physical and/or sexual abuse is virtually always present (but may be difficult to elicit). In this condition, unlike other parasomnias or nocturnal seizures, the complex behavior, during electroencephalographic (EEG) monitoring, is seen to arise from clear EEG-determined wakefulness.[129] Pseudoseizures may also arise from apparent sleep.[147]

Differential Diagnosis

It should be clear from the above that the clinical differentiation between sleep disorders and epileptic events may often be difficult, if not impossible, as primary or secondary sleep phenomena may perfectly mimic epileptic phenomena, and vice versa. Both epileptic and sleep phenomena should be considered in any case of recurrent unusual sleep-related events.

Diagnostic Investigation

The decision to investigate further unusual nocturnal events will depend upon the clinical situation. The most common condition is the disorder of arousal, which is very common (and normal) in the general population. Simple sleepwalking or sleep terrors can readily be diagnosed clinically. Indications for formal evaluation include behaviors that (a) are potentially injurious or violent, (b) cause disruption for other household members, (c) result in excessive daytime sleepiness, or (d) display unusual clinical features.

Clinical differentiation between sleep and epileptic phenomena may be most difficult, and misdiagnosis in both directions is common. The diagnosis of nocturnal seizures may be enigmatic if there is no history of diurnal spells. Both waking and sleep-deprived EEGs may not reveal the diagnosis,[10,107] necessitating all-night polysomnographic study using a full seizure montage and continuous video recording. Although exclusively nocturnal seizures may be uncommon, they are routinely misdiagnosed, and should never be overlooked as possibly etiologic in any sleep-related behavior that is recurrent, stereotyped, or inappropriate—regardless of the specific nature of that behavior. "Ambulatory" EEG monitoring has led to the misdiagnosis of functional psychiatric disease in a number of our patients subsequently demonstrated to have bona fide nocturnal seizures. Erroneous psychogenic labeling is enhanced by the bizarre nature of the spells and the fact that environmental clues may play a role in the context of psychomotor seizure.[38] Misdiagnosis is common even following formal and appropriate PSG evaluation. Reasons for misdiagnosis include[75]:

1. Obscuration of the scalp EEG by movement artifact
2. Absence of scalp EEG manifestation of the seizure activity
3. EEG seizure manifestation appearing to be an “arousal” pattern
4. Absence of EEG or clinical postictal period

Extensive polysomnographic monitoring employing a full scalp EEG montage is mandatory. Multiple studies may be necessary to capture an event. Continuous audio/visual monitoring and recording are indicated, and detailed technician observation may be invaluable. The difficulties in evaluating unusual sleep-related events emphasize the necessity of extensive, in-person laboratory monitoring with interpretation of all data (clinical, EEG, sleep, video, and technologist-provided information) by personnel experienced in both sleep medicine and epileptology.

Treatment

Effective treatment is available for most sleep disorders and for seizures, and is predicated upon an accurate diagnosis. If seizures are responsible for the sleep–wake complaint, treatment is similar to that for other seizure disorders. If a primary sleep disorder (such as narcolepsy, sleep apnea, or parasomnia) is identified, therapy is dictated by the specific diagnosis.

Summary and Conclusions

The interface between sleep disorders and epileptic phenomena is vast and inexorable, as sleep affects seizures, and seizures affect sleep. The myriad sleep and epileptic phenomena may perfectly counterfeit one another. A high index of suspicion and a

P.2762

full awareness of the broad spectrum of both sleep and epileptic phenomena is instrumental to an accurate diagnosis. A thorough clinical and laboratory evaluation of unusual phenomena that could be either sleep- or seizure-related will usually lead to a specific diagnosis, with important and effective therapeutic implications.

From a broader perspective, the intriguing relationship among these conditions is fertile ground commanding further investigation, the results of which will greatly expand our knowledge of brain function, sleep, and epilepsy, and which will undoubtedly result in deeper understanding and better classification, and identification of yet unknown, unusual clinical events. Close cooperation among the fields of sleep medicine, epileptology, and basic neuroscience in this arena of fascinating interface will be most productive—both from a clinical/therapeutic and scientific standpoint.

Chapter 277

Myoclonus and Myoclonic Syndromes

Mark Hallett

Hiroshi Shibasaki

Introduction

The history of myoclonus has been described by Marsden et al.[25] and Hallett.[17] Friedreich first defined myoclonus as a discrete entity in a case report published in 1881 of a patient with essential myoclonus. He wanted to separate the involuntary movement that he saw from epileptic clonus, a single jerk in patients with epilepsy, and chorea. For the next 10 to 20 years, many other types of involuntary movements, such as tic and myokymia, were also called myoclonus, but in 1903 Lundborg[23] proposed a classification of myoclonus that cleared up much of the confusion. Lundborg classified myoclonus into three groups: Symptomatic myoclonus, essential myoclonus, and familial myoclonic epilepsy.

It is important to recognize that certain types of myoclonus are essentially identical to epilepsy. Single jerks in patients with epilepsy have been recognized since ancient times. In the phrase of Muskens,[30] myoclonus can be a "fragment of epilepsy." One of the tasks for the clinician is to determine what is epilepsy and what is not.

Clinical Description

Myoclonus is characterized by quick muscle jerks, either irregular or rhythmic.[19] Myoclonic movements are always simple in nature, and this is often a critical feature separating myoclonus from other types of involuntary movements. Myoclonus can be focal, involving only a few adjacent muscles; generalized, involving many or most of the muscles in the body; or multifocal, involving many muscles but in different jerks. Myoclonus can be spontaneous, can be activated or accentuated by voluntary movement (action myoclonus), and can be activated or accentuated by sensory stimulation (reflex myoclonus).

In differentiating myoclonus from other movement disorders, in addition to the simplicity, the principal features that favor myoclonus are the quickness of the movement and the absence of ability for voluntary suppression. Some simple tics look identical to myoclonus and cannot be visually distinguished. A point in favor of tic is the ability to suppress the movements voluntarily, with a frequent concomitant rise in psychic tension dispelled when the movements resume. Some movements of chorea are quick, but slower movements and sustained postures are also present. The major differential diagnosis for rhythmic myoclonus is tremor and the distinction here is often just convention.

Some disorders of the peripheral nervous system can be confused with myoclonus. Electrodiagnosis can help make the diagnosis since these disorders all show characteristic physiologic findings. Fasciculation is the spontaneous firing of a single motor unit. Myokymia typically looks like an irregular oscillation of a muscle, but it can have the appearance of small jerks. Hemifacial spasm is characterized by jerks of the facial muscles and occasional tonic spasms.

A brief, paroxysmal pause of tonic muscular activity may also give rise to a jerk in the affected body part that is often visually indistinguishable from a movement produced by a burst of electromyographic (EMG) activity. This is called negative myoclonus, and the most commonly encountered form is asterixis. Negative myoclonus, like positive myoclonus, can also arise as an epileptic event.[36,40]

There are many types of myoclonus, and there are no common etiologic, physiologic, or therapeutic features. For this reason, recognizing that an involuntary movement is myoclonic in nature is only the beginning of the investigation. In those patients with epileptic seizures, it would be reasonable to suspect that the myoclonus would be related.

Classification

There have been many schemes proposed for classifying the large number of myoclonic disorders, and there are at least two useful approaches, etiologic and physiologic, that have usually been discussed separately.[19] From the point of view of differential diagnosis, the physiologic classification is most relevant, and it can help guide symptomatic treatment. The first consideration of therapy, however, should take the etiologic classification into account since the cause should be dealt with first, if possible. Here, the classifications will be combined using the physiologic classification as the primary index and the etiologic classification as a secondary index.

The starting point for a physiologic classification is to decide whether the myoclonus is a fragment of epilepsy. On this basis, the myoclonus is said to be epileptic or nonepileptic.[16,43] There are a number of subtypes in each category.

Epileptic Myoclonus

A significant feature in favor of epileptic myoclonus is if the patient has epileptic seizures. This would be more definitive, of course, if the myoclonus was clearly a fragment of the seizure including a part of the aura. The association of the myoclonus with paroxysmal activity in the electroencephalogram (EEG) is also indicative, and more will be said about the electrophysiologic evaluation in the next section.

Three types of epileptic myoclonus are now recognized: Cortical myoclonus, reticular myoclonus, and primary generalized epileptic myoclonus.[19,37,43] Cortical myoclonus is a fragment of focal or partial epilepsy, and can be subclassified as spontaneous cortical myoclonus, cortical reflex myoclonus, and epilepsia partialis continua. Each myoclonic jerk involves only a few adjacent muscles, but larger jerks with more muscles involved can be seen. The disorder is commonly multifocal and accentuated by action and sensory stimulation.

Reticular reflex myoclonus is a fragment of a type of generalized epilepsy. These jerks are usually generalized with predominance, which is proximal more than distal and flexor more than extensor. Voluntary action and sensory stimulation increase the jerking. Primary generalized epileptic myoclonus is a fragment of primary generalized epilepsy. The most common clinical manifestation is small, focal jerks, often involving only the fingers; thus, the myoclonus is sometimes called minipolymyoclonus. The term minipolymyoclonus was originally coined to refer to small jerks seen in patients with motor neuron disease. Minipolymyoclonus of central origin and minipolymyoclonus of peripheral origin have a similar clinical appearance and are probably most easily separated by the company they keep: Epilepsy and muscle denervation, respectively. A second clinical presentation of primary generalized epileptic myoclonus is generalized, synchronized whole body jerks, not unlike those seen with reticular reflex myoclonus. Electrodiagnosis can help define the type of epileptic myoclonus (see below).

Negative myoclonus can be isolated, but it usually occurs together with positive myoclonus.[15,36,40,43] Clinically, the appearance is called asterixis, and there can be large movements, small multifocal movements, and such frequent movements that the appearance is of an irregular tremor or tremulousness. Negative myoclonus can have a similar physiology to cortical myoclonus with electrophysiologic correlates and production by sensory stimulation. There may be associated seizures.

Myoclonus resulting from a defined pathologic process, the etiologic category of “symptomatic myoclonus,” is usually epileptic in type. The principal conditions follow, along with a brief consideration of their treatment.

Progressive Myoclonus Epilepsies

Progressive myoclonus epilepsy with the principal features of slowly progressive myoclonus and epilepsy is most frequently secondary to a degenerative disorder with some involvement of the cerebellum or cerebellar pathways (see also Chapter 252). The disorder can be sporadic, but is often familial. Typically the symptoms begin between 7 and 15 years of age and include action and reflex myoclonus and grand mal seizures.

Cerebellar ataxia is said to be common, but differentiation of ataxia and intention myoclonus is often very difficult. Occasional features include dementia, spasticity, myopathy, neuropathy, and deafness. The syndrome is clearly heterogeneous. Cases have been described under the names Unverricht-Lundborg syndrome, Ramsay Hunt syndrome, and "Baltic myoclonus epilepsy." The gene for Unverricht-Lundborg disease (EPM1) has now been linked to the long arm of chromosome 21q22.3 in a number of families, and the gene involved codes for cystatin B, a small protein that is a member of a superfamily of cysteine protease inhibitors.[21] Familial cortical myoclonic tremor with epilepsy or familial adult myoclonic epilepsy has been reported from Japan and Europe. This condition is characterized by autosomal dominant inheritance, late onset, benign course, and only infrequent epileptic seizures. Recently van Rootselaar et al.[45] reported an autopsy case of this condition, in which the pathologic changes similar to those seen in spinocerebellar ataxia (SCA) type 6 were found in the cerebellum.

There are no treatments for degenerative conditions, but there are some important therapeutic implications. It is of critical importance in these cases to recognize that phenytoin treatment may be associated with worsening of the condition.[10] Patients can be treated successfully with other anticonvulsants as described below. Storage diseases may also give rise to the syndrome of progressive myoclonus epilepsy, and for this reason the patients may be thought to have a degenerative condition. The most well-known entity is Lafora body disease. Other entities include lipidoses such as GM_2 gangliosidosis (Tay-Sachs disease), ceroid-lipofuscinosis (Batten disease), and sialidosis (cherry red-spot-myoclonus syndrome).

There are at least two clinical differences between Lafora body disease and Baltic myoclonus epilepsy.[10] Age of onset in Lafora body disease is 11 to 18 years, while the age of onset in Baltic myoclonus epilepsy is earlier, 6 to 16 years. For Lafora body disease dementia is present in two thirds of cases by 2 years after onset, and in all by 5 years; in contrast, in Baltic myoclonic epilepsy, only a rare patient shows dementia in the first 5 years (provided the patients do not receive phenytoin). Occipital seizures are frequent in Lafora body disease. The diagnostic feature of Lafora body disease is the periodic acid-Schiff (PAS)-positive inclusion body found in neurons throughout the gray matter of the brain including the dentate nucleus of the cerebellum. These inclusions can sometimes be found in liver, skeletal muscle, and skin. For clinical purposes, the method of first choice for confirming the diagnosis is skin biopsy, particularly of axillary skin. The gene responsible in about 75% of Lafora body cases (EPM2) has been localized to chromosome 6q and has been identified as encoding a protein tyrosine phosphatase (PTP) now called laforin.[27,35] With these storage diseases, there is no treatment, but screening and prenatal detection can be used for prevention.

Noninfantile neuronopathic Gaucher disease can cause myoclonus. There are rapid advances in Gaucher disease, with enzyme replacement therapy already available for the nonneuronopathic forms and gene replacement treatment on the horizon.

Biotin deficiency is especially important to keep in mind since replacement with biotin can lead to cure.[3]

Mitochondrial disorders are increasingly recognized as common causes of myoclonus and the "Ramsay Hunt syndrome" in particular. Indeed, most patients with progressive myoclonus epilepsy may have a mitochondrial abnormality.[2] One well-defined syndrome is MERRF (myoclonus epilepsy and ragged red fiber syndrome). A muscle biopsy looking for ragged red fibers might be helpful. Presently, there is no good treatment for mitochondrial diseases.

Dementias

Creutzfeldt-Jacob disease (subacute spongiform encephalopathy) frequently exhibits myoclonus as a relatively early feature. The myoclonus can be produced by external stimuli, such as noise, or can be spontaneous and rhythmic associated with a periodic EEG. Patients with Alzheimer disease can also exhibit myoclonus, although this feature typically occurs late in the illness. The myoclonus is multifocal and can be stimulus induced. Electrophysiologic investigations of these two disorders show distinctive results, but both are similar to cortical reflex myoclonus. Myoclonus also is seen in patients with the AIDS–dementia complex.[24]

Viral Encephalopathies

A variety of viruses and postviral syndromes cause myoclonus. Herpes simplex encephalitis is probably the most common example. Subacute sclerosing panencephalitis (SSPE) is frequently characterized by a slow periodic movement often called myoclonus, but its duration is on the order of 1 second and it does not fit the definition. At the first International Congress of Movement Disorders in 1990, the attendees voted to no longer use the term *myoclonus* to describe the involuntary movement in SSPE.

Metabolic Encephalopathies Including Endocrine Disorders

Disorders such as hepatic failure, renal failure, hyponatremia, hypoglycemia, and nonketotic hyperglycemia can give rise to myoclonus. Treatment should be directed to the underlying condition. For example, myoclonus in patients with chronic renal failure on hemodialysis can be due to aluminum toxicity and can be successfully treated with chelation therapy with deferoxamine mesylate.[39]

The opsoclonus-myoclonus syndrome is easy to diagnose because of the dramatic clinical feature of opsoclonus.[34,41] It may arise in a variety of settings including infections, toxins, and a paraneoplastic syndrome. In childhood the syndrome is often associated with neuroblastoma. If there is a tumor, it should be treated, and there may be symptomatic relief, but the disorder might be unaffected or even worsened. Symptomatic therapy that should be considered includes steroids or adrenocorticotropic hormone (ACTH). Trazodone may also be helpful.

Toxic Encephalopathies Including Drug Side Effects

Toxic causes include bismuth, heavy metals, methyl bromide, and drugs. Offending drugs include tricyclic antidepressants, opioids, and lithium.

Physical Encephalopathies Including Hypoxia

These conditions include trauma, heat stroke, electric shock, decompression injury, and hypoxia. Posthypoxic myoclonus, the Lance-Adams syndrome,[20] has received a great deal of attention since the demonstration that the myoclonus could be successfully treated with 5-hydroxytryptophan. The clinical syndrome as reported by Lance and Adams noted the precipitating feature of action and the association with cerebellar ataxia, postural lapses, gait disturbance, and grand mal seizures. The site of the responsible lesion in the brain is not certain, but there does appear to be a disorder of serotonin metabolism supported not only by the therapeutic response to 5-hydroxytryptophan, but also by the reduction in cerebrospinal fluid (CSF) levels of 5-HIAA, which improves with successful therapy.

Focal Brain Damage

The etiology of focal cortical myoclonus can be almost any type of focal cortical lesion; tumors, angiomas, and encephalitis should be suspected. Curiously, particularly in patients with epilepsia partialis continua, the cortex can appear normal to pathologic examination. With recent application of diffusion magnetic resonance imaging (MRI), increasing attention has been drawn to focal cortical dysplasia as a cause of neocortical epilepsy including epilepsia partialis continua.[28] In a number of patients, surgical excision of the excitable tissue has cured the myoclonus,[33] and this approach should be considered.

Nonepileptic Myoclonus

The types of nonepileptic myoclonus are particularly heterogeneous. It is important to recognize them, because each has its own treatment, and, in general, use of anticonvulsants is not valuable. Some physiologic phenomena are included in this group including hiccough, sneeze, and the hypnic jerk.

Dystonic Myoclonus and Fragments of Other Involuntary Movement Disorders

Patients with dystonia or chorea, for example, may have quick jerks as well as more prolonged involuntary movements. Other “basal ganglia” disorders such as Wilson disease, neuroaxonal dystrophy, pantothenate kinase-associated neurodegeneration (PKAN; formerly known as Hallervorden-Spatz disease), progressive supranuclear palsy, and Parkinson disease all may manifest myoclonus. The diagnosis is made on the basis of other clinical features. Treatments are available for Parkinson disease, of course. Myoclonus in Huntington disease can be improved with valproic acid, perhaps because of the involvement of the γ-aminobutyric acid (GABA) system in this disorder.[5] Focal myoclonus in the setting of dystonia can often be treated with focal injections with botulinum toxin. Myoclonus dystonia (DYT11) is an autosomal dominant syndrome where symptoms include dystonic myoclonus as well as more prolonged spasms.[13] Tremor, similar to essential tremor, may also be present. There is often a marked response to ethanol. In many families, the genetic abnormality has been identified to be in the protein epsilon-sarcoglycan.[1] In this condition, myoclonus involves mainly proximal or truncal muscles and occurs independently of dystonia in terms of the body sites involved and the time of occurrence.

Essential Myoclonus

This term can be utilized for those patients whose sole neurologic abnormality is myoclonus and specifically do not have seizures, dementia, or ataxia. The EEG and other laboratory investigations should be normal. Familial cases as well as sporadic cases are seen. The most common features of the familial cases are autosomal dominant inheritance with variable severity, equal involvement of males and females, onset in the first or second decade of life, and benign course compatible with normal life span. Essential myoclonus can be generalized or multifocal. The myoclonus is variable in amplitude, and in some cases, the jerks are so small that the disability can be minimal. Jerks can be present at rest and may be improved or worsened by action. Reflex myoclonus has not been described in this group.

In some families with essential myoclonus some involved patients also have essential tremor, and some family members had essential tremor without myoclonus. Some of these patients also may exhibit elements of dystonia, and the diagnosis in these cases may well be myoclonus dystonia (DYT11). The essential tremor, myoclonus, and dystonia may all be sensitive to alcohol in these patients.

Exaggerated Startle

Startle is a normal phenomenon that can be exaggerated if an excessive response occurs to a startling stimulus or if a startle response occurs to a stimulus that ordinarily would not be startling.[26] There are a number of startle syndromes including hereditary hyperekplexia, symptomatic hyperekplexia, startle epilepsy, and Latah syndrome. Startle epilepsy is principally characterized by epileptic seizures triggered by sudden, unexpected stimuli and initiated by a startle.

P.2768

Periodic Movements in Sleep

There are a variety of types of myoclonus that occur during drowsiness or sleep. There are two physiologic forms, the hypnic jerk and "physiologic fragmentary myoclonus," characterized by small, multifocal jerks maximal in the hands and face but present diffusely. Pathologic types of myoclonus include isolated periodic movements in sleep, restless legs and periodic movements in sleep, and excessive fragmentary myoclonus in non–rapid eye movement (NREM) sleep. Myoclonus associated with epilepsy, intention myoclonus associated with semi-volitional movements, and segmental myoclonus also occur in sleep, but are not primarily nocturnal.

Periodic movements in sleep (PMS) occurs in virtually all groups of patients referred to a sleep disorders laboratory, and the clinical correlation is not always clear. Patients with the restless legs syndrome often have PMS. Certainly, PMS can be asymptomatic for the patient, although, as with all types of nocturnal myoclonus, the disorder may cause distress to the patient's spouse. On some occasions, however, PMS can induce sleep fragmentation and excessive daytime sleepiness (see Chapter 276).

Segmental Myoclonus Including Spinal Myoclonus and Palatal Myoclonus

In this disorder, a segment of the spinal cord or brainstem produces persistent rhythmic repetitive discharges usually unaffected by sleep. A number of contiguous muscles produce synchronous contractions at a rate of 0.5 to 3 Hz. Involved regions can be one limb, one limb and adjacent trunk, or both legs. Lesions of the spinal cord giving rise to focal movements include infection, degenerative disease, tumor, cervical myelopathy, and demyelinating disease, and it may follow spinal anesthesia or the introduction of contrast media into the CSF. Unlike palatal myoclonus, spinal myoclonus would only rarely be idiopathic. Spinal myoclonus usually occurs spontaneously and may persist during sleep.

Another form of spinal myoclonus is propriospinal myoclonus.[4,6] This is clinically characterized by axial jerks that are nonrhythmic and that lead to symmetric flexion of the neck, trunk, hips, and knees. Jerks can be spontaneous or stimulus induced. The myoclonus is identified with electrodiagnostic studies that show the myoclonus starting in the midthoracic region and propagating slowly, about 5 meters/sec, both rostrally and caudally.

Palatal myoclonus, now preferably called palatal tremor, is most common in this group, and has now been shown to consist of two separate disorders, essential palatal tremor, which manifests an ear click, and symptomatic palatal tremor, which is associated with cerebellar disturbances.[8] The ear click in essential palatal tremor is the symptom that requires therapy.

Asterixis

Negative myoclonus may well have a subcortical origin as well as a cortical origin (epileptic), although there are no clinical rules for separating them. The distinction is made on the basis of electrophysiologic studies that may show EEG correlates with the cortical form, but this may not be a definite qualitative difference. Certainly, subcortical lesions may cause asterixis, but that does not necessarily imply where the movement is generated. For example, unilateral asterixis is caused by a vascular lesion in the contralateral thalamus, but this does not necessarily mean that this type of asterixis originates from the thalamus.[42] It is difficult to treat asterixis whether cortical or subcortical, and a search for a metabolic or toxic cause should be the first course of action.

Psychogenic Myoclonus

Myoclonus can also be psychogenic. Monday and Jankovic[29] reported the clinical features of 18 such patients. There were 13 women and five men with an age range of 22 to 75 years. The myoclonus was present for 1 to 110 months; it was segmental in ten, generalized in seven, and focal in one. Stress precipitated or exacerbated the myoclonic movements in 15 patients; 14 had a definite increase in myoclonic activity during periods of anxiety. The following findings helped to establish the psychogenic nature of the myoclonus: Clinical features incongruous with "organic" myoclonus, evidence of underlying psychopathology, an improvement with distraction or placebo, and the presence of incongruous sensory loss or false weakness. Over half of all patients with adequate follow-up improved after gaining insight into the psychogenic mechanisms of their movement disorder.

Diagnostic Investigation

Clearly the first issue is to seek an underlying cause for the condition. This would imply a full neurologic evaluation including blood studies, neuroimaging, and CSF evaluation.

Electrophysiologic assessment can be a significant help in deciding whether the movement is myoclonus, and, if so, which type.[19,37,43] Techniques to be employed include EMG to evaluate the EMG activity associated with the movement, EEG to determine if there is an EEG event related to the movement (averaging of activity may be needed), analysis of whether the involuntary movement can be produced reflexly, and evaluation of the evoked response in the EEG to stimulation that produces reflex involuntary movements. The physiologic characteristics of epileptic myoclonus are EMG burst length of 10 to 50 msec, synchronous antagonist activity, and an EEG correlate. Nonepileptic myoclonus shows EMG burst lengths of 50 to 300 msec, synchronous or asynchronous antagonist activity, and no EEG correlate.

With cortical reflex myoclonus, the EEG reveals a focal positive–negative event over the sensorimotor cortex contralateral to the jerk preceding both spontaneous and reflex-induced myoclonic jerks. With stimulus sensitivity, C-reflexes are seen and are correlated with giant somatosensory-evoked potentials. Some myoclonus is sensitive to flash stimulus, and in this case photic-evoked potential is markedly enhanced. The EEG event associated with reflex jerks is a giant P1–N2 component of the somatosensory-evoked potential. Often the P1–N2 has exactly the same topography as the positive–negative event preceding the spontaneous myoclonus, but at times there are some differences. A final feature is that if the cranial nerve muscles are active, then the timing of onset of activation is from above downward; that is, the masseter (fifth cranial nerve) is active before the orbicularis oculi (seventh cranial nerve), which is itself active before the sternocleidomastoid (11th cranial nerve). With reticular reflex myoclonus, there are brief generalized EMG bursts lasting 10 to 30 msec triggered by sensory stimulation such as touch or muscle stretch or by action; the EEG correlates, if present, are not time locked to the muscle activation, and the pattern of EMG activation in cranial nerve muscles is with the sternocleidomastoid muscle activated first and the other cranial nerve muscles activated in reverse numeric order. In primary generalized epileptic myoclonus, the EEG correlate is a slow, bilateral frontocentrally predominant negativity similar to the wave of a primary generalized paroxysm.

If an EEG event cannot be found with back-averaging, it might be valuable to look at EEG-EMG coherence during the jerking. This technique was used, for example, to identify the cortical involvement in a series of patients with cortical myoclonic tremor.[44]

Treatment

The first approach, as has been emphasized, is to try to find an etiology that can be reversed. Failing that, the myoclonus can be approached symptomatically.

Epileptic Myoclonus

If the myoclonus is part of a defined epileptic syndrome, it should be treated as the syndrome. If the myoclonus needs to be approached by itself, the first approach is anticonvulsants. The most useful agents are clonazepam and valproate, both of which work by promoting GABA action in brain. Primidone may also play a role. Serotonergic agents such as 5-hydroxytryptophan (5-HTP) may also be effective. Piracetam and levetiracetam can be very effective for epileptic myoclonus.[12,14,31] Zonisamide may also be a useful agent.[46] Obeso et al.[32] have pointed out that two or three drugs in combination may well be better than a single drug.

Posthypoxic myoclonus is a special condition to consider because of the specific deficiency of serotonin. 5-HTP, either alone or with carbidopa, is often beneficial in this condition. On the other hand, however, it is not often used as a drug of first choice because of adverse effects. Most patients will respond just as well to clonazepam, valproate, or clonazepam plus valproate. In some cases, posthypoxic myoclonus dramatically responds to levetiracetam.

Essential Myoclonus

Essential myoclonus is a heterogeneous disorder and therapy is largely empiric. Alcohol is most likely to be beneficial, but cannot be recommended for regular use. Sodium oxybate may be successful for alcohol-responsive patients.[11] There are also reports suggesting propranolol, 5-HTP, and clonazepam. Some patients have responded dramatically to benztropine.[9]

Exaggerated Startle

Clonazepam is the therapy of choice.[26] Other benzodiazepines, such as diazepam and chlordiazepoxide, have been used with similar results.

Periodic Movements in Sleep

Treatment of choice is now either dopaminergic therapy or opiate therapy.[22,38] For some patients clonazepam may be helpful.

Segmental Myoclonus

For spinal myoclonus, treatment should be directed to the underlying cause if possible. For example, surgery can ameliorate myoclonus caused by cervical cord compression. Antiviral therapy may improve segmental myoclonus associated with herpes zoster. On the other hand, sometimes drug treatment can be helpful, such as clonazepam, valproate, and L-5-HTP, or trihexyphenidyl. For the ear click of essential palatal myoclonus, a number of drugs may be useful in individual cases, such as clonazepam, tryptophan, carbamazepine, trihexyphenidyl, or ceruletide, but most seem refractory. The ear click can be successfully treated with focal injection of botulinum toxin.[7]

Summary and Conclusions

Myoclonus is a simple, quick involuntary movement that can be seen in a large variety of disorders. There are many types of myoclonus, and it is crucial to make a clear diagnosis before beginning therapy. Hopefully, an underlying cause might be uncovered that could be treated. In many cases myoclonus may be a fragment of epilepsy. If it is a feature of a well-defined epileptic syndrome, then treatment of the myoclonus is the same as the syndrome. If the epileptic myoclonus is not a part of a recognized syndrome, the first approach is still anticonvulsants. If the myoclonus is nonepileptic, then symptomatic treatment needs to be individualized to the particular disorder.

Chapter 278

Movement Disorders

Stanley Fahn

Steven J. Frucht

Introduction

As early as the late nineteenth century, neurologists noted overlap between certain movement disorders and epilepsy. This is perhaps most apparent in patients with myoclonus, as discussed in the preceding chapter in this book. Many patients afflicted with chronic myoclonus also have epilepsy, and forms of focal epilepsy can precisely mimic myoclonus. Most of the drugs effective at treating myoclonus (clonazepam, valproic acid, levetiracetam, zonisamide, acetazolamide) are antiepileptics. Besides myoclonus, there are other disorders that occur in brief or sustained paroxysms, without alteration in arousal or consciousness; these disorders are the subject of this chapter. Often these patients are referred for evaluation to epileptologists or movement disorder specialists. Video-electroencephalogram (EEG) monitoring may be necessary to rule out an epileptic cause, although most of these disorders can be recognized once the physician is familiar with the syndrome.

Several paroxysmal movement disorders that may be confused with epilepsy are considered elsewhere in this book. Myoclonus, as mentioned previously, is the closest mimic. Patients with hyperekplexia have an inherited disorder of exaggerated startle and sustained tonic contractions due to mutations in the glycine receptor. These patients usually present in the nursery with exaggerated startle, abnormal tone, and lack of habituation to startle. Recognition is critical because appropriate treatment with clonazepam prevents potentially life-threatening apneic episodes. Paroxysmal torticollis is another disorder beginning in early childhood, with episodes of sustained tonic contraction of neck muscles producing sustained head postures for hours or days. Events typically occur periodically, and alertness and arousal are preserved. This migraine variant is also usually easily distinguished from epilepsy. Infants may sometimes evidence paroxysmal, brief episodes of upward gaze, so-called tonic upgaze of infancy, which may raise the notion of epilepsy. These episodes are brief, typically last seconds, are unassociated with other abnormalities, and, although they are disconcerting to parents, usually disappear by early childhood.

Four other movement disorders mimicking epilepsy are considered further in this chapter: (a) stereotypies (complex tics), (b) episodic ataxia, (c) self-stimulatory behavior, and (d) the paroxysmal dyskinesias.

Stereotypies are highly patterned, complex, sustained movements, often lasting seconds, which are typically repeated multiple times. Examples of stereotypic movements include truncal rocking, skin picking, hand clapping, hand twirling, and complex hand-to-mouth routines (feeding, blowing, touching). Phenomenologically, there is little difference between a complex motor tic, that is, a complex sequence of involuntary movements performed in response to an inner urge, and stereotypies. Stereotypies are most commonly seen in patients with autism, pervasive development delay, and Asperger syndrome, but they may also occur in developmentally disabled individuals, in Rett syndrome, and in otherwise normal children.[19,45,87,116] Because these events are brief, involve complex involuntary movements, and may affect patients' ability to interact with the examiner, they may be mistaken for supplementary motor area seizures. It is not uncommon for video-EEG monitoring to be ordered to differentiate long-duration stereotypies from seizures, particularly when they occur in neurologically abnormal individuals.

Episodic ataxia is a rare, genetic paroxysmal movement disorder that should be easy to distinguish from epilepsy. The disorder occurs in two forms, types 1 and 2. Episodic ataxia type 1 is an autosomal-dominant disorder characterized by paroxysms of ataxia lasting several minutes, often with myokymia between attacks. The disorder has been linked to mutations in the voltage-gated K^+ channel gene, *KCNA1*.[14,27,48] Episodic ataxia type 2 is an autosomal-dominant disorder characterized by paroxysms of ataxia lasting hours, often with interictal symptoms of nystagmus or cerebellar dysfunction. The disorder is linked to mutations in the alpha 1A voltage-dependent calcium channel subunit, CACNA1A. Acetazolamide and 4-aminopyridine have been shown to be beneficial in affected patients.[59,60,125,128]

Self-stimulatory behavior is not infrequently encountered at centers that perform video-EEG monitoring. This condition typically begins in early childhood, affects girls more than boys, and is usually first noticed by parents. In a typical event the child crosses his or her legs, lies flat on the floor, or applies pressure to the groin or perineum against furniture. Children can be distracted during an episode, and there may be accompanying autonomic signs such as facial flushing or sweating. Videorecording is extremely useful in documenting the nature of these events. If the clinical appearance is classic, investigative studies are unnecessary. The term "infantile masturbation" should be avoided when discussing this condition with parents because there is significant stigma associated with it. We have encountered parents who refuse to accept this diagnosis, persisting in extensive evaluations to prove a different etiology for the condition. Most children respond to redirection and support.[32,96,103,149]

In the remainder of this chapter, we discuss the paroxysmal dyskinesias, a complex and unusual group of disorders that bear relation to epilepsy. Because the literature of paroxysmal disorders is extensive and often confusing, we first offer a historical review of the development of these disorders and then present current concepts related to their nosology and etiology.

Table 1 Clinical features of paroxysmal kinesigenic, nonkinesigenic, and exertional dyskinesia

Feature	PKD	PNKD	PED
Inheritance	AD	AD	AD
Male-to-female ratio	4:1	1.4:1	4:8 (*n*=12)
Age at onset			
Range	<1–40	<1–30	2–20
Median	12	12	9.5
Mean	12	12	9
Attacks			
Duration	<5 min	2 min–4 h	5–30 min

Frequency	100/d–1/min	3/d–2/y	1/d–2/min
Trigger	Sudden movement, startle, hyperventilation	Nil	Prolonged exercise
Precipitant	Stress	Alcohol, stress, caffeine, excitement, fatigue	Stress, caffeine, fatigue
Treatment	Anticonvulsants (acetazolamide), antimuscarinics	Clonazepam, benzodiazepines	?

AD, autosomal dominant; PED, paroxysmal exertion-induced dyskinesia; PKD, paroxysmal kinesigenic dyskinesia; PNKD, paroxysmal nonkinesigenic dyskinesia.

Paroxsymal Dyskinesias—History

Gowers[44] was probably the first to report "movement-induced seizures," in this case, in an 11-year-old girl who developed brief attacks that occurred when she suddenly arose after prolonged sitting. Numerous reports of "movement-induced seizures" followed, published under the designations of *ref- lex epilepsy* or *tonic seizures induced by movement*. Some cases

demonstrated more than tonic contractions—namely, sustained twisting, athetosis, and chorea. Even the presence of choreoathetosis, however, did not lead the earliest interpreters of these brief attacks to conclude that they represented a movement disorder. Rather, they considered them to be a form of epilepsy, with the cerebral site of the "seizures" in the basal ganglia or subcortical region.

After Gowers, the next report of movement-induced paroxysmal movements appears to be that of Spiller in 1927.[126] He described two patients with brief tonic spasms brought on by voluntary movement of the involved limbs, and in one of them by passive manipulation. Contractions were painful and accompanied by sensations of heat or burning. Wilson[145] later described a 5-year-old boy who had brief attacks of unilateral torsion and tonic spasm that lasted up to 3 minutes and were precipitated by pain. Wilson considered this to be reflex tonic epilepsy, and also thought it to be subcortical in origin.

The concept of attacks of tonic, often twisting, contractions without loss of consciousness as uncommon seizure disorders continued. Lishman et al.[80] described seven patients with tonic and athetoid spasms induced by movement while remaining conscious. Abnormal sensations of numbness, vibration, and tightness were noted in the affected limbs before the attacks. Two years later they reported an additional five cases of movement-induced "seizures,"[143] and Burger et al.[15] described two patients with this label. Some also referred to these cases as forms of epilepsy.[38,52]

In 1940, Mount and Reback[99] introduced a new concept—attacks of tonic spasms plus choreic and athetotic movements with unusual triggers. They described a 23-year-old man who had had "spells" since infancy, both "large" and "small." Both types were preceded by a sensory aura of tightness in parts of the body or by a feeling of tiredness. Movements involved the arms and legs, usually a combination of sustained twisted posturing and chorea. The "small" attacks lasted from 5 to 10 minutes; longer attacks were considered "large" and also involved the neck (retrocollis), eyes (upward gaze), face (ipsilateral to the limbs, if the limb involvement was unilateral), and speech. These "large" attacks lasted for as long as 2 hours. Drinking alcohol, coffee, tea, or cola would usually precipitate an attack, as would fatigue, smoking, and intense concentration.

The attacks cleared more rapidly if the patient lay down, and they were aborted by sleep. Between attacks, the neurologic examination was normal, and there was never loss of consciousness, clonic convulsive movements, biting of the tongue, or loss of sphincter control. Phenytoin and phenobarbital were without effect, and scopolamine was the only drug found to reduce the frequency, severity, and duration of attacks. The family history revealed 27 other members with similar attacks, with a pedigree showing autosomal-dominant inheritance with complete penetrance. Mount and Reback called this disorder *familial paroxysmal choreoathetosis*.

This paper by Mount and Reback became the seminal report in the field of paroxysmal dyskinesias. After its publication, it was referenced by most reports in the literature over the next five decades, although the next report of a large family with similar attacks of muscle spasms did not reference it. In 1961 Forssman[33] described a family whose members had attacks lasting from 4 minutes to 3 hours; inheritance was autosomal dominant. Attacks were induced by cold, mental tension, irritation, fatigue, lack of sleep, alcohol, and caffeine. Onset of symptoms was in early childhood; an attack might begin with a tonic spasm in one hand and spread up the arm to the other arm, to both legs, and then to the cranial muscles, including the tongue, so that the affected person could not speak during a severe attack. Forssman considered the disorder to be new, possibly related to myotonia and paramyotonia, and did not consider it a form of epilepsy because no alteration of consciousness was involved.

In 1963, Lance[73] reported eight similar patients with attacks of tonic (dystonic) spasms, some with choreoathetosis, usually affecting only one side of the body and often preceded by pain or tingling. Two patients had secondary attacks (static encephalopathy and multiple sclerosis), one case was idiopathic and sporadic, and the remaining five were members of the same family. The attacks lasted <1 minute in two patients, 2 to

5 minutes in the patient with multiple sclerosis, and 5 to 60 minutes in the five familial cases. They were not precipitated by movement, and the familial cases were exacerbated by excitement and fatigue. No EEG abnormality was recorded between attacks.

After the 1963 article by Lance,[73] Weber[142] reported a family of four affected members with nonkinesigenic paroxysmal dystonia and used the term *familial paroxysmal dystonia*. Richards and Barnett[114] reported the next big family with the same type of paroxysmal dyskinesia as Mount and Reback's and thought that Lance's family[73] represented a variant because its members had only tonic spasms and no movements. The family of Richards and Barnett consisted of nine affected members with the trait inherited in an autosomal-dominant pattern. They emphasized the nonkinesigenic nature of the attacks and felt that a wide array of terms could describe the attacks, depending on the severity of each one. Richards and Barnett coined the term *paroxysmal dystonic choreoathetosis* (PDC), which was later adopted by Lance in 1977.[74] The terms *paroxysmal nonkinesigenic choreoathetosis* and *paroxysmal dystonia* were sometimes used instead of PDC.[12] The term *paroxysmal nonkinesigenic dyskinesia* (PNKD), proposed by Demirkiran and Jankovic,[23] is currently the accepted designation for this syndrome (Table 1).

In 1967, Kertesz[65] introduced the label *paroxysmal kinesigenic choreoathetosis* (PKC). This label developed into a most useful and widely accepted designation. Kinesigenicity has an important place in the classification of the paroxysmal dyskinesias, and Demirkiran and Jankovic[23] recommended that the term *paroxysmal kinesigenic dyskinesia* (PKD) be used instead because movements can be dystonic, choreic, or a combination of the two. Rarely, the PKD designation can be applied to certain patients whose dyskinesias are not triggered by sudden movement (or startle).

In his paper, Kertesz reported 10 new cases of paroxysmal dyskinesia and reviewed the literature. It is significant that he differentiated the kinesigenic variety from the cases described by Mount and Reback, Forssman, and Lance, which were not exacerbated by movement but by alcohol, caffeine, or fatigue. Although phenytoin was recognized earlier as a very useful agent for PKD, carbamazepine was later found to be equally useful and was introduced as a treatment by Kato and Araki.[64]

The original cases reported as PNKD were idiopathic and usually familial. It was not long before symptomatic cases began to be reported in patients with perinatal encephalopathy,[119] encephalitis,[100] head injury,[117,144] as a manifestation of multiple sclerosis,[61,90,136] and idiopathic hypoparathyroidism.[2]

The next major advance in classification was by Horner and Jackson,[54] who described two families in which several members had attacks of involuntary movements that occurred during sleep. These appear to be the first reported cases of hypnogenic paroxysmal dyskinesia. In one family, some of the affected members had classic paroxysmal kinesigenic dyskinesia, some hypnogenic, and others a combination of the two. Case 3 in this family began with the hypnogenic variety when the patient was 8 years old. By the time he had reached the age of 11 years, daytime attacks were also occurring, sometimes triggered by sudden movement. The hypnogenic episodes gradually disappeared, leaving him with kinesigenic dyskinesia that responded to antiepileptic drugs.

Lugaresi and colleagues[83,84] independently rediscovered and eventually made known the syndrome of hypnogenic paroxysmal dyskinesia. Lugaresi and Cirignotta[84] described five patients with onset of hypnogenic dystonia at ages 5, 7, 26, 30, and 40 years. Attacks occurred almost every night during sleep, with onset in stages 2 to 4 of sleep. They lasted 15 to 45 seconds and might recur several times in the same night. They could awaken the patient, who might even emit a cry. The movements appeared to be a mixture of dystonia, athetosis, and some more rapid flinging movements. The EEG findings were normal during sleep and wakefulness. Carbamazepine was effective. In their article, Lugaresi and Cirignotta described the movements as choreoathetosis and ballism in addition to dystonia. Maccario and Lustman[85] emphasized that tachycardia is a characteristic occurrence during these episodes.

The disorder was originally described in nonfamilial cases but was later reported in three members of a family.[75] Other sporadic cases have been reported as well,[21,41,113,132] including one with a concurrent reflex dystonic reaction provoked by stimulation of the right foot.[77] Another link with PKD is suggested by the report of Morley,[98] who described a father with hypnogenic dyskinetic attacks and a son with PKD. Both responded to phenytoin.

There has long been considerable speculation as to whether the short-duration hypnogenic attacks might be a manifestation of epilepsy because they respond so well to antiepileptic drugs. The lack of abnormal EEG findings during these attacks has been used to argue against this concept. However, evidence accumulated that many hypnogenic paroxysmal dyskinesias are, indeed, caused by seizures. Tinuper et al.[133] described three patients with this disorder who had EEG evidence of frontal lobe seizures as a cause of their attacks. Sellal et al.[121] and Meierkord et al.[92] studied a series of patients with hypnogenic dystonias and concluded that they represent seizure disorders, particularly of frontal lobe epilepsy, because repeated nocturnal EEG recordings often reveal epileptic patterns of abnormalities. Seizures arising near the mesial posterior frontal supplementary sensorimotor area (SSMA) may be a particular culprit in inducing paroxysmal hypnogenic dyskinesias in children.[5] These types of seizures tend to be brief, frequent, and associated with bilateral tonic posturing, gross proximal limb movements, and preserved consciousness. Dystonic and other dyskinetic features may result from spread of epileptic activity from the mesial frontal region to the basal ganglia because the anatomic connections between these areas are close. The subject of epilepsy masquerading as a movement disorder has been reviewed by Hirsch et al.[51] and Fish and Marsden.[31]

Although most patients with paroxysmal dyskinesias fit into one of these classification schemes, it has become clear that some patients defy easy classification. Several patients have been reported with both nocturnal and daytime paroxysmal events without EEG correlate. Daytime attacks may be triggered by movement or may sometimes occur without trigger.[22,111] Results of imaging and EEG monitoring are usually not helpful, and patients are often difficult to treat.

Paroxysmal Kinesigenic Dyskinesia

Clinical Features

Attacks of PKD consist of any combination of dystonic postures, chorea, athetosis, and ballism. They can be unilateral—always on one side or on either side—or bilateral. Unilateral episodes may be followed by a bilateral episode. The attacks are brief, usually lasting only seconds, but rarely can last up to 5 minutes. A sudden movement or a startle precipitates them, usually after the patient has been sitting quietly for some time. The attacks can be severe enough to cause a patient to fall down and can occur up to 100 times per day. After an attack, there is usually a short refractory period during which an attack cannot be triggered. Speech can sometimes be affected, with an inability to speak resulting from dystonia, but alteration of consciousness never occurs. Attacks can sometimes be aborted if a patient stops moving or warms up slowly. Very often, patients report variable sensations at the beginning of paroxysms. These can consist of paresthesias, a feeling of stiffness, crawling sensations, or a tense feeling.

Equivalent to PKD are equally brief attacks that are not precipitated by sudden movement or startle. Because the duration and therapeutic response are the same as in PKD, these have been included under the PKD rubric rather than in an entirely new category. These attacks lasting a few seconds can often be triggered by hyperventilation.

Plant[109] emphasized the focal and unilateral nature of PKD in many patients. Of the 73 cases of PKD in the literature reviewed by him, he found the following features: unilateral, one side only, 25; unilateral, either side, 12; unilateral and bilateral, 11; bilateral only, 22; not stated, 3.

Idiopathic Paroxysmal Dyskinesias

Most reported cases of PKD are familial, with autosomal-dominant inheritance. The male-to-female ratio is 3.75:1 (75 male patients and 20 female patients reported by Fahn[28]). Symptoms begin in childhood between the ages of 6 and 16 years, but age at onset varies widely, ranging from as early as 6 months to 40 years.[35,78] The mean and median ages at onset are 12 years. Familial cases may be more common among the Japanese[37,64,67] and Chinese.[62] Findings on computed tomography (CT) are also normal[10,43,66,82,129] with a few exceptions: A case reported by Watson and Scott[141] suggested brainstem atrophy and one reported by Gilroy[40] had an ill-defined unilateral hemispheric lesion. EEG findings are generally normal; Hirata et al.,[50] however, demonstrated an abnormal EEG with rhythmic 5-Hz discharges over the entire scalp in a patient during episodes of PKD, raising the possibility of an epileptogenic basis.

Attacks tend to diminish with age. Fortunately, PKD responds dramatically to antiepileptic drugs. The early literature indicates that phenytoin was most popular, followed by phenobarbital and primidone. More recently, carbamazepine appears to be the drug most commonly used. Valproate,[129] oxcarbazepine,[134] and topiramate[55] have also been shown to be effective. Homan et al.[53] reported that children with PKD need doses of phenytoin similar to those used to treat epilepsy, whereas adults may respond to lower doses.

The pathophysiology of PKD is unclear, and its relationship with epilepsy remains speculative. The existence of movement-induced seizures (e.g., the case of Falconer et al.[29]) and the dramatic response of PKD to antiepileptic drugs are not sufficient reasons to consider PKD a form of epilepsy. The retention of consciousness and lack of postictal phenomena, as well as the presence of dystonia and choreoathetosis, should be sufficient to disqualify PKD as epilepsy. Franssen et al.[34] investigated the contingent negative variation (CNV) in one patient. This is a slow cerebral potential that follows a warning stimulus that prepares the subject to expect an imperative stimulus requiring a decision or motor response. The slow negative-wave component of the CNV was more pronounced compared with that of control subjects. It returned to normal after phenytoin treatment. Mir et al.[97] later demonstrated reduced intracortical inhibition, reduced early-phase transcallosal inhibition, and reduced first phase of spinal reciprocal inhibition in PKD patients; treatment with carbamazepine normalized the abnormality of transcallosal inhibition.

Two recent studies suggest that attacks of PKD are associated with contralateral hypermetabolism in subcortical nuclei. Using single photon emission computed tomography (SPECT), Ko et al. studied a 14-year-old patient and demonstrated increased perfusion in the contralateral basal ganglia at onset of attacks.[69] Shirane et al. studied a 6-year-old with PKD, also using SPECT; subtraction of interictal from ictal cerebral blood flow measures showed unilateral increase of thalamic blood flow during an attack.[123]

The differential diagnosis of PKD includes partial epilepsy, tetany, hyperexplexia, and psychogenic disorders, as noted in the misdiagnosis of the case reported by Waller.[140] The clinical features are so distinctive, particularly if triggered by sudden movement, that there is little likelihood of the condition not being diagnosed correctly once the physician is aware of its existence. However, nonkinesigenic brief attacks of hemidystonia, often precipitated by hyperventilation and controlled with antiepileptic drugs, may be a sign of epilepsy.[70] Therefore, each case of suspected nonkinesigenic paroxysmal dyskinesia should be evaluated for a convulsive disorder.

Two autopsies in PKD have been reported. After case 4 of Kertesz[65] died, apparently by suicide, a postmortem examination revealed no clear abnormality in the brain, just the presence of some melanin pigment in macrophages in the locus ceruleus. Stevens[127] had earlier reported the postmortem findings of one of his patients, which were also essentially normal, showing only a slight asymmetry of the substantia nigra.

Recent studies have linked PKD to two separate loci on chromosome 16.[7,50,130,135] In some families, PKD cosegregates with infantile convulsions, whereas in others, it does not.

Symptomatic Paroxysmal Dyskinesias

The overwhelming majority of reported cases of PKD are idiopathic or familial. Occasional cases of symptomatic PKD have been reported, most frequently in association with multiple sclerosis and head injury. Although sudden movement does not trigger most of the paroxysmal dyskinesias associated with multiple sclerosis, sometimes a patient with multiple sclerosis manifests typical PKD.[90] In fact, PKD can be the presenting symptom of multiple sclerosis, as in the case reported by Roos et al.[118]; the patient's attacks were associated with a lesion in the caudate nucleus and responded to phenytoin. In three of the eight patients reported by Berger et al.[8] with paroxysmal dyskinesia associated with multiple sclerosis, attacks were induced by sudden movement and were relieved with antiepileptic drugs.

As mentioned earlier, attacks lasting for seconds are sometimes induced not by sudden movement but by hyperventilation. These also usually respond to antiepileptic drugs, such as carbamazepine, and may be seen in multiple sclerosis.[122,136] Sethi et al.[122] reported successfully treating three patients who had paroxysmal dystonia (not induced by movement, but triggered by hyperventilation and lasting many seconds) using acetazolamide with or without a combination of carbamazepine. The case of PKD with multiple sclerosis reported by Burguera et al.[16] had a lesion in the left thalamus demonstrated by magnetic resonance imaging (MRI). Paroxysmal kinesigenic dyskinesia was the presenting symptom, as in other cases of demyelinating disease. Case 3 of Whitty et al.[143] was a 13-year-old boy with onset 9 months after mild head trauma. Robin[117] reported a 33-year-old man with severe head injury in whom PKD developed 8 months later. In two of the three cases of posttraumatic paroxysmal dyskinesias reported by Drake et al.,[25] movements were induced by sudden movement of the affected body part. Another posttraumatic case was reported by Richardson et al.[115] Like idiopathic PKD, these posttraumatic cases of PKD responded to antiepileptic drugs. Attacks of dystonia lasting several seconds and induced by tactile stimulation were reported secondary to a head injury; they disappeared within 2 months without treatment.[39] Another case of tactilely induced dyskinesias was reported by Nijssen and Tijssen[105] as a result of a thalamic infarct.

In case 2 of the five cases described by Kinast et al.,[66] attacks of left hemidystonia lasted 1 minute and occurred up to

50 times a day. The major precipitating factor was not sudden movement, but rather stress and the anticipation of movement. Technically, this patient does not fulfill the criterion of attacks induced by sudden movement. However, because of their brief duration, frequency, and response to phenytoin, which are features resembling those of PKD, they are placed under the PKD rubric in the classification scheme of this chapter. Examination revealed left-sided hemiatrophy and hyperreflexia, with normal findings on CT. Gilroy[40] reported a 32-year-old man with an abnormal right hemisphere on CT who had had multiple daily brief attacks of left hemidystonia since the age of 5 years that were typical of PKD.

With the advent of MRI, more cases of PKD have been reported as a result of cerebral infarcts—putaminal,[93] thalamic,[99,101,102] and cortical.[36] Paroxysmal kinesigenic dyski-nesia has also been reported in patients with progressive supranuclear palsy,[1] calcifications of the basal ganglia with or without hypoparathyroidism,[41,105,106] and hyperglycemia in the presence of a lenticular vascular malformation.[137]

In one family with X-linked mutations in the thyroid hormone transporter gene *MCT8*, paroxysmal dyskinesias accompanied global mental retardation.[13]

Paroxysmal Nonkinesigenic Dyskinesia

Clinical Features

Like attacks of PKD, attacks of PNKD consist of any combination of dystonic postures, chorea, athetosis, and ballism. They can be unilateral or bilateral, and unilateral episodes can be followed by a bilateral episode. They can affect a single region of the body or be generalized. The neck can be affected by a combination of torticollis and head tremor.[57] Features that distinguish these attacks from those of PKD are the longer duration, lesser frequency, and different aggravating factors. Attacks last minutes to hours, sometimes longer than a day. Usual duration ranges from 5 minutes to 4 hours. Attacks are triggered by consumption of alcohol, coffee, or tea, and also by psychologic stress or excitement and fatigue. There are usually no more than three attacks per day, and often attacks are spaced months apart. The attacks can be severe enough to cause a patient to fall down. Speech is often affected, with inability to speak caused by dystonia, but alteration of consciousness never occurs. The attacks can sometimes be aborted if a patient goes to sleep. As in PKD, patients very often report variable sensations at the beginning of the paroxysms. These can consist of paresthesias, a feeling of stiffness, crawling sensations, or a tense feeling.

Idiopathic Nonkinesigenic Dyskinesias

The initial reports of PNKD were familial with autosomal-dominant transmission. Kinast et al.[66] in 1980 (case 4) and Dunn[26] in 1981 each described a child with PNKD without a positive family history. Since then, Bressman et al.[12] described seven sporadic cases of PNKD, and Nardocci et al.[101] added another one. The familial cases of idiopathic PNKD still greatly outnumber sporadic cases according to the reports in the literature. The sporadic cases are much more difficult to diagnose, however, and they present the added difficulty of having to be differentiated from psychogenic etiology. Based on the experience of Bressman et al.,[12] the sporadic form may actually be more common than the familial form, but is just rarely reported.

There is a slight preponderance of male patients, with a male-to-female ratio of 1.4:1. Onset is usually in childhood between the ages of 6 and 16 years, but age at onset varies widely, ranging from 2 months to 30 years. The mean and median ages at onset are 12 years. Results of CT are normal.[58,91] The EEGs are also generally normal, but the case of Jacome and Risko[58] may be of interest. The patient had unilateral PNKD and normal interictal EEGs. Photic stimulation at low frequencies induced paroxysmal lateralized epileptiform discharges from the contralateral hemisphere. Two patients with PNKD have been studied with functional imaging. del Carmen Garcia et al.[22] performed an ictal SPECT in a 16-year-old patient with PNKD, showing hyperperfusion in the contralateral caudate and thalamus during an attack. Lombroso et al.[81] used fluorodeoxyglucose positron emission tomography (PET) in a patient with PNKD to show no metabolic asymmetry; flurodopa and raclopride PET, however, showed a reduction in presynaptic dopa decarboxylase activity in the striatum and increased postsynaptic D2 dopamine receptors.[81]

The attacks may diminish spontaneously with age. Unfortunately, the attacks of most patients are persistent and are difficult to treat. As a general rule, PNKD does not respond to the antiepileptic drugs that so effectively treat PKD. An occasional patient responds to such agents as carbamazepine and valproate. Clonazepam, as introduced for PNKD by Lance,[74] appears to be the most successful agent, both for idiopathic PNKD and symptomatic PNKD. A number of other drugs have been tried, sometimes with success. These include antimuscarinics,[99] chlordiazepoxide,[106,139] acetazolamide,[12,91] oxazepam and other benzodiazepines,[71,72] and l-tryptophan.[71] Kurlan and Shoulson[72] treated one patient with familial PNKD with clonazepam and oxazepam with relief for 2 to 3 weeks each, and he was placed on a regimen of 40 mg of oxazepam given on alternate days. Trials of the dopamine-receptor antagonist haloperidol were carried out by Przuntek and Monninger[112] and Coulter and Donofrio[20] with benefit; they also found that levodopa worsened the condition of one patient. At least one patient with PNKD has been treated successfully with deep brain stimulation of the globus pallidus interna.[147]

Lance[74] reported autopsies performed on two patients with PNKD with no pathology. Macroscopic findings in his case II.4 were normal. His case IV.2 died of crib death; macroscopic and microscopic findings were normal.

The gene for familial PNKD was cloned in 2004 by a collaborative consortium lead by Ptacek.[76] In 50 individual from eight families, PNKD was shown to be caused by mutations in the myofibrillogenesis regulator gene. The protein product of this gene may be involved in detoxification of methylglyoxal, a compound present in coffee and alcoholic beverages, perhaps explaining the triggering of attacks by these agents.

Symptomatic Paroxysmal Nonkinesigenic Dyskinesia

The overwhelming majority of reported cases of PNKD are idiopathic or familial. A number of cases of symptomatic PNKD have been reported, most frequently in association with multiple sclerosis and perinatal encephalopathy. In multiple sclerosis, the paroxysmal movements may affect only the eyes, lasting several minutes.[86] Other causes of PNKD are encephalitis,[12,100] cystinuria,[18] hypoparathyroidism,[124,148] basal ganglia calcifications without altered serum calcium,[94] thyrotoxicosis,[30] transient ischemic attacks,[6,89] infantile hemiplegia,[56] head trauma,[25,107] hypoglycemia, AIDS,[102] diabetes,[47] moyamoya,[42] anoxia,[12] and brain tumor.[12]

Paroxysmal nonkinesigenic dyskinesia caused by endocrine disorders responds to appropriate treatment. In general, however, treatment of symptomatic PNKD is often ineffective. Positron emission tomography performed in one patient with posttraumatic paroxysmal hemidystonia revealed decreased oxygen metabolism, decreased oxygen extraction, increased blood volume, and increased blood flow in the contralateral basal ganglia.[107]

Paroxysmal Exertional Dyskinesia

Lance[74] was the first to describe what he called an intermediate form of PDC (now better known as exercise-induced or exertional dyskinesia). It affected members of a family with attacks briefer than those of classic PNKD, typically lasting from 5 to 30 minutes. Attacks were precipitated by prolonged exercise but not by cold, heat, stress, ethanol, excitement, or anxiety. The spasms affected mainly the legs. A second family was reported by Plant et al.[110] In both families, the inheritance pattern was autosomal dominant. No one in either family derived any benefit from barbiturate, levodopa, or clonazepam. More recently, three other families have been reported with exercise-induced paroxysmal dyskinesia, each with different accompanying neurologic abnormalities. Guerrini et al.[46] reported a family with autosomal-recessive rolandic epilepsy, paroxysmal exercise-induced dystonia, and writer's cramp. Affected patients developed symptoms in childhood, and the disorder was linked to a locus adjacent to that of autosomal-dominant infantile convulsions and paroxysmal choreoathetosis.[46] Margari et al.[88] described a family with exercise-induced dyskinesias and generalized epilepsy, and Perniola et al.[108] reported a similar family autosomal-dominant inheritance.

A sporadic case (case 3) was later reported by Nardocci et al.[101] This patient, with no family history of a similar condition, also had interictal chorea. Treatment with clonazepam proved helpful. Another sporadic case was reported by Wali[138]; an 18-year-old youth had attacks of right hemidystonia lasting about 10 minutes that were precipitated by prolonged running (about 10 minutes) or by cold. The EEG and CT findings were normal; antiepileptic drugs were not helpful. Demirkiran and Jankovic[23] saw five patients, three of them female. Bhatia et al.[9] reported eight sporadic cases, with age of onset 2 to 30 years. A posttraumatic case has also been reported,[79] which was responsive to oral baclofen.

Paroxysmal exercise-induced dyskinesia is probably a heterogeneous disorder, and the underlying etiologies have not been fully discovered. It is worth noting that rare patients with young-onset Parkinson's disease may present in this manner before any other signs of bradykinesia or rigidity are evident.[11] Of note, a patient with exercise-induced dyskinesias without parkinsonism had increased cerebrospinal fluid levels of homovanillic acid and 5-hydroxyindoleacetic acid after an attack, suggesting that dopaminergic transmission is increased during an attack.[4] Ictal SPECT during attacks in two familial cases showed decreased frontal and striatal perfusion, with increased cerebellar perfusion.[68]

Summary and Conclusions

Overlap between paroxysmal movement disorders and epilepsy has been noted since the end of the nineteenth century. This reflects not only the shared phenomenology of paroxysmal movement disorders and movements that occur in epilepsy, but also a common etiology of subcortical hyperexcitability. Differentiating paroxysmal movement disorders from epilepsy can be challenging, sometimes requires video-EEG monitoring, and, as demonstrated in this chapter, allows for appropriate evaluation and treatment of these patients.

Chapter 279

Sensory Disorders

Carl W. Bazil

Introduction

Because partial seizures can begin anywhere in the cerebral cortex, their manifestations are diverse, and because large portions of the cortex are devoted to primary and secondary interpretation of sensory stimuli, a wide variety of visual, auditory, vestibular, gustatory, and tactile symptoms can be features of epilepsy. Because seizure-related sensory manifestations are so varied, other sensory abnormalities may sometimes be confused with epilepsy. In distinguishing epileptic from nonepileptic sensory symptoms on clinical grounds, a few general principles are important. First, the context of the symptom must be considered. Purely sensory seizures, without other manifestations at least some of the time, are uncommon, so a careful search for other symptoms or signs supportive of epilepsy should be performed. For example, if a single secondarily generalized seizure begins with focal numbness, it is much more likely that the preceding dozens of similar episodes of isolated numbness were actually simple partial seizures. Second, the time course of the patient's sensory event must be considered. Is it truly paroxysmal? Is the symptom recurrent and unprovoked? How long do the symptoms last? In general, epileptic seizures are unprovoked, paroxysmal, and 1 to 3 minutes in duration. Third, the quality of the sensory experience is relevant. Seizures typically consist of “positive” changes rather than “negative” ones, and this may be helpful in identifying nonepileptic sensory phenomena. For example, visions of swirling colors and shapes are more likely to have an epileptic origin than loss of vision, and localized tingling paresthesias are more likely to be epilepsy than diffuse numbness. Finally, the distribution of the sensory disturbance must be considered and whether it makes anatomic sense. Partial seizures arise from the cerebral cortex, and initial symptoms can therefore often be localized to a fairly discrete brain area. Subsequent evolution of symptoms generally involves adjacent cortex. Thus, visual symptoms typically involve one hemifield. Somatosensory seizures are more likely to involve the face and hand (because these have large areas of representation in the cortex) and should be restricted to one side of the body, at least at onset (insular seizures are an exception[7]).

It is clear that an accurate, detailed description of paroxysmal sensory changes is critical in separating epileptic events from a wide variety of nonepileptic conditions. Important sensory conditions that may be confused with epilepsy are listed in Table 1, and additional testing useful in distinguishing these conditions from epilepsy is listed in Table 2. This chapter describes all of these conditions in further detail and explains how they can best be distinguished from epilepsy.

Disorders of Olfaction

One of the classic (although not the most common) initial symptoms of seizures originating in the medial temporal lobe is a paroxysmal episode involving an unpleasant odor. Typical descriptions include references to burnt rubber, sulfur, and organic solvents,[39] although more commonly the patient is unable to provide a specific analogy. Such “auras” may occur in the absence of other seizure manifestations as an isolated simple partial seizure. However, virtually all such patients experience a complex partial or secondarily generalized seizure at some point, especially if untreated, and this event resolves any diagnostic uncertainty.

Because virtually all abnormalities of the olfactory system result in loss of smell rather than an abnormal sensation of smell, these are not commonly mistaken for epilepsy. The one important exception is psychiatric illness. In such cases, patients will frequently report abnormal smells in association with psychogenic seizures. Although these may superficially resemble the foul odors of temporal lobe epilepsy, more commonly they are described much more precisely and are even reported as pleasant. Thus, a floral scent has been described,[33] as have smells of "perfume," "food," and "pure oxygen." For a more extensive discussion of these seizures, the reader is referred to the section on psychiatric disturbances.

Disorders of Vision

The sudden visual loss that accompanies a *vertebrobasilar transient ischemic attack* (TIA) is not easily confused with an epileptic seizure. Transient ischemic attacks usually last longer than typical seizures. Both, however, may be associated with vertigo, impaired speech, or altered consciousness. The distinction is discussed more fully in Chapter 275. Recurrent, sometimes stereotyped visual hallucinations may also occur in cases of *cerebral amyloid angiopathy*[20] (see also later discussion).

The complex and sometimes confusing relationship between *migraine* and epilepsy is also discussed more fully elsewhere (see Chapter 274). Because of its high prevalence, the visual symptoms of migraine represent a common situation in which the sensory symptoms of another disease may be mistaken for epilepsy. The phenomena of the two disorders can be similar, although the classic hemifield scotoma seen in migraine is rare with epilepsy. On the other hand, patients with migraine may see stars, colored lights, or patterns similar to those seen by patients with epileptic seizures arising from the occipital or posterior temporal lobe.

Table 1 Sensory disturbances that can mimic seizures

Olfactory disorders
Visual disorders
Migraine
Transient ischemic attack
Peduncular hallucination
Other visual hallucinations
Hearing and vestibular disorders
Auditory hallucination
Dizziness
Benign positional vertigo
Paroxysmal vertigo of childhood

Ménière disease

Somatosensory disorders

Transient ischemic attack

Headache

Transient compression neuropathies

Trigeminal neuralgia

Paroxysmal sensory symptoms of multiple sclerosis

Amyloid angiopathy

Gastrointestinal symptoms

Psychogenic sensory symptoms

Table 2 Additional diagnostic testing useful in sensory disorders

Test	Useful condition(s)
MRI	Stroke, TIA, multiple scerosis, brainstem lesion; cerebral amyloid angiopathy
Audiometry	Hearing loss, BPV, Ménière disease
Electronysagmography; rotary chair testing	BPV
BAER	Brainstem lesion
EMG/nerve conduction testing	Peripheral nerve diseases

BAER, brainstem auditory-evoked potentials; BPV, benign positional vertigo; EMG, electromyography; TIA, transient ischemic attack.

Other unusual causes of visual hallucinations that can occasionally be confused with epilepsy include withdrawal from alcohol or sedative drugs and psychiatric disease. In both, the images are typically well formed, but their variability and long duration (hours to days rather than minutes) usually distinguish them from epilepsy, even in the absence of other clinical information. Hallucinations occurring exclusively during the transitions between sleep and wakefulness (hypnic hallucinations) are often visual. These can be associated with narcolepsy, but also occur sporadically in otherwise normal individuals and can be precipitated by sleep deprivation.[2]

Peduncular hallucinations, a more unusual cause of paroxysmal visual symptoms, were first described by Lhermitte.[32] These typically occur in the evening and may last for hours. They are quite vivid and well formed; examples include

P.2780

a brightly colored parrot[9] or other animals.[1,32,41] Affected patients may have alterations in consciousness, adding to the confusion with seizures. Associated symptoms such as cranial nerve palsies, hemiplegia, hemianesthesia, or ataxia are seen in many patients. Hypomania and increased tone occur often,[41] which may also help to distinguish peduncular hallucinations from seizures. The condition results from infarction of the thalamus or the pars reticulata of the substantia nigra.[9]

Disorders of Hearing and the Vestibular System

As with olfactory disturbances, most seizures that affect hearing and balance manifest the “positive” features of auditory hallucinations or distortions and vertigo. Therefore, it is these symptoms that are most often mistaken for epilepsy. Auditory hallucinations are common in schizophrenia (see Chapter 287) and also occur occasionally in acute withdrawal states from alcohol and other sedative drugs. In both cases, the variability of the hallucinations in any single patient and the particular clinical setting usually make the distinction from epilepsy fairly easy. Auditory hallucinations are rare in vascular disease. These may be transient, and the absence of psychiatric disease can lead to confusion with epilepsy. Auditory hallucinations, including musical hallucinations, can occur with hearing loss, drug intoxication, or drug withdrawal.[14]

Episodes of dizziness and, in particular, paroxysmal vertigo are more likely to be confused with epilepsy. Dizziness is a very common complaint, especially in the elderly, and although only a small fraction of cases may be confused with epilepsy, this still represents a substantial number. The causes of vertigo are quite diverse and may involve either central or peripheral vestibular mechanisms. Peripheral vertigo can result from cupulolithiasis, head trauma, acceleration injuries, and middle ear infections and typically lasts seconds to minutes. Central vertigo can be caused by drugs, cerebrovascular disease, tumors, and multiple sclerosis and typically lasts several days,[17] and therefore these would not typically be confused with epilepsy. The most common disorder is *benign positional vertigo*, which is usually idiopathic, the result of head trauma, or related to a viral infection.[5] Unlike vertigo associated with seizures, paroxysmal nonepileptic vertigo is rarely unprovoked. The diagnosis is made when positional changes (including Hallpike and Barany maneuvers) elicit the patient's typical symptoms with accompanying nystagmus. Paroxysmal vertigo is also usually of longer duration than vertiginous symptoms seen with epilepsy.

Benign paroxysmal vertigo of childhood is characterized by sudden, brief episodes of vertigo and nystagmus. It was first described by Basser.[6] The syndrome occurs most often in children, usually beginning after 4 years of age, but occasionally before age 1 year; it typically resolves by age 10 years. Episodes last from 20 seconds to 3 minutes and may be accompanied by nausea, vomiting, or headache. The child may stumble or fall because of disequilibrium and, not surprisingly, becomes frightened or confused, features that may further suggest a complex partial seizure. The typical frequency is one to five spells per month.[13] Results of audiologic, otologic, and neurologic examinations are normal. Findings of caloric/rotatory tests may be normal[13] or abnormal.[12] The electroencephalogram (EEG) is uniformly normal. Nystagmus occurs during the actual episodes and, if observed, helps in the distinction from seizures. Benign paroxysmal vertigo is associated with migraine[13,15,26] and may perhaps be a variant of basilar migraine. The disorder most likely results from a transient disturbance in the vertebrobasilar circulation that produces central vestibular dysfunction.[16]

In adults, *Ménière disease*, especially in its early stages, is sometimes confused with epilepsy. In the famous case of Vincent van Gogh, debate continues about whether he had Ménière disease or epilepsy.[4,35] Like seizures, attacks of Ménière disease are often preceded by a warning, typically a nonspecific feeling of fullness in the ears. Unlike seizures, attacks are usually accompanied by nystagmus, hearing loss, and tinnitus. Episodes of vertigo may last for hours but occasionally last only a few minutes. Patients may feel weak and unsteady after the episode, but there is never any alteration in consciousness during or after the attacks.[44] Spells may be so sudden and so severe that the patient actually falls to the ground (although without loss of consciousness). Diagnostic tests such as electronystagmography, audiometry, or auditory-evoked potentials may be helpful in confirming a peripheral vestibular disorder.

Disorders of the Somatosensory System

Purely sensory transient ischemic attacks (TIAs) are not uncommon and are manifested by a variety of sensory complaints involving the face and limbs. Although patients usually report numbness, they may also describe a variety of "positive" symptoms, such as pain, tingling, heat, or paresthesias. Because many TIAs resolve within 5 minutes, shorter attacks may be confused with epilepsy. The reader is referred to Chapter 275 for a more complete description of TIAs.

Similar symptoms may be seen in *cerebral amyloid angiopathy* (CAA), a common cause of lobar hemorrhage in older, normotensive patients.[24,42] The disease is characterized by deposition of ß-amyloid in the media of small and medium-sized cerebral arteries. Confusion with epilepsy may occur in the prodromal stages, when the patient has recurrent spells of numbness or tingling that spread over the body in minutes. Transient sensory symptoms can occur repeatedly in the same area,[20] mimicking the stereotypy found in partial seizures. Some authors have suggested that "CAA spells" are actually seizures, but most have concluded that they are more likely to be the result of spreading depression,[20] perhaps triggered by small hemorrhages. Although definitive diagnosis requires histologic confirmation, patients with CAA frequently have multiple cortical hemorrhages and are more likely to show the apolipoprotein E e-2 allele than is a population-based sample.[19] Distinction from seizures is clearly important, but CAA must also be differentiated from TIAs because anticoagulation leads to an increased risk for lobar hemorrhage. Finally, patients with CAA can also have true epileptic seizures,[8,20,23] which poses further diagnostic problems for the clinician.

Neuropathies rarely produce symptoms that are confused with seizures. The manifestations of neuropathies are typically indolent rather than paroxysmal, progressive or static rather than recurrent, and involve areas that are uncommonly symptomatic during seizures (e.g., stocking-glove distribution, mononeuritis multiplex). In unusual cases, a particular nerve may be recurrently and reversibly affected, and a patient may offer a description of repeated numbness or tingling in a particular area, which may seem paroxysmal. Examples include meralgia paresthetica, ulnar neuropathy, and carpal tunnel syndrome. These cases can usually be distinguished from epilepsy by careful history; if diagnostic uncertainty persists, electromyographic evaluation will resolve the issue.

Patients occasionally complain of paroxysmal head pain that can resemble a seizure. Headache as a sole manifestation of seizure is, however, exceedingly rare.[25,29] More commonly, headache occurs as a nonspecific prodrome, aura, or postictal phenomenon. Because ictal headache is so uncommon, even unusual types of headache are not usually confused with epilepsy.

Trigeminal neuralgia (*tic douloureux*) is a relatively common condition characterized by paroxysmal attacks of severe pain in the distribution of one or more branches of the trigeminal nerve. As in epilepsy, attacks are sudden and unpredictable, and are usually brief in duration. Sometimes, however, attacks of trigeminal neuralgia last for hours, a duration that is very atypical of seizures. Unlike epileptic seizures, attacks of trigeminal neuralgia occur frequently in clusters. The maxillary branch of the trigeminal nerve is involved most often; the ophthalmic division is rarely involved in isolation.[28] Carbamazepine is the most effective medical treatment; phenytoin can also be used. Attacks of trigeminal neuralgia are frequently provoked by sensory stimuli (e.g., touch, cold) to the affected region, which may suggest a form of "stimulus-sensitive" epilepsy. In fact, Pagni[36] proposed that trigeminal neuralgia represents a form of stimulus-evoked epilepsy. Classic trigeminal neuralgia is easily distinguished from epilepsy by the distribution, time course, and quality of the attacks. Atypical presentations, however, are occasionally mistaken for simple partial seizures, and the incorrect diagnosis seems to be further supported by a good response to antiepileptic drugs.

Paroxysmal sensory symptoms, including trigeminal neuralgia, can occur in patients with *multiple sclerosis* (MS). A common paroxysmal disturbance is burning dysesthesia, often restricted to one limb, that lasts <1 minute and often only a few seconds. There are no associated convulsive movements. Attacks may be induced by voluntary movements and respond well to carbamazepine.[46] Episodes of painful chorea, dystonia, and various tonic postures also occur in MS.[27,34,38] These probably arise from an ectopic generation of action potentials in demyelinated axons, with subsequent spread along sensorimotor pathways.[46]

Gastrointestinal symptoms, such as nausea and vomiting, are treated first by general practitioners or internists, although these can be manifestations of simple partial seizures. Gastrointestinal reflux is unlikely to be confused with epilepsy in adults from whom an accurate history may be obtained. It can pose a diagnostic problem in young children, in whom episodes of reflux may be accompanied by vomiting, cyanosis, and posturing simulating epilepsy.[37] In children, recurrent abdominal pain may develop at about 5 years of age. Episodes usually last several hours and are not associated with any gastrointestinal diagnostic abnormalities.[3] Cyclic vomiting is seen at the age of 2 years and disappears after 3 to 4 years.[22] These episodes are frequently accompanied by severe nausea and abdominal pain. Both recurrent abdominal pain and cyclic vomiting are associated with migraine[37] but not epilepsy. They were formerly often misdiagnosed as “abdominal epilepsy.”

Psychogenic Sensory Symptoms

Psychiatric disorders are discussed in Chapters 281,282,283,284,285,286,287; however, they deserve special mention in a discussion of sensory phenomena. Because sensory symptoms are usually not accompanied by objective changes, the clinician often must rely entirely on the history for an initial diagnosis. Particularly in the case of a patient with psychiatric illness, this description may be vague and unhelpful, adding to the difficulty in distinguishing epileptic from nonepileptic events.

Psychogenic nonepileptic seizures (PNES) are paroxysmal alterations in movement, sensation, or experience that resemble epileptic seizures but arise from purely psychological causes (see also Chapter 282). Although up to 80% of patients with PNES have motor manifestations,[18,21,30] in other cases, PNES are characterized by sensory changes,[43] including numbness, paresthesias, pain, odors, tastes, and visual/auditory hallucinations.[21,31,33] Psychogenic nonepileptic seizures usually have a more gradual onset and longer duration than epileptic seizures, but these features alone cannot reliably be used to make the distinction from epilepsy.[31]

The presenting symptoms of *panic disorder*, with or without hyperventilation, may include dizziness, vertigo, perioral tingling, numbness or tingling of the hands, generalized weakness, or syncope, and panic disorder may be confused with epilepsy.[40] Paroxysms of unexplained fear are typical in panic disorder; these may be confused with a limbic seizure. For a more complete discussion, see Chapter 285.

Distinguishing PNES or panic disorder from epileptic seizures may be difficult. Stereotyped attacks favor epileptic seizures, although subjective descriptions of purely sensory symptoms are often difficult to interpret. When diagnosis remains unclear following a careful history, video-EEG monitoring may be required to make the distinction.

P.2782

Summary and Conclusions

Many sensory symptoms and disorders have some resemblance to epilepsy and, in certain circumstances, may be confused with it. In most cases, careful history taking supplemented by appropriate diagnostic testing provides a reliable basis for making the distinction. In some patients, recording one or more of the patient's habitual events with concurrent electroencephalography (video-EEG monitoring) may be required to distinguish epileptic from nonepileptic events reliably. A time-linked ictal discharge during an episode is diagnostic of epilepsy. False-negative results may occur with simple partial seizures, which have no scalp EEG correlate in the majority of cases.[11] In such instances, however, video recording and careful clinical testing should reliably establish the clinical semiology and determine whether this is consistent with an epileptic seizure. Prolonged EEG recordings may also show interictal epileptiform discharges; these strongly suggest a diagnosis of epilepsy,[10,47] but their detection is not equivalent to demonstration of a seizure discharge occurring simultaneously with the symptom in question. When spells occur on a daily basis, 6- to 8-hour EEG with video monitoring on an outpatient basis is a reasonable alternative. Infrequent attacks usually require inpatient video-EEG monitoring, and antiepileptic drugs (if used) may need to be withdrawn. Recent advances in extended outpatient EEG monitoring are making this an alternative to inpatient monitoring in selected cases, although these still suffer from the lack of trained personel to ensure proper recording at all times and to test the patient appropriately during spells.

Chapter 280

Nonepileptic Neurologic Paroxysmal Disorders and Episodic Symptoms in Infants

Natalio Fejerman

Introduction

Misdiagnosis of epileptic seizures in young children is frequent and generally due to considering various paroxysmal or episodic symptoms as epileptic when they are not.[12,59,61,107]

Nonneurologic paroxysmal disorders, such as breath-holding spells, syncope, and psychogenic events, are discussed in Chapter 273. Most of the neurologic conditions listed in Table 1 are uncommon. Nevertheless, they can be an important part of the differential diagnoses of epileptic seizures. Table 1 groups various symptoms and conditions according to their general nature.[116]

Enhanced Normal Phenomena

Sporadic Myoclonic Jerks During Sleep (Hypnic Jerks) or Physiologic Sleep Myoclonus

These are universally present in normal people. They appear during the initial stages of sleep and also during rapid eye movement (REM) sleep. Typically, they manifest as slight contractions of face muscles and brief movements of the fingers or toes. There are no electroencephalographic (EEG) correlates.[69] Massive bilateral jerks, mainly involving the legs, can occur during the initial stages of sleep in association with a change in sleep state or arousal.[114]

Localized Myoclonus During Wakefulness

This represents a rare physiologic phenomenon that usually occurs during and after muscular fatigue and when the linear or a particular group of muscles are placed in unsupported postures. The affected muscle groups may vary, but in any individual, each episode of myoclonus involves the same muscles. The myoclonic jerks last a few seconds to several minutes. There are no EEG changes accompanying the myoclonus, and a spinal origin has been suggested.[69] Even hiccoughs, considered a physiologic phenomenon, may occasionally be intense and simulate a paroxysmal disorder in small infants.

Startle Responses

These have been called *sursaut diurne* in the French literature[69] and are sudden, bilateral myoclonic jerks that may be either tight or massive and appear as a surprise reaction to a sudden sensory stimulus. Although segmental myoclonus is rare in young children, startle responses are very common. The Moro reflex has a startle component, and some kind of startle response can be demonstrated in most normal infants. These normal physiologic responses must be distinguished from the exaggerated Moro reflex and pathologic stimulus-induced myoclonus, often with opisthotonus seen in children with static or progressive encephalopathy.[58]

Bruxism

The majority of adults and children have nocturnal bruxism at some point in their lives.[13] In children with autistic behavior and mental retardation, bruxism also occurs in the waking state and may lead to severe dental attrition.[109]

Parasomnias

More common disorders are considered in Chapter 276 (see also Hanson and Peck[79]).

Transient or Benign Movement Disorders

Benign Neonatal Sleep Myoclonus

In 1982, Coulter and Allen[35] reported three infants who had sleep myoclonus that began in the first month of life. The myoclonic jerks were bilateral, repetitive, and located mainly in the forearm and hands. Neurologic examinations and EEG were normal and continued to be normal during follow-up. Coulter and Allen coined the term *benign neonatal sleep myoclonus* (BNSM) for this phenomenon.

Subsequently, several other small series of cases were published that emphasized the importance of distinguishing BNSM from seizures.[123,143] This condition is probably quite frequent, as suggested in more recent, larger series.[37,42,43]

Table 1 Nonepileptic neurologic paroxysmal disorders and episodic symptoms in infancy

Disorder	Symptoms
Enhanced normal phenomena	Hypnic jerks and waking myoclonic jerks Bruxism
Transient or benign movement disorders	Benign neonatal sleep myoclonus
	Tonic reflex seizures of early infancy
	Benign myoclonus of early infancy (benign nonepileptic infantile spasms)
	Benign paroxysmal tonic upward gaze
	Transient paroxysmal dystonia
	Benign paroxysmal torticollis
	Shuddering attacks
	Adverse reactions to exogenous agents

Habit-type movements and self-gratification phenomena	Head banging Head or body rocking Other stereotypic movements Masturbation-like episodes
Symptomatic abnormal movements	Neonatal posturing and other nonepileptic episodes
	Opsoclonus-myoclonus syndrome
	Bobble-head doll syndrome
	Encephalopathic nonepileptic myoclonus
Other paroxysmal episodes or neurologic conditions	Nonepileptic apnea Hyperexplexia Cogan oculomotor apraxia Benign paroxysmal vertigo Spasmus nutans Alternating hemiplegia of childhood Paroxysmal dystonia and choreoathetosis

Benign neonatal sleep myoclonus appears in term newborns during the first few weeks of life. One infant born prematurely developed BNSM at 42 weeks of conceptional age,[120] and the earliest reported onset is in a 5-hour-old newborn.[35] The intensity and frequency of the muscle jerks increase up to the third week of life; more subtle myoclonus appearing earlier may go unnoticed. Myoclonic jerks are mainly present during non–rapid eye movement (NREM) sleep; they are less frequent during REM sleep. In some children, BNSM occurs exclusively during NREM sleep.[42] In most cases, jerks predominately

involve the arms, but the feet, face, axial, and abdominal muscles can also be affected.[29,37,42,118,123] Myoclonic jerks may be bilateral; localized or multifocal; rhythmic or arrhythmic. The jerks occur frequently in clusters repeating at 1 to 5/sec for several seconds. Clusters of jerks usually recur irregularly in series lasting 20 to 30 minutes[42] or up to 90 minutes.[20] Longer-lasting episodes of BNSM have been mistaken for convulsive status epilepticus.[5,148]

Sleep state does not change during the episodes, and arousal always terminates the jerks. Occasionally, BNSM is stimulus sensitive and can be elicited, for instance, by noise.[35] Crib rocking can provoke BNSM, which is helpful diagnostically.[5] Curiously, benzodiazepines may increase the intensity of BNSM.[120]

Benign neonatal sleep myoclonus subsides spontaneously beginning with the second month of life and usually disappears before the sixth month. Ictal EEG is, by definition, normal in BNSM. However, one series reported a higher-than-normal incidence of interictal sharp transients in 4 of 10 newborns.[37] Benign neonatal sleep myoclonus may be genetically determined because affected siblings have been reported in two small series of patients, and a history of night jerks in one of the parents has also been found in several cases.[29,143]

Although Coulter and Allen[35] attributed BNSM to an arousal response, EEG recordings have not demonstrated this. Benign neonatal sleep myoclonus shares some features with nocturnal myoclonus seen in adults,[100] and it may reflect transient immaturity or imbalance of the serotonergic system.[123] In our last series of 21 patients, myoclonus disappeared before the age of 7 months, and 2 cases subsequently developed benign myoclonus of early infancy. Prognosis is uniformly good, and no treatment other than reassurance is necessary.[56]

Tonic Reflex Seizures of Early Infancy

This disorder was described in 1996, and a second series of 13 cases was published in 2001.[153,154] Onset occurs between the first and third month of life, with spontaneous remission 2 to 3 months after onset. These are normal infants presenting diffuse tonic contractions with extension of the four limbs, apnea and cyanosis, without loss of consciousness, lasting 3 to 10 seconds. Seizures occur only during wakefulness and with the child being held in an upright position. Because tactile stimulation often triggers the episodes, reflex myoclonic seizures come to mind. Normal interictal and ictal EEGs help to rule out brief tonic or myoclonic seizures and infantile spasms. The main differential diagnosis is with benign myoclonus of early infancy.

Benign Myoclonus of Early Infancy (Benign Nonepileptic Infantile Spasms)

In 1976, Fejerman[54] reported 10 infants with recurrent spells that resembled infantile spasms but in whom neurologic status, EEG, and outcomes were normal, allowing clear differentiation from West syndrome. Additional cases were added in subsequent reports.[16,30,55,56,67,74,75,98,101,102] Fejerman termed their conditions *benign myoclonus of early infancy* (BMEI).

We have now followed a total of 41 patients (26 male, 15 female) for 2 to 27 years.[60] In general, a diagnosis of West syndrome had been made, even with normal EEGs[137]; the correct diagnosis was established only in retrospect. Infants came to attention because of repeated jerks of the neck or upper limb muscles, causing abrupt flexion or rotation of the head with extension and abduction of the arms. Movements are often described as shuddering of the head and shoulders. In a minority of cases, only the arms are involved; sometimes, shuddering movements alternate with unequivocal myoclonic jerks. Occasionally, the only feature is symmetric or asymmetric extension of one or both arms with abduction, head rotation, or head drops. The jerks may be isolated or repeat in a series. They typically occur multiple times a day.

Consciousness is not affected, even when the myoclonic jerks last as long as 30 minutes. Benign myoclonus of early infancy occurs only rarely during sleep.[45] Although feeding may trigger attacks, this does not justify a separate designation, as has been proposed.[53] Benign myoclonus of early infancy is not related to anger or frustration. Myoclonus appears between 1 and 12 months of age, with onset in 90% of cases between 3 and 9 months. This overlap with the peak occurrence of infantile spasms further confounds diagnosis (Table 2) (see Chapter 229). Furthermore, we reported 4 infants who were normal until onset of typical infantile spasms without hypsarrythmia or other abnormalities in their EEGs. Thus, ictal EEG is very important in differential diagnosis.[27]

Table 2 Differential diagnosis between cryptogenic West syndrome and benign myoclonus of early infancy (BMEI)

Coincidences	Age of onset 3–9 mo
	Normal neuropsychic development (until onset)
	Myoclonic or brief tonic contraction in neck, shoulders, and upper limbs
	Occurring in series
	Several fits per day

Differences	West syndrome	BMEI
Seizures	During waking and during sleep	During waking, exceptionally during sleep
Electroencephalogram	Always abnormal, almost always hypsarrhythmia	Always normal
Psychomotor retardation	In all nontreated cases	Never

Table 3 Differential diagnosis of benign myoclonus of early infancy

1. Other nonepileptic phenomena
   a. Hyperexplexia
   b. Sandifer syndrome
   c. Tonic reflex seizures of early infancy
   d. Adverse reactions or intolerance to exogenous agents (monosodium glutamate, metoclopramide, etc.)
   e. Shuddering attacks (early symptom of familial essential tremor)
   f. Paroxysmal dystonia or choreoathetosis (paroxysmal torticollis, kinesigenic paroxysmal choreoathetosis, benign infantile dystonia)
2. Epileptic seizures
   a. Early myoclonic and tonic epileptic seizures
   b. Benign familial and nonfamilial infantile convulsions
   c. Infantile spasms (West syndrome)

Neurologic examination is always normal, as are interictal and ictal EEG recordings. There are no other laboratory

abnormalities, and behavioral and neurologic development is normal.

Symptoms, once present, may increase for several weeks, but they gradually subside over a few months. Most children are free of attacks by the end of their second year and always by the end of their third. Other conditions that used to be considered in the differential diagnosis of BMEI are listed in Table 3.[2,49,56,57,133]

Some authors consider shuddering attacks to be different from benign myoclonus of early infancy, and they were initially described as associated with essential tremor.[82,87,150] In fact, I consider that the syndrome named BMEI includes always normal infants who start with fits frequently repeated in bursts, consisting in myoclonic jerks, brief tonic contractions, or shuddering episodes. We do not know the neurochemical basis of this disorder, but we do know that it is a transient phenomenon that may have different neurophysiologic expressions. This interpretation allows the inclusion of some neurophysiologic findings within the spectrum of BMEI.[108]

Transient immaturity or imbalance of the serotonergic system might underlie various myoclonic phenomena, as has been postulated for BNSM,[123] and which could be genetic, thus accounting for occasional familial cases of both BNSM and BMEI.[29,68] We have seen one child with both BNSM and BMEI. Defining pharmacologic subgroups of the various myoclonic disorders is important, not only for understanding the clinical and neurophysiologic heterogeneity of myoclonus,[112] but also for providing rational pharmacotherapy. The areas of brain involved in BMEI are unknown.

Benign Paroxysmal Tonic Upward Gaze

This syndrome is characterized by bouts of tonic upward eye deviation accompanied by ataxia.[106] Age of onset is between 6 and 24 months, and children are otherwise healthy. The episodes of upward eye deviation occur in clusters every 2 to 8 seconds over a period of several minutes.[37,51] During episodes, consciousness is preserved, and attempts visually to track objects downward produce vertical nystagmus. Affected children usually exhibit a compensatory tilt of the head with the chin down. Symptoms occur only during wakefulness. During attacks, EEG recordings are normal. The frequency of the episodes gradually declines, and attacks disappear after 1 to 2 years. Even when the episodes disappear, patients may show slow motor development.[127] Three cases have shown a familial incidence.[23] The brain of one child who died accidentally was normal.[106]

Some children have benefited from treatment with dopa, and this has suggested a possible relationship to Segawa syndrome.[23,40]

Transient Paroxysmal Dystonia

Episodes of paroxysmal dystonia beginning at 3 to 5 months of age were reported in a group of nine infants. The attacks, which occurred only when the children were awake, were characterized by opisthotonus, symmetric or asymmetric increased tone in the arms with extreme pronation of the wrists, and preserved consciousness. Attacks usually lasted several minutes and occurred from once per month to several per day. Sometimes,

P.2786

however, episodes increased in duration to several hours or even days. In all cases, attacks disappeared in the second year of life.[10]

A similar picture had been described earlier as "benign idiopathic dystonia with onset in the first year of life." These infants had dystonic postures, mainly of the hands, lasting seconds to minutes and associated with intention tremor of the arms.[38,41,157]

Benign Paroxysmal Torticollis

Of all of these paroxysmal nonepileptic neurologic disorders, benign paroxysmal torticollis probably least resembles epileptic seizures. Benign paroxysmal torticollis is characterized by recurrent episodes of cervical dystonia lasting a few hours or days. Attacks are frequently associated with vomiting, pallor, irritability, and, sometimes, drowsiness or ataxia.[33,39]

Onset occurs in the first year of life, and attacks repeat several times per year. Over time, they decrease in severity and disappear after a few years. Electroencephalography is always normal. Gastroesophageal reflux, brainstem/cerebellar, or vestibular dysfunction should be excluded. The benignity of the condition has been emphasized in new series of 22 and 11 cases each.[46,6] In another report, two of the four cases came from a kindred with familial hemiplegic migraine linked to CACNA1A mutation.[73] Benign paroxysmal torticollis is now regarded as a migraine equivalent.

Adverse Reactions to Exogenous Agents

Adverse reactions or intolerance to various exogenous agents can include dystonic posturing, shuddering, tonic postures, and myoclonic jerks. Drug ingestion should be sought by careful inquiry, and blood or urine drug screens may be necessary. Metoclopramide,[71] carbamazepine,[110] phenothiazines (especially prochlorperazine), droperidol, and trimeprazine[138] have all been implicated. Intolerance to food additives has also been incriminated as a cause of shuddering attacks.[121]

Habit-Type Movement and Self-Gratification Episodes

Head Banging, Head Rolling, Rocking, and Other Stereotypic Movements

These represent a group of repetitive motor behaviors in children that are typically rhythmic and persistent. They are usually not paroxysmal and, therefore, rarely suggest epilepsy.

Head banging and head turning are common in normal infants at the time of going to bed, especially during the first year of life. Occasionally, children seem withdrawn and inattentive, which may suggest a seizure with automatisms. In some children, the rhythmic head movements persist during sleep (jactatio capitis nocturna). Generally, such movements disappear before 3 years of age, and neurologic development is normal.[1] Similar, often exaggerated motor behaviors occur during wakefulness in children with autistic behavior and mental retardation. A unique case of a parasomnia with rhythmic head and body movements and with tongue biting was reported in a 2-year-old girl.[149]

Rocking is less common in normal children and occurs most often in children with mental retardation, developmental disorders, or sensory deficits. The abnormal behavior starts during the first year of life when the child is sitting. Later, lateral or to-and-fro rhythmic movements of the head or body occur while standing as well.[124] A small proportion of normal children has similar behavior.[38,63,129]

Other stereotypic behaviors such as buccal and lingual movements may be mistaken for the oral automatisms of partial seizures, and hand flapping and related mannerisms may be confused with myoclonus.[24] In older children, repetitive hand waving in front of the eyes is used to self-induce photosensitive seizures. In young children, psychogenic seizures can manifest as brief staring episodes that are not easily distinguished from atypical absence seizures. In such cases, video-EEG monitoring will allow definitive diagnosis.[48,103]

Masturbation-like Episodes

Infants, usually girls, are sometimes referred because of brief episodes of staring, adducted thighs, rhythmic contractions of the leg and trunk, flushing, perspiration, and a dazed appearance. Such episodes are frequently mistaken for epileptic seizures, but self-gratification episodes and masturbation should be considered, despite the child's young age.[3,58,135,138] A helpful differential point is that the child is awake and may resist or resent being interrupted.

Symptomatic Abnormal Movements

Neonatal Posturing and Other Nonepileptic Episodes

Motor automatisms and tonic postures are the most common paroxysmal events in newborns who do not have a consistent EEG abnormality. They are usually seen in infants with severe encephalopathies and depression of forebrain function. Kellaway and Hrachovy[88] hypothesized that these behaviors are mediated at a brainstem level due to failure of normal cortical inhibition and proposed that they represent “brain stem release phenomena.”[88,104] Similar motor activities can be epileptic; however, EEG monitoring is usually necessary to define the underlying pathophysiologic mechanisms.[155,156]

Tonic postures in the newborn may be focal or generalized, and some may have myoclonic components. Many of these motor behaviors were formerly classified as “subtle” or “minimal” seizures, but their inconsistent relation to EEG ictal patterns have called their association into question (see Chapter 56). Other nonepileptic motor behaviors in newborns include oral-buccal-lingual movements such as chewing and sucking, random eye movements, rhythmic blinking, and peculiar limb movements like pedaling or swimming. In older infants, such activities may be part of an epileptic ictal event. The argument persists, however, and the question of whether dissociation between scalp EEG findings and stereotypical paroxysmal motor behavior excludes the possibility of an epileptic mechanism can probably never be answered definitively to everyone's satisfaction.[31,99,104] Nonetheless, therapeutic decisions (e.g., whether to use antiepileptic drugs) require an operational decision to be made in individual cases[155,156] (see Chapter 123).

Thus, several observations that can be made at cribside help to distinguish an epileptic seizure from a nonepileptic event with a strong degree of probability for therapeutic purposes. The following criteria reinforce the presumption that a particular event is nonepileptic: (a) It increases with sensory stimulation (spatial or temporal summation, irradiation); (b) it can be suppressed by gentle passive restraint; and (c) it is not accompanied by autonomic features (tachycardia, apnea, changes in blood pressure).[155] In such newborns, antiepileptic drugs are generally neither necessary nor desirable.

Independent of therapeutic decisions or nosologic questions, motor automatisms and tonic postures in newborns have significance in terms of etiology and prognosis. In one study, 53% of infants with tonic postures and 54% of those with automatisms had hypoxic-ischemic encephalopathy, and, of these, only about 25% were normal at hospital discharge.[104]

Segmental or spinal myoclonus in early infancy can be seen with sepsis, birth trauma, and various degenerative diseases. Isolated cases of spinal myoclonus have been reported in a child with hyperglycorrhachia secondary to parenteral nutrition administered through an improperly placed, indwelling femoral catheter[14] and in a 2-month-old infant with a spinal cord tumor.[122]

Opsoclonus-myoclonus Syndrome

Several years after the initial description of opsoclonus-myoclonus syndrome (OMS),[90] its frequent association with neuroblastoma was recognized.[50,136] Mean age of onset is around 14 months, and symptoms usually appear a few days after an apparent viral infection.[64] The following features are typical: (a) ataxia with marked tremor leading to inability to walk; (b) opsoclonus ("eye dancing") with episodes of rapid eyelid flutter; (c) myoclonus of the face of limbs; and (d) marked irritability and excitability. Brain imaging studies, EEG, and cerebrospinal fluid are normal. Brainstem auditory-evoked potentials can be abnormal early in the course.[86]

Some authors have argued that OMS is always associated with neuroblastoma and that such tumors may regress spontaneously,[22] but this is not true. Nonetheless, emphasis must be placed on a systematic search for neuroblastoma. Routine laboratory tests, including catecholamine levels, may be normal. Abdominal computed tomography (CT) may be necessary to detect small (1.5–2.0 cm) neuroblastomas arising from the abdominal sympathetic chain.

Several cases associated with different acute viral infections have been reported.[68,85,94,132] It is clear that there is still much to learn about the neurobiology of OMS.[113] Low concentrations of 5-hydroxyindoleacetic acid and homovanillic acid were found in the cerebrospinal fluid of 27 children with OMS.[115] There are three main etiologic groups for OMS: (a) OMS associated with neuroblastoma, (b) OMS associated with special viral infections, and (c) OMS without a definable etiology. Acute immune pathogenesis is surely involved, and there are new advances in this sense. Autoimmune antibodies binding to the surface of isolated rat cerebellar neurons were found in 10 of 14 children.[19] Children with OMS manifested a four- to sevenfold higher percentage of total B cells in cerebrospinal fluid compared with controls, and its determination is proposed as a biologic marker of the disease.[117]

Some children show a prompt and persistent response to corticosteroids or adrenocorticotropic hormone (ACTH), but most cases follow a chronic course with remissions and relapses often related to new viral infections.[90] Intravenously administered immune globulin seemed to produce remarkable improvement in an 18-month-old infant with OMS associated with a nonresectable abdominal ganglioneuroblastoma.[111]

Long-term follow-up reveals that some children, especially those with neuroblastoma, become symptom free. The majority, however, have chronic neurologic deficits, including cognitive and motor delays, language deficits, and behavioral abnormalities, regardless of etiology.[78,92]

Bobble-head Doll Syndrome

This is a rare disorder associated with obstructive hydrocephalus due to lesions in the region of the third ventricle and aqueduct.[146] In most of the reported cases, head movements have been characteristically to-and-fro nodding, which creates a peculiar 2- to 3-Hz rhythmic head nodding similar to that seen in dolls with weighted heads attached to coil-spring necks. The movement can be stopped voluntarily and is most obvious when the child is in the upright position. It disappears during sleep and when the head is supported. Pendular movements of the arms may also be seen.

Onset can occur in infancy or up to the fourth year of life.[146] Macrocephaly is a constant finding, and remarkable improvement follows treatment of the hydrocephalus. Ventriculocisternostomy through endoscopic treatment was recommended in cases associated with arachnoid cysts.[65,77] The condition is less often confused with epilepsy than with tremors, habit spasms, or even hysterical disorders.[79,146] Eight cases with head stereotypies resembling bobble-head doll syndrome, in association with axial hypotonia, ataxia, oculomotor abnormalities, and motor delay, were reported. In two of them, a congenital cerebellar abnormality without hydrocephalus was found.[83]

Encephalopathic Nonepileptic Myoclonus

Nonepileptic myoclonic jerks often appear in children with static or progressive encephalopathies, including some storage diseases, various toxic encephalopathies, and encephalopathies secondary to physical agents.[53] Different subcortical lesions that affect the basal ganglia may lead to myoclonus with or without dystonic features.

Other Neurologic Conditions with Paroxysmal or Episodic Symptoms

Nonepileptic Apnea

Detailed analysis of nonepileptic apnea in newborns is beyond the scope of this chapter. Apnea during sleep is a common, normal phenomenon in premature and term newborns; it is more common in REM sleep than in NREM sleep.[72] The frequency of these normal respiratory pauses decreases after the neonatal period; apnea is rare in normal infants after a few months of age.[76] Video-EEG and polygraphic studies are fundamental tools for differential diagnosis between epileptic and nonepileptic apnea in newborns. Although apnea is common in the course of neonatal and infantile seizures, it is rare for apnea to be the sole manifestation of an epileptic seizure.[32,104]

Most of the information about infantile apnea has been obtained from polygraphic studies of infants diagnosed as having had near-miss for sudden infant death syndrome (near-miss SIDS). This term defines the infant who is found limp, blue, and not breathing, and who presumably would have died without intervention and resuscitation. Most children with SIDS have had a previous near-miss SIDS event.[76] Sudden infant death syndrome and near-miss SIDS have their peak incidence between 2 and 4 months of age, and different etiologies have been implicated.[12] Gastroesophageal reflux is frequently associated with episodes of apnea and can be confused with epilepsy, especially when apnea, choking, and cyanosis are accompanied by unusual head and neck postures and even opisthotonus (Sandifer syndrome).[140] A near-miss SIDS episode can be complicated by a convulsion due to hypoxia.[12,66]

P.2788

Hyperekplexia

Hyperekplexia ("startle disease") is a rare condition that is often confused with epilepsy in the first year of life. Both major and minor variants have been reported. Most cases are familial, and both autosomal-dominant[9,139] and recessive[128] transmission have been reported. Other cases are sporadic.[70] Hyperekplexia was linked to the short arm of chromosome 5.[119] Several mutations were later found, and data seem to show a direct relationship between the mechanisms of inheritance and the location of the molecular defect. For instance, mutations in the domain of GLRA1 (alpha subunit of the glycine receptor) are frequent in autosomal dominant hyperekplexia.[96] A report of recessive hyperekplexia with a new mutation in the GLRA1 gene was recently presented.[34] In my experience, however, sporadic hyperekplexia was more frequent than the familial forms.[62] This finding is ratified with a recent series of 39 sporadic cases in neonates and infants.[131]

Most cases involve infants with marked muscular hypertonia and severe jerks induced by sound or tactile stimuli. Touching the dorsum of the nose is especially effective in eliciting symmetric myoclonic jerks of the arms and legs. Tonic and clonic generalized attacks with cyanosis occur during sleep. Such children are usually misdiagnosed as having spastic quadriparesis with stimulus-sensitive myoclonic epilepsy, and artifacts in the EEG are commonly misinterpreted as abnormal discharges. The hypertonia decreases with time, and open pyramidal signs are not present. Affected children walk at 2 to 3 years of age and usually have mild mental retardation.

Clonazepam is the drug of choice, effectively reducing the paroxysmal episodes that occur during sleep and drop attacks due to stimulus-induced myoclonus.[62] “Minor” and atypical cases may lack early hypertonia or a clear response to tactile stimuli.[56,105]

The condition usually improves, although rarely an infant may die from cardiopulmonary arrest during an episode occurring in sleep. This type of attack can be stopped by forced flexion of the head and legs.[151] We reported four sporadic cases with the conviction that they were malignant forms of hyperekplexia.[11] Following this line, two children with hyperekplexia associated with refractory status epilepticus who died were recently reported, suggesting that they might represent a new autosomal-recessive syndrome.[97]

Cogan Oculomotor Apraxia

Oculomotor apraxia may be symptomatic of different congenital and acquired conditions, including brain malformations, mesencephalic-diencephalic lesions, and genetic diseases associated with other neurologic signs and mental retardation.[3]

The form of oculomotor apraxia known as Cogan syndrome is usually recognized after 6 months of age by the peculiar head thrusts and impaired saccadic eye movements. These abnormal movements of the eyes and head are usually horizontal and may be mistaken for tics or even epileptic seizures.[138] There is a tendency for the eyes to improve with time, although persistent clumsiness and learning difficulties are frequent.

In two children with this condition, a newly recognized association with nephronophthisis type 1 was reported. Both patients carried the lesions in the NPHP1 gene.[18] Familial occurrence of congenital oculomotor apraxia was also reported in four patients.[84]

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo (BPV) must be considered in the differential diagnosis of seizures in children from 1 to 4 years of age.[15,58,91] The child usually begins crying, clings to the nearest person, or falls to the floor. Pallor and a frightened expression are constant features, but nystagmus occurs in only 35% to 40% of cases. Vomiting is infrequent.[91]

Children old enough to have developed language express fear of falling and a rotational sensation: “The room is turning around,” “the floor is moving,” “the walls are falling.”[61] Episodes last about 1 minute, and recovery is prompt. Attacks usually recur monthly and tend to disappear in a few years. Electroencephalography and neurologic examination between attacks and development are normal.

According to some investigators, vestibular function tests have been consistently abnormal, with labyrinthine dysfunction on one or both sides.[91] In a more recent series, however, such abnormalities were not found.[47] Relation to migraine, instead, seems to be strong: A family history of migraine in 53% of 19 cases and a family history of kinetosis in 83% of the same series were reported.[47] Cyclic vomiting may be associated and was considered together with BPV as part of the so-called periodic syndrome that may be a precursor to migraine.[47,80] More recently, serum creatine kinase-MB (CK-MB) levels were elevated in 22 children with BPV, and the authors suggested that CK-MP may be a diagnostic marker for this condition.[125]

Benign paroxysmal vertigo must be distinguished from other causes of recurrent vertigo in childhood. When attacks last more than a few minutes and are associated with ataxia and other neurologic symptoms, the diagnosis of BPV is unlikely, and other etiologies should be considered.[61,145]

Spasmus Nutans

Spasmus nutans is characterized by the triad of nystagmus, head nodding, and head tilt. Head nodding is most frequently horizontal and may occur in bursts; nystagmus is more constant and usually monocular. Age of onset is usually from 6 to 18 months.[3,63]

Spasmus nutans tends to disappear within a few months or years. The incidence of new cases seems to have declined in the last few decades.[61] The etiology is unknown. However, a recent comparative study of 23 patients with spasms nutans (SN) and 24 patients with idiopathic infantile nystagmus (IIN) demonstrated significant differences between SN and IIN patients and their families with regard to socioeconomic status and exposure to light early in life, concluding that low socio-economic status is a factor of risk for spasmus nutans.[158] Normal complete neurologic and ophthalomologic examination as well as normal brain magnetic resonance imagining (MRI) are necessary to confirm diagnosis.[44] Differential diagnosis with such pathologies as optic glioma and congenital retinopathies is mandatory.[44,89]

Alternating Hemiplegia

The initial description of alternating hemiplegia (AH) of childhood included eight children described as having complicated migraine beginning in infancy.[151] The condition was later identified as a distinct entity[93] and has been thoroughly reviewed and reconsidered.[7]

A relation of AH with familial hemiplegic migraine (FHM) has been recently suggested, with a novel ATP1A2 mutation reported in a kindred with features in common between AH and FHM.

Differentiation from epilepsy is not easy early because the initial manifestations are usually partial tonic attacks beginning in infancy or even in the neonatal period. Paroxysmal nystagmus, especially monocular nystagmus, is frequently associated with the episodes of unilateral tonic attacks.

Hemiplegia is not usually the first symptom, but it almost always appears during the first year of life. Hemiplegia occurs suddenly and may be preceded by screaming and fussiness. The affected side is hypotonic, with persistent tendon reflexes, and each attack lasts from 30 minutes to several days. A distinct feature of alternating hemiplegia of childhood is the disappearance of all abnormalities when the child falls asleep. Paralysis recurs on awakening in prolonged episodes. Although the hemiplegia, by definition, alternates from side to side in successive attacks, bilateral weakness and variations in tone are not unusual.[4]

Seizures occur in 50% of cases, and partial status epilepticus may occur. The seizures occur independent of, but sometimes in close relationship to, a hemiplegic attack.[4,36]

The episodes of alternating hemiplegia recur at variable intervals but seem to become less severe over time. However, most children develop some degree of ataxia with choreo-athetosis and are left with significant mental retardation. Cases of benign familial alternating hemiplegia of childhood are exceptions to this usual evolution.[8]

Flunarizine has benefited some children with alternating hemiplegia by reducing the duration but not the frequency of hemiplegic attacks. Only rarely has flunarizine abolished attacks completely.[7,134]

The etiology and pathogenesis are still debated. Although a possible relationship to migraine has not been completely rejected, there are abnormalities of energy metabolism and mitochondrial function that merit further investigation.[7]

Paroxysmal Dystonia and Choreoathetosis

Two rare familial conditions are *paroxysmal dystonia and choreoathetosis* and *paroxysmal kinesigenic choreoathe-tosis*.[95,144] In the former, onset is usually between 1 and 2 years of age, and attacks are mainly of dystonia, which lasts from 2 minutes to a few hours. The frequency of attacks ranges from several per day to one every 2 months.[21] Familial cases must be distinguished from the sporadic transient paroxysmal dystonic episodes already discussed.

Paroxysmal kinesigenic choreoathetosis is also an auto-somal-dominant disease, but it starts after 5 years of age.[126] A constant feature is that attacks are precipitated by sudden movement, and episodes last only a few seconds to several minutes; they occur several times a day.[138] Antiepileptic drugs usually suppress attacks, but EEGs have been abnormal in only one case.[81]

A genetic bridge between paroxysmal choreoathetosis and benign familial infantile convulsions was established in 1997 in describing a new neurologic syndrome linked to chromosome 16.[142] Caraballo et al. later reported linkage to chromosome 16 in children with benign familial infantile convulsions. Our group was actively involved in this search, and in our cases, paroxysmal choreoathetosis appeared years after onset of benign familial infantile convulsions.[25,26,28] Paroxysmal kinesigenic choreoathetosis also seems to map to chromosome 16.[17,147]

Acquired nonepileptic paroxysmal dystonia is associated with static encephalopathies, but it begins outside infancy.[52] It probably represents different forms of "delayed-onset dystonia."[63] The differential diagnosis includes hereditary progressive dystonia with marked diurnal fluctuation and other dopa-responsive dystonias.[130]

Summary and Conclusions

All of the conditions reviewed in this chapter are intermittent, often paroxysmal, and have been confused with epileptic seizures. On one extreme are abnormal movements that are symptomatic of severe brain pathologies requiring specific treatments, such as the opsoclonus-myoclonus syndrome and the bobble-head doll syndrome. Alternating hemiplegia includes both abnormal movements early on and, later, negative phenomenon, namely, hemiplegia.

On the other end of the spectrum are exaggerations of movement and conditions that can be collectively considered "transient or benign movement disorders" because they disappear spontaneously in the course of months or a few years without neurologic sequelae.

All of these conditions should be known to pediatricians and neurologists because misdiagnosing them as epilepsy delays appropriate treatment, exposes small children to the risks of antiepileptic drugs, and creates unnecessary physiologic burdens.[59]

EEG is almost always required to rule out epilepsy, and adding video-EEG recordings increases its value in the study of children with frequent paroxysmal events.[157]

Chapter 281

Overview: Psychiatric Disturbances

Michael R. Trimble

Introduction

This section is dedicated to the many thousands, probably millions, of people who still receive an erroneous diagnosis of epilepsy, even several years after the publication of the first edition of this book. It is a testament to the broad view of the editors that they have again allotted so much space to this topic, but it also reflects the recognition of the serious clinical issues that surround it.

Historical Perspective

The problem of patients with pseudoneurologic symptoms seen by physicians is as old as the history of medicine,[2] and it became of special interest to neurologists around the end of the nineteenth century, notably with the works of Charcot. Patients with seizures have always been of special interest, so much so that the Salpêtrière school reserved a specific category for such attacks, denoted by the term *hysteria major*. For the first three fourths of the twentieth century, however, interest seems to have dwindled. Even those with a great interest in hysteria, such as Freud and succeeding psychoanalysts, wrote little about seizures, and the borderlands between epilepsy and psychiatry for a long time attracted little in the way of clinical or research interest. Things changed in the last quarter of the twentieth century (see Chapter 199), and with this renewed interest, the question of the misdiagnosis of epilepsy for symptomatically related syndromes, especially psychiatry disorders, was reborn.

Current Problems of Differential Diagnosis

The introduction of new techniques of investigating seizure disorder patients, but especially videotelemetry, led to the realization that many patients who at first sight appeared to have epilepsy and who were given that diagnosis along with prescriptions for anticonvulsant drugs with pronounced sedative effects in fact did not have epilepsy at all.

How frequently this problem occurs is hard to say. It has been estimated, however, that the attacks of up to 20% of patients attending clinics for chronic seizure disorders are nonepileptic in nature, but the epidemiologic studies on this vary, as reviewed by Kanner and colleagues in Chapter 282. The important point is that the figures are not going down with time, in spite of the growing clinical awareness of the problem. These patients often attend for many years, consume large amounts of antiepileptic drugs, and have huge social burdens that in part derive from having been given the label of "epileptic." Why should these errors of diagnosis be so frequent? It is difficult to conceive of a medical diagnosis other than epilepsy that has such important consequences for the patient and that is so frequently incorrectly given.

The problems may be said to begin with terminology. If the words used by physicians are unclear, ambiguous, or misleading, then the concepts that relate to those words will likewise be obscured. The term *pseudoseizures* is popular, but it is problematic. The Oxford English Dictionary defines *pseudo* as "that which is false, counterfeit, pretended or spurious." However, the seizures that are being discussed for the most part have none of these characteristics; they are real. They are experienced by patients, observed by bystanders, and thought about by physicians.

Alternative terms, such as *hysterical seizures* or *hysterical pseudoseizures*, *hysteroepilepsy*, and *psychogenic seizures*, all seem to imply pejoratively that the episodes are false and feigned by a patient for motives apparently unknown, although deception of the doctor essentially is one of them. The designation *psychogenic seizures* entails further difficulties. As Fenwick[1] correctly pointed out, this term should logically be reserved for a form of reflex epilepsy induced by mental activity.

For many, the preferred term for the seizures discussed in the following chapters is *nonepileptic seizures*, thereby acknowledging that these episodes are different from epilepsy, but also that the sudden paroxysmal attacks may resemble epilepsy. The preferred term used in this section is *psychogenic nonepileptic seizures* (PNES), but whatever term is used, it is important that the user have a clear idea of why the label is being given and exactly what is meant. Clarification of concepts, and therefore of patients' problems, cannot be achieved in the middle of a semantic muddle.

The semantic problem leads directly to the problem of differential diagnosis and why the seizures of so many patients are misdiagnosed. Thus, the phenomenon of seizures, not epilepsy, should be at the top of the diagnostic tree (Fig. 1). Many people still confuse seizures and epilepsy and can only equate the two. However, patients come to a seizure rather than an epilepsy clinic (however it is labeled), and during the initial differential diagnosis of a seizure, epilepsy can be considered as only one branch of a diagnostic tree; the other options are numerous. The ready acceptance of the notion that paroxysmal episodes of altered consciousness must be epilepsy is a clinical faux pas on a grand scale, and is in part responsible for the diagnostic errors discussed in the following chapters.

As FIGURE 1 illustrates, the diagnostic possibilities in patients with seizures are considerable. Thus, anyone professing to assess and manage patients with seizure disorders needs more than a passing knowledge of this spectrum of disorders. Because many conditions represented fall within a category of psychopathology, psychiatric experience should be seen as central.

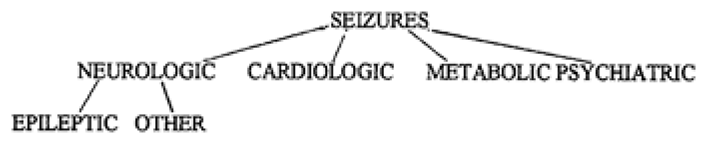

FIGURE 1. Differential diagnosis of seizures.

The chapters in this section cover most of the topics in this diagnostic area, although cross-references are made to some other sections of the book. Although in most cases of epilepsy

P.2794

a clear diagnosis can be given, it is apparent that this is not so for a significant proportion of patients, who are poorly treated as the consequence of an inadequate diagnostic process. Confusions with psychotic disorders are not frequent, and more often the clinical dilemma falls within the personality disorder/anxiety disorder spectrums. Aggression and its link to epilepsy is an old but important chestnut, and it still remains a problem in psychiatric clinics, where people with spontaneous aggressive outbursts are seen, whose electroencephalogram may be abnormal, and in whom the diagnosis of epilepsy is entertained. The diagnosis rarely turns out to be epilepsy (see Chapter 212), but the referring psychiatrist will need reassurance on diagnosis, and the clinical conclusion may well have important forensic relevance. The space devoted to hyperventilation, panic attacks, dissociation, and PNES reflects both the importance of these overlapping areas for neuropsychiatry and the complexities of the underlying concepts and clinical constructs. Different clinical syndromes within this *olla podrida* of presentations may direct different treatments, and familiarity of referral patterns is therefore important for anyone in a seizure disorder clinic with a broad view on their practice. To simply label someone as having a psychiatric problem and to discharge them from the clinic is simply not helpful because they will appear again sooner or later at another clinic with the same problem, and the expense and morbidity simply increase.

Summary and Conclusions

It is sometimes said that it is better to err on the side of caution and give an uncertain diagnosis of epilepsy if presence of the disorder is suspected but not confirmed. Uncertainties arise, for example, when an electroencephalographic report makes use of the much abused word *epileptiform* or contains unhelpful comments such as "This record does not rule out temporal lobe epilepsy." An uncertainty becomes a probability, and the patient with suspected epilepsy becomes "the epileptic." Ten years later, this has been transformed to "this well-known epileptic." Actually, if the diagnosis is uncertain, it should remain so until further evidence allows clarification. In reality, from a patient's point of view, if an incorrect diagnosis is to be made, it is better to err in favor of a psychiatric diagnosis. The social stigma is rather less, and the drugs given probably have fewer side effects, than if the patient is mistakenly given the diagnosis of epilepsy and treatment based on that diagnosis.

It is hoped that the information in the following chapters will provide helpful information for those wishing to explore the world of seizures beyond epilepsy and for psychiatrists who deal at the interface of epilepsy and psychiatry as well as neurologists. If the seizures of fewer patients are misdiagnosed, the inclusion of this section in a comprehensive textbook of epilepsy will have been justified.

Chapter 282

Psychogenic Non-Epileptic Seizures

Andres M. Kanner

W. Curt LaFrance Jr.

Tim Betts

Introduction

It has been known since the earliest recorded medical writings[51,100,141,148] that not all seizures in humans are of epileptic origin. From ancient times onward, instruction was given in medical texts about how to determine the clinical difference between epileptic and nonepileptic events. Many modern authorities make an assumption that it is only in recent years, with the advent of the electroencephalogram (EEG), that we have been able to detect this difference, but this is not so. Our forbearers had their own conception of what was epilepsy and what was not. Gowers' meticulous description of the hysterical convulsion bears a close relationship to a type of nonepileptic seizure that we recognize today.

The advent of the EEG and, from the late 1960s, continuous EEG monitoring (with or without video recording) led to an increased interest in distinguishing between seizures of epileptic and nonepileptic origin. It is undoubtedly true that the ability to monitor an EEG over a long period of time and register an EEG during a seizure (and to be able, in tranquility, using video, to retrospectively look at the behavior that the patient displayed during a seizure) has enormously helped our ability to distinguish between events that are epileptic and those that are not.

Nonepileptic seizures (NESs) are paroxysmal events that mimic (or are confused with) epileptic seizures, but which do not result from epileptic activity. NESs can be the expression of organic or psychogenic processes. The type of organic disorders often confused with epileptic seizures include convulsive syncope, various forms of sleep and movement disorders, and migrainous processes and are reviewed in Section XI of this book. The decision as to whether a patient's seizures belong in the domain of epilepsy or nonepileptic events may have to be based on various sets of criteria, in addition to the EEG data. The distinction between epilepsy and nonepilepsy cannot always be made with complete confidence, and the physician working in this field must be able to tolerate some degree of uncertainty. Epileptic and nonepileptic seizures also may coexist. This chapter will focus on nonepileptic seizures of psychogenic origin.

Nomenclature

The most commonly used term for nonepileptic seizures is *pseudoseizure*; this term first came into use in the 1960s and was widely used in the 1970s and 1980s. Yet, psychogenic NESs have been labeled with various eponyms over the last two centuries. For example, Charcot referred to these attacks as “hysteroepilepsy”[77] in the 19th century, and he had recommended the use of ovarian compressors for their treatment, based largely on the theory of the ancient Greeks that such attacks were due to the “wandering of the uterus throughout the body, away from its normal location in the pelvis.” Other terms used more recently have included *nonepileptic seizures, psychogenic seizures,* and *hysterical seizures.*

There is an increasing tendency to abandon the term *pseudoseizure* as it is considered to have a pejorative connotation and to imply falseness. Deliberate deceit plays only a small part in the genesis of most nonepileptic seizures (i.e., cases of malingering),[22] although, sadly, many clinicians think otherwise. The term *pseudoseizure* also conveys the implication that anything that is not epilepsy is not interesting and that no further attention need be paid to the attacks.

There is an ongoing debate on the use of the term *seizure* as many patients are unable to discriminate between the concepts of *psychogenic* versus *epileptic* processes and get fixated on the word *seizure*. To avert such potential confusion the term *psychogenic nonepileptic event* has been suggested. Such terms help differentiate the nonepileptic nature of these attacks from epileptic seizures and convey their probable psychogenic cause.

Psychogenic seizures is a term much used in the United States and on the continent of Europe to describe psychologically based nonepileptic seizures. It is correct providing that there is agreement about what it means and the range of disorders it covers. Unfortunately, the term also has been used to refer to those epileptic seizures that are triggered by an emotional experience.[44] Potential confusion could be avoided by using the terms *nonepileptic psychogenic seizure* and *epileptic psychogenic seizure*.

The terms *hysterical seizure*, *hysterical epilepsy*, and *hysterical convulsion* should not be used. The word *hysteria* is no longer used in psychiatric parlance because it is meaningless. It has been so much abused and misused that it should be abandoned,[100] and the term *conversion disorder* should be used instead. Not all nonepileptic attacks are related to conversion disorder.

Functional seizure is also sometimes used, but the term is imprecise and has more than one meaning. An epileptic seizure, for instance, that occurs or is precipitated at a propitious time (e.g., before a stressful event) so that the patient avoids a threatening situation could legitimately be called functional. Blumer[36] has suggested the term *paroxysmal somatoform disorder*. In some ways this is an attractive term. However, it does imply that all nonepileptic events of psychological origin relate to the somatoform disorders when they clearly do not. The term could be used as part of a classification of psychologically based nonepileptic seizures, and this would be more acceptable.

Psychogenic nonepileptic seizure (PNES) is the term that has been chosen for this chapter and is coming into common use. It may not be ideal, but it is less pejorative and more meaningful than *pseudoseizure*; however, clinicians must always ensure that the patients and family understand that the

inclusion of the term *seizure* does not imply a diagnosis of epilepsy.

Epidemiology of Psychogenic Nonepileptic Seizures

There are relatively little data on the incidence and prevalence rates of PNESs. Various estimates of prevalence have been given by various investigators in different settings. It is important to try to determine the influence that the setting has both on the way that seizures present and on their frequency. Prevalence will be different if patients with new-onset seizures are being assessed in a primary care setting compared with reassessment of patients who have an intractable seizure disorder in a tertiary referral center.

An indirect estimate of the possible incidence of nonepileptic seizures in a primary care setting can be derived from the work of Sander et al.,[121] which was a careful phenomenologic study of patients presenting to their general practitioner with a seizure disorder and who were carefully assessed and followed. It was shown that some 28% of patients suspected of having epilepsy after presentation to their general practitioner either did not have it (7%) or the diagnosis could not be substantiated even a year after the initial presentation (21%). In the only nationwide population-based study done to date, Sigurdardottir and Olafsson found the population-based incidence of PNESs to be 1.4 per 100,000 in Iceland, compared to an incidence of 35 per 100,000 for true epilepsy among persons older than 15 years.[129] In a retrospective study carried out in Hamilton County, OH, investigators established the incidence of PNESs between 1995 and 1998. They found a mean incidence of 3.03 per 100,000, with the highest incidence in 1998 (4.6 per 100,000). Most patients with the diagnosis of PNES were aged 25 to 45 years (4.38 per 100,000).[138]

The prevalence rates of PNESs have been estimated to range from 10% to 40% among patients referred to epilepsy centers for the evaluation of poorly controlled seizures.[26,30,74,77] The prevalence of comorbid PNES and epilepsy varies according to the type of population studied. For example, in a study of 1,590 patients who underwent a video-EEG (V-EEG) monitoring study at the Epilepsy Center of the University of Alabama in Birmingham, 514 (32.3%) were diagnosed with PNES and 29 (5.3%) of these patients were found to have both PNES and epilepsy.[96] Henry and Drury conducted a V-EEG in 145 patients who had temporal interictal EEG spikes and reported ictal semiology characteristic of temporal lobe seizures for presurgical evaluation of medically refractory seizures. PNESs were unexpectedly identified in 12 (8%) of these patients.[57] On the other hand, a study from Germany found that among 329 consecutive patients in whom the diagnosis of PNES was established, 206 (62%) had only PNES, and 123 (37%) had PNES and epilepsy.[118] In a critical review of the literature, Ramsey et al. came to the conclusion that the comorbid occurrence of epilepsy and PNES was rare with prevalence rates ranging between 4% and 10%.[116] Relatively high prevalence rates can be expected when studies are carried out in populations of cognitively impaired or in pediatric patients, however. Neill and Alvarez, for example, reported prevalence rates of up to 40%.[104] Kotagal et al. found that 25% of pediatric patients with PNES also suffered from epilepsy.[75] Higher prevalence rates of comorbid PNES and epilepsy in these two patient populations is not surprising, as they learn that fewer demands are placed on them when they have a seizure. Hence, they are likely to experience a PNES when facing situations that cause distress or that they consciously or unconsciously are trying to avoid.

PNESs are much more common in women than men; in most series 60% to 75% of patients are women.[12,58,77,78,91,93,110,117] The onset of PNESs most often occurs in the third and fourth decades of life,[12,53,77,89] though they have been described in both children and the elderly.[7,42,68,152,153]

Clinical Manifestations

PNESs can mimic convulsive and nonconvulsive epileptic seizures; they may present as isolated events or occur in clusters and, often, may mimic status epilepticus. The advent of V-EEG has facilitated the recognition of PNESs among neurologists and epileptologists, and it appears that nonneurologists are increasingly becoming more aware of this type of paroxysmal event. There have been multiple review articles on the diagnosis of PNES[7,21,54,66,68,71,92,126] and various investigators have tried to emphasize the clinical differences between PNESs and epileptic seizures with lists and tables of distinguishing features.[53,78,89] While certain features of convulsive PNESs may be highly suggestive of this diagnosis, there are no clinical phenomena that are 100% specific to one or the other.[151] Because our ability to recognize PNESs is not infallible and in some patients, with different kinds of events, it is impossible to decide if they have epilepsy or not, a diagnosis cannot be established on the bases of clinical phenomena alone, but has to be corroborated with electrographic recordings, and occasionally, functional neuroimaging studies with ictal single photon emission computed tomography (SPECT) may be necessary to reach a correct diagnosis (see below). In short, the diagnosis of a PNES is based on a considered judgment of all relevant history, seizure phenomena, electrophysiologic data, and results of other investigations and remains a clinical one. Using one or two phenomena in a differential diagnosis table to make a rapid diagnosis would be injudicious and could lead to inadvertent misdiagnosis. Furthermore, several studies published in the last 15 years have demonstrated that clinical phenomena associated with PNESs can occur in certain types of epileptic seizures, a fact that still remains underrecognized by many clinicians, including neurologists, and has often lead to the inverse diagnostic problem (i.e., patients with epilepsy being falsely diagnosed with PNES). For example, in a study of 100 consecutive patients that were undergoing a diagnostic V-EEG, Parra et al.[110] found that referring physicians correctly suspected a diagnosis of epileptic seizures in only 9 (43%) of 21 patients, while 12 (57%) patients were incorrectly thought to have PNESs. This misdiagnosis was especially likely in patients with clinical seizures of mesial frontal or parietal lobe origin. To confuse matters further, there are a number of patients who suffer from both epileptic seizures and PNESs, with coexistence of both types of disorders ranging from 7% to 37%. Most studies have found incidence rates ranging between 10% and 20%.[14,38,58,72,90] This point is examined in greater detail in Chapter 208.

Needless to say, reaching a correct diagnosis is of the essence as a misdiagnosis of PNESs as epileptic seizures, and vice versa, exposes patients to ineffective, costly, and potentially dangerous treatments. Indeed, several investigators have found that 69% to 78% of patients with PNESs have been treated with antiepileptic drugs (AEDs)[14,120] and up to 30% of patients have been misdiagnosed at some point with status epilepticus and admitted to an intensive care unit where they were treated with parenteral medications that are associated with potential serious adverse events, and which in some cases caused respiratory arrest.[59,117,120]

In general, a diagnosis of PNES is easier to suspect in convulsivelike events, while in nonconvulsive events a diagnosis of PNES may be impossible without concurrent electrographic recordings. In the next section we review the value and

limitations of clinical phenomena in suspecting the diagnosis of PNES.

Convulsive Psychogenic Nonepileptic Seizures

Motor Phenomena

In convulsivelike PNES, motor signs include cloniclike, myo-cloniclike, and toniclike movements of the extremities and trunk. However, violent thrashing of the extremities and/or of the entire body, opisthotonic arching of the back, pelvic thrusting motions, and side-to-side head movements are the typical motor phenomena associated with PNESs. Frontal lobe seizures have been shown to present with the same type of motor phenomena; for example, Geyer et al. found pelvic thrusting to be equally common in frontal lobe seizures and PNESs[48] (also see below).

Out-of-phase and asynchronous cloniclike movements in the upper extremities (as opposed to in-phase and synchronous during epileptic seizures) is another "typical" motor sign suggestive of PNESs.[46] However, Leis et al. were not able to make this same distinction in their analysis of the motor phenomena of PNESs.[89]

The absence of any facial cloniclike activity in the presence of generalized cloniclike activity can be another "helpful" sign in suspecting a diagnosis of PNES. Family members need to be instructed ahead of time to look for such sign, however.

Incontinence and Self-injury

Contrary to old beliefs, patients with PNES *do get hurt*. Indeed, in a study by Reuber et al., almost 60% of patients had experienced PNES-related injuries, 32.3% had reported urinary incontinence, and 31.5% tongue biting (patients with both PNESs and epileptic seizures were not included in these percentages).[120] Incontinence has been reported to range between 10% and 44% in PNESs, most of which consist of urinary incontinence, but fecal incontinence has been also described.[95,112,120] Bruising and minor lacerations from falls followed by tongue biting (that may be severe enough to cause bleeding) are among the more common injuries reported in patients with PNESs. Tongue biting, which often does occur in a tonic–clonic seizure, also can occur in complex partial seizures, in faints (if the patient falls and bites the tongue as a result of the fall), and in PNESs (either as a result of falling or as a result of deliberate injurious behavior, not necessarily to simulate a seizure but because the patient is responding to inwardly driven motivation to try to hurt himself or herself). The site of the bite may yield clues but can be misleading. In a tonic–clonic seizure the bite is usually on the side of the tongue and is deep, although it may occur at the tip of it. In tongue injury as a result of falling, the bite is usually at the tip. In complex partial seizures the bite may be at the tip or occasionally at the side of the tongue or may involve the cheek. However, patients having PNESs also can bite the side of the tongue, tip of the tongue, and cheek. Finally, serious injuries, including facial bone fractures, are less common but have also been reported and tend to occur in patients with a psychiatric history of suicide attempts.[112]

Vocalizations

Vocalizations can be often seen in convulsivelike PNESs, but occasionally occur in non–convulsivelike events. Vocalizations associated with shedding of tears tend to suggest a strong possibility of PNESs.[17] In convulsivelike events, vocalizations consist of shouting, screaming, and sobbing often associated with understandable speech.[46,53,89,95] In contrast, in epileptic seizures, vocalizations are typically more primitive, such as grunting or a simple shout.[46] Vocalizations are more likely to occur in the middle of PNESs, unlike epileptic seizures, where vocalizations usually occur at the onset of the event.

Nonconvulsive Psychogenic Nonepileptic Seizures

Nonconvulsive PNESs can mimic either absence and/or partial complex seizures; more often than not, a correct diagnosis is unlikely to be reached until patients are referred for V-EEG with a presumed diagnosis of "intractable epilepsy." Patients may be unresponsive while exhibiting a motionless stare and they may exhibit semipurposeful movements simulating motor automatisms of complex partial seizures.[53] Maintenance of eyes closed and responsiveness to "selective" external stimulation, including verbally, in the course of an event during which they "appear" to be unresponsive are two clinical "clues" that should raise the suspicion of a PNES. More commonly, patients remain nonverbal but display active avoidance to both noxious and nonnoxious stimuli and/or resist attempts at eye opening, but this type of avoidant behavior may also be identified in complex partial seizures.

Other Clinical Characteristics of Psychogenic Nonepileptic Seizures

Sudden collapse to the ground with apparent unconsciousness but no movement can be part of epilepsy and can occur without warning. It is usually a primary generalized seizure (either a tonic seizure in which the patient falls stiffly or an atonic one in which the patient collapses with sudden loss of muscle tone). In both seizures recovery of consciousness (unless the patient has injured the head in falling) is swift and there is little postictal confusion (unless, again, the patient's head has been struck in the fall). Occasionally sudden loss of consciousness with falling can be seen in seizures originating in the temporal or frontal lobe.[28] The fall may be flaccid (but can occur with a tonic spasm), and consciousness usually is regained fairly quickly. The patient who falls in a flaccid way and remains apparently unconscious for some time is unlikely to have epilepsy. Epileptic seizures with falls, if monitored via EEG, may not be detected either because the patient is in bed and the characteristic falling is therefore not seen, or because the fall itself produces such artifact in the recording device that the ictal nature of the event is obscured. It also is possible that the preliminary collapse was due to epilepsy but the subsequent withdrawn behavior is a psychological elaboration of the brief epileptic experience. This may not be an uncommon occurrence.

Psychogenic Nonepileptic Seizures as "Drop Attack"

Physical and emotional causes of collapse are considered in other chapters (e.g., syncope in Chapter 271 and hyperventilation in Chapter 285). A not-uncommon cause of collapse and flaccid unconsciousness of a psychological type of nonepileptic seizure is the so-called swoon.[19] Here the patient, when threatened by external events or unpleasant memories or by a situation reminiscent of an unpleasant experience, will close the eyes, sink to the floor, and lie inert and not moving for various lengths of time, sometimes for over an hour. Passive movement and eye opening may be resisted, but usually the patient just lies inert and unresponsive and comes to quite quickly with little in the way of postictal symptoms. Presumably this is a form of learned behavior; it is a common childhood behavior that may have persisted into adult life. There is some evidence[20,61] that it also may be a common mechanism for avoiding flashbacks and reawakened memories in adults with a chronic posttraumatic stress disorder related to previous childhood sexual abuse,

P.2798

particularly if it was the way that the individual dealt with the abuse at the time it was occurring. Some abused people cope with their abuse by lying inert and retreating into themselves or by splitting their consciousness so that they almost seem to be watching events from a corner of the room and become passive observers of themselves; this may become a persistent unconscious learned pattern of behavior to deal with stressful events and later may be mistaken for epilepsy.

Deliberate Simulation of Unconsciousness

Deliberate simulation of unconsciousness, which may involve falling, is part of the repertoire of people with somatoform disorders or with factitious disorder or malingering (deliberately simulated disease). In the case of factitious disorder, individuals simulate illness to maintain the sick role; malingerers do so for social or financial gain. It is easy to sustain for long periods of time and difficult to detect, particularly if the patient does not resist passive movement or eye opening and does not respond to noxious stimuli. Such behavior (often seen as attention-seeking behavior in nurses and other caring professionals who are particularly prone to factitious disorder) is sometimes mistaken for epilepsy. Some professional simulators may inject themselves with insulin beforehand to add further authenticity to their performance.

Nonstereotypic Events?

PNESs have typically been thought of as nonstereotypic events (within patients), while the reverse has been considered to be a clinical sign supportive of a diagnosis of epileptic seizures. While the absence of a stereotypic semiology within patients should raise suspicions of a diagnosis of PNES, the reverse does not rule out this diagnosis. In fact, in four studies, 60% to 90% of patients with PNESs had spells that varied little from event to event.[38,48,53,99] However, even when clinical features and their sequence is relatively stereotypic, the duration of seizures in patients with PENSs tends to be more variable than in those with epileptic seizures.

Events of Long Duration

PNESs are more often than not significantly longer in duration than epileptic seizures and often lead to a misdiagnosis of status epilepticus (see below). A rapid recovery of cognitive functions following a prolonged convulsivelike or non–convulsivelike event should raise suspicions of possible PNESs (see below).

Psychogenic Nonepileptic Seizures Only Occur in Awake State

PNESs can only occur when the patient is awake, and events occurring out of sleep, documented with electrographic recordings, cannot be considered as PNESs. Having said that, clinicians cannot accept the patients' assertion of events occurring out of sleep without electrographic corroboration, as PNESs have been described in patients that "appear to be asleep" but in reality are awake.[16]

Psychogenic Nonepileptic Seizures Mimicking Status Epilepticus

One of the most serious consequences of PNES is their mimicking "status epilepticus" that is not properly diagnosed, which in turn results in unnecessary admissions to intensive care units, aggressive use of parenteral AEDs, and placement of endotracheal tubes. Iatrogenic damage (respiratory arrests, toxic effects from anticonvulsants) are common, and because PNESs do not respond to AEDs, prolonged hospital stays with expensive and dangerous treatments (including paralysis, anesthesia, and assisted ventilation) often occur.[59,117,120] For example, in a study by Reuber et al., 51% of patients with PNESs presented as "pseudostatus" (lasting more than 30 minutes) and 27.8% were admitted to intensive care units.[120] Howell et al.[59] suggested that perhaps 50% of patients admitted to emergency care in the United Kingdom in status epilepticus do not actually have epilepsy.

Some investigators have suggested that PNES mimicking status epilepticus occurs mainly in women whose seizures relate to a posttraumatic stress disorder from previous sexual abuse,[20,29] in individuals with hyperventilation attacks that are easily prolonged by inadvertent reinforcement, or in patients with conversion or factitious disorder (e.g., Münchhausen syndrome or malingering). Accordingly, emergency room staff should be encouraged to observe seizures critically before starting treatment, to use a pulse oximeter to distinguish patients who need immediate intubation from those who can be safely left to breathe without assistance, and to obtain arterial blood gases, which may also detect those who are hyperventilating.

Epileptic Seizures Mimicking Psychogenic Nonepileptic Seizures

As stated above, a study by Parra et al.[110] suggested that as clinicians have become increasingly aware of PNESs, epileptic seizures with atypical features are being misdiagnosed as PNESs. The error rate in diagnosing nonepileptic seizures in patients who clearly have epilepsy probably lies between 5% and 10%.[116,151] Complex partial seizures of mesial frontal origin can present with complex automatisms, very often with "bizarre" features that mimic the typical phenomena of PNESs. These include kicking or pedaling motions of the lower extremities; thrashing and flailing motions of the extremities or entire body, at times with very violent thrusts; and affect-laden vocalizations, such as screams and loud cries. Other phenomena that may contribute to the diagnostic confusion include a preserved consciousness in seizures originating in supplementary sensory motor area, despite a bilateral tonic posturing, and the absence of postictal lethargy or confusion. Kanner et al.[70] compared the clinical phenomena of supplementary sensory motor seizures with those of PNESs and found clinical phenomena suggestive of PNESs in 82% of all seizures recorded in 91% of the frontal lobe epilepsy patients studied.

The atypical clinical phenomena of these seizures are frequently coupled with undetected interictal and ictal epileptiform activity on scalp recordings. The difficulty in identifying any epileptiform discharges results from the great amount of muscle and movement artifact masking the underlying electrical activity. The inability of the angle subtended by scalp electrodes to identify the source of the epileptic activity in mesial or orbitofrontal regions is another contributing cause to this problem. Thus, it is not surprising that these seizures are frequently confused with PNESs.[70,103,123,147,151] Morris et al.[103] have demonstrated the presence of a subtle rhythmic theta pattern in parasagittal leads, buried within muscle and movement artifact. The use of high-frequency filters may be necessary to recognize such pattern. In addition, the presence of a structural lesion on magnetic resonance imaging (MRI) in mesial or orbitofrontal regions should raise suspicions of epileptic seizures in patients diagnosed with PNESs.

There are certain clinical features that may help the clinician distinguish this type of frontal lobe seizure from PNES: (a) frontal lobe seizures are very short in duration (<30 seconds); (b) they are stereotypic, including the complex automatisms; (c) they often occur out of sleep, whereas PNESa *always* occur in the awake state; and (d) they often display a tonic posturing in abduction of the upper extremities, a sign that was found to be specific to epileptic seizures involving the supplementary sensory-motor area and never seen in PNES.[70,103,147] A

cautionary note is in order: PNESs may be reported by patients to arise out of sleep, but V-EEG monitoring demonstrates an awake EEG pattern preceding the onset of the PNESs.[16,139] Benbadis et al.[16] coined the term "pre-ictal pseudosleep" to describe the state of wakefulness while appearing asleep in these patients with PNES.

Comorbidity of Epilepsy and Psychogenic Nonepileptic Seizures

This topic is reviewed in great detail in Chapter 208. Briefly, quoted rates for the coexistence of epilepsy and PNES vary from <10% to >90% of the population studied.[66,68,71,92,116] The literature is confusing because different populations of patients have been studied by different investigators and because of the uncertainty about the diagnosis of PNESs. It is impossible to be dogmatic about how commonly patients with established epilepsy develop PNESs, particularly because the association at times must be purely coincidental, but coexistence of epilepsy with PNESs is not a common problem. Probably no more than 5% of people with established epilepsy develop nonepileptic seizures.

In the literature, completely different methods have been used for diagnosing nonepileptic seizures, based sometimes on EEG criteria (but not necessarily EEGs recorded during the ictus itself), on clinical criteria, or on a mixture of both. It is also sometimes not clear, when the prevalence of the two conditions is compared, whether the investigator is referring to patients with nonepileptic seizures and present epilepsy or merely a history of it in the past. It is likely, as Ramsey et al. have concluded,[116] that if the history is one of past as opposed to present epilepsy, the proportion of patients with both epilepsy and nonepilepsy is likely to be higher, particularly in patients with learning difficulty.[104]

Sometimes the question can only be answered by withdrawing the antiepileptic medication and seeing if epilepsy re-emerges. If it does, one must pose the question, "Was this all epilepsy that I was trying to treat, or am I dealing with somebody who has controllable epilepsy but who has a psychological need for it?"

A review of the literature suggests that 10% to 30% of patients who appear to have established nonepileptic seizures also have a past history of epileptic seizures, which means that even when it is obvious that a patient's seizures are nonepileptic, slow and cautious reduction of anticonvulsant medication is indicated.[66,71] Rapid reduction of anticonvulsant medication, even in patients who do not have epilepsy, may precipitate pharmacologic withdrawal seizures, which will make the picture even more difficult to assess. A final consideration: The literature suggests that if one is assessing a patient with an unknown attack disorder that has two different presentations, 5% to 30% of the time one may be dealing both with epilepsy and a nonepileptic seizure.[116]

Diagnostic Evaluation of Psychogenic Nonepileptic Seizures

Neurologic Workup

The diagnostic workup of PNES consists first and foremost of neurophysiologic studies aimed at capturing the patient's typical events and documenting the absence of a concurrent epileptic ictal pattern. However, the fact that a patient has PNES does not rule out the presence of comorbid neurologic disorders, including a coexisting or past epileptic seizure disorder. In fact, people with a correct diagnosis of NES have been found to have a clearcut history or evidence on examination of cerebral injury,[72,78,118] whereas a significant percentage of people with epilepsy have no such history. Once the diagnosis of NES is established, a psychogenic cause must be investigated with psychiatric and neuropsychological evaluations. Yet, although many people with proven NES have a recognizable psychiatric illness or history or evidence of emotional precipitation of seizures, so do many people with epilepsy. The diagnosis of an NES cannot depend solely on these features but is based on the judicious and considered review of all the evidence available to the clinician. This is particularly important when certain psychological or psychiatric conditions are present in a patient who has an undiagnosed attack disorder. For example, a history of sexual abuse is not uncommon in people with proven epilepsy and may be pathoplastic in the seizure content.[19,52]

The neurologic evaluation of patients with suspected PNES must include V-EEG or ambulatory EEG studies to capture the typical event, and neuroimaging studies including brain MRI to rule out the presence of structural pathology that may be associated with a past or present comorbid neurologic disorder. In addition, the presence of a structural lesion in mesial-frontal regions of the brain may alert the clinician to be cautious on reaching a false-positive diagnosis of PNES and rule out the presence of epileptic seizures mimicking PNESs. In some patients functional neuroimaging studies such as ictal SPECT may be necessary when the distinction between PNES and epileptic seizures with atypical features may be difficult.

Video-electroencephalographic Monitoring

The electrographic diagnosis of PNESs is based on the recording of one of the patient's typical events in the absence of any electrographic change from their baseline "awake" activity. To ensure that a typical event has been captured, the recordings have to be shown to family members who have witnessed the patient's events. Furthermore, it is important to enquire from these family members about the occurrence (in the present or in the past) of events different than those captured during the V-EEG. This will minimize the risk of failing to identify a comorbid epileptic seizure disorder that may be either occurring simultaneously with PNES or a prior seizure disorder that may have remitted with AEDs. Clearly, such information is pivotal on the decision to discontinue AEDs.

When Should Antiepileptic Drug Dosages be Lowered during the Video-electroencephalogram?

PNESs are likely to occur in the early stages of a V-EEG. For example, Parra et al. found that up to 96% of patients with PNESs had a typical event within the first 48 hours of V-EEG.[111] Accordingly, it is reasonable to maintain the patients' usual AED doses during the initial 2 days of the study so as to minimize the risk of facilitating the occurrence of an epileptic seizure early in the monitoring study of patients with both PNES and epilepsy. It has been our experience that once an epileptic seizure has been recorded, clinicians prematurely conclude that all the events are epileptic, leading to a false-negative diagnosis of PNES.

Benzodiazepines should not be discontinued during V-EEG of patients with suspected PNESs, as their abrupt discontinuation may trigger withdrawal seizures or withdrawal psychiatric symptoms, particularly panic attacks and anxiety, resulting in false-negative or false-positive data.

AEDs can be lowered or even discontinued to establish the existence of suspected concurrent epileptic seizures. Such can

be the case in patients with documented PNESs whose V-EEG recordings reveal interictal epileptiform activity and who are reported to exhibit other paroxysmal events that by their semiology may be suspected of being epileptic seizures. In the case of suspected epileptic seizures that preceded the onset of PNESs and remitted with pharmacotherapy, discontinuation of AEDs may not necessarily result in their occurrence during the course of a typical V-EEG.

The Significance of Interictal Epileptiform Activity

Interictal EEGs are reported to be abnormal in 23% to 50% of patients with PNESs; although diffuse or focal slowing is the most common abnormality, interictal epileptiform activity is seen in 35% to 50% of patients with PNESs.[14,38,58,72,78,90,104,116,118] The presence of interictal epileptiform activity in recordings of patients with a documented PNES raises the possibility of comorbid occurrence of PNESs and epileptic seizures, or of a prior history of epileptic seizures. As stated above, this comorbidity has been reported in 5% to 40% of patients with PNESs. Devinsky et al. have shown that the semiology of PNESs and epileptic seizures differ from each other in patients with comorbid disorders.[38]

Ictal Recordings

The absence of any electrographic ictal patterns while the patient is unresponsive documents a diagnosis of

PNES in most patients. However, 10% of patients with epileptic seizures may not show any ictal pattern on scalp recordings, especially when the ictal activity originates from mesial frontal, mesial parietal, and, occasionally, mesial temporal structures.[70,103,123,147,151] In addition, scalp recordings will fail to reveal any electrographic changes in up to 75% of simple partial seizures,[39] given that scalp electrodes are able to detect epileptiform activity only if a cortical area of 6 cm^2 or more has been synchronously activated. Thus, reliance solely on EEG recordings to make a diagnosis of PNES may yield false-positive data. Accordingly, in the presence of paroxysmal events that are not associated with any loss of consciousness and normal concurrent EEG recordings, clinicians must consider the possibility of a diagnosis of simple partial seizures before concluding that they are PNESs. In the presence of events with unresponsiveness, bizarre clinical phenomena, and concurrent undetectable electrographic ictal patterns, a diagnosis of mesial frontal or parietal lobe seizures should be considered in the presence of the clinical characteristics described above. A diagnosis of PNES is more likely in the absence of clinical signs typical of frontal lobe seizures and if these events can be induced and stopped with the use of suggestive techniques.

Special electrodes have been used during the V-EEG to facilitate the detection of electrographic ictal patterns. These include orbitofrontal electrodes and the use of the 10-10 electrodes over parasagittal areas to identify ictal activity of mesial and orbitofrontal origin.[9,67] In these seizures, the electrographic ictal pattern consists of a very subtle rhythmic theta activity over parasagittal regions.[103] Sphenoidal electrodes inserted under fluoroscopic guidance can identify interictal and ictal activity of mesial temporal origin with a very restricted electric field.[69,73]

Induction of Psychogenic Nonepileptic Seizures

The use of induction protocols to trigger a PNES has been the source of much controversy, first with respect to the potential of a false-positive diagnosis (either by provoking atypical events or by facilitating epileptic seizures) and second with respect to the “ethical” use of many of the protocols used that ultimately can lead the patient to feel that he or she was lied to.

There is a general agreement that induction protocols do facilitate the occurrence of PNESs.[11,32,38,87,89,95,111,131,145] Among the different studies, the sensitivity of various protocols has ranged between 37% and 91%, with most studies reporting a successful induction in 77% to 84%.[11,32,38,87,89,131,145] While most studies report the specificity of induction of PNESs to be 100%,[32,38,87,131] there have been reports of epileptic seizures triggered by induction. Walczak et al.[145] reported that 10% of patients with epilepsy experienced seizures after induction; others have also reported similar findings.[92,111] Therefore, a positive induction does not document a diagnosis of PNES, and to avert this type of error, induction protocols should not be carried out in the absence of concurrent electrographic recordings. The study by Parra et al.[111] previously cited is particularly noteworthy as it addresses the question of whether induction protocols are necessary during V-EEG. Indeed, of 100 patients admitted for V-EEG monitoring studies, 87 experienced their typical event and 82 of these did so spontaneously, without induction. Among the patients with PNESs, 96% experienced their typical event without induction in the initial 48 hours. Slater et al.[131] reported similar findings in which 75% of patients with PNESs had spontaneous events without induction.

Several induction protocols have been suggested. Every protocol is based on the use of a “placebo,” which raises serious ethical issues and may jeopardize the patient–physician relationship, the patient's trust of all physicians, and the patient's acceptance of the diagnosis of PNESs. The most frequently used protocol consists of intravenous infusion of a saline solution after the patient is told that he or she will be given a medication likely to induce seizures.[32,38,131,145] Other protocols have relied on the placement of an alcohol-soaked patch on the patient's neck after informing the patient that this was likely to provoke a seizure,[87] while other protocols consist of having the patient undergo photic stimulation and hyperventilation, as performed in any routine EEG study. Clearly, with the former two protocols patients may realize that they have been deceived, while the use of hyperventilation and/or photic stimulation does not carry this risk as these are established maneuvers used in all EEG studies to facilitate the occurrence of seizures.

The potential ethical problems associated with induction protocols may put in jeopardy the entire treatment process, as the nature of the protocol precludes informing patients on the true nature of the procedure, and with the exception of protocols using hyperventilation and photic stimulation, clinicians are in essence lying to patients as to the potential effect of the stimulus on seizure activity. Such misrepresentation of the facts can compromise the patient–physician relationship and trust and give the patient reasons to reject outright the diagnosis of PNES and the suggested treatment. Despite these concerns, several authors have defended the use of induction protocols arguing that by aiding in the accurate diagnosis of PNES, induction may help prevent the patient from receiving inappropriate, potentially harmful AEDs and the incorrect diagnosis of epilepsy, with its potential psychological and social hardships, and that therefore the use of induction techniques is ethically justifiable.[37] While no one questions the value of induction protocols, the use of techniques that may lead patients to feel deceived should be a deterrent to the use of induction protocols relying on a "placebo," as the same results can be reached with protocols relying on the use of regular activation methods in EEG such as photic stimulation, hyperventilation, or both combined.[13,111] Finally, the use of hypnosis as a trigger of PNESs has been gaining increasing interest among psychiatrists.[97] Experts in hypnosis, following full disclosure

of the technique, should be the only ones attempting such procedures, however.

Outpatient Electroencephalographic Studies

Attempts to avoid inpatient evaluations and to rely on outpatient diagnostic studies have become necessary with greater frequency in patients suspected of having PNESs, given an increase in medical costs and greater limitations of resources faced by governmental and private third-party payers. Two modalities of outpatient EEG studies have been used: (a) outpatient V-EEG of 2 to 8 hours' duration and (2) ambulatory EEG studies.

Outpatient Video-electroencephalography

There is an increasing body of literature documenting the value of using this type of diagnostic studies. Patients with daily events and those with suspected PNESs are potential candidates. For example, in a prospective study of 37 children with daily paroxysmal episodes, with outpatient V-EEG averaging 3 hours typical events were recorded in 23 patients; in 11 the study allowed clinicians to distinguish epileptic from nonepileptic seizures.[3] In a study of 50 consecutive patients with suspected PNESs, Bahtia et al. used ambulatory V-EEG with the use of an induction protocol consisting of saline infusion.[24] Fifteen patients had a spontaneous event and another 15 had an event induced with induction.

This type of study has an important limitation, as it may fail to record interictal epileptiform activity in patients who may have coexisting rare epileptic seizures or who suffered from epileptic seizures in the past that remitted with AEDs. Clearly, if this type of study is to be used, a detailed history of the patient's present and past events is of the essence, above all when the decision to discontinue AEDs is being considered. Furthermore, some patients may need to undergo a prolonged V-EEG before a definite diagnosis is reached.

Ambulatory Electroencephalography

The advantage of these studies is that the EEG recordings are obtained while the patient is in his or her habitual environment. The disadvantage is that EEG recordings are often masked by movement and muscle artifact during the event, and in the absence of any video, it is impossible for the clinician to establish the nature of the event. Aminoff et al.[6] and Berkovic et al.[18] had concluded that ambulatory EEG studies are useful to identify epileptic seizures. However, events without an electrographic ictal pattern cannot necessarily be considered nonepileptic. Nevertheless, with the availability of ambulatory V-EEG home systems and the ability to use a larger number of channels, and to reformat recordings, ambulatory studies may end up replacing inpatient V-EEG in the future in a significant percentage of cases.

Neuroimaging Studies

Magnetic Resonance Imaging Studies

As stated above, patients with PNES may have abnormal neurologic examinations, EEG studies, and MRI studies. For example, in a study of 45 patients with PNESs, 43% had an abnormal MRI.[72] In these patients, an abnormal MRI finding may identify comorbid neurologic disorders that may explain some of their symptomatology, not related to PNES. More importantly, however, a structural lesion in mesial frontal or parietal regions should lead the physician to seriously reconsider the diagnosis of PNES.

Single Photon Emission Computed Tomography

The use of this type of study can be of great assistance in clarifying whether a paroxysmal event with atypical clinical phenomena is in fact an epileptic seizure mimicking PNES (i.e., partial seizure of mesial frontal origin), provided that the radionuclear marker is injected at the time of the event (ictal SPECT). The epileptogenic zone is represented by an area of hyperperfusion on ictal SPECT. While, the sole use of interictal SPECT yields unreliable data in patients with epilepsy and is of no diagnostic value,[40,105,114,133,135,149] its use in conjunction with an ictal SPECT (SISCOM study) has enhanced the diagnostic yield of data obtained with ictal SPECT. A negative SISCOM or ictal SPECT, however, does not imply a diagnosis of PNES. Conversely, an abnormal SPECT scan does not mean epilepsy is always present. Studies of small series of ictal and interictal SPECT scans in NES revealed a small number of patients with lateralized perfusion abnormalities. The findings did not change, however, when comparing the ictal and the interictal images.[41]

Laboratory Tests

Two blood tests have been used in the differential diagnosis between epileptic and nonepileptic seizures: Prolactin (PRL) and creatine phosphokinase (CPK) serum concentrations.

Serum prolactin levels are commonly elevated following generalized tonic–clonic seizures and complex partial seizures of temporal lobe origin, provided that levels are drawn within 20 to 30 minutes of seizure onset. Prolactin levels are generally not elevated following simple partial seizures, complex partial seizures of frontal lobe origin, or PNESs,[33,35,88,98] though Alving et al. reported a statistically significant increase in prolactin levels in patients following PNESs.[5] Another study reported a significant rise in serum prolactin levels following episodes of hypotensive syncope.[108] The Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology recently published its report on the use of serum PRL in differentiating epileptic seizures from NESs. The authors reviewed the PRL seizure literature and concluded that a twice normal relative or absolute serum PRL rise, drawn 10 to 20 minutes after the onset of the ictus, compared against a baseline nonictal PRL, is a useful adjunct in the differentiation of generalized tonic–clonic seizures or complex partial seizures from NESs.[31] Unfortunately, this test is not useful for differentiating the epileptic seizures that are more likely to be confused with NESs (i.e., frontal lobe seizures) from NES proper, which limits the utility of this test when it is most needed.

Wyllie et al. have reported an increase in serum CPK levels following 15% of generalized tonic–clonic seizures, but not after partial seizures or PNESs.[154] The levels of CPK peak between 18 and 24 hours postictally. Thus, a high serum CPK following a convulsive event is suggestive of an epileptic seizure, but normal CPK *does not confirm* the diagnosis of PNESs. The gap of 18 to 24 hours between event and peak serum concentrations makes this a useful test to consider in outpatients.

Psychiatric Disorders Associated with Psychogenic Nonepileptic Seizures

General Considerations

Two considerations in reviewing the psychiatric diagnoses in PNES are (a) etiologic and (b) epidemiologic. The etiologic

P.2802

question is, "What is causing the PNES?" The epidemiologic question that arises is, "What are the psychiatric comorbidities in patients with PNES?" We are gaining in our knowledge of the latter, but presently, we have only theoretical approaches for the former issue of etiology. Both etiology and epidemiology of comorbidities are of great importance, as they influence prognosis and may be treatment targets for patients with PNESs.

No single psychopathogenic process is known to cause PNESs. PNESs are clinically classified under different *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (DSM-IV) diagnoses, including conversion, somatization, and dissociation disorders, and a much smaller percentage as factitious disorder and malingering. A psychosocial stressor (e.g., sexual or physical abuse, loss of a relationship, work stress, parental divorce)[153] is often identified but may take months to uncover.

The presence of a structural lesion in the brain does not preclude a diagnosis of nonepileptic seizures,[90,94] and the presence of a psychological disorder does not preclude a diagnosis of epilepsy. Many psychiatric conditions are overrepresented in the population of people with epilepsy.[85] Thus, mood and anxiety disorders are pervasive both in epilepsy and in PNESs. Neurologists have underrecognized patients who have a severe anxiety or depressive disorder along with their neurologic disorder.[63]

Etiologic Diagnostic Considerations

Somatoform Disorders

These are a group of disorders in which physical symptoms or signs present without any apparent physical cause and which have an assumed psychological cause. They are distinguished from factitious disorder and malingering. There are several subdivisions of the somatoform disorders, of which two are particularly important in patients with PNESs, conversion and somatization disorders.

Conversion Disorder.

The DSM-IV diagnostic criteria for conversion disorder are the presence of one or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurologic or other general medical condition; psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors. The symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering).

The diagnosis, now, is based not on psychological guesswork as to what is going on in the patient's mind, but on observable phenomena. This laudable attempt to simplify the definition of conversion disorder and therefore make it easier to diagnose has unfortunately resulted in the concept of dissociation (which many European psychiatrists would feel is an essential part of conversion disorder) being relegated to a completely different diagnostic category that will be briefly considered later.

Conversion disorder (unlike the old concept of hysteria and Briquet syndrome) has therefore become almost exclusively neurologic, and seizures feature prominently in its definition. A large proportion of people with PNESs fall into this diagnostic category. It is a diagnosis that is easy to make but one that psychiatrists and neurologists find difficult to substantiate because of each profession's discomfort with the elements of "the other profession." While it is open to misuse (because it is partly based on subjective criteria), a positive diagnosis of conversion disorder can be made in the context of acknowledging the diagnostic criteria; a thorough history, oftentimes uncovering a series of medically unexplained symptoms; and a nonneuroanatomically based examination.

The emotional problems that are causing the conversion disorder are often discoverable, particularly in the early stages of the condition, but not always. Many people with genuine physical symptoms also have psychological problems that may sometimes exacerbate their symptoms. Examples include patients with multiple sclerosis who might embellish their responses on physical examination, in order to "help" the examiner. It is important for patients to see the connection between the symptom and problem for themselves rather than having someone else's explanation being forced on them.

Somatization Disorder (Previously Known as Briquet Syndrome).

The full DSM-IV diagnostic criteria are basically related to a history of many sustained, relentless, multisystem physical complaints without neuroanatomic basis, but which are not intentionally produced, occurring over a long period of time with many treatment requests and significant social impairment. Some patients whose primary presenting symptoms are PNESs fall into the category of somatization disorder if a careful assessment is made and a complete medical and surgical history is taken. Care must be taken, however, realizing that some somatic and psychiatric disorders (e.g., connective tissue disorders, depression) can cause widespread somatic complaints, often over long periods of time, which can be mistaken for a somatoform disorder.

Dissociative Disorders

Dissociation is defined as disruption in the usually integrated functions of consciousness, memory, identity, and perception. Splitting of apparent consciousness from present experience can present as amnesia, as a fugue state, as an identity disorder, or as depersonalization and thus may enter into the differential diagnosis of paroxysmal behavior. Depersonalization, amnesia, and, occasionally, fuguelike behavior also may occur as symptoms of epileptic activity.[127,134,155] Dissociative amnesia is currently much associated with theories about repression of later recovered memories of previous childhood abuse. There is some evidence[20] that some particular types of PNESs (swoons and abreactive attacks) are more common in people who have disclosed a previous history of sexual abuse as a child. Swoons can be described as a kind of dissociative state related to avoiding unpleasant memories; abreactive attacks can be seen as an acting out of unpleasant memory flashbacks. Some clinicians argue that dissociation is the underlying mechanism in PNESs based on studies showing that patients with PNESs score higher on dissociative experiences scales than patients with epilepsy.[2,115]

Factitious Disorder

Factitious disorder is a deliberately simulated disease, the simulation of which does not appear to convey any advantage except that of assuming the sick role. External incentives, unlike in malingering, are absent. The condition is therefore inwardly driven by psychological forces, although the patient is aware of the deception. Patients may display considerable ingenuity in maintaining the deception and often deny deception. A smaller proportion of people with NESs belong to this group. Their performance may be polished and practiced. They may, in the interests of verisimilitude, even inflict physical damage on themselves and repeatedly present to different emergency rooms, apparently in status epilepticus. This is sometimes referred to as Münchhausen syndrome.[122]

Diagnosis can be difficult and should not be made until the team managing the patient is absolutely certain that it is correct. Premature diagnosis without concrete evidence, based purely on the puzzling nature of the patient's symptoms, can be a costly mistake.

A variant of factitious disorder is Münchhausen disorder by proxy, in which factitious symptoms of a disorder (often a seizure disorder) are produced in a dependent (usually a child) of the complainant.[4] The actual victim is usually a child, but it is the parent or caregiver who has the factitious disorder and the kind of personality that wants not so much to be in the sick role, but to have someone dependent on them in the sick role. In caregivers (such as nurses) who exhibit this behavior, there is also often a compulsive need not just to have people dependent on them, but to be seen as the dramatic rescuer of the victim. Unfortunately, such personality types are often attracted to nursing, and nurses are particularly likely to show factitious disorder or to initiate Münchhausen syndrome by proxy. This can have an unfortunate rebound effect on nurses with genuine illnesses.

Malingering

Malingering is not a psychiatric disorder, but one where there is a voluntary and conscious production of symptoms (and signs) for gain. The motivation might be to avoid a court case or to obtain disability payments or medication. Nonepileptic seizures are infrequently part of the repertoire of someone who is deliberately malingering.[55] Here the false symptoms and signs are being produced to change external circumstances rather than being internally driven and are usually easier to understand. People who use seizures for malingering purposes are often practiced and accomplished and much harder to detect. Unfortunately, some people who have had a chronic disability such as epilepsy and who have gained financial support as a result (as is only right and proper) may be reluctant to abandon their symptoms because they will lose the benefit if they do. Some people in such a situation may unconsciously or consciously simulate their seizures, long after the seizures themselves have stopped, in order to continue to gain benefit.

A clear distinction cannot always be made between somatization disorder, conversion disorder, factitious disorder, and malingering as the conditions blur into each other (it can be difficult to decide sometimes whether someone's motivation is truly unconscious). Apparent motivation is also based to some extent on a clinician's subjective interpretation. Currently, there are no diagnostic tests that definitely rule in or rule out conscious or unconscious motivation.[80]

Epidemiologic Considerations: Comorbid Diagnoses in Psychogenic

Nonepileptic Seizures

Bowman's review revealed that many patients with PNESs also suffer from mood (12% to 100%), anxiety (11% to 80%), personality (33% to 66%), nonseizure conversion/somatoform (20% to 100%), and nonseizure dissociative disorders (up to 90%) co-occurring with their primary PNES diagnosis of conversion, somatoform, or dissociative disorder.[25] The diagnostic frequencies noted in Bowman's PNES population studies using the DSM-III-R were confirmed in a French study using the DSM-IV criteria.[102] Axis II personality disorders also are found in patients with PNES, largely, but not exclusively, of the impulsive, cluster B personality.

Mood Disorder

Mood disorders are common in people with epilepsy. Both depression and hypomania are probably more common than would be expected by chance.[62] The prevalence of mood disorder, particularly depression, is also high in people who have PNESs.[27] It is unlikely that depression itself causes nonepileptic seizures, but the onset of depression is well known for releasing psychopathologic behavior, including conversion disorder.[113] Depression in some patients with PNESs may be related to the environmental stressors and life circumstances that have caused the seizures themselves. Mood disorder is also prominent in somatoform disorder (which may independently be associated with PNESs) and may need to be treated independently.[132]

Anxiety

Nonepileptic seizures are often associated with panic disorder with or without agoraphobia. The DSM-IV defines a panic attack as a discreet period of intense fear or discomfort in which four or more autonomic symptoms develop abruptly and reach a peak within 10 minutes, including palpitations, tachycardia, diaphoresis, tremulousness, dyspnea, feelings of choking, angina, dyspepsia, feeling dizzy, feeling lightheaded, feeling faint, paresthesias, and temperature changes, along with derealization, feelings of unreality, feelings of depersonalization, feelings of being detached from oneself, fear of losing control or going crazy, or fear of dying.

Some panic attacks are, of course, accompanied by hyperventilation (indeed, some of the above panic symptoms are related to hyperventilation) and at times can lead to apparent unconsciousness and be mistaken for epilepsy.[23] Panic attacks also may be mistaken for epilepsy if they occur in the context of agoraphobia or a specific phobia.[124] The agoraphobia or other anxiety symptoms may be mistaken for an emotional reaction to the mistakenly diagnosed epileptic seizure.[47] Patients with generalized anxiety disorder also may be mistakenly diagnosed as having epilepsy if the symptoms of their anxiety are such as to suggest a temporal lobe origin for them.[130] Anxiety also can coexist with a somatoform disorder, which may itself give rise to nonepileptic seizures.

Panic disorder, agoraphobia, specific phobias, anxiety disorder due to epilepsy, or adjustment disorder with anxiety related to epilepsy can all occur in people with genuine epilepsy, making differentiation difficult.[125]

Posttraumatic stress disorder (PTSD), in which sudden intrusive memories (flashbacks) or dissociative experiences occur, can be mistaken for epilepsy, particularly if the flashback leads to an alteration in behavior.[29] Occasionally patients can develop a posttraumatic stress disorder related to their epilepsy if they had a seizure in a particularly frightening or life-threatening situation (e.g., a patient who had a tonic–clonic seizure in the bath and had to be rescued by strangers). Related to their histories of trauma and abuse, patients with PNESs have high frequencies of PTSD.[27] There is a significant literature on the association between childhood or adult trauma and abuse and the development of PNESs with PTSD.[45]

Finally, anxiety commonly co-occurs with a mood disorder, and it can sometimes be difficult to decide which is which. Both can occur in epilepsy, and both may be present in people with PNESs.

Psychotic Illness

A few patients with PNESs also may have a coexistent psychosis, and the seizures may sometimes have a relationship to the patient's disordered psychopathology. Psychoses occur in people with epilepsy, and sometimes the phenomena of schizophrenia (catatonia, made movements) can be mistaken for epilepsy.[142]

The Role of Psychometric Testing in the Diagnosis of Psychogenic Nonepileptic Seizures

Psychological Tests

As an adjunct to the gold standard V-EEG diagnosis of PNES, some clinicians use psychological tests. When used with V-EEG, the Minnesota Multiphasic Personality Inventory (MMPI) is a useful predictor of PNESs[136]; however, its reliability and validity in detecting patients with PNESs also has been criticized.[65] Derry and McLachlan[36] have shown that the revised version of the MMPI (the MMPI-2) discriminated with a 92% rate of accuracy between patients with epilepsy and patients with PNESs. They also felt it useful in detecting those patients who have epileptic seizures but who have marked psychopathology, and who, therefore, also may have PNESs. People with PNESs demonstrate a personality profile suggestive of a conversion or somatoform disorder.

Hypnosis also has been used as a diagnostic tool for PNES for over half a century.[137] Kuyk et al. used the technique for recovering memory in psychogenic amnesia and recalling memory of events taking place during the seizure itself with the premise that if ictal memory can be recovered, then the event is a nonepileptic one, and found 100% specificity and 85% sensitivity for a diagnosis of PNES.[79] Barry found that using the hypnotic induction profile reliably distinguished patients with PNES from those with epilepsy.[10]

Cragar et al. reviewed the literature on adjunctive tests for diagnosing PNES and reported sensitivity and specificity of the different measures.[34] A summary of their findings noted that PNES and ES patients did not differ on intelligence tests or on neuropsychological (NP) measures consistently. Both PNES and ES groups did have cognitive deficits when compared to normal controls, and the PNES group tended to perform better than patients with ES on various NP tests. Similarities and differences in these tests are discussed more fully in Chapter 208.

Prognosis/Predictors of Psychogenic Nonepileptic Seizures Outcome

Depending on the psychiatric makeup of the individual with NES, outcomes vary. Kanner et al. found that the presence of a mood disorder, a history of abuse, and a personality disorder were associated with a higher frequency of a patient having persistent PNESs.[72] Betts and Boden suggested that the short-term prognosis of nonepileptic seizures was relatively good, but that relapse, once the patient was discharged into the community, was frequent.[19] Also, a significant number of patients continue to have PNES, even with the institution of therapy.[1] Walczak et al. investigated the outcome of 72 patients with V-EEG–diagnosed PNESs, followed for a mean period of 15 months (range, 12 to 22 months). Patients were asked about the frequency of PNESs in the last 6 months, AED use, occupational status, and extent of psychotherapeutic treatments. PNESs had ceased in 18 patients (35%), decreased >80% in 21 (41%), and decreased <80% in 12 of 51 (24%). Thirty-three patients (65%) were not taking AEDs. Occupational status improved in 20% and did not change in 75%. Overall, 29 of 51 (57%) rated themselves markedly improved and 15 of 51 (29%) rated themselves unchanged or worse. Persisting PNESs were significantly associated with longer duration of PNES before diagnosis and presence of additional psychiatric disease. Persisting PNESs were not associated with gender, presence of epileptic seizures, or extent of psychotherapeutic treatments after diagnosis.[144]

A handful of studies have demonstrated that a certain population of patients with PNESs experience complete remission of their events after their diagnosis is given, even in the absence of any therapeutic interventions. One group reported that 18 of 22 patients with PNESs had a reduction of PNESs in the 24 hours postdelivery of their V-EEG diagnosis.[43] One-year follow-up, however, revealed that 87% of patients with PNES had the return and persistence of their PNESs.[146] In the study by Kanner et al.,[72] 13 of 45 (29%) patients stopped having PNESs after the diagnosis was established and remained free of events until the last follow-up 6 months later. Unfortunately, most of the studies published to date suggest that only about one third of patients had stopped experiencing PNESs at the time of follow-up, 1 to 5 years after diagnosis.[120]

Long-term outcome studies yield disappointing outcomes. Krumholz and Neidermeyer evaluated the prognosis of PNES in 41 patients discharged from the Johns Hopkins Hospital who had follow-up data of 5 years or longer after discharge.[78] Among these 41 patients, there were coexisting organic neurologic disorders in 18 (44%) and mental retardation was identified in 17%. Concurrent epileptic seizures were found in 37% and EEG abnormalities found in 38%. Persistence of PNESs was found in 56% of patients, which was associated with psychosocial problems.

On the other hand, a significantly better outcome has been found in outcome studies of children and adolescents. For example, Wyllie et al. compared the outcome of PNESs documented by V-EEG in 18 nonepileptic children and adolescents (ages 8 to 18; median, 14.5 years old) and 20 adults (ages 25 to 56; median, 34.0 years old).[152] The outcome was significantly better for the younger patients at 1 year, 2 years, and 3 years after diagnosis, as 73%, 75%, and 81% of children and adolescents were free of events at these follow-up times, respectively; at the same follow-up times, the percentages of adults free of psychogenic attacks were only 25%, 25%, and 40%.

In a recent study of 147 patients with PNESs contacted after a mean of 4.2 years after diagnosis (mean age at follow-up, 38.1 years), Reuber et al. found that 71.4% continued to have PNESs, and 28.6% had achieved seizure remission[119]; 60.0% of patients with continuing PNESs and 42.7% of patients in remission were "unproductive." More severe psychopathology was associated with persistence of PNES and unemployment.

Understanding the role of certain psychiatric and neuropsychological variables in the PNES outcome of our patients can be of paramount importance in planning treatment strategies. For example, in a prospective study of neurologic and psychiatric predictors of PNES outcome in 45 patients carried out at the Rush Epilepsy Center, the persistence of PNESs was investigated at 1 month and 6 months after diagnosis.[72] Three outcome patterns were identified: (a) uninterrupted PNESs (n = 20), (b) transient cessation of PNESs for a period of at least 3 months with subsequent recurrence (n = 12), and (c) cessation of PNESs since diagnosis (n = 13). The 20 patients that continued with uninterrupted PNESs were significantly more likely to have a history of abuse (physical, emotional, sexual, mixed), a history of recurrent major depression, a personality disorder, and a history of dissociative disorder (not presenting as PNESs). Given the frequent history of abuse, it is reasonable to expect that PNESs are an expression of a dissociative process. This observation is further supported by the higher frequency of a history of dissociative disorder that preceded and presented in forms other than PNESs. Thus, the uninterrupted persistence of PNESs in these patients is not surprising, since the mere fact of being told that they do not have epilepsy is meaningless to them. Indeed, as long as their events are the expression of a "dissociative state" and patients have not found

other means of dealing with stress, PNESs are expected to persist. Furthermore, having made the connection that their events constitute a dissociative process does not necessarily result in their cessation. Of interest is the fact that, despite their severe psychopathology, 17 of these 20 patients readily accepted the psychogenic nature of their events, and were able to recognize their PNESs as a form of dissociation soon after their diagnosis was discussed with them.

Twelve of the 45 patients experienced a transient cessation of PNESs following the diagnostic V-EEG for a period of at least 3 months. They differed from those with the two other outcomes in two areas: They were more likely to deny the presence of any psychiatric or psychological problems. In fact, 8 of the 12 patients with this outcome refused a recommendation to start psychiatric treatment. All patients accepted that their events were not epileptic, however. In addition, patients in this group were more likely to develop new somatic complaints after the diagnosis of PNES was established. In these patients we suspect that somatoform/conversive disorders are mediating their PNESs, in contrast to patients with persistent events who were more likely to have a dissociative disorder.

Thirteen patients stopped experiencing PNES after diagnosis. Paradoxically, this group of patients is the most puzzling from a psychiatric standpoint. Most had psychiatric disorders of mild severity, but in 5 of the 13 patients, *no current psychopathology* was identified during the psychiatric and neuropsychological evaluations. In those cases, no psychiatric treatment was suggested and they were followed in the clinic with visits every 3 months initially and then every 6 months. In the other patients, treatment was tailored to the nature of the identified psychiatric disorder. One of the 13 patients refused referral for psychiatric treatment; yet, there was no PNES recurrence up to the time of the last follow-up visit. The findings of this study provide relevant information to clinicians. Patients who stop having PNESs after disclosure of diagnosis differ significantly in their psychiatric profile from those who experience PNES recurrence. Among the latter patients, a distinct psychiatric profile can be associated with a particular PNES recurrence pattern. These findings suggest that more than one psychopathogenic mechanism is operable in PNES. Second, the psychiatric variables identified commonly in these patients can be predictive of PNES recurrence.

Presentation of the Diagnosis of Psychogenic Nonepileptic Seizures

In any medical disorder, acceptance of the diagnosis is the first step in the therapeutic process. In the case of PNESs, presentation of the diagnosis of PNESs is a pivotal step in helping the patient "come to terms" with a diagnosis that implies a "psychogenic cause." Reluctance to accept the diagnosis of a psychogenic process on the part of the patient may be based on concerns that family members and friends will think that he or she is "crazy" or that he or she is "faking" the spells to get attention or avoid responsibilities. Yet acceptance that the patient's events are not epileptic seizures or events of organic origin is of the essence as the biggest potential source of morbidity and mortality are the physicians in emergency rooms who may not recognize the true nature of the events and treat the patient as one in status epilepticus.

Often the way the diagnosis is presented to the patient and family members accounts for their refusal to accept it and by the same token to refuse recommendation for psychiatric treatment. Interestingly enough, there is no consensus among experts on what is the best way of presenting the diagnosis. At a treatment workshop on PNESs sponsored by the National Institutes of Health and the American Epilepsy Society held in May 2005, it became very clear that there are no systematic data to determine the best protocol to follow in discussing the diagnosis of PNES with patients and family.[140] For example, the following questions were raised: (a) Should a psychogenic cause be implied automatically if no organic cause can be identified, even before a psychogenic cause or evidence of psychopathology has been established? (b) Should the diagnosis be presented by the neurologist or should the psychiatrist (or the psychologist) be present at the meeting?

Shen et al. developed a protocol for the presentation of the diagnosis of PNESs that is now considered classic by many epilepsy centers.[128] This protocol contains six main points:

1. A review of the recorded events with the patient and family to ensure that the captured event is typical for the patient.
2. Explanation in "positive terms" of the nature of the spells (i.e., their nonepileptic cause), and hence the possibility of discontinuing AEDs.
3. An acknowledgement that the nature of the event is yet to be established, and that its cause may not always be found.
4. The observation that in many cases, such events may be of psychogenic origin (with an added explanation that the causes may be related to "upsetting emotions" that remain unconscious (i.e., and therefore the patient is unaware of) and that an evaluation by a psychiatrist, psychologist, or counselor may be indicated. Shen et al. emphasized that having these types of conflicts in no way implies that the patient may be "crazy."
5. Making the observation that a history of sexual abuse is often encountered in patients with these events.
6. A statement to the effect that the spells may spontaneously resolve on their own and that, although one component is subconscious in nature, "one can exert a conscious voluntary effort to abort these attacks."

We have borrowed on most of the points raised in Shen's protocol when discussing the diagnosis of PNES with patients and family members at the Rush Epilepsy Center. We are careful, however, not to impute a psychogenic cause in the absence of evidence obtained in the course of a psychiatric evaluation, informal discussion with the patient and/or family, or neuropsychological data. Furthermore, while we also tell our patients that their spells may stop occurring just by knowing that they are not epileptic in nature, we do not suggest to them that they can exert a conscious voluntary effort to abort these attacks. Our reasons are threefold: First, unless the patient is malingering (which is a minority of the cases), we do not believe that the patients have a conscious control over the occurrence of their events, at least at the beginning. Second, patients (and family members) may often interpret such observation as a suggestion that they are voluntarily faking the events, which in turn raises their resistance to accept the diagnosis further. Third, we are convinced that the exertion of control of the events occur eventually, as a result of the treatment (see later).

It is only after the above-cited explanations that we ask patients if they think that their episodes may be related to a psychogenic process, if they have not volunteered that observation on their own. From this point on, we guide the discussion according to the answer we get from the patient:

1. If patients accept the possibility of a psychogenic process as a cause of their spells, we encourage them to

elaborate on their reasons and to cite examples that may illustrate potential conflicts, and we suggest that they undergo a complete neuropsychological and psychiatric evaluation.

2. If patients acknowledge a history of abuse or having been victims of traumatic experiences, we ask them to recall

how they "dealt" with such situations at the time of their occurrence. It has been our experience, and that of others, that most patients have no recollection of the actual traumatic event(s). We use that "personal" experience to illustrate the phenomenon of dissociation, by again reiterating the fact that "when individuals is facing a traumatic experience, their mind will automatically protect itself by blocking any awareness of their surroundings." We then add, "This is similar to what may happen when you are having a spell" and go on to explain that after repeated traumatic experiences, one's mind may learn to automatically "shut out" the outside world, *even in the presence of less traumatic situations*. We repeat the statement, "There is only so much trauma one person can endure before fending the traumatic experience off one's mind." Usually, patients with a history of abuse can easily relate to these observations. This, in fact, becomes the beginning of the therapeutic process. We emphasize to these patients that their process of dissociation will most likely continue until they learn, with the assistance of a counselor, to identify the precipitants, which by now need not be necessarily of a traumatic nature.

3. In the case where patients *adamantly refute* the possibility of any psychogenic cause to their events, we suggest that they undergo a neuropsychological and neuropsychiatric evaluation to rule out that possibility. We reiterate the unconscious nature of these processes, which may preclude patients from recognizing an underlying psychological process. At the same time, we acknowledge the possibility that their spells may not have a psychogenic cause and that we may not be able to find a cause by the completion of the evaluation. We always add, "If we don't look for it, we'll never find it. It's better to rule out completely a possible psychogenic cause." Patients are told that we would like to continue following them in the clinic and we ask them to keep a diary in which they are to write down the circumstances surrounding the occurrence of future events, were they to continue. Note that we do not push patients to accept a psychogenic cause of their spells when it becomes obvious that they are not ready. In our opinion, the best course to take with such patients is to continue following them in the clinic, strengthening our relationship and their trust in us, while at the same time we continue reminding them that their spells are not epileptic (and that no other organic cause has been identified). In our experience, patients eventually end up accepting our recommendation for psychiatric treatment after a few months. During that time we continue achieving our primary therapeutic goal: Averting that their spells be treated as epileptic seizures by other physicians.

4. Occasionally patients may be adamant about their certainty of some organic or epileptic process triggering their spells, and that we may have erred in our evaluation. While in such patients we are likely to suspect a factitious disorder or malingering, we try to keep an "open mind." We review the diagnostic process with patients, show the captured events and recordings of epileptic seizures, and graphically demonstrate on the actual paper to both patients and family the differences between the two. If the diagnosis was based on an ambulatory EEG study, we repeat the evaluation in an inpatient V-EEG monitoring unit, with the use of sphenoidal electrodes. In fact, we have had three patients in whom an erroneous diagnosis of PPS was reached with ambulatory EEG studies. Two of the three patients had neuropsychological testing that failed to reveal any propensity for conversive disorder. A correct diagnosis of epilepsy was established during V-EEG. In short, we must *always* consider the fact that patients may be correct. After all, they know themselves better, notwithstanding the unconscious nature of a potential psychogenic process.

Treatment of Psychogenic Nonepileptic Seizures

General Considerations

In the treatment section, we address the transition from neurologist to psychiatrist, the use/withdrawal of AEDs, pharmacotherapy, and psychotherapy for PNESs. Before examining the various aspects of the treatment modalities, there are certain important general points that must always be borne in mind in conceptualizing the treatment of patients with PNESs.

The first point is that patients (and their families) may well have been living with the assumed diagnosis of epilepsy for a considerable period. When patients who have been treated for epilepsy are diagnosed with

PNESs, they are immediately transformed from a "neurologic" patient to a "psychiatric" one.[81] Suddenly changing the diagnosis, however justified it may be, can have a profound psychological effect on the person who receives the new diagnosis, particularly because that person may already have a recognizable psychiatric disorder and may be living with a dysfunctional family. We have frequently encountered the patients who react with, "So, you are saying I'm crazy?!?" From the epilepsy monitoring unit, a number of patients are referred, then lost to follow-up. Therefore, the confrontation process must be handled tactfully and appropriately.[22]

Neurologic Treatment (or, "How Long Should the Neurologist Follow the Patient with Psychogenic Nonepileptic Seizures?")

The neurologist's task, once a firm diagnosis of nonepileptic seizures has been made, does not suddenly cease. The neurologist should continue to offer support to the patient while arrangements are being made for ongoing care. The parting of the ways between the patient and the neurologic specialist should certainly not be an abrupt one. The neurologist should certainly remain available for consultation in case new seizure types develop or there remains some doubt about the certainty of the diagnosis (particularly as new investigatory methods emerge). Although reinvestigation can be justified on occasion, this should only be undertaken if there are clear clinical indications that the diagnosis may have been wrong.

In our opinion, discharge of patients with PNESs from their neurologist's practice should not take place before they have had an opportunity to complete the transition of their care to the psychiatrist or psychologist to whom they were referred. Furthermore, the neurologist may well need to remain in contact with the patient while a slow reduction is made in anticonvulsant medication. Reducing medication on which the patient may have become psychologically and pharmacologically dependent should always be slow. Abrupt termination of some anticonvulsants will lead to pharmacologic withdrawal seizures, which complicates the diagnostic picture. As a matter of ethical necessity, the neurologist should make certain that his or her patient has been appropriately placed with another care team or facility that is competent to manage the nonepileptic seizures. Abrupt termination of the relationship between the neurologist and the patient will make the next doctor's job much harder.

Communication and collaboration between neurology, psychiatry, and psychology in the process of diagnosing and treating the patient with PNESs is an essential part of the multidisciplinary approach needed to assess and manage these patients. Harden et al. noted psychiatrists' lack of confidence in the V-EEG diagnosis as compared to neurologists,[56] and interdisciplinary discussion may improve management of PNESs. A model of PNES treatment has been proposed, composed of accurate diagnosis with V-EEG by the epileptologist; presenting the diagnosis to patients and their family; constructing a problem list of precursors, precipitants, and perpetuating factors of PNES; and prescribing psychotropics, with discontinuing AEDs in lone PNESs, or adjusting appropriately in mixed ESs/PNESs.[83] While no single treatment has been shown to treat all NES patients, the National Institutes of Health and the American Epilepsy Society have supported an international PNES treatment workshop where neurologists, psychiatrists, and psychologists convened to discuss and develop various models to be systematically tested.[140]

Psychiatric Treatment

Ideally, a psychiatrist asked to manage a patient with nonepileptic seizures should have had some experience in this area, should be part of the team that has been assessing the patient, should have confidence in the diagnosis of nonepileptic seizures, and, in particular, should not feel (as sometimes happens) that a difficult patient has been dumped in his or her lap by a neurologic service eager to be rid of the patient. Patients being dismissed sometimes results in the rapid return of the patient to the neurologic facility or, worse, the patient being abandoned by everybody and the whole diagnostic process having to be reundertaken.

Psychiatric assessment of the patient should start long before the diagnosis of PNES is finally given so that the patient's upbringing, social background, personality development, present living circumstances, and relationships with other family members (plus the presence or absence of contributing traumas such as abuse) are already established.

Pharmacotherapy

Barbiturates have been used in diagnosing and treating patients with conversion disorder effectively for over a half a century.[86] Open-label trials of antidepressants in patients with conversion disorders have shown some response.[107,143] Controlled studies of the benefit of psychotropics in PNESs, however, have not been completed, and apart from anecdotal reports, their effect in PNES is unknown.[84] Formal medical psychiatric treatment is necessary for the treatment of any underlying psychotic disorder or depression. Whether antidepressants directly treat PNESs has not been studied in a controlled fashion. Another approach being studied in NES treatment is to treat the comorbid psychiatric disorders (depression and anxiety frequently occur with PNESs) to reduce PNESs. A pilot randomized controlled trial of a selective serotonin reuptake inhibitor (SSRI) for depression and anxiety in patients with PNESs is under way.[82] Benzodiazepines have also been shown to reduce PNES in open-label studies.[8] When pharmacotherapy of the patient's mental state is used, it should be accompanied by psychological support, if not formal psychotherapy.

Clarifying the role of AEDs in patients with PNESs is another major pharmacotherapy issue to be addressed by the treating neurologist and psychiatrist. During the process of withdrawing anticonvulsant medication, psychological symptoms may emerge (e.g., a previously undiagnosed mood disorder with carbamazepine withdrawal or significant anxiety symptoms with benzodiazepine withdrawal). Oto et al. showed that AEDs could be safely discontinued in patients with lone PNESs after V-EEG monitoring.[109] Some have argued for the mood-stabilizing benefits of AEDs as a reason to continue the antiseizure medications. AEDs, however, do not treat PNESs, and toxicity may exacerbate PNESs.[106]

Psychotherapies

If the psychiatrist is not delivering the psychotherapy personally, he or she may work in collaboration with psychologists and nurse practitioners who administer the therapy. The various therapies for PNES are described below.

Cognitive and Behavioral Techniques

The general principle of the behavioral techniques used in managing PNESs is to prevent the reinforcement of seizure activity and to reward and reinforce nonseizure activity (operant conditioning).[60] A randomized controlled trial of cognitive behavioral therapy (CBT) for NESs is being conducted based on an open-label CBT trial in the United Kingdom.[50] It is important to recognize that all the behavioral and cognitive techniques described below are equally applicable to epilepsy itself.[49] This is one reason why (in neuropsychiatric practice) people with PNESs continue to be managed within the seizure clinic, particularly if by doing so they can save face. Operant conditioning infrequently causes a sharp increase in seizure frequency of a temporary nature (often with an equally dramatic decrease). This is actually a good prognostic sign but can disrupt the treatment plan if not anticipated.

Specific behavioral techniques exist for the management of nonepileptic seizures.[22] They are based on anxiety control measures to help the patient to recognize the early stages of an impending anxiety attack and then to apply control techniques based on suddenly lowering arousal or on cognitive techniques to interrupt negative thinking so that seizure progression is interrupted. The patient need no longer be afraid of the seizures because he or she is confident they can be stopped. This can be an effective treatment technique for nonepileptic attacks related to panic or hyperventilation and may have a more general use in some of the seizures related to somatoform disorders.

Psychotherapy

Psychotherapy in the sense of dynamic psychoanalytically based therapy probably has little part to play nowadays in the management of PNESs. Kalogjera-Sackellares published her book describing the use of psychodynamic psychotherapy in PNESs, giving a thorough presentation of the psychotherapeutic technique for patients with PNESs.[64] Psychodynamic psychotherapy, however, is relatively unproven in terms of its efficacy, given the limitation that it is a difficult technique to analyze by controlled trials.

Family Therapy

Patients with PNESs and their family members score in the unhealthy range on measures of family functioning.[76,150] Therapeutic work with the patient's family is extremely important in the management of these disorders because, even if family dynamics are not the prime cause of the seizures, often family tension may be conspiring to keep the patient in the sick role. Family anxiety may reinforce seizure behavior. Under those circumstances, managing the patient and the seizures without also managing the family may well be a fruitless exercise. An open trial of family therapy is being conducted in the United States presently. There has been little written about the use of family therapy in PNESs, and it is an area that needs extensive study.

Other

Hypnosis has been recommended for some patients as a treatment strategy.[101] Particularly for those patients in whom the seizure can be seen as a conversion or dissociative disorder, hypnosis might be helpful, although it would usually be used in conjunction with other therapies. It sometimes can be used as an abreactive agent.

Pilot trials of group psychoeducation (Zaroff 2004) and group psychotherapy (Wittenberg 2004) have been reported, and may provide a general support in anxiety reduction or more specifically a support while the patient is transitioning from neurologic care to psychiatric care.

Additional Considerations

Driving and Nonepileptic Seizures

Benbadis et al. found that 49% of neurologists surveyed applied the same restrictions to patients with PNESs as for patients with epilepsy. Driving records of a sample of PNES patients revealed no statistically significant difference compared with the expected number of motor vehicle crashes for the sample. The authors concluded that their small series did not support the use of driving restrictions for patients with PNESs.[15] Kanner has found that restricting driving privileges to patients with PNESs until they become seizure free is a motivational factor for patients to seek psychiatric treatment (Kanner AM, unpublished data). In our opinion, the decision to lift up the usual "seizure precautions" has to be individualized.

Summary and Conclusions

PNESs are commonly mistaken for epilepsy and are often difficult to recognize. Their investigation requires obtaining a thorough history, capturing one of the typical events on V-EEG, and a team prepared to think and act holistically. Like epilepsy, PNESs lie in the disputed territory between the provinces of neurology and psychiatry, and their successful recognition and management require careful and considerate liaison between the two disciplines. This is of particular importance in the small percentage of patients where PNESs and actual epilepsy exist concurrently in the same individual (see Chapter 208). In summarizing the treatment of lone PNESs, along with AED discontinuation, addressing the underlying psychological factors with psychotherapy, with adjunctive antianxiety/antidepressant medication to treat the comorbid axis I disorders, is currently thought to be the preferable treatment regimen for PNESs. Controlled studies are being conducted using pharmacotherapy for the comorbid depression and anxiety found in PNESs, and with cognitive behavioral therapy.

Chapter 283

Episodic Dyscontrol

Ludger Tebartz van Elst

Michael R. Trimble

Introduction

Episodic dyscontrol (ED) is a rare but severe form of human aggressive behavior. The following case report illustrates the phenomenology of such troubling paroxysmal behaviors.

- A.E. was a 33-year-old white carpenter who was one participant of our study into episodic dyscontrol or intermittent explosive disorder in epilepsy at the Institute of Neurology.[77] A.E. was completely healthy and did not suffer from any major medical, neurologic, or psychiatric condition up to the age of 28 years, when he developed herpes encephalitis and subsequently suffered from temporal lobe epilepsy (TLE). He presented to the Chalfont Centre with complex partial seizures with a frequency of two to three clusters of up to six seizures a day. On these occasions, he would feel agitated somewhat 2 to 3 hours prior to the seizure. He then typically would feel odd; both sides of his face would start twitching, followed by salivation. During these seizures, which lasted 2 to 3 minutes, he would be awake but unresponsive to other people, with eyes wide open. Once to twice a month, a classic secondary–generalized tonic–clonic seizure evolved out of such a complex partial seizure. Neuropsychiatric assessment revealed a normal interictal electroencephalogram (EEG) with no ictal EEG available at time of presentation. Structural magnetic resonance imaging (MRI) displayed bilateral hippocampal and amygdala volume loss and increased hippocampal signal in T2 images. On psychiatric assessment, there was no formal diagnosis, and in particular no evidence for any affective, psychotic, or personality disorder or attention-deficit hyperactivity disorder (ADHD) apart from episodic dyscontrol.
- With a frequency of two to three episodes a year and a duration of 30 to 60 minutes, A.E. could behave in a very aggressive and violent way. Typically, there were no adequate triggers and a sudden onset of severe arousal, anger, and rage. The patient then became physically aggressive, attacking people and objects. The attack did not follow any obvious premeditated plan, and the behavior was poorly organized, with A.E. attacking every person or object at hand.
- On one such occasion at the tertiary referral center, A.E. was queuing for his medication when suddenly he gripped a nearby billiard stick, hitting the nurses and fellow patients at hand. He then left the ward and destroyed three cars before he could be restricted by the police. During this episode, there was no obvious evidence for an epileptic seizure and no evidence for hallucinations or persecutory delusions. The day before the attack, the he had had a pint of lager beer; apart from that, however, there was no evidence for any other drug abuse. The day after the attack, the patient felt extremely ashamed for this behavior. He could not recall and describe his feelings and thoughts during the episode in detail and remained vague in his recollection of the scene. At the same time, he was not absolutely amnesic and felt very guilty and depressed because of this behavior.

This case illustrates the complexity and danger of episodic dyscontrol and illustrates why many authors believe that ED might be related to epilepsy in particular because of its paroxysmal nature. Before we discuss the precise phenomenology and neurobiology of ED, however, we first have to clarify the relationship of this special form of aggressive behavior to aggression and violence as a general phenomenon of human life.

Human aggression is an important social and clinical problem.[32,67,75,82] The phenomenologic and probably neurobiologic heterogeneity of aggressive and violent behaviors is a major scientific problem leading to difficulties in assessment and classification. An important distinction has emerged between the terms *violence* and *aggression*. Treiman defined violence as forceful infliction of abuse or damage on another individual or object.[81] However, according to this concept, violence is not necessarily the result of intentional aggression. Aggression, in contrast, is defined as an offensive action directed toward another individual or object with the premeditated intention to harm, threaten, or control other subjects, groups, or situations.[81]

An advantage of this distinction is that it can be used to describe different destructive behaviors more precisely by referring to a special mental state, that is, the intentionality that does or does not motivate the destructive behavior. It leaves researchers with the problem of assessing intentionality, however, which in clinical practice is often impossible.

Therefore, it seems to be desirable to define phenomenologic criteria of specific behavioral syndromes of interest to obtain a nontheoretical approach to classifying aggressive and violent behaviors.

Classifying Aggression

One approach to doing this is to refer to basic research on animals. Here, aggressive behavior is classified according to the context in which it is observed. Authors like Moyer distinguished different subtypes of aggressive behavior in animals based on a precise characterization of the behavioral context in which such behavior is observed.[55] For example, predatory aggression is defined as violent behavior in which a predator kills its prey. It is characterized by a calm and very concentrated mental state of the aggressive animal and behavior that is well structured and goal directed. Maternal aggression, in contrast, is characterized by high arousal of the aggressive animal and a specific situational trigger when its offspring is menaced by predator. Table 1 summarizes the context-specific classification of aggressive behavior in animals.

Table 1 Subtypes of animal aggression

Aggression type	Example of animal behavior	Behavioral characteristic
Predatory aggression	Cat kills mouse	Calm, concentrated, goal directed, well structured
Intermale (territorial) aggression	Two lions fight for supremacy	Arousal, concentrated, goal directed, well structured
Maternal aggression	Bird attacks cat when it approaches the nest	Arousal, concentrated, goal directed, well structured
Sex-related aggression	Mantis kills male after copulation	Calm, behavioral stereotypes
Fear-induced aggression	Flight–fight Reaction Buffalo fight predator	Arousal, vocalization, less well structured, diverse behavioral pattern, reactive behavior

Source: Modifed from Moyer KE. *Violence and Aggression—A Physiological Perspective.* New York: Paragon House; 1987.

Contrary to animal behavior, human behavior depends less on external cues and stimuli, and behavioral programs are less preformed. Therefore a simple transfer of the context-based classification of animal aggression to human behavior is not

possible.[42] Nevertheless, there is general agreement that at least two different phenomenologic and neurobiologic subtypes of aggressive behavior can be differentiated in humans: (a) predatory and (b) defensive aggression.[35,42,55,56,85]

Predatory aggression as described earlier is characterized semiologically as a well-structured and goal-directed behavior performed in an emotionally calm and concentrated state of mind. Defensive aggression, in contrast, is generally seen in the context of high emotional arousal and is associated with vocalizations and signs of anger or fear. The behavioral pattern itself is less structured and is defensive.[83]

Most forms of human aggression that are generally seen in a clinical context are considered to be defensive, that is, the behavior is generally poorly structured and a reaction toward a perceived threat, be it adequate or not.[2] Obviously, the perception of whether a stimulus is threatening is decisive in the information processing leading to this kind of aggressive behavior. However, there are also forms of offensive aggression that are often seen in criminals or patients with a diagnosis of dissocial personality disorder (ICD-10 Classification of Mental and Behavioural Disorders [ICD 10] F60.2), conduct disorder in adolescents, or hyperkinetic disorder of social behavior (ICD-10 F90.1).

Aggressive Behavior in Clinical Practice

In clinical practice, aggressive behavior can be observed in the context of different medical, neurologic, and psychiatric disorders and diseases. In patients with mental retardation, it is a common problem, possibly as a consequence of impaired social perception or deficits in expressing personal needs.[9,37,44,67] Furthermore, aggression is often seen in the context of organic brain disease such as frontal or hypothalamic brain tumors, neurodegenerative disease, delirium, or drug abuse. These common forms of aggression in the clinical setting tend to be malstructured, defensive, and generally occur in the context of states of confusion and diffuse emotional arousal.

Well-structured, premeditated, and goal-directed aggressive behaviors can occur on the background of psychiatric disorders such as psychosis with delusional states, ADHD, or bipolar disorder. It is frequently observed in patients with antisocial personality disorder (APD), in which it is part of the characteristic traitlike behavior.[9,53,71]

The only clinical syndrome of aggression that has been identified as a distinct category in the international classificatory system is intermittent explosive disorder (IED) according to the guidelines of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (DSM–IV).[5] The concept of IED has been modeled on the clinical descriptions of episodic dyscontrol.[8]

Phenomenology of Episodic Dyscontrol

As mentioned, IED is basically a synonym for episodic dyscontrol. Because IED is an internationally accepted diagnostic construct, we will use this term in this chapter rather than ED. Both entities are characterized by several discrete episodes of failure to resist aggressive impulses that result in serious assaults or destruction of property. The behavior is out of proportion to any apparent precipitating psychosocial stressors and is not due to substance abuse, another mental disorder such as personality disorder, any other first-axis psychiatric disorder, or a general medical condition such as head trauma or neurodegenerative diseases. Consequently and in spite of the sometimes suggestive paroxysmal semiology, IED cannot be regarded as a special semiology of epilepsy. Whether this distinctive conception will stand the test of time, however, remains to be seen.

Epidemiology of Intermittent Explosive Disorder

There are only a few studies analyzing the prevalence of IED in primary medical settings. One study aimed at determining the lifetime and current prevalence of IED along with other demographic characteristics and patterns of comorbidity in an outpatient psychiatric sample of 1,300 individuals presenting for outpatient psychiatric treatment.[21] Following structured diagnostic assessment for axis I and II disorders, the authors reported a lifetime prevalence of IED of 6.3% (SE, ±0.7%) and a cross-sectional prevalence of 3.1% ± 0.5% of psychiatric patients. IED was the current principal diagnosis in only 0.6% ± 0.2% of patients. Most of these patients (80%) were interested in treatment for their intermittent aggressive

behavior. The authors concluded that DSM-IV IED in psychiatric samples is far more common than previously thought and pointed out that IED develops early in life, especially in male patients.

Neurobiology of Intermittent Explosive Disorder

There are few studies looking at neurobiologic mechanisms specifically in IED. The fact that there is some controversy as to the reliability of the clinical diagnosis aggravates the problem of neurobiologic research into this entity.[54] Nevertheless, there is some evidence that disturbances of the functional integrity of frontotemporal brain circuits might play an important role in the genesis of IED and ED.

Clinical Studies

There are numerous studies addressing the relationship between focal lesional brain pathology and aggressive and impulsive behavior. Prefrontal brain damage and in particular orbitofrontal brain pathology have been closely associated with aggressive dyscontrol.[17] The specific entity of ED or IED has scarcely been addressed in any of these studies, however, although there are a few cases in which ED has been related to hypothalamic or basal ganglia lesions.[27,80]

With respect to neurochemical brain pathology, there is some vague evidence that functional disturbances of the serotonergic system might play a critical role in impulsive aggression in general.[43] In fact, one consistent finding in biologic psychiatry is an association between low cerebrospinal fluid 5-hydroxyindole acetic acid levels and impulsive aggressive acts, suggesting a decreased serotonin turnover. Again, however, there no specific studies in IED or ED.

Electroencephalographic and Imaging Studies

EEG studies point to an increased prevalence of unspecific EEG abnormalities in disorders with disturbed impulse control in general and ED in particular.[12,30] Drake et al., for example, reported a significant increase of diffuse or focal slowing in the EEGs of ED patients as compared to healthy volunteers or depressed patients.[30] N100 and P160 auditory-evoked potential amplitudes were lower in episodic-dyscontrol patients than in controls, but the difference was not significant. The authors concluded that such findings suggest that nonspecific cerebral dysfunction and EEG changes may be associated with disordered impulse or behavior control.[30]

A systematic literature review based on PubMed searches did not reveal any positron emission tomography, single photon emission computed tomography, or functional MRI study that specifically looked at neurobiologic mechanisms of ED or IED. There are two studies by our group, however, in which we addressed IED in the context of epilepsy, using structural MRI techniques.[78,88]

In these studies we hypothesized that, in patients with TLE and intermittent affective aggression, amygdala sclerosis in the context of hippocampal sclerosis would be more common as compared to control patients. In addition, we aimed to analyze a possible association between aggression on one hand and hippocampal sclerosis, low IQ, and poor social adjustment on the other in patients with TLE. In a further approach, we analyzed cortical gray matter abnormalities in these patients to gather evidence for frontal lobe pathology in patients with TLE and IED.

Amygdala Pathology in Patients With Temporal Lobe Epilepsy and Episodic

Dyscontrol

For that purpose, we compared 25 patients with TLE and IED with 25 control patients with TLE without any psychopathology and 20 healthy volunteers.[78] Both patient groups were matched for age, gender, demographic background, duration of epilepsy, and seizure severity. There was no significant group difference regarding the history of birth complications, febrile convulsions, or status epilepticus. In the IED group, however, the incidence of encephalitic brain disease (Fisher's exact test: $p = .05$) and left-handedness (chi-square test: $p < .05$) was significantly increased. There was less right-sided focal EEG abnormality and more bilateral EEG abnormality in the aggressive group, and hippocampal sclerosis was significantly less common in patients with TLE and IED. Other left temporal pathology, including 3 patients with amygdala pathology (amygdala sclerosis, amygdala glioma, amygdala dysembryoplastic neuroepithelial tumor), 2 patients with multiple small temporal infarctions, and 2 patients with diffuse left temporal atrophy of unknown origin, was significantly more common in patients with TLE plus IED. In the aggressive patients, a subgroup of 5 patients (20%) showed amygdala atrophy as compared to only 1 in the nonaggressive group (chi-square test: $p = .04$). An increased incidence of encephalitis (chi-square test: $p < .005$; Fisher's exact test: $p = 0.1$) was the only clinical feature that distinguished patients with amygdala atrophy from those with normal amygdala volumes. In 12 of 25 patients, we could prove some evidence of amygdala-related brain pathology as compared to only 1 in the nonaggressive group. Furthermore, there was a highly significant group difference in IQ figures, with the verbal IQ (VIQ), the performance IQ (PIQ), and hence the full IQ (FIQ) all being lower in the aggressive group. In addition, there was a significant group difference in Beck Depression Inventory and Spielberger State Trait Anxiety Index scores, with the aggressive group rating much higher in depression ($p < 0.05$), state ($p < 0.05$), and trait anxiety ($p < 0.01$).[78]

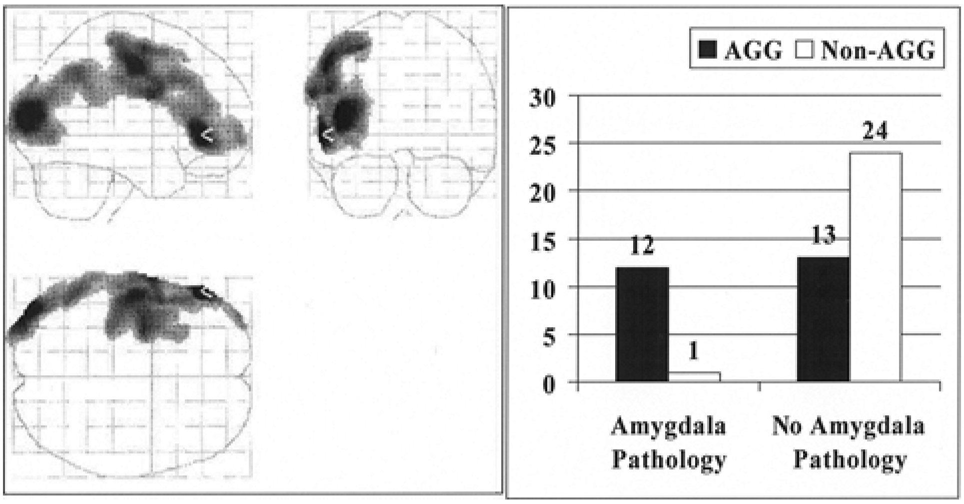

FIGURE 1. Prevalence of amygdala-related brain pathology and cortical gray matter density loss in 25 patients with temporal lobe epilepsy and episodic dyscontrol. AGG, aggression. (Redrawn after Tebartz van Elst L. Aggression and epilepsy. In: Trimble M, Schmitz B, eds. *The Neuropsychiatry of Epilepsy*. Cambridge: Cambridge University Press; 2002:81–106.)

Cortical Abnormalities in Patients With Temporal Lobe Epilepsy and Episodic Dyscontrol

In a second analysis, we employed the method of voxel-based morphometry to detect possible subtle cortical brain pathology that was not present on visual assessment of the MRI scans analyzing the same study sample.[88] Both TLE patient groups were compared with each other and with the control subjects on a voxel-by-voxel basis for increases and decreases of gray matter. Details of the methodology are published elsewhere.[88,89] In this study, we were able to demonstrate reductions of gray matter density over large areas of the left extratemporal neocortex with maxima in the left frontal neocortex; one maximum difference projection had a Z score of 5.67 at Talairach coordinates $x = 58$, $y = 36$, $z = 9$ mm (left anterior frontolateral cortex), the other a Z score of 4.78

in a more-posterior left frontal lobe location (Talairach coordinates $x = 66$, $y = 0$, $z = 28$ mm). Patients with TLE who did not have IED showed no significant decrease of cortical gray matter compared with control individuals. Patients with TLE with IED also had reduction of left frontal gray matter compared with patients with TLE without IED, although this was less marked than when compared with control individuals (Z score of 3.49 at Talairach coordinates $x = 66$, $y = 2$, $z = 26$ mm). The statistical parametric mapping–based voxelwise correlation of social dysfunction and aggression scale scores and automatically segmented gray matter in all patients with TLE showed a left frontal gray matter area

being negatively correlated with these scores, which expressed social consequences of interictal affective aggression (Z score of 3.65 at Talairach coordinates $x = 66$, $y = 2$, $z = 26$ mm). Age, scores of depression and anxiety, IQ measures, or scores of verbal fluency did not significantly correlate with specific decreases in gray matter in all patients with TLE.[88] FIGURE 1 illustrates the main findings from these two studies.

Neurobiology of Aggression in General and Intermittent Explosive Disorder in Particular

Various brain structures are known to play an important role in the generation of aggressive behavior in animals and humans. The most important of these structures are the periaqueductal gray,[10,16] the hypothalamus,[7] the amygdala and associated limbic structures,[1,29,39,45,66] and the frontal lobes.[23,53,61]

Even though the precise function of the aforementioned structures and their role in the complex interplay of the different brain circuits in regulating different aggressive behaviors is unclear, the first elements of a functional anatomy of aggression can be identified (Table 2). Brainstem structures like the periaquaductal gray are crucial for the activation of evolutionarily preformed behavioral programs like attacking or defensive behavior in animals.[10,16] These structures are controlled by higher neuronal centers in the hypothalamus,[13,84] which in addition to controlling these behavioral brainstem programs, adjust the internal endocrinologic and immunologic environment to aggressive behavior in flight-or-fight situations.[50,63,69,90]

The frontal lobes are known to play a critical role in the ability to suppress behavioral impulses. Thus, patients with frontal lobe lesion often lose the ability to suppress aggressive impulses and therefore might present with severe aggressive and violent psychopathology.[23,46,59,71]

Table 2 Functional relevance of different brain structures for aggressive behavior

Brain structure	Assumed function
Frontal lobe	Inhibitory function Suppression of aggressive behavioral drive
Amygdala and limbic circuits	Emotional evaluation of multimodal sensory and cognitive input Emotional drive and arousal
Hypothalamus	Control of brainstem behavioral programs
	Regulation of internal environment
	Coordination of behavioual programs and internal

	environment in flight–fightsituations
Brainstem structures, i.e., periaqueductal gray	Evolutionarily preformed behavioral flight–fight programs

Source: Modified from Tebartz van Elst L. Aggression and epilepsy. In: Trimble M, Schmitz B, eds. *The Neuropsychiatry of Epilepsy*. Cambridge: Cambridge University Press; 2002:81–106.

The amygdala is thought to play a crucial role in the mediation of fear-induced aggression, a subtype of defensive aggression.[1,20,33,48] They receive input from various levels of sensory information processing and project to most of the other critical brain structures, including the brainstem, hypothalamus, thalamus, and frontal lobe.[3,4] From a neurophysiologic perspective, they are in a key position for the affective evaluation of multimodal sensory input. Thus, pathology within the circuits affecting the amygdala might lead to mental states in which the misinterpretation of sensory input as threatening leads to aggressive outbursts. In agreement with this assumption, electrical stimulation of the amygdala can lead to experiences like fear, anxiety, or anger,[19,34] and lesioning of the amygdala severely impairs fear conditioning in animals[25] and humans.[47] Furthermore, in an open retrospective study of 481 cases of bilateral amygdalotomies performed for the control of conservatively untreatable aggressiveness, moderate to excellent improvement of aggressive behavior was reported in 70% to 76% of cases.[62]

Dual Brain Pathology in Patients With Episodic Dyscontrol

Based on our findings in patients with TLE and IED in which significant brain pathology could be observed in amygdala-related circuits on one hand and the prefrontal lobe on the other, we suggested that a dual brain pathology affecting limbic brain structures and prefrontal areas at the same time might be a critical pathogenetic element in the genesis of episodic

dyscontrol and intermittent explosive disorder.[77] Within this concept, both clinical entities are understood as hyperarousal-dyscontrol syndromes. The clinical phenomenology of hyperarousal, that is, the sudden onset of extreme arousal, fear, and rage, is probably related to some sort of amygdala-network instability. Following this line of thought, we associate the failure to control the aggressive impulses resulting from emotional arousal in the context of functional amygdala instability with prefrontal lobe dysfunction.

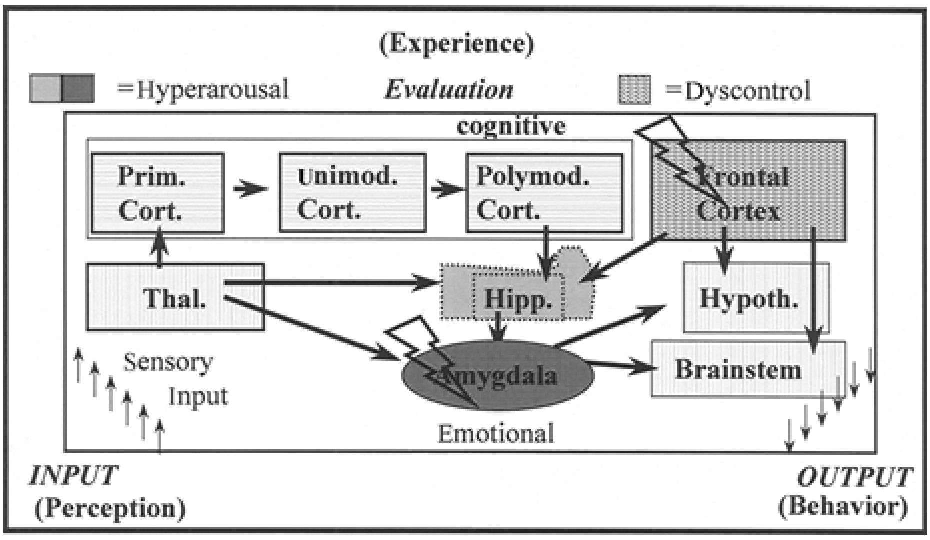

FIGURE 2. Dual brain pathology in hyperarousal-dyscontrol syndromes. Thal, thalamus; Prim Cort, primary cortex; Unimod Cort, unimodal cortex; Polymod Cort, polymodal cortex; Hipp, hippocampus; Hypoth, hypothalamus. (Redrawn after Tebartz van Elst L. Aggression and epilepsy. In: Trimble M, Schmitz B, eds. *The Neuropsychiatry of Epilepsy*. Cambridge: Cambridge University Press; 2002:81–106; and Tebartz van Elst L, Trimble MR, Ebert D, et al. Dual brain pathology in patients with affective aggressive episodes. *Arch Gen Psychiatry.* 2001;58;1187–1188.)

The observations of our study support this notion. Brain pathology in patients with epilepsy and aggression was more diverse in nature and more diffuse in distribution. We found an increased prevalence of a history of encephalitis in patients with epilepsy plus aggression. Encephalitis in the past might have been a pathogenetic element for the more diffuse and widespread pathology in the temporal lobe seen in our aggressive patients. Furthermore, the increased prevalence of left-handedness in our aggressive patients may indicate early brain pathology such as encephalitis affecting the left hemisphere (i.e., lateralization of dominance to the right hemisphere).

Eleven of 12 patients with amygdala-related brain pathology displayed this pathology on the left-hand side, and the only patient with right-sided amygdala atrophy alone was left-handed. Thus, the dominant hemisphere seems to play a more important role in the mediation of affective aggression than the nondominant hemisphere.

The finding of frontal cortical gray matter loss was clearly lateralized too. Patients with TLE plus IED displayed highly significant left frontal gray matter loss that correlated with the aggression psychometry scores. This, together with the left-lateralized finding of amygdala-related brain pathology, could support a theory of left-lateralized dual brain pathology in IED.[77]

This theory is further supported by earlier functional imaging and MR spectroscopy studies showing a reduced prefrontal glucose metabolism in those convicted of murder and significantly lower neuronal markers in the frontal lobes of repetitively violent patients with learning disabilities, although without clear lateralizing effects.[60,61]

Figure 2 illustrates this pathogenetic model of hyperarousal-dyscontrol syndromes. Pathology within the amygdala or amygdaloid circuits might result in hyperarousal states in which patients become angry and aroused without a sufficient external stimulus (hyperarousal syndrome). This dysfunctional arousal resulting in aggressive behavioral impulses normally can be suppressed by learned behavioral rules. In the case of additional frontal lobe pathology, however, the capacity of the affected patients to suppress behavioral impulses arising from the "emotional brain" is limited, and thus an additional dyscontrol syndrome leaves the patients vulnerable to the development of hyperarousal-dyscontrol syndromes, that is, episodic dyscontrol or intermittent explosive disorder.[77]

Intermittent Explosive Disorder—Is It Epilepsy?

When analyzing the phenomenology of episodic aggressive behavior as illustrated in the case report at the beginning of this chapter, the question arises as to whether this episodic aggressive behavior might be understood as some form of frontal or limbic lobe epilepsy. The ictal nature of the aggressive outbursts, the lack of adequate psychosocial triggers, and the discrepancy with the interictal undisturbed personality all support this suspicion. Because frontal or limbic lobe epilepsy can be observed without pathologic findings in the surface EEG and it is difficult anyway to obtain an EEG during the aggressive episodes from the affected patients, this hypothesis is very difficult to investigate.

The observation that antiepileptics often are very effective in controlling impulsive aggression (see later comments) further supports the notion of a link between ED and epilepsy. The fact that they do not help in another substantial subgroup of patients with IED or ED does not contradict the hypothesis because many patients with classical epilepsy do not respond to antiepileptic treatment either.

From deep brain recording in patients with postictal psychosis we know, however, that there are other nonictal but still epilepsy-related pathomechanisms that can result in severe psychiatric symptoms including aggression that are not truly ictal in nature.[68] Therefore, although the hypothesis that IED might be some form of undiagnosed limbic or frontal epileptic attack disorder is far from being falsified, it is not proven either, and other epilepsy-related pathomechamisms could also explain the paroxysmal behavioral dysfunction. Further studies comparing patients with and without various neurologic diseases using even more sophisticated methods of functional brain assessment will be necessary to solve this question.

Social and Psychological Aspects of Aggression in Epilepsy

Another important observation that arose from our studies was that there was a strong link between aggression and high levels

of depression and anxiety, confirming other reports of such an association in the non–psychiatrically ill population.[14] It seems plausible that high levels of anxiety result in states of hyperarousal that might be facilitated by amygdala pathology, as suggested by other authors.[18] Regarding the relationship between depression and aggression, there are only few and inconclusive reports in the general literature.[15] Our findings point to a clear association among depression, anxiety, and hyperarousal-dyscontrol states at least in TLE.

Social disadvantage, prejudice, poor housing, poverty, and poor communication skills are further factors that make hyperarousal states and states of discontentment and anger more likely and thus might increase the probability of aggressive behavior. Disentangling the complex interaction among these different psychobiologic elements, however, is often not possible.

Therapy of Aggression and Episodic Dyscontrol

Intermittent explosive disorder and episodic dyscontrol are not unitary nosologic entities; they are essentially clusters of symptoms or syndromes that may occur in quite different medical, psychological, or social contexts. The most important point for an adequate therapy of ED and IED is a thorough medical and psychosocial diagnosis. Care should be taken to investigate any possible medical, neurologic, or psychiatric problem or comorbidity that might contribute to these most devastating and distressing behavioral syndromes. In case such diagnoses or comorbidities do exist, they have to be treated properly because this might in some cases solve the problem. For those patients in whom IED occurs in the context of established or suspected epilepsy, we refer to Chapter 212, where we outline the treatment principles for aggression in the context of epilepsy. The treatment of IED in the context of other psychiatric disorders such as schizophrenia, bipolar disorder, ADHD, borderline personality disorder, or conduct disorder should basically follow the treatment guideline of these respective disorders (see the standard psychiatric textbooks).

In case there are no medical, neurologic, or psychiatric comorbid or contributing diseases or disorders (which is probably a rare constellation), a symptomatic treatment should be started. To our knowledge, there are no systematic double-blind, placebo-controlled therapy studies in IED or ED. However, there are many case reports of successful therapy of this condition.

The two pharmacologic agents that are most often reported to be successful in IED are selective serotonin reuptake inhibitors (SSRIs)[26,31,38,64] and antiepileptic agents.[6,49,51,58,73,74] Carbamazepine in particular has been reported to be successful in as many as 65% of patients with IED.[28] The latter observation further supports the assumption that IED might be pathogenetically related to epilepsy. An alternative explanation of this observation, however, is the notion that IED might be pathogenetically related to bipolar disorder because most antiepileptics—carbamazepine in particular—are potent mood stabilizers. Following this line of thought, we could see episodic dyscontrol as a brief quasi-manic episode.[52] In line with this assumption, there is some evidence that lithium might be helpful in treating ED or IED.[41,72] Apart from that, there are reports of successful treatment of IED with beta-blockers such as propanolol[36,65] and antipsychotic agents.[40,57,86]

Finally, it must be stressed that anger management, contingency management, and psychotherapy all can be very helpful and successful in treating impulsive aggressive behavior. In particular, in the context of mental handicap and personality disorders, aggression and impulsivity might be part of attention-seeking behavior and role testing. In these cases, the feedback strategies and the reactions of relatives and caregivers are very important, and methods of contingency management may be a critical element of any successful treatment.[11,22] Apart from that, different methods of anger management, cognitive–behavioral therapy, or skills training that have been developed irrespective of whether impulsive behavior is seen in the context of ED or epilepsy or not may be very helpful in the therapy of aggression in whatever context.[24,70,79,87]

It should be stressed again, however, that there are no well-designed treatment studies and that all recommendations basically follow expert opinions.

Summary and Conclusions

Episodic dyscontrol and its DSM-IV correspondent intermittent explosive disorder represent severe forms of a paroxysmal aggressive attack disorder. In contrast to premeditated antisocial aggression, IED is characterized by high levels of arousal, anxiety, anger, and fear. The behavior is generally poorly structured, but it can be very dangerous.

The question of whether IED is pathogenetically related to epilepsy is unresolved. There is evidence that frontolimbic brain pathology does play an important role in the pathogenesis of IED. IED often is accompanied by other neurologic or psychiatric disorders such as epilepsy, other organic brain disorders, or bipolar or schizophreniform disorder even though these are exclusion criteria following DSM-IV. In these cases, basic treatment should follow the principles for the respective disorders. The epilepsy and bipolar or schizophreniform disorders should be treated first. Often, depressive symptoms in the context of IED are undiagnosed, and in these cases, depression again should be treated.

If IED persists in spite of up-to-date treatment of all comorbid conditions or if none of these are recognizable, the clinician should try to implement a symptomatic treatment of the aggressive behavior itself. Although there are no well-designed treatment studies, there is evidence to support attempts for symptomatic relief using antidepressants and SSRIs in particular, antiepileptics, lithium, antipsychotic agents, and even beta-blockers. In these cases, the decision of which of these different drugs should be used first depends on the specific history, family history, response to earlier medication attempts, comorbid and possibly subsyndromal psychopathologic findings, and experience of the specialist. In any case, the target syndrome is of sufficient importance to support systematic trials of all therapeutic options even if they are off-label as is generally the case. If therapists feel unfamiliar with this approach, they should consider referral to specialists or ask for advice from tertiary referral centers. Our experience that some of these interventions in fact help even though all other substances failed to bring any relief motivates this approach.

Chapter 284

Dissociative Disorders

Richard J. Brown

Michael R. Trimble

Introduction

Within the context of psychiatry and neurology, the term *dissociation* is extremely difficult to define satisfactorily. Since its introduction in the late nineteenth century, the term has been applied to a wide range of neurologic, psychiatric, and psychological phenomena. As a result, there is considerable confusion over what actually constitutes dissociation, and the concept is frequently misapplied. This is particularly true within the field of epilepsy. Many epileptic phenomena have been labeled as dissociative, including the sensory, affective, and cognitive features of partial seizures, behavioral automatisms, postictal amnesia, and fugue.[27] Similarly, certain psychiatric phenomena that mimic epileptic events, so-called “nonepileptic seizures,” have been identified as primarily dissociative in nature. Indeed, many authorities have argued that the dissociative nature of nonepileptic seizures could provide the basis for their conceptual and practical differentiation from “genuine” epileptic events.[44] If, however, dissociation is experienced both by individuals with epilepsy and by those with pseudo-epileptic seizures, how can its occurrence aid in the differential diagnosis of these conditions?

Historical Aspects

The term *dissociation* originates in the work of Pierre Janet, who proposed one of the earliest systematic accounts of the psychological mechanisms underlying hysteria. According to Janet,[36,38] a fundamental weakness in the hysterical individual's mental character makes the person susceptible to a breakdown in the normally integrated functions of consciousness when faced by environmental stress or trauma. As a result, organized sets of knowledge pertaining to the trauma may become “dissociated” from the main body of consciousness and may serve to take control of behavior and experience if activated by environmental events. The automatic activation of these dissociated memories results in a hysterical reaction (or “somnambulism”) that, in some instances, takes the form of a nonepileptic attack. Following Charcot's demonstrations at the Salpêtrière in which hysterical symptoms were shown to be both induced and removed by hypnosis, Janet's dissociation theory assumed that this process of dissociation was driven by an autohypnotic state. According to this view, two aspects of the hysterical individual's psychophysiologic makeup are responsible for the processes of dissociation and somnambulism. First, the hysterical individual possesses an abnormally high degree of suggestibility that allows ideas from the external environment to develop within him or her in the absence of his or her effort or awareness. Second, the hysterical individual suffers from an attentional dysfunction or “retraction of the field of consciousness” (Janet,[38] p. 314), which prevents them from entertaining alternative states of mind, thereby accentuating their responsivity to external suggestion. The resulting process of dissociation leads to “dedoublément,” or double consciousness, whereby two or more discrete but conscious modes of being existed alongside one other, separated by amnesia. In extreme cases, the autonomy of this dissociative consciousness gave rise to one or more alter personalities.[54]

Although it was originally assumed that these processes were triggered by external traumas, subsequent psychoanalytic theory gravitated from external happenings to an inner efficient causation based on traumatic conflict arising from the patient's psychically unacceptable desires and fantasies. Thus, the etiology was expanded to include subjective traumatization or "vehement emotions" whereby "every memory, every thought, competent to arouse strong and lasting emotions, can play the part of a fixed idea, and may originate hysterical symptoms."[39] In these terms, symptomatology became a composite of fact and fantasy, metaphor and symbolism. This was the case even when there was an association with objective traumatic events because, in classical Freudian theory, before the onset of symptoms, there is a reconstruction in memory overlaid with fantasy (Freud,[23] p. 625). Freud also proposed that falsifications are introduced into memory in order "to interrupt disagreeable and causal connections" (Freud,[24] p. 446, footnotes).

These discoveries led Freud to view hysterical etiology as fantastic, so that, as with dreams, the symptoms became the "the royal road" to the unconscious:

> Hysterical symptoms are nothing other than fantasies brought into view through *"conversion."*… So far as the symptoms are somatic ones, they are often enough taken from the circle of the same sexual sensations and motor innervation as those [that] originally accompanied the fantasy when it was still conscious. (Freud,[21] p. 90; italics added)

This move from fact to fantasy is evident in Freud's revision of his early seduction theory,[35] which suggested that some hysterical patients suffered from unconscious memories of childhood seduction. Later he asserted that such memories were infantile wish fulfillments, although not always: "So often they are not fantasies but real memories…. A fantasy of being seduced when no seduction has occurred is usually employed by a child to screen the autoerotic period of his sexual activity" (Freud,[22] p. 417).

Although popular for nearly a century, recent interest in the prevalence of childhood abuse has led to a backlash against Freudian theory, coincidental with a renewed interest in Janet's work on dissociation,[19] adaptations of his theory in cognitive psychology,[30,31] and a mushrooming of publications linking objective traumatic experiences to dissociative psychopathology. This is particularly relevant for the evaluation of nonepileptic seizures. Indeed, both the *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition (DSM-IV),[2] and the *International Classification of Diseases* (ICD-10)[65] make an explicit link between traumatic events and the onset of dissociative symptoms. Moreover, a number of studies have found disproportionately high rates of physical, sexual, and emotional abuse in patients with dissociative disorders.[16,34,53] Bowman,[7]

P.2820

for example, found that 70% and 77% of her sample of 27 nonepileptic seizure patients had experienced physical or sexual abuse, respectively. Similarly, Betts and Boden[6] obtained positive sexual abuse histories from 54% of 96 patients with nonepileptic seizures.

Table 1 Classification of dissociative disorders in ICD-10 and DSM-IV

ICD-10 dissociative (conversion) disorders	DSM-IV dissociative disorders
Dissociative amnesia	Dissociative amnesia
Dissociative fugue	Dissociative fugue
Dissociative motor disorders	Dissociative identity disorder
Dissociative convulsions	Depersonalization disorder

Dissociative anaesthesia and sensory loss	Dissociative disorder not otherwise specified
Dissociative stupor	
Trance and possession disorders	
Mixed dissociative (conversion) disorders	
Other dissociative (conversion) disorders	
Dissociative (conversion) disorder, unspecified	

ICD-10, *International Classification of Diseases* (ICD-10)[65]; DSM-IV, *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition.[2]

Thus, 100 years of thought about hysteria has brought the traumagenic theory full circle, and yet the difficulties encountered by nineteenth century investigators remain. Trauma is ill conceived and now tends to be exclusively considered only as an objectively measurable event, ranging from natural disasters to childhood abuse. As a result, there is a lack of consideration given to inner efficient causes, such as an individual's perceptions of events, which would seem important in the process of traumatization. Not only could this explain the obvious lack of psychopathology in some victims of abuse,[66] but it might also account for the presence of psychopathology following relatively harmless events. For example, in LaBarbera and Dozier's study of pseudoseizures,[45] three of the four girls reported no history of sexual abuse but had experienced minor sexual events perceived as traumatic. Equally, in cases in which there have been false allegations of serious trauma,[14] there is often an incidence of minor sexual traumatization. Finally, the determinism of trauma in the development of nonepileptic attacks and psychopathologically related disorders is problematic in terms of the unquestioned and overgeneralized evocation of dissociation as a defense mechanism as well as the lack of explanations for its prolonged use, even years after the event.[63]

Classification of Dissociative Disorders

The Dissociative disorders category in the latest edition of the *Diagnostic and Statistical Manual*[2] encompasses dissociative amnesia, dissociative fugue, dissociative identity disorder (formally multiple personality disorder), depersonalization disorder and dissociative disorder not otherwise specified (see Table 1). According to DSM-IV,[2] "the essential feature of the dissociative disorders is a disruption in the usually integrated functions of consciousness, memory, identity, or perception of the environment" (p. 477). A slightly broader definition is offered in the latest edition of the *International Classification of Diseases*,[65] which identifies the loss of control over bodily movements as an additional dissociative phenomenon. As such, the ICD-10 Dissociative (conversion) disorders category encompasses dissociative amnesia, dissociative fugue, dissociative motor disorders, dissociative convulsions, dissociative anesthesia and sensory loss, dissociative stupor, mixed dissociative (conversion) disorders, other dissociative (conversion) disorders, and dissociative (conversion) disorders, unspecified (Table 1). The Somatoform and Dissociative disorders are related in that these phenomena are characterized by symptoms that, on the face of it, resemble those that occur in certain physical conditions but are presumed to be psychological in origin. Dissociative and somatoform phenomena differ in that the symptoms of the former resemble those of neurologic illness, whereas the symptoms of the latter are more akin to those encountered in internal medicine. As Kihlstrom[40] cogently argued, all of the phenomena identified as dissociative disorders within DSM-IV and ICD-10 are linked by the fact that each has a temporary disruption in consciousness or volition as its primary defining feature.

The differences between DSM-IV and ICD-10 in their classification of the Dissociative and Somatoform disorders are readily apparent. First, unlike ICD-10, DSM-IV places nonepileptic attacks in the Somatoform rather than the Dissociative disorders category along with other so-called “conversion” phenomena, such as unexplained motor and sensory symptoms, that are identified as dissociative in ICD-10. This difference is more practical than conceptual, with DSM-IV placing greater emphasis on the importance of excluding physical illness in the differential diagnosis of these phenomena.[2] Second, unlike DSM-IV, ICD-10 does not identify depersonalization as a dissociative phenomenon, due to the lack of any significant loss of control over sensation, memory, or movement in this condition and its limited affect on personal identity. Third, DSM-IV identifies a distinct category for multiple personality disorder, relabeled dissociative identity disorder in the latest edition of this scheme. In contrast, ICD-10 places multiple personality disorder in the other dissociative (conversion) disorders category, reflecting controversy over whether this syndrome is iatrogenic or culturally bound to North America. Inconsistencies aside, both DSM-IV and ICD-10 explicitly state that physical conditions such as epilepsy should be excluded in the differential diagnosis of the Dissociative and Somatoform disorders.

Contemporary Views of Dissociation

To some extent, the differences between DSM-IV and ICD-10 demonstrate ongoing controversy about the definition of the term “dissociation.” When the term was originally introduced in the nineteenth century, it was used to refer to a specific mental mechanism thought to be associated with a relatively limited set of psychological symptoms. Over the years, however, the number of phenomena thought to be attributable to dissociation has expanded considerably, and the dissociation label is now applied to an extraordinary range of psychological symptoms, states, and processes. Cardeña[15] described a useful taxonomy that captures the different ways in which the concept of dissociation has been used. According to this scheme, there are three major facets of the dissociation construct: (a) dissociation as nonconscious or nonintegrated mental modules or systems;

P.2821

(b) dissociation as an alteration in consciousness; and (c) dissociation as a defense mechanism.

Dissociation as Nonintegrated Mental Modules or Systems (“Compartmentalization”)

Dissociation in this sense reflects the original meaning of the concept introduced by Janet[36,38] as the basic psychopathologic mechanism underlying hysterical symptoms. This concept encompasses the medically unexplained symptoms characteristic of the DSM-IV conversion disorders, as well as dissociative amnesia, dissociative fugue, and dissociative identity disorder.[33] Holmes et al.[33] used the term *compartmentalization* to refer to the putative process involved in the generation of these conditions.

These phenomena should be distinguished from other pathologic phenomena characterized by a lack of integration between mental modules or systems that are caused by neurologic rather than psychiatric events. Blindsight, a rare condition in which the sufferer displays above-chance visual discrimination despite reporting a lack of visual experience, provides one example of how normally integrated functions can become dissociated through neurologic damage. Many of the unusual behaviors often displayed by patients following commissurotomy also fall within this category, as do those exhibited by individuals suffering from hemi-neglect. In each of these cases, the dissociation is between the individual's ongoing behavior and his or her introspective verbal report.

Neurologic dissociations such as blindsight are superficially analogous to those observed in psychiatric instances of dissociation, such as the preservation of implicit perception[a] in the context of dissociative blindness (see, e.g., Kihlstrom[40]). Neurologic and psychiatric dissociation differ, however, in that the former is often permanent, reflecting irreversible damage to the underlying neurologic subsystems in question.[40] Psychiatric instances of dissociation, in contrast, are thought to be the product of an alteration in the parameters governing otherwise intact psychological functions; they are, therefore, reversible by definition. Similarly, neurologic and psychiatric dissociations differ in that, unlike the former, the latter involves symptoms (e.g., “glove” anesthesia) that need not, and typically do not, relate to the actual organization of the nervous system and its many distributed components. On these grounds, it is apparent the “dissociation” in these cases is an entirely different phenomenon, and the two must not be confused.

The idea that normally integrated psychological processes can become temporarily dissociated and exist in isolation of one another has also been cited as the basis for other, less pathologic, phenomena.[15,32,64] Many apparently "hypnotic" phenomena fall within this category, including profound amnesia, the loss of perceptual experience, and complex behaviors characterized by a sense of involuntariness, all of which can be temporarily produced by appropriate suggestions in certain individuals. The extent to which similar processes are involved in these phenomena and those displayed by individuals with dissociative psychopathology has been a matter of debate since the time of Janet. Conceptually, there are good grounds to assume a common mechanism in hypnotic and dissociative phenomena[11,12] and recent functional imaging evidence provides some support for a link between the two.[29]

According to Cardeña,[15] this particular definition of dissociation has also been inappropriately applied to a number of other normal psychological phenomena. Following Hilgard,[32] the execution of complex behaviors with only minimal conscious awareness, such as the action of driving a car while holding a conversation, has often been identified as a dissociative phenomenon. As Cardeña pointed out, however, the dissociation label should not simply be applied to any behavior or psychological process that, for whatever reason, occurs without full awareness. Such a practice ignores the fact that, in many such cases, the individual can bring the apparently "dissociated" process into awareness by an act of selective attention. Other such cases involve "dissociation" between systems or processes that one would not normally expect to operate in an integrated fashion. According to Cardeña, mental modules or systems should only be regarded as truly dissociated from one another if their dissociation is (a) in contrast to a normal state of integration and (b) cannot be overcome by an act of will.

Dissociation as an Alteration in Consciousness ("Detachment")

A second use of the dissociation concept refers to an altered state of consciousness characterized specifically by a disengagement from the self or the environment.[15,33] Holmes et al.[33] used the term *detachment* to refer to this category of conditions. As Cardeña pointed out, this sense of the dissociation concept should not be applied to everyday phenomena, such as daydreaming and other states of distraction, in which engagement with the environment is less than complete. Instead, it should be reserved specifically for states that are regarded by the experiencing individual as qualitatively different from their normal state of awareness. Although a number of different phenomena fall within the bounds of this definition (e.g., "trance" and "possession" states), probably the most commonly reported are depersonalization and derealization. In depersonalization, the individual experiences a profound feeling of detachment from his or her thoughts, perceptions, actions, and emotions, often characterized by a sense of numbness or disembodiment. In derealization, the individual experiences an intact sense of self coupled with a feeling of detachment from the external environment, which often feels unreal or at a distance. Such feelings are extremely common, and frequently occur in the context of psychiatric illnesses such as depression and anxiety; they also occur as a circumscribed problem in their own right, such as in depersonalization disorder.

Although DSM-IV identifies depersonalization disorder as a dissociative phenomenon, this condition clearly relates to a different sense of dissociation than that which applies to the other members of this category; this difference further justifies the separation of depersonalization disorder from the Dissociative disorders category in ICD-10. Depersonalization and derealization are also found in certain drug states (e.g., those produced by marijuana, LSD, and ketamine) and neurologic conditions such as temporal lobe epilepsy and can occur spontaneously in the context of stress or fatigue.

Table 2 Dissociative disorders and dissociative events[a]

Neurologic	Psychologic
Temporal lobe epilepsy	Dissociative identity disorder

Transient global amnesia	Dissociative amnesia
Epileptic fugues	Dissociative fugues
Body image disorders	Dissociative (conversion) disorders
Somnambulisms	Depersonalization
Drug-dependent learning	Derealization
Sleep amnesia	Déjà-vu
	Hypnosis
	Out-of-body experiences

[a]Showing the main neurologic and psychological states associated with dissociation, with decreasing levels of pathology in descending order.

Dissociation as a Defense Mechanism

Finally, dissociation has been described as a defense mechanism that protects the individual from potentially overwhelming pain or anxiety. In many respects, this account of dissociation is indistinguishable from the Freudian concept of repression.[20]

This sense of the dissociation concept is typically used to describe the psychological *function* served by the creation of a detached state or the compartmentalization of mental modules or systems.[15] In this view, exposure to a traumatic situation may trigger the compartmentalization of memories, which preserves psychological integrity by preventing the distressing material from entering consciousness after the event. Alternatively, such traumatic exposure may spontaneously elicit a depersonalized state that prevents extreme emotion from inhibiting an appropriate behavioral response. As such, this definition of dissociative may relate to either of the definitions described previously. In both cases, dissociation of this sort could be either an acute response to an isolated traumatic event or a trait-like characteristic acquired as a result of repeated exposure to trauma.

Epilepsy and Dissociation

Although the differential diagnosis of ICD-10 and DSM-IV Dissociative disorders explicitly requires the exclusion of symptoms with an identifiable neurologic basis, many of the phenomena associated with epilepsy, particularly temporal lobe epilepsy, have been regarded as dissociative in nature (Table 2).[18,27] Indeed, ICD-10 includes a specific category for Dissociative disorders due to a general medical condition, which encompasses many of the symptoms exhibited by those with epilepsy. The absence of such a category from DSM-IV, however, reflects doubt concerning the value of attaching the dissociative label to these phenomena. In our view, such doubt is well justified in many cases.

The notion that many epileptic phenomena can be regarded as dissociative is based, to a considerable extent, on the frequent occurrence of amnesia in epilepsy (see, e.g., Good[27]). Complex partial and generalized seizures typically provoke profound amnesia for events occurring during the ictus. Moreover, certain individuals experience a postictal fugue state characterized by apparently purposeful behavior for which they are subsequently amnesic, much like dissociative fugue. Despite their prima facie resemblance to dissociative phenomena, however, these events should *not* be regarded as episodes of dissociation.[27] Dissociative amnesia is characterized by an inability to retrieve information that has been learned and is present in memory despite its inaccessibility.[2] Amnesia for ictal events, in contrast, reflects a disruption in normal information processing, resulting from uncontrolled neural activity, that prevents the encoding of new material during the ictus. The ictal amnesia is not a product of a retrieval failure, therefore, but simply the absence of memories to retrieve. It is for this reason that this form of amnesia is irreversible, unlike most cases of dissociative amnesia.[2]

Postictal fugue should not be regarded as a dissociative episode for similar reasons. Unlike dissociative fugue, postictal fugue is characterized by a disruption in consciousness associated with significant confusion and an abnormal electroencephalogram (EEG).[62] The apparently purposeful behavior displayed in postictal fugue is not dissociated from ongoing cognitive activity as it is in dissociative fugue; rather, it occurs in the relative *absence* of such activity. The inability to reverse the amnesia associated with postictal fugue serves as an illustration of this fact. The behavioral automatisms often observed in the context of complex partial seizures and regarded as a dissociative phenomenon by some (e.g., Good[27]) are amenable to a similar interpretation. As with the behaviors exhibited during postictal fugue, ictal automatisms only occur in the context of a disruption in consciousness and disturbed behavioral control; genuinely dissociated behaviors are noteworthy because they occur despite an otherwise intact ability to control action.[b] In both cases, it is likely that these behaviors result from the uncontrolled activation of circumscribed motor programs by epileptic discharges in neural sites associated with behavioral control. The fact that such automatisms are particularly characteristic of seizures originating in the frontal lobes lends support to this view.

Many of the phenomena associated with partial seizures originating in the temporal lobes, such as hallucinations, sensory and cognitive auras, déjà-vu, and déjà-veçu, should also be distinguished from true episodes of dissociation. Although hallucinations and auras have a phenomenology that departs from external reality, these phenomena involve the paradoxical *integration* of information within conscious awareness. As such, they may be more appropriately regarded as phenomena of *association* rather than dissociation.[40] The phenomenology of epileptic hallucinations and auras probably originates in the activation of representational structures in the temporal lobes, either directly, by seizure activity in representational networks, or indirectly, through seizure-related stimulation of limbic structures such as the amygdala and anterior cingulate.[3] Experiences of epileptic déjà-vu and déjà-veçu are also more associative than dissociative and may involve a similar neurophysiologic process. For example, stimulation of the amygdala by seizure-related discharges could imbue current perceptions and cognitions with an unwarranted emotional coloring that may be experienced as a sense of having encountered the situation before (see, e.g., Bancaud et al.[3] and Sierra and Berrios[58]).

Certain phenomena associated with temporal lobe epilepsy, however, can be regarded as examples of dissociation according to the scheme described by Cardeña.[15] Depersonalization and derealization commonly occur in the context of temporal lobe epilepsy and involve an alteration in consciousness characterized by dissociation from the self and/or the environment. According to Sierra and Berrios,[58] depersonalization and derealization are the products of a vestigial defense mechanism evolved to provide the optimum processing conditions for adaptive behavior in the face of threat. By this view, extreme anxiety triggers an inhibitory response from the left prefrontal cortex that dampens output from the sympathetic nervous system via the inhibition of the amygdala and anterior cingulate.

P.2823

In turn, the right prefrontal cortex is activated by ascending arousal systems controlled by uninhibited amygdala circuits, generating further inhibition of the cingulate. As a result, the individual experiences a sense of vigilant alertness devoid of any emotional or cognitive content, a state that is ideally adapted for the control of action in the face of extreme and potentially debilitating danger. If this response is triggered in the absence of threat, however, the resulting sense of depersonalization and derealization can be highly unpleasant and incapacitating. Given the validity of this account, depersonalization and derealization in the context of temporal lobe epilepsy may be the result of seizure activity in the amygdala that prevents the emotional tagging of perceptual and cognitive information prior to its entry into conscious awareness.[c] Alternatively, it may reflect an indirect defensive response in the face of anxiety elicited by seizure-based stimulation of the amygdala. Intuitively, one suspects that the former is the more plausible possibility, although the latter cannot be ruled out a priori. Following this account of depersonalization and derealization, these phenomena can be regarded as dissociative in sense (b) of the term; whether they should, in the context of epilepsy, be regarded as the result of a dissociative defense mechanism remains an empirical issue.[3]

The fact that few epileptic phenomena can be regarded as dissociative in any strict sense reflects widespread confusion over what actually constitutes dissociation. Although widely endorsed, the idea that any breakdown in memory, consciousness, identity, perception, or behavioral control is dissociative overextends the term and diminishes its descriptive validity.[15] Amnesia cannot be considered dissociative unless it involves an inability to retrieve intact information that should, under normal circumstances, be available for recall.[40] Amnesia resulting from a failure to encode information, including that which occurs in the context of epilepsy, does not fall within this category. Loss of behavioral control can only be considered dissociative if it is within the context of an otherwise intact ability to control action. Seizure-related motor phenomena, including complex automatisms, are not dissociative because they occur only in the context of reduced behavioral control in general. Current psychiatric taxonomies do not make these distinctions clearly enough, and rely instead on a purely descriptive approach that precludes precise classification based on the mechanisms underlying different phenomena.

Nonepileptic Seizures and Dissociation

The concept of dissociation is particularly important in relation to nonepileptic attacks because it sheds light on both the mechanisms and, potentially, the differential diagnosis of these phenomena.

In all cases, nonepileptic attacks involve a temporary loss of behavioral, sensory, or cognitive control that occurs in the context of intact neuropsychological functioning, as evidenced by a normal EEG during the nonepileptic ictus. The absence of paroxysmal brain discharges serves as the principal feature that distinguishes nonepileptic from “genuine” epileptic events. By itself, however, the EEG cannot provide a completely reliable basis for the identification of epileptic and nonepileptic seizures,[13] which underlines the potential value of dissociation as a criterion for an inclusive diagnosis of nonepileptic attack disorder.

Several converging lines of evidence indicate that these events involve a dissociative psychological mechanism, namely compartmentalization.[44] In the first instance, nonepileptic seizures are commonly found in the context of other forms of dissociative psychopathology. Bowman[7] and Bowman and Markand[8] found that the vast majority of those with nonepileptic attacks meet criteria for DSM-IV dissociative disorders such as dissociative amnesia and identity disturbance. Posttraumatic stress disorder, commonly assumed to involve a dissociative mechanism, was also particularly common in this group of patients.[7,8] Other studies have found that nonepileptic seizures frequently occur alongside other unexplained physical symptoms (e.g., Krishnamoorthy et al.[41] and Maldonada and Spiegel[47]), suggesting that they may be one aspect of a broader tendency to express psychological distress somatically, so-called “somatization.”[46] A number of authorities have suggested that compartmentalization is an important aspect of this phenomenon also (e.g., Brown[11]). Eating disorder symptoms, which have been linked to a dissociative process (e.g., Pettinati et al.[51]), also appear to be particularly common in patients with nonepileptic seizures.[41]

The frequent cooccurrence of dissociative psychopathology in patients with nonepileptic attacks appears to indicate a general propensity for dissociative experiences in this population. Consistent with this notion is a study by Kuyk et al.[43] showing that individuals with nonepileptic attacks display elevated levels of hypnotic susceptibility. In a related vein, in many cases, nonepileptic attacks can be provoked using suggestion, placebo. or hypnosis (e.g., Dericioglu et al.[17]). High hypnotic susceptibility is commonly found in patients with dissociative psychopathology,[25,57,60] and a dissociative interpretation of hypnosis has been offered by a number of authorities (e.g., Hilgard[32] and Woody and Bowers[64]). Bowman[7] also found that individuals with nonepileptic seizures had elevated scores on the Dissociative Experiences Scale (DES),[5] a self-report measure assessing everyday occurrences of dissociation compared to nonclinical controls. However, in a more recent study, Alper et al.[1] found that DES scores are also elevated in patients with complex partial seizures (see also Devinsky et al.[18]); indeed, there was no significant difference in overall DES scores between these patients and a group with nonepileptic seizures. Nevertheless, both epileptic and nonepileptic groups scored higher on the DES than typically observed in nonclinical populations. This finding demonstrates the danger of conflating the various definitions of dissociation within a single measure such as the DES. Because the DES treats dissociation as a unitary concept, it cannot differentiate between conditions that are characterized by different forms of dissociative phenomena, such as epilepsy and nonepileptic attack disorder.

Evidence implicating high dissociative comorbidity, hypnotic susceptibility, and exposure to trauma in individuals with nonepileptic seizures provides only indirect evidence for a dissociative interpretation of this phenomenon. Although such evidence suggests that a tendency to dissociate may be a common feature of these individuals, it does not constitute conclusive proof that nonepileptic attacks are themselves dissociative. A recent study by Kuyk et al.[43] places such an interpretation on a firmer footing. Like epileptic seizures, nonepileptic attacks are often associated with a dense amnesia for events occurring during the ictus. We have already stated that epileptic amnesia should not be considered a dissociative phenomenon, because it arises from a seizure-related disruption in memory encoding rather than an inability to retrieve intact memory traces. However, Kuyk et al.[43] showed that the amnesia associated with nonepileptic attacks may actually be the product of such a retrieval deficit. They compared a group of individuals with amnesia for events occurring during well-documented non-epileptic attacks with a group displaying amnesia following complex partial and generalized epileptic seizures. All individuals were hypnotized and given suggestions designed to facilitate the recovery of ictal events; the experimenter remained blind to

group status at all times. Using a free-recall paradigm, 17 of 20 patients with nonepileptic seizures recovered significant information concerning the designated attack; this information was verified by video recordings or third-party reports. In contrast, not one of the 17 patients with epilepsy retrieved information concerning their attack during hypnosis. Such a finding appears to demonstrate that, unlike that found in epilepsy, nonepileptic amnesia results from a process that prevents the individual from accessing memories successfully encoded during the attack. This apparent separation of intact memorial information from conscious awareness following a nonepileptic attack, coupled with the phenomenologic character of these events, clearly identifies these phenomena as examples of dissociative compartmentalization.

Table 3 Psychogenic amnesias in approximate order of chronicity

Situational amnesia
Posttraumatic stress syndrome[a,b]
Ganser syndrome[c]
Psychogenic fugue[b]
Hysterical dementia
Depressive dementia
Multiple personality disorder[b,c]
Histrionic personality disorder[a]

[a]Amnesia is not always a feature.

[b]Those disorders are most likely to be confused with epilepsy.

[c]Nosologic validity of these syndromes is in doubt.

Differential Diagnosis of Epilepsy and Dissociative Phenomena

The differential diagnosis of epilepsy and nonepileptic attack disorder is considered elsewhere in this book. In this section, we describe the nature and differential diagnosis of other conditions that are often confused with epilepsy.

Dissociative Amnesia

Dissociative amnesia is one variant of psychogenic amnesia; a list of the differential diagnoses for these conditions is given in Table 3. Dissociative amnesia is often overlooked and mistaken for a diagnosis of complex partial seizures. Thus, it is important to reemphasize that loss of awareness and amnesia should not automatically lead to a diagnosis of epilepsy.

Fugues

Fugues are characterized by the patient "coming to" in a strange place and professing no knowledge of how he or she arrived there. Again, there is a profound amnesia, sometimes extending backward in the patient's life for many years. Patients may adopt a different identity, which may be of brief duration, but in some cases may be retained in a remarkable way for a number of years.[52]

Table 4 Clinical assessment of fugue states

Psychogenic fugues	Postictal fugues
Identifiable emotional precipitant	Unlikely to be first presentation of epilepsy
Wandering is socially appropriate	Associated with obvious confusion
Gradual recovery of orientation	Rapid recovery
Electroencephalogram is usually normal	Abnormal electroencephalogram

Such fugues are often a clinical manifestation of depression, but they often seem to come on after a trauma, and head injury is frequently reported. Some points of differential diagnosis between psychogenic fugue and postictal fugue are given in Table 4. Psychogenic fugues also need to be distinguished from transient global amnesia, poiromania, somnambulism, and postconcussional amnesia.

Somnambulism

Somnambulism implies sleepwalking, and this is much more common in childhood. In adults, it has distinct psychopathologic significance. It is one of the parasomnias, usually arising in non–rapid eye movement (REM) sleep. There may be only brief wandering or lengthier episodes, with the completion of quite complex but purposeless tasks, for which there is profound amnesia. During the attack, the eyes are open; the patient seems confused and expresses surprise if awakened. Its onset in adulthood is usually associated with emotional trauma.

A family history of sleepwalking or night terrors is reported in 80% of somnambulists, and many children have isolated and clinically nonsignificant sleepwalking episodes. It is often considered one of the neurotic traits of childhood, alongside nailbiting, phobias, enuresis, food faddisms, tics, and mannerisms. In themselves they have little import, but they may cluster and suggest a tendency to later neurotic breakdown. Certainly the onset of somnambulism in adult life suggests some underlying psychopathology, often depressive, and, in association with seizures, suggests that the latter will be nonepileptic.

Sometimes the somnambulism can be distinguished from epilepsy only with polysomnography and telemetry, and third-party accounts of the attacks may be misleading.

Dissociative Identity Disorder (Formerly Multiple Personality Disorder)

Dissociative identity disorder is characterized by the presence of two or more identities or personality states. Each state is often, although not always, amnesic for the other. Patients typically complain of an inability to remember the full sequence of their personal history. The sudden switch from one state to another may give rise to a suspicion of epilepsy, and nonspecific EEG changes may add further confusion. Many reported cases give histories of earlier physical and mental deprivation, abuse, and head injuries. The fact that multiple personalities are described in association with epilepsy,[4] especially temporal lobe epilepsy,[56] adds confusion because the nosologic status of this condition is held in doubt by some authors.[49]

Table 5 Criteria for posttraumatic stress disorder[a]

Exposure to a traumatic event
Experienced, witnessed, or confronted with event(s) involving actual or threatened death, serious injury, or threat to integrity of self or others
Response of intense fear, helplessness, or horror
Persistent reexperiencing of the trauma
Recurrent and intrusive distressing recollections
Recurrent and distressing dreams of the event
Acting or feeling as if the traumatic event were recurring
Intense psychological distress at exposure to internal or external cues
Physiologic reactivity on exposure to internal or external cues

Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness

Efforts to avoid associated thoughts, feelings, or conversations

Efforts to avoid associated activities, places, or people

Inability to recall an important aspect of the trauma

Markedly diminished interest in significant activities

Feeling of detachment from others

Restricted range of affect

Sense of a foreshortened future

Persistent symptoms of increased arousal

Difficulty falling or staying asleep

Irritability or outbursts of anger

Difficulty concentrating

Hypervigilance

Exaggerated startle response

Duration of the disturbance >1 mo

The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

[a]309.81 in *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition.[2]

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) has assumed considerable importance in recent years, yet it is an easily missed diagnosis. The current criteria, as laid down by DSM-IV,[2] are given in Table 5. Obviously, the precipitating trauma is the significant criterion for entry, but in many cases the trauma may have occurred in the past and perhaps been reactivated by recent events. The similarity between PTSD and nonepileptic seizure disorder patients has been commented on by some authors (see Chapters 207 and 282), and the hyperexplexia of PTSD may be mistaken for myoclonic seizures. In such cases, the patient's seizures are seen as the central and often only complaint, and the accident that may have preceded them provided a head injury as an etiology for the attacks. However, typically, the posttraumatic amnesia will be brief, and the accident terrifying. Careful history taking will unravel the pervasive underlying symptoms of a PTSD, although in some patients there may be extreme reluctance to discuss the accident. Psychogenic amnesia is a cardinal clinical symptom of this condition.

Déjà-vu

Déjà-vu and its associated states such as jamais-vu and déjà-veçu are experienced by many people and do not necessarily signify psychopathology. The most common medical association with déjà-vu is an anxiety disorder, in which setting the experience fails to have the vivid and clearly repetitive nature that the aura of a temporal lobe focus brings.

Posttraumatic Amnesia

Posttraumatic amnesia is distinguished by the clear relationship to a head injury, although in some cases this is clinically obscure. For example, a patient may deny any such injury, or, more commonly, a seemingly trivial injury may provoke a profound loss of memory that seems enduring. Such cases are unlikely to be taken for a seizure disorder, but if they are associated with some apparent confusion, a partial status needs to be excluded. A prolonged retrograde amnesia, especially with loss of personal identity, in the presence of normal learning abilities or minimal posttraumatic amnesia is usually indicative of a psychogenic amnesia.

Measurement of Dissociation

Several scales to measure symptoms of dissociation have been developed, but few have been evaluated in neurologic populations, such as those with epilepsy. Moreover, the descriptive nature of the scales means that they are unable to separate out the mechanisms responsible for the dissociative symptoms in question. As such, they cannot be used to aid in the differential diagnosis of epilepsy, although they can be useful for determining the extent and nature of dissociative symptoms in research settings.

The Dissociative Experiences Scale (DES) is a brief self-report questionnaire designed to elicit information regarding lifetime experiences of "dissociation" in normal and clinical populations.[5] Although the DES is the most widely used measure of dissociation, the use of total scores on the scale is problematic because they conflate different types of dissociation (e.g., detachment and compartmentalization) within the same measure. It is more appropriate to identify and use separate subscales pertaining to the types of dissociation under scrutiny. Most factor-analytic research suggests that the scale comprises three subscales measuring amnesia, depersonalization–derealization, and absorption.[3] Alternatively, scales specifically developed to assess different types of dissociation, such as the Cambridge Depersonalization Scale,[59] the Multidimensional Dissociation Inventory,[10] or the Somatoform Dissociation Questionnaire,[50] can be used.

The Structured Clinical Interview for DSM-IV Dissociative Disorders (SCID-D) is more specific for diagnosis of DSM-IV dissociative conditions than the DES, having separate subscales for symptoms of dissociative amnesia, depersonalization, derealization, identity confusion, and identity alteration.[61]

Treatment

Pharmacotherapy

When there is an indication for pharmacotherapy, for example, antidepressants with an affective disorder, these should be prescribed. In addition, antidepressants are helpful in countering the symptoms of other disorders such as the intrusive events of posttraumatic stress.[47]

In nonepileptic seizures, anticonvulsants are unnecessary and should be withdrawn. Although some physicians

maintain patients on anticonvulsants such as carbamazepine for their mood-enhancing properties, there is evidence that the prescription of anticonvulsants for pseudoseizures without epilepsy may aggravate such attacks.[28] In many cases, slow withdrawal of anticonvulsants, with reassurance that patients do not have epilepsy, in a supportive clinical environment will lead to a resolution of attacks without further intervention.

For many patients with dissociative disorders, the nonmedical therapeutic interventions described in what follows are the most appropriate.

Hypnotherapy

Both Janet and Freud used hypnosis to access the isolated memories in patients and make "associative corrections." In other words, they attempted to reproduce the supposed hysterical action of autohypnosis under controlled conditions and "disinfect" the dissociated traumatic memories, either by direct countersuggestion or, more indirectly, catharsis. Freud soon abandoned this practice, however, because of its lack of success. He found that patients were either unable to be hypnotized, in spite of the apparent autohypnotizability of such patients, or, more important, they were cured but later produced another set of symptoms (symptom substitution).

Today hypnosis is still used in two ways. It is sometimes used to induce an attack, in other words, to help with the diagnosis. This has variable success and in part relates to the effectiveness of the person doing the hypnosis as a hypnotist. It is not widely used and not recommended to the inexperienced. Furthermore, as with other induction methods, outcome should be viewed with caution because epileptic seizures can also be triggered in this way.[42]

Hypnosis is also used to elicit the traumagenic events of dissociative disorders isolated in memory as part of treatment. It is a controversial option, however, not least because "lost truths" and discovered fantasies are difficult to differentiate, especially in an altered state of consciousness. Evidence gathered by both the British False Memory Syndrome Association and its American equivalent suggests that hypnotherapy and "recovered memory therapy" are major instigators of false allegations.[14]

Psychotherapy

Colloquially known as "the talking cure," psychotherapy encompasses a vast array of theoretical orientations and practices, ranging from individuals to groups. Psychodynamic psychotherapy views dissociative symptoms as signals of individual and/or family distress. As such, they are not the focus of psychotherapeutic treatment but are indirectly alleviated by allowing patients to explore the factors that have contributed to their disorders, including past history and interpersonal difficulties. Cognitive behavior therapy (CBT) aims to identify and alter maladaptive thoughts and behaviors that are contributing to the maintenance of symptoms.[26]

The choice of treatment for the patient depends on a number of factors, including an identifiable cause such as past trauma, age, family dynamics, intellectual impairment, compliance, patient preference, and psychological mindedness. In addition, this is not such an easy option as it at first sounds. Patients with nonepileptic attacks are often difficult to manage, and the combination of apparent neurology with psychopathology is confusing for the inexperienced. It is recommended that patients be referred to therapists with special knowledge, experience, and interest in conversion and dissociative disorders.

There is only very limited evidence demonstrating the efficacy of psychotherapeutic intervention in patients with dissociative disorders, and substantial randomized, controlled trials are urgently needed.

Summary and Conclusions

Dissociation is a complex and multifaceted concept that is frequently misapplied within the field of epilepsy. In this chapter, we have explored the various components of the dissociation concept and how they relate to the phenomena of epilepsy and nonepileptic seizures. We have demonstrated why many epileptic phenomena often thought to be instances of dissociation, such as amnesia, postictal fugue, behavioral automatisms, aura and hallucinations, should not be regarded as dissociative at all. We have also argued, however, that depersonalization and derealization occurring in the context of epilepsy can be regarded as dissociative, in the sense that they involve an altered state of consciousness characterized by disengagement from the self or environment. We have also presented evidence indicating that nonepileptic attacks should be considered dissociative phenomena, in this case involving a temporary disruption in behavioral control and subjective awareness despite intact neuropsychological functioning. Although certain aspects of epilepsy are dissociative, therefore, they do not involve the same type of dissociation as that underlying nonepileptic attacks.

If the dissociation concept is to prove useful in this area, much greater precision, both conceptual and methodologic, is required. Researchers and clinicians should be explicit about which definition of dissociation they are referring to, and efforts should be made to use measures of dissociation that, unlike total scores on the DES, are "phenomenon pure." Assessing the reversibility of nonepileptic amnesia, which may prove to be invaluable as an aid to differential diagnosis in this area, provides one illustration of the potential utility of such an endeavor.

Chapter 285

Panic Disorder and Hyperventilation Syndrome

Alan B. Ettinger

Jonathan M. Bird

Andres M. Kanner

Introduction

Panic disorder and hyperventilation syndrome (HVS) are frequently underrecognized conditions that are easily mistaken for epileptic seizures. This chapter highlights practical diagnostic strategies for distinguishing these disorders. We explore etiologies of HVS and conclude with a discussion of the effects of hyperventilation on seizures and the EEG because these issues may arise in the context of the evaluation of hyperventilation symptoms. Potential areas of commonality in the pathogenesis of panic disorder and epilepsy are discussed in Chapter 206.

Panic Attacks and Panic Disorder

A 28-year-old woman had undergone a subtotal resection of a right temporal ganglioglioma at 11 years of age. This had presented with complex partial seizures associated with déjà-vu sensation followed by altered responsiveness. She was seizure free until 8 years later, when typical seizures recurred, but now with secondary generalization. A further resection of a large part of the right temporal lobe was undertaken. This resulted in significant improvement in the epilepsy, but the patient continued to have occasional complex partial seizures with a rising epigastric aura, déjà-vu sensations, and complex motor automatisms.

She subsequently developed new episodes, different from her typical complex partial seizures. These began with a sense of shortness of breath and a choking feeling. She experienced nausea that was distinct from the earlier rising epigastric aura. The episodes also included dizziness and a perception that things were unreal around her. She also had an overwhelming feeling that she was going to die. With great concern about these episodes, the husband gave up his job to be constantly by her side.

Video-electroencephalographic (EEG) monitoring demonstrated that, although the patient has had ongoing epileptiform discharges and slow waves over the right temporal region, the new episodes were unassociated with electrographic correlate. A diagnosis of panic attacks was rendered. The patient has undergone a process of psychoeducation, reassurance, and discussion with the appropriate neurosurgeons. She began to articulate her fear of dying from her tumor. Panic attacks improved significantly with this treatment but occasionally recurred without clear provocation. Her husband was trained to be observant but not overindulgent in response to the episodes, and he ultimately returned to work.

One of the most common episodic symptoms that can be confused with a seizure is a *panic attack*. Numerous series attest to the common misdiagnosis of seizures in patients with panic attacks[26,38] and the erroneous diagnosis of panic attacks among patients with seizures.[1,14,51,78] Recurrent unexpected panic attacks define the condition termed *panic disorder*.[66] Diagnostic criteria for panic attacks and panic disorder are listed in Table 1. Significant morbidity associated with epilepsy or panic disorder and with the failure to allocate appropriate treatment makes the need to distinguish these two disorders especially crucial.

Epilepsy has a lifetime prevalence of 3% to 4%,[36] and panic disorder has a lifetime prevalence of 1% to 2%.[64] Although there is a fairly equal overall rate of epilepsy in men and women, panic disorder is twice as likely in women.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[3] a panic attack is a "discrete period of intense fear or discomfort" in which four or more of the symptoms listed in Table 1 "develop abruptly and reach a peak within 10 minutes." Many of the symptoms of panic attacks are reminiscent of symptoms that may appear during some types of epileptic seizures. Differences between panic attacks and seizures are highlighted in Table 2 and elaborated on in the following discussion.

Fear is a commonly encountered component of partial seizures and is the most common ictal psychiatric symp-tom.[13,81] The importance of the temporal lobe as a site of localization for fear auras is validated by electrical stimulation of mesial temporal structures such as the amygdala, which produces many of the symptoms reminiscent of panic attacks (intense fear, dizziness, nausea, tachycardia, chest pain, and depersonalization).[29] Gloor argued that "the aura of fear in a temporal lobe seizure may take exactly the form of a typical panic attack."[29] He further contended that this "situation is further compounded in those patients with epilepsy who also have panic attacks that may provoke their epileptic seizures, either by hyperventilation or by some direct effect of the CNS arousal."[29]

Table 1 Symptoms of Panic Attack and Panic Disorder

Panic attack (summary of DSM-IV criteria)
A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 min
Cardiopulmonary symptoms
Chest pain or discomfort
Sensations of shortness of breath or smothering
Palpitations, pounding heart, or accelerated heart rate
Neurologic symptoms
Trembling or shaking
Paresthesias (numbness or tingling sensation)
Feeling dizzy, unsteady, light-headed, or faint

Psychiatric symptoms

Derealization (feelings of unreality) or depersonalization (being detached from onself)

Fear of losing control or going crazy

Fear of dying

Automic symptoms

Sweating

Chills or hot flushes

Gastrointestinal symptoms

Feeling of choking

Nausea or abdominal distress

Panic disorder (summary of DSM-IV criteria)

With agoraphobia

A. Recurrent, unexpected panic attacks
B. At least one of the attacks has been followed by 1 mo or more of persistent concern about having additional attacks; worry about the implications of the attack or its consequences; a significant change in behavior related to the attack
C. The presence of agoraphobia, i.e., anxiety about being in places or situations in which escape might be difficult (or embarrassing) or in which help might not be available in the event of having a panic attack

Without agoraphobia

A. Both A and B above
B. Absence of agoraphobia

DSM-IV, *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition.

The fear aura tends to be associated more with a typical rising epigastric aura, whereas panic attacks are associated more with a spreading abdominal discomfort. The aura tends to be described as if it has a "harder," more organic feel. Williams[81] described ictal fear as unnatural rather than seeming more reality based. The intensity of ictal fear sensation is mild to moderate and rarely reaches the intensity of a panic attack.

Anxiety symptoms in panic attacks vary in nature among different individuals. Some experience a nonspecific sensation of "impending doom," whereas others may experience a fear of having incurred a devastating medical problem such as a heart attack or stroke. Sometimes, the anxiety is less prominent than the other features, such as palpitations or chest discomfort, noted in Table 1. It is thus of little wonder that most patients with a panic attack present initially to an emergency room or a nonpsychiatric medical clinician rather than to a psychiatrist.[34]

In panic attacks, autonomic symptoms and other bodily symptoms appear such as palpitations, sweating paresthesias, dizziness, nausea, feeling faint, and a sense of abdominal or central chest discomfort, and it is not uncommon for patients experiencing a panic attack to be thought of as having an acute

coronary attack or a stroke. Autonomic symptomatology is also common in seizures, but these are of lesser "subjective" intensity than in panic attacks. Of note, paroxysmal salivation is a typical autonomic symptom in seizures of mesial temporal or insular origin and not of panic attacks. Salivation may often be copious and associated with nausea and vomiting.

Subjective dyspnea often experienced during a panic attack led to the earlier confusion and often mislabeling of panic attacks as hyperventilation syndrome, although some might argue that they are intimately related (see later discussion).[28] Alteration in breathing pattern is very common to both seizures and panic attacks, so that the documentation of hyperventilation has limited distinguishing value. If hyperventilation is severe, tetany may occur, which could be confused with seizures associated with tonic activity.

In contrast to complex partial seizures, distinct confusion or loss of consciousness is unusual in a panic attack, although patients may become completely absorbed by the panic experience to the point at which they are unable to report what is going on around them. A panic attack associated with profound hyperventilation could also conceivably lead to a "subjective perception" of loss of consciousness. Symptoms of derealization, depersonalization, and déjà-vu may occur in both conditions.[73] The patient with panic attacks associated with these symptoms could end up undergoing an extraordinarily extensive testing if panic is not considered in the differential diagnosis by the medical clinician. Because of dissociation during panic attacks and subsequent claims of amnesia for the episodes, the patient may never make it to a psychiatrist for treatment (M. Trimble, personal communication). Distortion of perception should raise additional suspicion for partial seizures.

"Reported" preservation of awareness of surroundings and responsiveness during the ictus are usually interpreted as supportive evidence of a panic attack. It is important to remember, however, that in seizures of nondominant mesial temporal origin, patients may continue to follow commands and interact with the examiner or other interlocutors during the ictus, giving the appearance of "intact" consciousness.[23] Careful testing of these patients, however, after the event reveals that they do not recall what happened during it. In such cases, recording of these events with video-EEG may be the only way of establishing a correct diagnosis.

Ictal fear usually lasts <30 seconds and is usually more stereotyped than panic attacks. A partial complex seizure during which ictal fear may occur usually lasts only 2 minutes. However, partial complex status epilepticus associated with isolated fear has been reported.[62] In contrast, panic attacks usually last from 5 to 20 minutes and have a longer buildup of anxieties.

Table 2 Differential Diagnosis of Seizure Versus Panic Attack

Characteristics	Seizure	Panic attack
Signs and symptoms		
DSM-IV–based panic symptoms	Less common	Common

Repetitive, highly stereotyped presentations	More common	Rare
Atypical symptoms (aphasia, perceptual distortions)	More common	Less common
Association with rising epigastric sensation	More common	Not present
Disturbed behavior in sleep	More common	Less common
Altered consciousness	May occur	Usually preserved, patient may report it though
Fear duration	Usually 30 s; entire seizure usually <2 min; postictal fear may occur	Usually 5–10 min, up to 20 min
Agoraphobia	Less common, but may occur	More common
Rapid onset of episodes	More common	Less common
Postepisode confusion	Can occur	Not present
Postepisode fatigue	More common	Less common
History		
History of seizure risk factors (e.g., febrile seizures, head trauma)	Common	Less common
Family history of panic	Uncommon	Common
Anticipatory anxiety	Uncommon	Common
Findings		

Interictal neurologic deficits	Common	Uncommon
Abnormal sleep-deprived interictal electroencephalogram	Often present	Usually absent
Electrographic seizure activity during episode	Common, but "surface-negative events" may occur	Not present
Automatisms during episode	Common	Not present
Treatment		
Response to anxiolytics (nonbenzodiazepine)	Not helpful	Helpful
Response to antidepressants	Rarely worsens	Helpful
Response to antiepileptic drugs	Usually	Occasionally and depending on agent

DSM-IV, *Diagnostic and Statistical Manual for Mental Disorders*, 4th edition.
Source: Modified from Lee DO, Helmers SL, Steingard RJ, et al. Case study: seizure disorder presenting as panic disorder with agoraphobia. *J Am Acad Child Adolesc Psychiatry.* 1997;36(9):1295–1298.

Postictal symptoms of panic and symptoms of primary panic disorder can often lead to confusion. For example, in a study of 100 patients with refractory epilepsy, Kanner et al.[44] found that 10% of patients experienced postictal symptoms of panic after >50% of their seizures. The median duration of these symptoms was 24 hours. A careful history of the context in which symptoms occur as well as a review of other clues (Table 2) should help to avoid militate against this potential confusion.

Seizures can begin at any age, although certain forms of seizures, such as absence seizures, are much likelier to begin in childhood. Panic disorder usually begins in late adolescence or early adulthood, although onset in the 30s and even 40s can occur.[64] Symptoms suggestive of panic attacks that begin in older age groups should be vigorously investigated for the possibility of a seizure disorder.

The value of performing a detailed history (including contacting witnesses of an episode) when distinguishing seizures from panic attacks cannot be overemphasized. Anecdotal experience and review of case series of seizures[79] mistaken to be panic attacks often reveals some evidence of associated classic ictal phenomenology during some of the attacks such as automatisms or motor activity suggestive of spread of seizure activity. Patients often fail to recognize or report such associated symptoms such as transient confusion or subtle automatisms, and therefore it behooves the clinician to search for these clues. Sometimes, a frank convulsion following fear symptomatology clinches the epileptic diagnosis. Identifying a past medical history of febrile seizures or other risk factors for spontaneous seizures provides additional diagnostic clues.

Panic attacks tend to be somewhat less stereotyped than seizures, although this is best documented on video-EEG because historical accounts of observers may not necessarily emphasize the obvious replicability of ictal episodes.

Although some panic attacks may be linked to specific situations, panic disorder comprises at least two spontaneous panic attacks, at least one of which is associated with worry about subsequent attacks or avoidance behavior. Controversy

P.2831

exists whether agoraphobia (a common comorbid condition consisting of fear related to places from which escape may be difficult)[48,64,76] is a component of panic disorder or represents an independent condition that may be provoked by a panic attack. Similar to epilepsy, anticipatory anxiety may become so severe that the individual begins to restrict travel and activity for fear of finding himself or herself in the midst of an attack. Social phobias are common in panic disorder, but agoraphobia may also occur in epilepsy.

Although sleep can be provocative for many types of seizures, it is worth remembering that two thirds of patients with panic attacks have had one or more events at night. Polysomnography has demonstrated panic attacks occurring at sleep onset during stage 2 sleep or slow-wave sleep, but most commonly after awakening.[10,53,61,63]

The EEG may be helpful in suggesting an epileptic disorder both interictally, if epileptiform abnormalities or other focal cerebral abnormalities are found, or ictally, if an episode is caught during an episode while the EEG is running. Not uncommonly, the epileptologist is consulted to help to distinguish a seizure disorder from panic disorder and extended EEG monitoring such as video-EEG is ordered. Video-EEG has the advantage of permitting a detailed review of recorded clinical behavior in addition to detailed EEG analysis. Experienced electroencephalographers are aware, however, of the limitations of the EEG, in that simple partial and sometimes even complex partial seizures may not reveal an obvious correlate on scalp EEG[14] and that, therefore, the absence of an obvious electrographic seizure during an episode does not necessarily exclude seizures.[18] Supplementation of routine EEG recording

P.2832

with meticulously placed sphenoidal electrodes may enhance the yield on EEG.[43] Elevated serum prolactin levels 15 to 20 minutes after an episode may help to point to a seizure as the etiology, even when there is no obvious change on the surface EEG recording.[9]

It has been suggested that lactate infusion could be used as a diagnostic tool to provoke panic if it is present, but this is rarely necessary or even feasible.[57,70] Hyperventilation may provoke a panic attack in those prone to panic disorder, but evidence suggests that such provoked attacks are subjectively different from natural panic attacks.[31] It is generally considered that both these procedures have their effects by causing alterations in pCO_2 and pH.[66]

As in epilepsy,[19] comorbid depression and possibly bipolar disorder[20,64] are commonly found in panic disorder, as is the development of secondary psychosocial problems.[50] Whereas the risk of suicide among epilepsy patients is five times that in the general population,[5] the combination of panic attacks with major depression raises the risk of suicide beyond that encountered in major depression alone.[64]

Patients with ictal panic may also suffer from interictal panic attacks. However, studies of the comorbidity of panic disorder and epilepsy are limited. One of the few available surveys[68] suggests that up to 21% of epilepsy patients experience panic attacks compared to only 3.8% of the population.[45] Although the timing of the panic attacks in relation to the onset of epilepsy was not revealed by this study, the assumption that panic attacks were reactive to developing epilepsy cannot be made, especially in light of studies of other psychiatric comorbidity (i.e., depression) in epilepsy, which showed that depression may often precede the first seizure.[15,37] Agoraphobia, however, may develop in epilepsy due to the fear of having a seizure while crossing the street or in a public place. Mechanisms of potential commonality between panic disorder and epilepsy are described in Chapter 206.

Long-term outcome studies are lacking in panic disorder, although studies and anecdotal experience suggest that many patients will have a waxing and waning of episode frequency, whereas others may have more prolonged episode-free periods, which is again similar to the variability of outcomes seen among some epilepsy patients.

Similar to the risks among epilepsy patients of seizure exacerbation following abrupt withdrawal of benzodiazepines,[35] misuse of benzodiazepines by patients with panic disorder attempting to relieve their symptoms may be associated with worsened panic attacks during benzodiazepine withdrawal.

Panic disorder should also be distinguished from numerous medical conditions that may give rise to similar symptomatology, such as cardiac dysrhythmias in younger people (e.g., Romano-Ward syndrome; prolonged-QT syndrome) and paroxysmal metabolic disorders (e.g., carcinoid syndrome, hypoglycemia, pheochromocytoma, and Cushing syndrome). All of these disorders, however, are relatively rare. Other conditions to consider include alcohol drug withdrawal, illicit drug effects (amphetamines, cocaine, marijuana-induced tachycardia), vertigo-related disorders, and asthma.[21,46] Such alternative conditions should be strongly considered when panic attacks are unresponsive to the usual treatments or do represent seizures.

As discussed in Chapter 206, treatments for panic disorder (benzodiazepines, selective serotonin reuptake inhibitors, tricyclic antidepressants, and, more rarely, monoamine oxidase inhibitors) may affect the same neurotransmitters (e.g., γ-aminobutyric acid, norepinephrine, and serotonin) that are also crucial in aborting or promoting epileptogenesis. Other treatments for panic disorder include cognitive–behavioral therapy[4] and psychotherapeutic approaches.

Panic symptoms may often be identified in psychogenic nonepileptic events (PNES) that often are misdiagnosed as epileptic seizures. This topic is reviewed in great detail in Chapters 207 and 282.

Hyperventilation Syndrome

A 20-year-old student of environmental studies presented with episodes occurring several times per day in which she would complain of feeling very light-headed and then fall backward. She would appear confused and express uncertainty as to where she was. She would feel cold and numb and experience tingling sensations in her hands. Her hands would subsequently begin to shake with a coarse tremor, which would then evolve into profound hand stiffness. In the most severe episodes, she would experience tetanic contraction of the hands accompanied by considerable distress and crying. After the event, the patient remained distressed and complained of headache.

Video-EEG monitoring demonstrated no epileptiform discharges, but there was notable hyperventilation observed before and during each episode, resulting in diffuse slow wave changes. During an EEG study, hyperventilating volitionally on command reproduced her typical symptoms completely. This case illustrates the clinical expressions of the hyperventilation syndrome (HVS).

Successful treatment involved demonstrating the video-EEG carefully to her and taking her through a course of relaxation training, including exercises in controlled breathing. The episodes of hyperventilation reduced significantly, although it was possible that they could recur during stressful moments. Overall, the patient felt more in control of her symptoms and found them much less disabling. She was able to return to her routine course of studies.

The hyperventilation syndrome is another challenging diagnosis that overlaps with but is distinct from panic disorder. Although some believe that HVS is simply one variety of panic or anxiety disorder, others argue for recognizing it as an independent entity.

The evolution of the recognition of this syndrome is nicely described by Evans.[22] As early as the Civil War, a mysterious condition characterized by palpitations, shortness of breath, dizziness, and headaches afflicting Union soldiers was described by DaCosta.[11,22] Similar symptoms were noted among soldiers in World War I.[56] Gowers described a similar syndrome of difficulty breathing, yawning, reduced concentration, and a sense of unreality influenced by emotion and more commonly seen among women.[32] Goldman identified the relationship of "forced ventilation" with tetany as well as dizziness, paresthesias, and attacks of nervousness and crying associated with hysteria.[30] The term "hyperventilation syndrome" was introduced in the late 1930s to describe diverse symptoms associated with anxiety and often reproduced by having patients willfully hyperventilate. Lewis argued that acute and chronic hyperventilation syndrome presented frequently and ubiquitously.[69a]

Since at least 1929,[80] it has been recognized that some individuals may hyperventilate chronically. White and Hahn[80] called this "sighing dyspnoea"; this is not quite an accurate description, however, because, although "sighing" can describe the form of breathing, patients rarely complain of discomfort of breathing (dyspnea). Some may, however, complain of an inability to breath deeply enough.

Pincus[55] drew neurologic attention to the condition of chronic hyperventilation syndrome in his influential book *Behavioural Neurology*. He commented, "of all psychophysiological reactions, probably the most common one dealt with by physicians is the hyperventilation syndrome." Lum[58] observed that the typical and known cases of HVS were just the

"tip of the iceberg" and that as many as 6% of general medical outpatients may have the syndrome.

HVS occurs in most age groups, with a peak between ages 15 to 55 years[65]; it occurs predominantly in women. It presents as one of two varieties—a less common but much more obvious acute form and a less obvious but more common type termed chronic HVS. Acute HVS presents with obvious overbreathing and tachypnea and may have associated chest pain, dyspnea, dizziness, palpitations, and muscle spasms related to tetany, paresthesias, and syncope.[65] Chronic HVS is more challenging to recognize because it is associated with a diverse array of somatic complaints that are often misdiagnosed based on the organ system suggested by the symptomatology. Furthermore, overbreathing is usually not apparent; instead, intermittent deep sighs and frequent yawning may be seen. Symptoms of chronic HVS are best categorized according to bodily symptoms (Table 3).

Table 3 Symptoms and Signs of the Hyperventilation Syndrome

General
Fatiguability, exhaustion, weakness, sleep disturbance, nausea, sweating
Cardiovascular
Chest pain, palpitations, tachycardia, Raynaud phenomenon
Gastrointestinal
Aerophagia, dry mouth, pressure in throat, dysphagia, globus hystericus, epigastric fullness or pain, belching, flatulence
Neurologic
Headache, pressure in the head, fullness in the head, head warmth
Blurred vision, tunnel vision, momentary flashing lights, diplopia

Dizziness, faintness, vertigo, giddiness, unsteadiness

Tinnitus

Numbness, tingling, coldness of face, extremities, trunk

Muscle spasms, muscle stiffness, carpopedal spasm, generalized tetany, tremor

Ataxia, weakness

Syncope and seizures

Psychological

Impairment of concentration and memory

Feelings of unreality, disorientation, confused or dreamlike feeling, déjá-vu

Hallucinations

Anxiety, apprehension, nervousness, tension, fits of crying, agoraphobia, neuroses, phobia, panic

Respiratory

Shortness of breath, suffocating feeling, smothering spell, unable to get a good breath or breathe deeply enough, frequent sighing, yawning

Source: From Evans RW. Hyperventilation syndrome. In: Kaplan PW, Fisher RS, eds. *Imitators of Epilepsy*. New York: Demos; 2005: 241–252, Table 18.1 .

The neurologist is likely to encounter HVS in the context of one or more diverse symptoms including general dizziness, diffuse weakness, confusion or agitation, paresthesias in the extremities or periorally, and depersonalization sensations. Pincus[69] studied 550 neurologic outpatients and found 30 to suffer from this syndrome. These patients were asked to hyperventilate voluntarily to see if they could evoke the symptoms of which they were complaining. The typical clinical features were light-headedness, headache, paresthesias, giddiness, weakness, and difficulty concentrating. They tended to be aged between 15 and 30 years, to be female, and to have a history of psychosomatic illnesses. The majority (80%) showed some episodes of alteration of consciousness, and 6% had episodes of loss of consciousness, whereas 3% had episodes of tetany. Twenty percent had been given a diagnosis of epilepsy at some stage. Some patients also had gastrointestinal complaints, such as difficulty swallowing and abdominal pain or of chest symptoms such as chest pain, palpitations, and dyspnea.

HVS-related symptoms affecting thinking function and mood are the most likely symptoms to lead to a referral to the epileptologist. Complaints of déjà-vu or hallucinations are rare but have been reported.[2]

Hyperventilation is characterized by ventilation exceeding metabolic demand, leading to hemodynamic and chemical alterations that foster diverse symptomatology. Although a reduction in pCO_2 from willful hyperventilation can often reproduce these symptoms, many individuals with HVS do not in fact have reduced pCO_2 during HVS episodes. The terms "behavioral breathlessness" or "psychogenic dyspnea" have been proposed as alternatives.[65]

Breathing may be atypical in HVS, in which a more thoracic (as opposed to abdominal) breathing occurs. Typically, there is heaving of the upper sternum and a lack of lateral costal expansion—like a normal sigh. This may, therefore, be a learned behavior (a habit). In depression, there may be evident sighing hyperventilation, and chronic hyperventilation may be associated with depression. If chronic, hyperventilation will result in diminished reserve due to chronic mild hypocapnia, and, thus, a slight exacerbation under mild stress may lead to decompensation and marked symptoms. Patients with chronic hyperventilation syndrome are found to have a tendency to a childhood history of emotional problems, a family history of anxiety disorders, and a relative failure of psychosexual adjustment.[71]

Conflict thus may lead to worsening of hyperventilation, which is part of a preparation for "fight or flight." Hyperventilation may also be a learned way of avoiding conflict in an individual with a strong sense of personal vulnerability. If, however, hyperventilation occurs when the individual is actually at rest (as is often the case, possibly the result of inner conflict), the preparation, as if for fight or flight is physiologically unnecessary.

Although the etiology of HVS is not definitively clear, one theory suggests that some individuals are prone to specific abnormal respiratory responses to stimuli like stress (or chemical or other triggers) that result in excessive and disordered breathing, emphasizing thoracic rather than normal diaphragmatic respiration, thereby producing an expanded chest and increased residual lung volume. This then precludes inspiring the normal volume and produces a sensation of dyspnea. A "suffocation alarm" then leads to an autonomic response with symptoms including palpitations, anxiety, and diaphoresis.[65]

HVS may be medically more benign than some of the alternative diagnoses suggested by its symptoms (e.g., myocardial infarction); therefore some HVS sufferers incur significant morbidity from the numerous testing procedures often performed in search of an explanation for symptoms. Furthermore, HVS patients experience genuine discomfort and psychological distress related to their symptoms.

The most critical aspect of making a diagnosis of HVS is to consider it when considering a differential diagnosis; this helps to temper an otherwise excessive laboratory testing plan. In the face of acute HVS, the clinician may want to exclude internal or external organic causes, including lesions in the pons or midbrain tegmentum, liver disease, and salicylate poisoning. Occasionally, complex partial seizures (arising particularly from the insular cortex) may involve hyperventilation as part of the

P.2834

aura, although this is usually accompanied by automatisms and other obvious signs of a seizure. In the face of presentation with chest pain, diagnoses like pulmonary embolus and myocardial infarction may need to be ruled out.

Diagnosis of chronic hyperventilation syndrome may be made from a careful history taking, possibly combined with an attempt to precipitate or exacerbate the symptoms by voluntary hyperventilation typically by increasing respiration to 60 per minute or encouraging sustained deep breaths for 3 minutes.[59] The validity of this "hyperventilation test" has been challenged more recently.[41] Antecedent anxiety may be more compelling than the hyperventilation itself in bringing about the symptoms A negative test does not necessarily exclude this diagnosis.

Knowledge about the treatment of HVS is based predominantly on small case series and anecdotal experience. The management of acute hyperventilation by the time-honored method of rebreathing from a paper bag should be prescribed with caution because severe complications may arise if the diagnosis is wrong and a more serious condition exists. Some argue that this technique sometimes exacerbates anxiety through retention of CO_2. Simple reassurance alone is often sufficient to attenuate an acute episode. For the longer term, teaching patients how to use abdominal (diaphragmatic) breathing or other breathing retraining techniques (including reducing depth of ventilation) are often effective. Stress reduction methods, sometimes in conjunction with psychotherapy, biofeedback, or hypnosis, have been used. Psychotropic agents for potentially associated anxiety or depression include benzodiazepines, tricyclic antidepressants, and selective serotonin reuptake inhibitors.

Hyperventilation and the Electroencephalogram

Normal and common central manifestations of hyperventilation include light-headedness, a sense of unreality, and, eventually, loss of consciousness. The psychological effects of acute hyperventilation are marked. At first, heightened perception may be reported and may be a partial explanation for certain beatific visions and spiritual experiences in states of religious excitement.[42] However, this is then followed by dulling of consciousness and diminished awareness of the environment. As the dominant rhythm of the EEG drops below 5 Hz, there is increasing impairment of reaction time, memory, and calculation abilities. On recovery, there may be amnesia for the episode. If hyperventilation is prolonged, mental confusion, myoclonic jerking, convulsions, and loss of consciousness may ensue.[27,75]

The quality and nature of respiration have a profound effect on the brain. Two deep breaths significantly reduce arterial carbon dioxide; further hyperventilation results in respiratory alkalosis. There is a direct relationship between pCO_2 and the caliber of the cerebral blood vessels. During hyperventilation, Doppler ultrasound measurements of the mean flow velocity in the middle and posterior cerebral arteries drop by up to 50% after 4 minutes.[7] After cessation of hyperventilation, the mean flow velocity increases briefly to 130% to 140% of normal.

Hyperventilation is a well-established procedure during the performance of the EEG[39] and it is considered helpful for producing focal slow-wave abnormalities suggestive of regions of focal disturbance, as well as generalized epileptiform abnormalities (especially idiopathic generalized epilepsies in the young such as typical absence).[12,40] It is much less useful for bringing out focal interictal epileptiform abnormalities.[49] Hyperventilation results in slowing of EEG rhythms in normal individuals, independent of the inspired oxygen concentration.[47] It is the hypocapnia that causes the decreased cerebral blood flow, as well as increased hemoglobin affinity for oxygen, and results in cerebral tissue hypoxia. Hyperventilation also leads to a marked surface negative direct current shift, possibly due to depolarization of the apical dendritic trees of the cortical pyramidal cells.[72,77] This surface negative shift is likely to represent increased excitability of the cortical neuronal networks and may explain the resultant potential epileptogenicity. It is of interest that certain antiepileptic drugs have the opposing effect of reducing surface negativity in normal controls.[72]

Hyperventilation and hypocapnia significantly increase the length of seizures evoked by electroconvulsive therapy in a progressive fashion[6] directly related to decreasing pCO_2. Thus, hyperventilation has effects in the human cerebral cortex that might be expected to produce epileptic activity.

Hyperventilation-induced Seizures

Voluntary hyperventilation was proposed as a means of eliciting epileptic seizures as early as 1924.[24] There are many case reports in the literature in which a variety of forms of epileptic attack are provoked by this means.[8,25,60,67] Many of these reports involve individuals (adults or children) with mental retardation and often with absence or atypical absence attacks.[8,60] The report by Bruno-Golden and Holmes[8] describes two children with severe mental impairment and a history of infantile spasms followed by tonic seizures. Observation demonstrated that the seizures were often preceded by hyperarousal and hyperventilation. Management involved a behavioral approach, training in uninostril breathing (more successfully completed than training in diaphragmatic breathing in this population), and a program of physical exercise. Very considerable reduction in seizure frequency was recorded. A similar story is described by Magarian and Olney,[60] this time in a 66-year-old man with a 20-year history of absence spells. Educational and behavioral therapy was again successful; however, there remains doubt as to whether these “absence spells” were epileptic. Fried et al.[25] described a group of 18 patients with undoubted intractable epilepsy who were given diaphragmatic breathing training. Ten of them completed the training and had significantly reduced seizure frequency and severity.

As early as 1947 Engel et al.[16] raised doubts that hyperventilation resulted in tonic–clonic or partial seizures. This issue remains controversial. Although Holmes et al.[40] found that hyperventilation elicited a clinical seizure in only 2 of 433 consecutive patients with proven epilepsy, Guaranha et al.[33] found that up to 24 of 97 patients had hyperventilation-induced seizure activation (although in the context of reduction of antiepileptic medications in patients with the most severe seizure disorders undergoing presurgical evaluations.)

There has been debate about whether physical exercise induces seizures or reduces their frequency. In general, exercise is seen as a good thing, and, although it results in fast breathing, this is not regarded as a problem because alkalosis does not ensue. Esquivel et al.[17] compared exercise with voluntary hyperventilation in a group of 12 children with absence epilepsy undergoing EEG monitoring. They found a decrease in the number of absence attacks during the physical exercise and an increase during hyperventilation. Plasma pH was also measured and showed a positive correlation with seizure frequency. In general, therefore, it is felt that moderate exercise is good for epilepsy control. In some individuals, however, seizures are clearly induced by exercise[67,74] but not necessarily by voluntary hyperventilation. The mechanisms of seizure induction in these cases are unclear, nor is it known why some people have seizures during the “let-down” period after physical exercise. Careful history taking, possibly with EEG monitoring during exercise, will be required to give the patient appropriate advice about exercise.

Peripheral physiologic effects of hyperventilation may be as important to the epileptologist as are central effects. Respiratory alkalosis reduces the proportion of ionized calcium in the blood and causes tetany. Peripheral neuromuscular manifestations, short of tetany, include paresthesia, weakness, and muscular cramps. These symptoms and signs may be misdiagnosed as a seizure by the unwary. Nonspecific ST- and T-wave changes will be provoked on the ECG, causing confusion to the cardiologist reviewing an ECG in the absence of careful history taking and observation, especially because an increased pulse rate and palpitations are common autonomic concomitants of hyperventilation, along with epigastric distress and swallowing difficulties.

Finally, hyperventilation is a frequent procedure used to elicit suspected PNES during the course of a diagnostic video-EEG. In fact, the use of hyperventilation and photic stimulation is favored over other induction techniques (e.g., intravenous saline infusions). Given that hyperventilation can induce epileptic seizures and PNES, the diagnosis should not be based solely on clinical observations, but must also be documented with concurrent EEG recordings (see also Chapters 74 and 282).

Summary and Conclusions

Panic disorders and HVS are common conditions that are misdiagnosed as epileptic seizures. A careful history is very often sufficient to reach a correct diagnosis, although in some instances a recording of the paroxysmal episodes with video-EEG may be necessary. Some patients may experience epileptic seizures and panic disorder and/or HVS, and, hence, the presence of one condition should not automatically exclude the other(s). As with any other neurologic or psychiatric disorder, treatment of paroxysmal episodes presenting as panic attacks or recurrent episodes of hyperventilation should be based on robust diagnostic evidence.

Chapter 286

Obsessive-compulsive Behavior

Mark S. George

Marco Mula

Introduction

The neuropsychiatric syndrome of obsessive-compulsive disorder (OCD) was discovered and described >150 years ago. Unfortunately, for many years, OCD was thought to be rare, untreatable, and result from hidden conflicts. All of these notions now appear to be mistaken. Occurring in about 2% of all adults, OCD consists of recurrent intrusive thoughts (obsessions), senseless repetitive actions (compulsions), or both. Although the etiology of OCD is unclear, recent neuroimaging studies and cases of secondary OCD implicate the basal ganglia, cingulate gyrus, and orbital and prefrontal cortex as crucial structures in the pathogenesis of OCD. A true cure for this disorder is elusive. However, OCD symptoms partially respond to treatment with antidepressants, especially selective serotonin reuptake inhibitors (SSRIs),[10,17,25,28,44] and, among tricyclics, clomipramine,[40] and behavioral therapy is effective for some patients in stopping rituals and compulsions.[11] Once thought to be the quintessential psychoanalytic disorder, OCD is now viewed as a largely biologic illness arising from abnormal brain function.

In this chapter, we discuss interesting new findings in OCD, paying particular attention to how OCD patients might be distinguished from patients with epilepsy. The symptoms of senseless repetitive actions (compulsions) or recurrent intrusive thoughts (obsessions) on some occasions might resemble the automatisms that occur with complex partial seizures arising from the temporal or frontal lobes. To make a proper differential diagnosis, the practicing epileptologist must be familiar with both primary OCD and other disorders that might have obsessive-compulsive behaviors (OCB) as part of their presenting symptomatology.

Clinical Presentation

Obsessive-compulsive Disorder

Primary OCD, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV),[2] consists of recurrent urges to perform an action (compulsions) or recurrent intrusive thoughts (obsessions), or both. Furthermore, for the symptoms to qualify as true OCD, the compulsions or obsessions must cause significant dysfunction, be recognized by the sufferer as coming from his or her mind (not externally planted), and be egodystonic (i.e., unpleasant and not pleasurable).

An important clinical point is that the obsessions in OCD must be recognized by the individual as senseless, at least at some point in the disorder. A patient with OCD realizes that his or her compulsions do not result from mind control or from some other form of thought insertion, such as might be seen in schizophrenia. Because the obsessions are unpleasant and often of a violent or sexual nature, OCD sufferers attempt to ignore, control, or suppress the obsessions, often with a compulsion. For example, a husband with an obsessional worry about harming his new bride might be forced or compelled to repeatedly check on her welfare to assure himself that he has not harmed her. To summarize, obsessions are recurrent, persistent, resisted by the individual, and unpleasant. Often, obsessions center on certain themes such as contamination, aggressive thoughts concerning harming others or oneself, the need for symmetry or exactness, excessive somatic worries such as about AIDS or terminal cancer, and sexual or religious worries. A common feature of OCD is pathologic doubt and the person's inability to convince himself or herself that he or she has made a correct decision or that the environment is safe.

In contrast, compulsions are repetitive, purposeful, intentional actions sometimes performed in response to an obsession. It is important that the person recognizes or has recognized the senselessness of the actions. Performing the behavior often reduces anxiety. If an OCD sufferer resists performing a compulsion, invariably inner tension mounts until the compulsion is yielded to and the tension disappears. Common compulsions include checking, cleaning, ordering, counting, repeating, and hoarding. The DSM-IV has placed qualifying criteria on compulsions, which must be distressing to the individual, time consuming (>1 hour/d), and cause impairment in function. The phenomenology of obsessions and compulsions varies, depending on whether a person has pure OCD, OCD accompanied by motor tics, or OCD with motor and vocal tics [a disorder known as *Gilles de la Tourette syndrome* (GTS)].[15,21] For example, OCD/GTS subjects have increased touching compulsions and only rarely have washing compulsions—the most common compulsion in pure OCD.

Most cases of OCD begin in middle to late adolescence. The course can vary from chronic and unremitting to a more episodic illness featuring episodes of remission and relapse. Obsessive-compulsive behavior was, until the last few decades, thought to be rare; however, the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area Survey revealed a U.S. prevalence of 2% to 3%.[26,46] Obsessive-compulsive behavior is also often accompanied by other psychiatric disorders. For example, one study found that 30% of OCD patients suffered from a major depressive episode, 27% had simple phobias, 14% had panic disorder, 9% had agoraphobia, and 5% had GTS. The exact gene or genes for OCD and its pattern of transmission are unknown. However, Pauls et al.[41,42,43] established that OCD is linked to GTS and chronic motor tics. OCD in GTS seems to respond in a similar fashion as primary OCD to drug treatment with SSRIs and behavioral therapy.[16,48]

P.2838

Obsessive-compulsive Disorder Spectrum

In addition to pure OCD as defined earlier, there are many OCD-related disorders that some have labeled an *OCD spectrum*. This spectrum includes a collection of disorders or behaviors that resemble OCD in some way and often respond to treatment with antiobsessional agents. Dysmorphophobia is the fixed idea that a part of one's anatomy is disfigured or wrongly proportioned.[20] Trichotillomania is the compulsive pulling of one's hair, often seen in young to middle-aged women.[1,53] There is interesting research into the relationships between the eating disorders, particularly anorexia nervosa, and OCD. In addition, some obsessions involve sexual themes, and some forms of fetishism respond to treatment with serotonin-reuptake inhibitors.[56] Similarly, some obsessions involve violent, aggressive themes, and new research has shown that periodic impulse dyscontrol disorders respond to treatment (or, paradoxically, can be made worse by) serotonin-reuptake inhibitors.[8,35,37]

The Neuroanatomy of Obsessive-compulsive Behavior—Results of Neuroimaging Studies in Obsessive-compulsive Disorder

Structural studies of OCD subjects have yielded inconsistent but intriguing results. Luxenberg et al. in 1988,[33] using computed tomography (CT) scans, found decreased volume of the caudate heads in OCD subjects compared with controls. Follow-up studies by Garber et al.[12] and Kellner et al.,[27] however, using more sophisticated magnetic resonance imaging (MRI), failed to confirm these initial findings.

With regard to functional neuroimaging studies [positron emission tomography (PET), single photon emission computed tomography (SPECT)], a fairly consistent picture emerges. Numerous studies conducted in different centers with both PET[3,4,5,6,34,39,50,54] and SPECT[19] have consistently found *abnormalities in the orbitofrontal white matter and basal ganglia that change with pharmacologic or behavioral treatment.* This is one of the more consistent and remarkable findings in the recent history of biologic psychiatry and serves as the foundation for the ongoing revolution in understanding OCD.

It is important to realize that the differences noted in OCD are always found only on comparing group means. Unfortunately, we lack the ability to diagnose OCD on an individual basis using PET or SPECT. In addition, for almost all patients studied, as their OCD symptoms improve with either pharmacologic or behavioral treatment, the brain metabolism also changes to a more "normal" pattern.[19] The changes in brain metabolism thus appear to mirror the clinical improvement.

Recently, using oxygen PET and then in a later study with fast MRI, Rauch et al.[47] imaged regional brain activity in OCD patients before and during symptom provocation. Compared with before they are exposed to a provoking stimulus (such as a dirty rag for someone with a cleaning compulsion), OCD patients, when actively obsessing, show greatly increased activity in the right orbitofrontal lobe. At the NIMH, Greenberg et al.[18] attempted to expand on these studies and used noninvasive, repeated transcranial magnetic stimulation (rTMS) over the dorsolateral prefrontal cortex in an attempt to influence OC symptomatology. Results in OCD patients have been mixed with this promising technique of probing brain function.

Putative Neuroanatomic Model

These imaging studies begin to outline a tentative neuroanatomic model of primary OCD. This model may, in turn, help us to understand and organize the secondary causes of OCB. The circuit involved links the orbitofrontal region with the caudate nucleus, which projects to the globus pallidus, which then sends inhibitory fibers to the thalamus. The thalamus then sends excitatory fibers back to the prefrontal cortex, forming a closed loop. The final common pathway for OCD symptoms results from increased thalamofrontal activity. This fronto-caudate-pallidal-thalamo-frontal loop explains most of the cases of secondary OCD. According to this model, irritative lesions (e.g., epilepsy) of the frontal cortex or cingulate gyrus might produce OCD symptoms. Similarly, destructive lesions of the basal ganglia would also be predicted to worsen OCD symptoms by releasing the brake on the thalamus.

Table 1 Differential diagnosis of obsessive-compulsive behavior

Primary or idiopathic obsessive–compulsive disorder
Gilles de la Tourette syndrome[15]
Sydenham chorea[52]
Postencephalitic Parkinsons disease[24]
Stimulant abuse (particularly amphetamines)[9]
Tumors and infarctions of the orbitofrontal lobe [55,57]
Multiple sclerosis[13]
Following closed-head injury with damage to prefrontal, cingulate, or basal ganglia[36]
Manganese toxicity[38]
Epilepsy[32,56]

Differential Diagnosis

Primary or idiopathic OCD is, by definition, not associated with any known gross structural brain pathology. Obsessions or compulsions can, nevertheless, sometimes arise in other conditions or diseases that affect the critical brain regions just outlined (see Table 1) (for review, see George et al.[14]). When evaluating a patient with repetitive senseless actions, it is important to exclude obsessions or compulsions that may arise due to Sydenham chorea,[52] vascular or toxic basal ganglia lesions,[31,32,36,38,45,51,55,57] postencephalitic Parkinson disease (Von Economo encephalitis—encephalitis lethargica),[23,24,49] and central nervous system stimulant use.[9,29] Most of these disorders involve the *prefrontal lobes*, the *cingulate gyrus*, or the *basal ganglia*. These are the same regions that behave abnormally in recent neuroimaging studies of primary OCD subjects.

Properly evaluating the symptom of repetitive behavior can be a diagnostic challenge. Table 2 is an aid in determining whether the behavior is due to OCD or to localization-related epilepsy.

Patients with seizure discharges in the prefrontal or cingulate gyrus can present with OC symptoms. Ward described three patients with no past psychiatric or neurologic history who reported the new onset of the "feeling of compulsion" with no associated movement.[56] A 59-year-old woman suddenly developed an urge to walk to the left that she could not resist. Several weeks later, she developed a mild left hemiparesis. The electroencephalogram (EEG) showed a focal abnormality in the right frontal region, and CT scan revealed a *right frontoparietal glioblastoma*. A 43-year-old man experienced eight episodes over 2 months of a strong urge to shake his right arm, sometimes accompanied by an urge to shout, blurry

P.2839

vision, or spatial disorientation. He later developed speech arrest and right arm weakness. EEG abnormalities were found in the left frontal and temporal areas, and a CT scan revealed a *left frontal glioblastoma*. Finally, a 62-year-old woman suddenly developed episodes in which she had the urge to shake her right arm, sometimes accompanied by an expressive dysphasia. An EEG showed left temporal slowing but no definite discharges or spikes. A CT scan showed *small lacunar infarcts in the right superior cerebellar peduncle and the left basal ganglia*. Kroll and Drummond[30] reported an interesting case of a 26-year-old man with a 6-year history of bizarre behavior who had been diagnosed as paranoid schizophrenic and was refractory to standard neuroleptic treatment. He had staring episodes, along with left shoulder and arm twitching. During these episodes, he described his thoughts as muddled or blocked, with increases in anxiety and obsessive thoughts, sometimes with an associated smell of sulfur. He had obsessive, intrusive thoughts about harming his mother, women, and babies. His neurologic exam and MRI scan were normal. An unmedicated EEG showed irregular activity at 5 to 7 Hz and focal slowing in the left temporal area. A presumptive diagnosis of *left-sided complex partial seizures* was made, and he was successfully treated with carbamazepine with resolution of the spells and obsessive thoughts.

Table 2 Differential diagnosis of obsessive-compulsive behavior (OCB): primary obsessive-compulsive disorder (OCD) versus OCB related to focal epilepsy

	Primary OCD	OCB related to focal epilepsy
History	Chronic, remitting	Acute onset
Family history of OCD	+	–
Other OCD symptoms	+	–

Accompanying mental state	Clear, totally aware	Cloudy, +/- amnestic
Aware of senselessness of action	+	–
Clinical tests		
Neuropsychological tests	++	
Electroancephalogram	–	Slowing, localized discharge[a]
Single photon emission camputed tomography	–	Abnormal[a]
Serum prolactin	–	Increased[a]
Magnetic resonance imaging	–	Possible mesial temporal sclerosis
Clinical neurologic exam	Normal	Possible localization-related signs

[a]These may often be normal as well in patients with epilepsy.[2]

These cases illustrate that obsessive-compulsive behaviors may arise in the setting of localization-related epilepsy, although this is rare. In all of the reported cases of OCB arising in the setting of epilepsy, key points in the history or physical or clinical investigations point toward the proper diagnosis and away from primary OCD. Thus, in contrast to primary OCD, localization-related seizures with OCB usually have an abrupt onset with no other associated OC behaviors and a negative family history for OCD. Often, focal seizures with OCB are found in someone with a clouded mental state who exhibits other behaviors that are not found in OCD (motor or sensory changes, smells, etc.). In almost all cases, the EEG or brain imaging studies were abnormal. EEG changes are not commonly seen in primary OCD,[22] and, as reviewed earlier, brain imaging studies in individual patients are normal. If the diagnosis remains unclear even after a thorough history, physical examination, and clinical workup, a treatment trial with an anticonvulsant may be in order. In general, anticonvulsants have not been found to be effective in primary OCD.

Investigations

There is no definitive clinical test for primary OCD. Thus, it is quite important to perform a thorough history and physical examination and to use the appropriate diagnostic tests to exclude the other diseases in the clinical differential (Table 1). To distinguish primary OCD from localization-related seizures with OCB, one would likely perform an MRI scan of the head, as well as an EEG (Table 2). Neuropsychological testing does not distinguish between idiopathic OCD and OCB in epilepsy because it is similar in both cases, showing a specific frontal-subcortical dysfunction.[7] If the diagnosis is still unclear, one could possibly obtain a serum prolactin after an OC event (probably elevated in epilepsy, normal in OCD) or even a SPECT scan (focally abnormal in seizures).

Summary and Conclusions

Recurrent obsessions and compulsions arise in a variety of clinical disorders that affect key brain regions (the cingulate, frontal and temporal lobes, and basal ganglia). Localization-related epilepsy is an infrequent cause of obsessions or compulsions. Much more commonly, OCB is due to primary OCD, although other neurologic illnesses must be excluded. In most cases of a patient presenting with obsessions or compulsions, a thorough history, physical exam, and associated diagnostic tests will lead to the proper diagnosis and treatment.

Chapter 287

Nonaffective Psychoses, Schizophrenia, and Schizophrenia-like Psychoses

Michael R. Trimble

Bettina Schmitz

Introduction

In this chapter, in contrast to Chapter 204, we consider the clinical occasions in which some of the symptoms of schizophrenia may be mistaken for those of epilepsy. In reality, there are very few situations in which this arises, and when they do, there are usually obvious causes for the confusion. We do not discuss the clinical phenomenology, investigations, and treatment of schizophrenia per se, and refer the interested reader to Chapter 270 by Jadresic in the first edition of this work.[9a]

In contrast to disorders of affect, psychotic states, although they imply a severe disturbance of neurologic function, are less frequently encountered than disturbances of mood in neurologic practice. There are many reasons for this, not the least being that many people with neurologic disorders and reduced quality of life experience depression as a consequence, and, in general, a number of neurologic disorders influence areas of the brain that are linked to the regulation of mood, emphasizing the frontal-striatal axis.

The brain must allow the individual to interpret the world in which he or she lives in an orderly manner so that he or she can behave in a logical and adaptive way. The symptoms of psychosis, however, such as hallucinations and delusions, suggest deviant neurologic processing, and underlying this will be disturbances of neurologic function, often secondary to structural disease. The close association between some neurologic disorders and psychoses suggests neurochemical and or neuroanatomic bases for the abnormal mental states, for example, the psychoses associated with Parkinson disease and l-dopa therapies. There are biologic underpinnings to the psychotic disorders of epilepsy, and these are discussed in Chapter 204. It is interesting that, as noted, the discussions revolve around similar anatomic deviations as in schizophrenia in the absence of epilepsy and involve medial temporal structures, the amygdala and hippocampus in particular, and their efferent projections.[17]

Terminology

The term *psychosis* generally refers to a condition in which there are hallucinations and delusions associated with abnormalities in behavior such as excitement and overactivity or psychomotor retardation, or catatonia, in which insight is diminished or lost.

A *hallucination* is a perception in the absence of an adequate sensory stimulus, and it must be distinguished from an *illusion*, which is due to a misinterpretation of perceptions. *Pseudo-hallucinations* are hallucinatory experiences that occur in subjective rather than objective space, are less clearly delineated, and thus lack the objectivity of hallucinations proper. The latter have concrete reality and are linked to a lack of insight into their nature.

Delusions are unshakable convictions that are manifestly incorrect. They have to be interpreted within the patients' cultural setting, but it is the tenacity with which patients hold onto their beliefs against all logic that inevitably reveals the delusion. They need to be distinguished from overvalued ideas, which are strongly held beliefs that are not incorrigible.

Delusions are the hallmark of a paranoid illness and occur in a spectrum of psychiatric disorders, including schizophrenia. In the affective disorders, they are characteristically mood congruent, whereas mood-incongruent delusions are typical for schizophrenia. In the *Capgras syndrome*, a significant person in the patient's life is replaced by a supposed identical double, and in the *Fregoli syndrome*, a supposed persecutor can change his or her appearance and appear as other people. These are referred to as *misidentification syndromes*.

Hallucinations that occur in clear consciousness for which there is no insight and that are mood incongruent are very suggestive of schizophrenia. In this condition, they are usually auditory, although patients may experience them in any modality. Specific auditory hallucinations noted in association with schizophrenia are referred to as being among the Schneiderian first-rank symptoms. These are listed in Table 1. When present in clear consciousness, they usually signify schizophrenia, although this is not diagnostic because they are sometimes noted in other psychotic disorders—for example, in mania. Furthermore, the diagnosis of schizophrenia can be made in their absence based on history and other observed abnormal behavior.

Olfactory hallucinations are reported in schizophrenia and in simple partial seizures of the uncinate variety. In epilepsy, these experiences are typically brief, unpleasant, hard to characterize, and consistent in their phenomenology. In schizophrenia, they are much more variable and may last for considerable periods of time, and they are usually accompanied by a delusional interpretation. In coenesthetic hallucinations, the body or part of the body feels altered or distorted, often in quite fantastic ways. Although often reported in schizophrenia, they may occur in migraine or following cerebrovascular accidents.

A characteristic feature of schizophrenia is alteration of thought and language. This may vary from a subtle flattening of the expression and concrete thinking to a florid schizaphasia. In the latter, neologisms (paraphasias) emerge, there are loose connections between thoughts and tangential thinking, and intrusive delusional content can lead to a veritable "word salad."

Table 1 The First-Rank Symptoms of Schneider[a]

Thought withdrawal
Thought broadcasting
Hearing one's thoughts spoken aloud
Hearing voices arguing about or discussing one
Hearing voices comment on one's actions
Delusional perception[b]
Experiencing bodily sensations as if imposed from outside

Experiencing affects as if imposed and controlled from outside

Experiencing impulses as if imposed and controlled from outside

Experiencing motor actions as if imposed and controlled from outside

[a]These are not diagnostic of anything, but when present in the setting of clear consciousness, support a diagnosis of schizophrenia.
[b]Abnormal significance is attached to a real perception without any logical explanation.

Paroxysmal Symptoms in Schizophrenia

The diagnosis of schizophrenia is usually not difficult to make in the advanced case, especially with knowledge of the patient's history. However, by the time the patient has revealed his or her aberrant behavior and psychotic thinking, the underlying disorder will be well advanced. There is often evidence of difficult and unusual behavior going back to childhood, with comments about the person being different, a loner, and the like, and perhaps using unusual language or manifesting unusual thought processes for several years. A family history may be revealed (but is often concealed), and typically academic decline becomes apparent in the teenage years, often blamed on either stress or illicit drug taking.

Such cases usually first go to a psychiatrist for diagnostic evaluation, and if the diagnosis is clear, these patients may remain under psychiatric care for many years. In the early, uncertain stages of the disorder, however, patients with a developing schizophrenia may be referred to a neurologist, but usually on the grounds of academic failure and personality change, suggestive of a developing organic brain syndrome—the dementia praecox of Kraepelin. Such referrals, however, are not usually in reference to epilepsy.

The signs and symptoms of schizophrenia that are most likely to be confused with epilepsy are quite limited. They relate especially to the paroxysmal nature of the presentations and to the neurologic-soundingness of them. The signs are those of the motor disturbances of catatonia, and the symptoms are usually hallucinations, especially affecting the body image. Certain first-rank symptoms are also relevant, especially thought withdrawal and thought insertion.

Movement Disorders

The classic motor disorder of schizophrenia is catatonia, and for Kraepelin this deserved a separate nosologic category.[10] It seems that catatonic forms are much less apparent now than 100 years ago; one reason may be the effective intervention of psychotic disorders with neuroleptic drugs. The original descriptions of these movement abnormalities revealed a wide range of motoric instability, from tics and dyskinesias to frank dystonia. Stereotypies, echophenomena, mannerisms, and special signs such as automatic obedience and negativism were reported, and such abnormal movements were thought to be integral to the condition. This was before the introduction of neuroleptic drugs and the later widespread reporting of tardive motor syndromes. It is estimated that around 50% of untreated schizophrenics display such motor abnormalities.[11,12]

Cutting referred to catatonia as follows[6]:

> Catatonia is the generic name for about eight separate disorders of movement and posture, which have in common a tendency to be intermittent, to defy classification as disorders of power, tone, co-ordination, praxis or involuntary movement, and in a general sense to involve the surrender of the affected person's will. (p. 277)

The paradigmatic picture is of immobility, and the classic picture of catatonia with unresponsiveness and postures held sometimes for hours, which may reveal a waxy flexibility, was often illustrated in early pictures and film clips of schizophrenia. However, this represents only a part of the catatonic spectrum. More relevant for the diagnostic issues of epilepsy are the sudden episodes of catatonic excitement. These can vary from brief to longer disruptions of behavior (seconds to hours), in which the patient suddenly becomes overactive with hyperkinesis, even violent, as if being strung from their motoric slumber by the sudden onset of a seizure. These episodes seem free from environmental or emotional precipitants, and after the period of overexcitement, there is a resumption of the status quo.

Other abnormal movements that may occasionally lead to diagnostic confusion are tics. These will only very rarely be myoclonic in form, however, and are much more often brief but repetitive, associated with other behavior changes of the type noted earlier such as in habits and mannerisms.

After noting that patients may have seizures (and in his time epileptic seizures were reported quite often in schizophrenia, presumably because of the number of secondary forms he was witnessing from, e.g., encephalitis and syphilis), Kraepelin continued[10]:

> There are spasms in single muscle groups (face, arm), tetany or even apoplectic seizures with paralysis which last for a considerable time…. In a whole series of patients (6% of the men and 3% of the women) spasms and fainting fits occurred previously in youth…. The spasmodic phenomena in the musculature of the face and of speech… resemble movements of expression, wrinkling of the forehead, distortion of the corners of the mouth, irregular movements of the tongues and lips, twisting of the eyes, opening them wide and shutting them tight. (p. 83) The patient who has been senselessly excited may suddenly become mute and motionless; the patient who has been stuporous, perhaps for weeks, abruptly begins to utter unintelligible screams… or he leaps with long bounds through the room… and then remains again inaccessible, or possibly even passes through a longer period of excitement. (p. 148)

These paroxysmal bursts of abnormal behavior, which were so well described in the past, are much rarer today, and are not recognized by a generation of psychiatrists and neurologists poorly versed in the intricacies of phenomenologic psychiatry. When they do occur, they often lead to a question of an underlying seizure disorder and a request for neurologic evaluation. It is then not uncommon to ask for an electroencephalogram (EEG), which may then be reported as abnormal, raising further the suspicion of epilepsy (see later discussion).

A good history will confirm the diagnosis of schizophrenia, but a clear description of the abnormal behavior from a nurse, physician, or caregiver can be revealing by fairly quickly establishing that the paroxysms are simply not like epileptic seizures in their semiology. There is no clear seizure as such, no alteration or loss of consciousness, and no repetition of the progression of the attack with each recurrence as there is with epileptic seizures. The earlier history is that of schizophrenia, as outlined previously, and not that of epilepsy. In fact, careful questions about attacks resembling complex partial or secondary

generalized seizures note an absence of such a background: There are no febrile convulsions, no clear episodes of loss of consciousness, and no suggestions of a localizing neurologic sign.

Further questioning will reveal the diagnosis; it is the company that such symptoms keep that is relevant. There will be ongoing delusions, a failure of the patient to explain or even describe his or her attacks, and a lack of insight.

Hallucinations

Hallucinations may be in any modality, but the coenesthetic and olfactory ones are the most likely to cause diagnostic confusion. Olfactory hallucinations are reported in patients with simple partial seizures and very rarely as the sole manifestation of the seizure. No more than about 7% to 10% of patients with temporal lobe epilepsy, however, report olfactory hallucinations,[4] and the classification of the seizure is often referred to as an uncinate seizure. In reality, the site of origin of the episode may be in the hippocampal uncinate, but it may arise from elsewhere, such as the insula. The experience, however, is vivid, repeated, unpleasant, and evanescent. It is not usually accompanied by an abnormal taste, but the latter is not perhaps unexpected. In clinical practice, the question is often put to a patient, “Do you have any unusual tastes or smells that accompany your attacks?” The answer is often given in the affirmative, and such replies as “a metallic taste” or a variant of that are given. This is recorded in the patient's notes as an uncinate event, in spite of the fact that it is nothing like the descriptions of patients with epilepsy with established smell auras. Such fleeting metallic tastes and other variant smells are commonly reported in patients who are then misdiagnosed as having epilepsy and are later rediagnosed as nonepileptic.

In a similar way, the smell hallucinations in schizophrenia may be misinterpreted. These are the third-most-common form of hallucination reported in schizophrenia (after auditory and visual ones), but gustatory hallucinations are less frequent. Cutting[5] gave a figure of 6% reporting of olfactory hallucinations in schizophrenia. The latter are rather diffuse; sometimes good and sometimes bad; may be flitting or lasting in an individual patient; and are often characterized, unlike those of the uncinate seizures, which are hard to specify and describe. The schizophrenic smells himself or herself, others, food, or evidence of good or evil, whereas the patient with epilepsy refers to unpleasant smells as unpleasant, perhaps like burning rubber. As with the aberrant motoric behaviors described earlier, further questioning will reveal the psychotic attachments to the smell experience, and the underling schizophrenic disorder.

Coenesthetic hallucinations relate to disturbances of the body and the body image. For probable historical reasons, they are poorly discussed in English-language texts on psychopathology, but they have attracted much more attention on the European continent. Fleeting sensory disturbances, shots of pain, pulling, squeezing, twisting, and the like of the body or parts of the body are described, and their paroxysmal nature gives rise to the suspicion of a simple partial seizure. Many physicians are unaware of the relative frequency of such hallucinations, tending to identify only visual and auditory events with hallucinations proper. Corporeal sensations are common in schizophrenia, however, and like olfactory hallucinations, have a different quality from the equivalent epileptic event. They are usually unpleasant or painful, and may be sexual. They last for varying lengths of time and vary with each description. They come and go over time, without the stereotyped nature of the experiences of a simple partial seizure. Again, a few questions will reveal the attached delusional thinking.

Formal thought disorder refers to patterns of thinking seen in schizophrenia and other psychoses, central to which is disorganization and concretization of thought. Such terms as fusion, derailment, lack of association, and interpenetration of thoughts are self-explanatory, however these are revealed by the patients during history taking, and would not relate to any diagnostic confusion with epilepsy.

The three symptoms that are sometimes confused are thought insertion, in which ideas or words are interpenetrated into the patient's mind; thought blocking; and thought withdrawal. In the latter two, patients claim that their thoughts are being interfered with by some outside agency, with sudden stoppages to the flow of the thoughts. The patient suddenly ceases to speak, his or her line of thought is interrupted, and he or she may momentarily appear blank or confused. The paroxysmal and brief nature of this may make it seem like an epileptic seizure, and the episodes can be frequently repeated, but clinical perception soon reveals the psychotic form underlying these events.

Electroencephalographic Findings in Schizophrenia

Hill[7] reviewed the results of early EEG findings of abnormalities in schizophrenia. Schizophrenic patients typically exhibit low-amplitude irregular EEGs, described as “choppy,”[7] and numerous qualitative studies indicate abnormal conventional EEG findings in 20% to 60% of schizophrenic patients. The abnormalities described in schizophrenia included left-sided slow-wave asymmetries, especially at the left anterior temporal area and occasionally involving the left frontal and parietal areas, slow bursts, and spikes or sharp waves.[13,14] Stevens et al.[15] showed by 24-hour telemetry recordings that temporal EEG abnormalities occur in 30% of schizophrenic patients. Schizophrenic patients with EEG abnormalities that appeared either before or during neuroleptic treatment had more evidence of brain dysfunction than did patients without such EEG abnormalities.

Considerable attention has been devoted to the hypothesis that schizophrenia is primarily associated with dominant hemispheric dysfunction. Abrahams and Taylor[1] showed that schizophrenic patients had twice as many, mostly left-sided, temporal abnormalities compared to patients with affective disorders, who have more right-sided EEG findings.

A recent study by Inui et al.[9] looked into electroencephalographic abnormalities in 143 patients whose discharge diagnoses met the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition,[2] criteria for mood disorder, schizophrenia, and other psychotic disorders. The study revealed that the frequency of epileptiform variants, including the phantom spike and wave, positive spikes, and small sharp spikes, was significantly higher among patients with mood-incongruent psychotic mood disorder (33%), schizoaffective disorder (33%), and schizophreniform disorder (30%) as compared with patients with nonpsychotic mood disorder (3.2%) and schizophrenia (0%). The results implied that patients with "atypical" psychoses, which are located between typical mood disorder and schizophrenia, might have a biologic vulnerability to seizures, as represented by these epileptiform EEG variants. These associations also pose diagnostic challenges, however, because patients with atypical presentations are the ones most likely to lead to diagnostic confusion.

Structural Abnormalities

Another potential source of confusion arises in cases in which a patient with schizophrenia has some paroxysmal behavior

disorder and, in addition to the EEG, a brain scan is performed. It has been known for a long time that schizophrenia is associated with changes on scans, both computed tomography and magnetic resonance imaging, the main findings being ventricular dilation and tissue loss, including loss of hippocampal neurons. Thus, some dilation of the temporal horns of the lateral ventricles may be noted, with decreased temporal lobe volume, increasing the suspicion that the case may be one of epilepsy.[16] This rarely relates to a hippocampal sclerosis, however, and in fact one of the consistent differences in the neuropathology of temporal lobe epilepsy in comparison to schizophrenia is the absence of gliosis in the schizophrenic hippocampus. Nonetheless, cases of hippocampal sclerosis are rarely described in patients with schizophrenia who do not have overt epileptic seizures, and the links between the sclerosis and the subsequent psychosis are unclear.

Comorbidity of Epilepsy and Psychosis Due to a Common Underlying Condition

There are a number of disorders in which epilepsy and psychosis both develop secondary to an underlying usually progressive neurologic disorder. The causes are legion although each individual disorder itself is quite rare. The reader is referred to Cummings and Mega[3] for an extended list of neurologic disorders that can be linked to the development of schizophrenia-like states, but most are not also linked to epilepsy. However, encephalitides, some storage disorders, endocrine disorders such as hypoparathyroidism, and inflammatory conditions such as systemic lupus erythematosis may all occasionally cause diagnostic confusion as to whether the developing psychosis is somehow linked to an underlying epilepsy, although the progressive nature of the disease will likely soon be revealed.

Summary and Conclusions

In clinical practice, schizophrenia is not often confused with epilepsy, but the reasons that this sometimes does occur are clear. Many physicians who manage epilepsy are unfamiliar with the polymorphous presentations of schizophrenia and are unaware of the paroxysmal nature of many of the symptoms, especially the motor disorders. Further confusion may arise with misinterpretations of the EEG and, occasionally, any brain imaging. Careful clinical evaluation should resolve diagnostic confusion, however, although neuropsychiatric evaluation will most likely be essential to this endeavor.

Chapter 288

Overview: Delivery of Health Care and Socioeconomic Issues

Robert J. Gumnit

Josemir W. Sander

Simon D. Shorvon

Introduction

As medical care becomes more sophisticated and thus more expensive, people and governments find that they must make difficult choices about where money earmarked for health will be spent. The expectations for care of people may vary from country to country and from culture to culture, although the desire for good treatment and cure will not. The duties of a conventional health care delivery system in relation to epilepsy, regardless of location, are similar (Table 1). The means to deliver care and the way it is organized, however, differ from country to country.

This section explores the ways in which different countries seek to meet the health needs of people with epilepsy. Before beginning a country-by-country survey, it is worthwhile defining, as far as possible, the general issues that each country must face. This section also reviews the socioeconomic issues that confront epilepsy care. Full socioeconomic appraisals of different epilepsy treatments and health delivery have not been undertaken, and therefore there are many remaining questions in this area.

Levels of Care

Primary Care

Primary care is defined as the care given by the first physician whom the patient ordinarily consults. The primary care physician is expected to possess some knowledge of a broad range of medical problems. Primary care physicians provide excellent care for many medical conditions, especially common problems. It is more difficult, however, for a primary care physician to keep abreast of modern methods of diagnosis and treatment of diseases with a low incidence. For example, in the United States, the average primary care physician sees one new case of epilepsy every 2 years. In the United Kingdom, a general medical practitioner (GP) might expect to diagnose one or two new cases each year, as well as having a caseload of 8 to 12 people with active epilepsy. The responsibility for long-term prescribing for patients varies from country to country. In the United Kingdom, this is an important responsibility of primary care physicians, but in other settings it is usually devolved to secondary care providers.

The ratio of primary care physicians to specialty physicians varies widely from country to country and within countries, especially between urban and rural areas. This ratio affects national policy regarding the management of chronic disease of relatively low incidence. In some countries, primary care is provided by nurses, health visitors, and also by other health care workers. In some resource-poor countries, practitioners of traditional medicine may also play a role.

Secondary Care

Secondary care denotes the most common type of specialty care. A general surgeon, general internist (physician), pediatrician, and, in some parts of the world, a neurologist would be considered to provide secondary care. In some countries, the dividing line is not sharp; in the United States, a general internist may practice some primary care medicine. Nonetheless, the underlying concept is that the practice is limited to certain problems so as to allow for greater in-depth knowledge on the part of the physician. Even so, in secondary care, the range of problems dealt with is relatively broad.

Tertiary Care

Tertiary care is the most specialized level. In epilepsy care, physicians with a prior qualification in neurology usually provide this, although physicians from other specialties are often involved (notably neurosurgery, psychiatry, clinical neurophysiology, and internal medicine). In most countries, tertiary care is available in teaching or university settings.

Specialized Centers or Fourth-level Care

With the increasing complexity of medicine, a fourth level of specialized care is developing in many countries. Patients with complex forms of blood dyscrasias or who require bone marrow transplantation or heart, lung, or liver transplantation are examples of people who receive fourth-level care in highly specialized centers. Epilepsy is one of few chronic diseases for which highly specialized centers have developed, although these are usually restricted to developed countries, with only a few in resource-poor countries.

Table 1 The duties of a health care system in relation to epilepsy

1. Identification of people with the condition
2. Diagnostic evaluation
3. Choice of drug treatment at all stages of the condition
4. Initial management, reevaluation of patients who have not responded to the initial choice of therapy, and long-term management of the disease
5. Management of emergencies
6. Management of complications and secondary consequences of the condition
7. Delivery of preventive care

Organization of Health Care Systems

The organization of systems by which care is delivered varies widely from country to country and often even within countries. In most countries, a mix of systems is found. In some countries, however, practitioners no longer practice alone, and in other, particularly resource-poor countries, multispecialty clinics have not developed, again largely because of socioeconomic factors.

P.2846

Individual Practitioners

Classically, in the United States, physicians were in private practice, often alone in a solo practice. For reasons of convenience (sharing night calls) or expense (sharing overhead costs), groups of physicians began to practice together in a single office. In the United Kingdom, at the start of the National Health Service in 1948 many GPs were "single handed," but currently GPs are more likely to work in partnerships of three to six doctors.

Single-specialty Groups

All members of these groups of physicians are ordinarily engaged in a single specialty, for example, family practice or pediatrics. Groups of this sort are found in many parts of the world where there is a private system of medicine, but in the United Kingdom they are generally only found in the case of GP partnerships.

Polyclinics

The term *polyclinic* has different meanings in different countries. It is used here to mean a highly organized group of physicians, usually on a salaried basis, who provide a full range of services, from primary through specialized care. The degree of specialization, of course, varies widely.

Multispecialty Clinics

Much more commonly found in European countries and the United States, multispecialty clinics often do not include primary care physicians. Rather, aggregations or departments based on specialty are housed under an umbrella organization. In most parts of the world, these multispecialty clinics are organized about major hospital centers or universities.

Forms of Hospital-based Practice

There is great variability in the way that hospital-based care is provided throughout the world. In some countries, primary care physicians can admit patients directly to a hospital and decide whether to consult a specialist. In other places, only a specialist can admit a patient to a hospital where specialized care is available, and the primary care physician relinquishes control over the patient. In some countries, these hospital-based practices are essentially run by the government, either through a health authority or under the aegis of a university.

Socioeconomic Considerations

In most countries, health care delivery is often limited by financial considerations and the availability of resources. In each country, therefore, decisions are made about priorities. For instance, in resource-poor countries, the treatment of infection may be more of a priority than the treatment of chronic diseases.

A logical decision on health care provision may involve the most cost-effective treatment for any condition. The cost-effectiveness of delivery of epilepsy care in different systems, however, has not been carried out. For example, surgery is often viewed as a most cost-effective treatment for some forms of epilepsy, but little is known about its use and cost-effectiveness in resource-poor countries.

Government Versus Private Bureaucracy

As soon as medical care involves more than a single doctor, a bureaucratic structure begins to develop. When medical care involves many physicians and large support staffs, bureaucratic considerations become a primary issue. Decisions may be based on health care priorities or other political reasons. In democratic settings, there is at least some degree of accountability, but in many parts of the world, political decisions are made for personal or self-interested reasons. In some parts of the world, government is trusted and the decisions of government authorities respected, but in others, government is mistrusted and the decisions of government authorities are seen at best as a barrier and at worst as malevolent. These same themes exist whether the bureaucracy is part of government or is apparently of a private nature.

In most systems of health services, the allocation of resources becomes a political matter. In some cases, the politics involves the government and health ministers, whereas in other cases, it depend on relationships that exist within a private bureaucracy.

The major difference between public and private bureaucracies is that, in public bureaucracies, decisions are often influenced by broad governmental priorities, for example, the need to win the next election. In private bureaucracies, decisions are influenced usually by primarily financial considerations. Whether high-quality care and serving patients are primary goals varies from provider to provider.

These differences in care are seen in purest form in the private bureaucracies that run large health care systems in a capitalistic market economy, such as that of the United States. The large health service organizations in the United States struggle continuously to instill a customer-oriented attitude in their employees. Although to some extent this orientation toward customer service is altruistically motivated, for the most part it is motivated by the desire to increase market share and expand the business. To do so, the health service organization must offer a low price and, it is hoped, high value to the purchaser of the contract; it must also please the patient. The extent to which the patient can exercise free choice and take business from one group to another is the extent to which the patient can influence the quality of care provided.

Summary and Conclusions

In most areas of the world, care is provided in a tiered system. The ways in which the systems are funded and the funding available vary widely from country to country and particularly between industrialized and resource-poor countries. This section provides a snapshot of service provision for people with epilepsy in a number of countries as well as a brief review of the socioeconomic issues that affect epilepsy.

Chapter 289

Brazil

Carlos A. M. Guerreiro

Introduction

Brazil is a country of continental dimensions (8,511,965 km^2), divided into 26 states and a federal district. In 2004, its population was estimated to be 178.4 million inhabitants; life expectancy at birth (male/female), 66.0/73.0 years; gross domestic product (GDP) per capita (international $, 2002), U.S. $7,762; health life expectancy at birth (male/female), 57.2/62.4; child mortality (male/female) per 1,000, 39/32; adult mortality (male/female) per 1,000, 240/129; and total health expenditure per capita (international $, 2002), 611; and total health expenditure as percentage of GDP (2002), 7.9.[53] In October 2005 the estimated population was 184.7 million inhabitants.

Brazil has achieved dramatic results in improving living conditions: Infant mortality declined from around 50 per 1,000 live births in 1990 to 33 per 1,000 in 2000, and net enrollment in basic education rose from 84% in 1991 to 97% in 2002. Brazilians with access to an improved water source rose from 73% of the population in 1986 to 87% in 2001.

Despite Brazil's impressive advances, the poorest one fifth of Brazil's 184.7 million people account for only a 2.2% share of the national income. Brazil is second only to South Africa in a world ranking of income inequality. More than one quarter of the population live on <$2 a day and 13% live on <$1 a day. Brazil's northeast contains the single largest concentration of rural poverty in Latin America. Past development programs have failed to make a major dent in a region in which 49% of the population is classified as poor.

Crime is plaguing urban Brazil. Political corruption is also a serious problem in the country.

In global terms, Brazil rates 13th in economic strength and among the first group of countries in agricultural production.[54]

Information related to demographic, socioeconomic, and health indicators of the country is listed in Tables 1 and 2.[16,54]

General Data on the Health System

Some states in the country suffer more than others, particularly from some long-standing endemic diseases such as dengue, cholera, Chagas disease, schistosomiasis, and malaria. New diseases, such as AIDS, are also a growing problem.

The rate of reported AIDS cases increased from 10.6 per 100,000 in 1992 to a high of 18.7 per 100,000 in 1998. Brazil has experienced a stabilizing trend with rates of 16.5, 16.4, and 14.8 per 100,000 in 1999, 2000, and 2001, respectively. In the last decade, heterosexual transmission of reported AIDS cases grew from 25.8% in 1991 to 56.1% in 2002. Since 1998, the death rate from AIDS has stabilized at 6.3 per 100,000. This tendency is attributed to Brazil's guarantee of access to free antiretroviral drugs since 1996.

The country also rose to the challenge posed by the single biggest health threat in the modern world, pioneering an anti-HIV/AIDS strategy that became an international model by guaranteeing universal access to retroviral medication.[15]

Brazil has a constitution that states that health is the right of every citizen and the duty of the state to provide. A law was passed on September 19, 1990, creating the Unified Health System (Sistema Único de Saúde [SUS]). The SUS is composed of the health activities and services provided by municipal, state, and federal organizations and institutions. This same law assumed the coexistence of private medicine in its various forms.

Despite this legislation, a great number of problems remain. These range from the social policies practiced by the federal government to the management of responsibility at the different levels and the effective management of rendering services.

Although SUS theoretically offers total coverage to everyone, in reality, only 77% of the population is covered, according to an estimate that we have applied using data from the federal government from 1994 (from the Bulletin of Ministry of Economy, 1994). Of those not covered, 22% were unassisted, and another 55% received some assistance. The remaining 23% sought assistance from the private sector: Medical insurance, health maintenance organizations (HMOs), traditional fee-for-service providers, and others.

Large portions of citizens receiving private medical care eventually seek, or are directed to, public health services. This happens especially in cases of chronic or terminal diseases and those involving complex and costly procedures. In these cases, there is no reimbursement from the public sector.

Epilepsy Data

An epidemiologic study with a selected sample size of 17,293 individuals revealed that the cumulative prevalence of epilepsy in São José do Rio Preto, a 350,000-inhabitant city in São Paulo state, was 18.6 per 1,000 inhabitants with 8.2 being active, defined as at least one seizure within the last 2 years. The prevalence per 1,000 inhabitants for the age groups (years) was 4.9 (0 to 4), 11.7 (5 to 14), 20.3 (15 to 64), and 32.8 (65 or over).[12]

Table 1 Socioeconomic, Demographic, and Health Indicators Data about Brazil

	Most recent year	Data
Socioeconomic context		
Total population (000s)	2003	176,596
GNI per capita, Atlas method (U.S.$)	2003	2,760
Expected years of schooling	2002	15
Adult literacy rate (% of population ages 15+)	2003	88
Demographic indicators		
Average annual population growth rate (%)	1990–2003	1.4

Age dependency ratio (dependents as a proportion of working-age population)	2003	0.5
Total fertility rate (births per woman)	2003	2.1
Adolescent fertility rate (births per 1,000 women ages 15–19)	2003	68
Contraceptive prevalence rate (% of women ages 15–49), any method	1996	76.7
Health status indicators		
Life expectancy at birth (yr)	2003	69
Infant mortality rate (per 1,000 live births)	2003	33
Under 5 yr of age mortality rate (per 1,000)	2003	35
Maternal mortality ratio (per 100,000 live births), modeled estimates	2000	260
Prevalence of child malnutrition—underweight (% of children under age 5)	1996	6
Health care indicators		
Child immunization rate, measles (% of ages 12–23 months)	2003	99
Child immunization rate, DPT3 (% of ages 12–23 months)	2003	96
Births attended by skilled health staff (% of total)	1996	87.6

Very recent data from the Demonstration Project of Global Campaign Against Epilepsy, in Brazil, supported by the International League Against Epilepsy, the International Bureau for Epilepsy, and the World Health Organization, revealed that the prevalence of cumulative and active epilepsy, respectively, was 9.1 per 1,000 and 5.3 per 1,000 people in Campinas and São José do Rio Preto, both in São Paulo state.[40] The prevalence of active epilepsy was higher in the more deprived social classes (range from A = richest to E = poorest) in Campinas and in São José do Rio Preto (Class D + E = 7.4 vs. Class A = 1.6 per 1,000). Over one third of patients with active epilepsy had inadequate treatment, including 19% who were on no medication. These data illustrate the treatment gap in the area.[40] In another study based on data from the central municipal pharmacy of Campinas and São José do Rio Preto in 2003, it was estimated that in the best-case scenario, 50% of patients with epilepsy were not on medication on a regular basis.[41]

P.2850

Campinas and São José do Rio Preto are two cities located in one of the wealthier regions of Brazil, where there is a good public and private health care system and where the population has easy access to treatment.

Neurologists

Based on data furnished by a Novartis profile, 4,863 neurologists were identified in Brazil in 2005. This probably included clinical neurologists, pediatric neurologists, and some neurosurgeons who practice clinical neurology. According to the Brazilian Academy of Neurology, there are 1,197 members, and the Brazilian Epilepsy Society had 477 members in 2005. The distribution of the number of neurologists per 100,000 inhabitants in the different states is shown in FIGURE 1. An analysis of FIGURE 1 reveals a distinct relationship between the per capita income of the state and the number of accessible neurologists. The higher-income areas have more neurologists,

P.2851

P.2852

as in the case of the Federal District and the states of Rio de Janeiro, São Paulo, and Rio Grande do Sul. The latter state's rates are close to those of the northeastern states in the United States.[38]

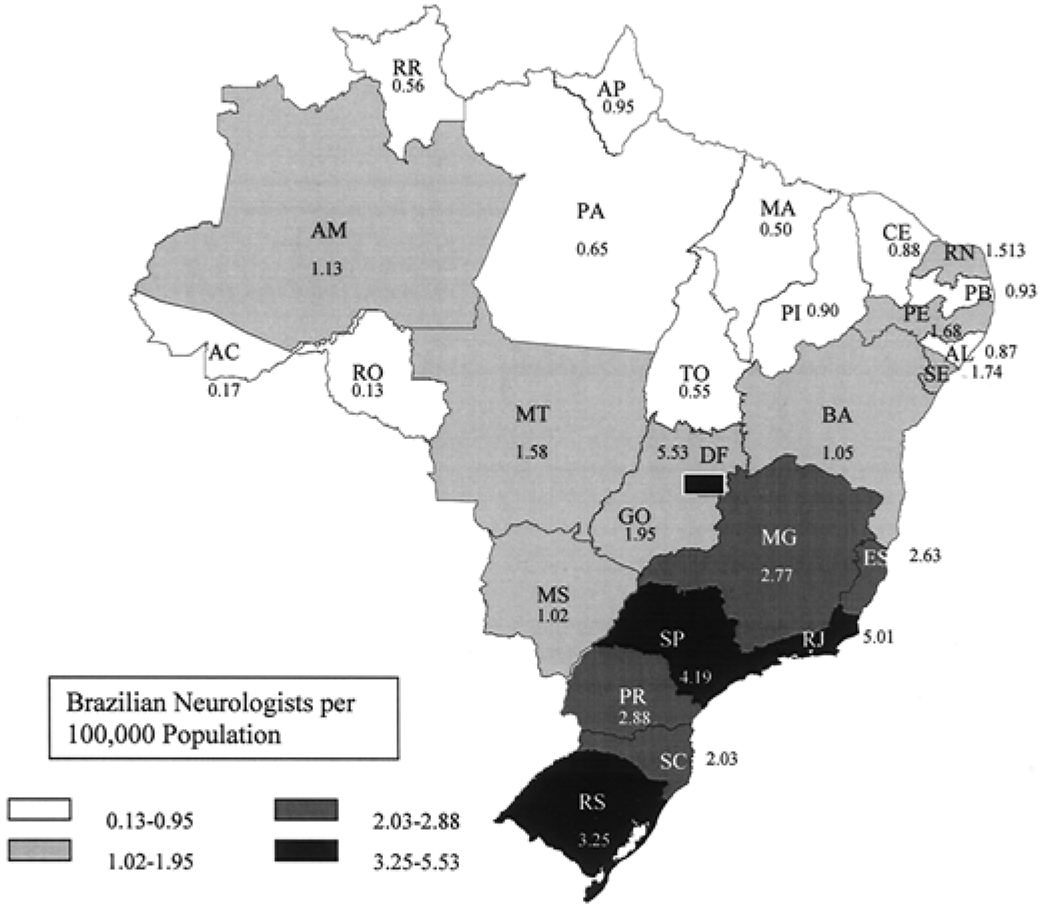

FIGURE 1. The distribution of neurologists per 100,000 inhabitants in the different states of the federation.

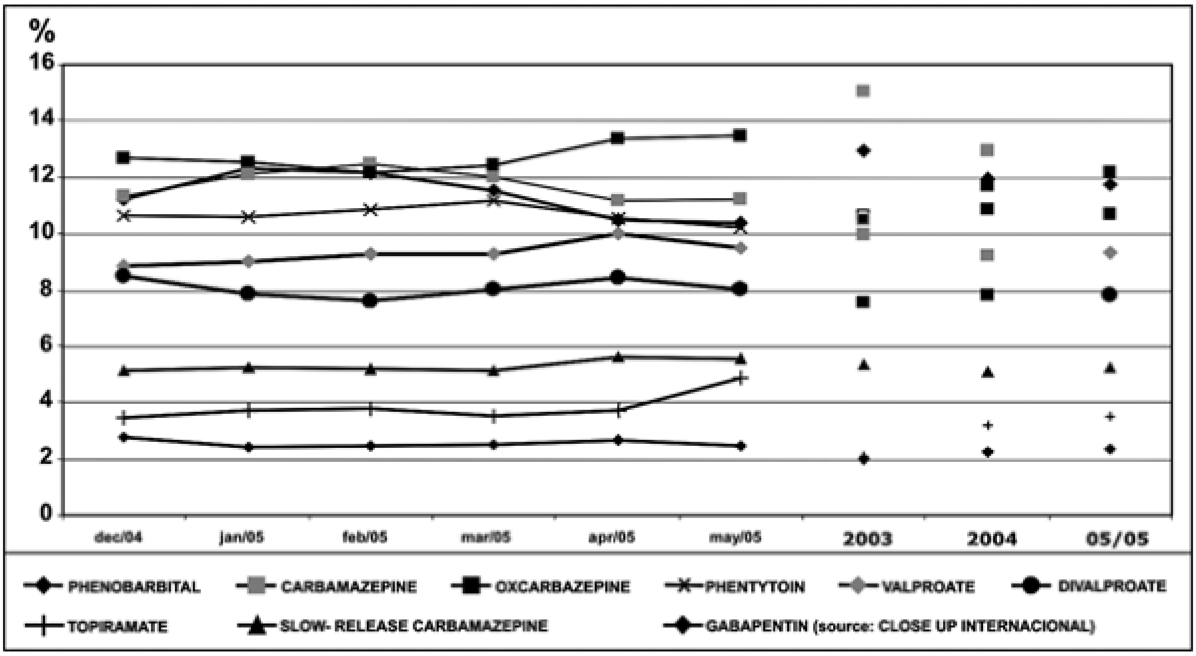

FIGURE 2. Sales of the main antiepileptic drugs available in Brazil by private practices (averages through May

2005).

Neurologists practice principally in the private sector (52%), in specialized outpatient clinics or HMOs (22%), in hospitals (23%), and in the federal health system (3%).

Drugs

Clinicians and Neurologists

In clinical practice, the drugs most prescribed (almost a third of prescriptions) by neurologists are antiepileptic drugs (AEDs). General practitioners and pediatricians are also responsible for a good number of AED prescriptions in Brazil.

Recent research conducted at the end of 2004 and beginning of 2005 in the private sector in Brazil and the relative sales of some basic antiepileptic drugs in private practice are shown in FIGURE 2.[14]

Drug Consumption and Treatment

Recently, there has been a tendency to decrease the use of sedative drugs and to substitute them for carbamazepine or valproate. This indicates a change in the AED prescribing patterns described in 1979 and 1980.[32]

There are few quantitative data about compliance in patients with epilepsy in Brazil.[1] To evaluate adherence, tolerance, and efficacy of the first AED prescribed, the author and colleagues followed 78 diagnosed epilepsy patients, ranging in age from 6 to 61 years (average, 17.96 years) for up to 29 months (average, 12.68 months). It was found that 11 patients (14.10%) did not adhere to the prescribed treatment, and 14 (17.94%) did not tolerate the first drug. Sixty-six percent of the patients were seizure free after 8 weeks of treatment, and 63.8% were seizure free after 56 weeks.[28] These data are consistent with the international literature.[9,13,18]

Brazil is a good example of many intermediate-economy countries where there is unequal wealth distribution and low-income areas where only phenobarbital is available. In other areas, the four basic AEDs (carbamazepine, phenytoin, phenobarbital, and valproate) are available in public health care, and in some more organized parts of the country, the new drugs (gabapentin, lamotrigine, topiramate, and vigabatrin) are available, sponsored by the federal government. The latter scenario is probably found in the black areas of the Brazilian map shown in the FIGURE 1.

The Sistema Único de Saúde Reference System

The data mentioned above demonstrate the political, social, and economic heterogeneity of the country's diverse regions. The public health system in one of the country's most populous and prosperous regions, the state of São Paulo, illustrates this.

The state of São Paulo is divided into five large regions (macroregions). The following will focus on the region of Campinas, which comprises 19 urban communities and a population of approximately 3 million. This region is responsible for approximately 9% of the gross national product (GNP), being three times higher than the Brazilian GNP and twice the state average. Despite this, social inequities such as growing slum areas and urban violence have been revealed.

Health care is divided into three areas: Primary, secondary, and tertiary care. Primary care consists of home care, health

P.2853

centers that support general clinics, and diagnostic and therapeutic support services (SADTs). On a secondary level, besides SADT, there are specialized outpatient clinics and local and macroregional hospitals. Tertiary care includes specialized outpatient clinics (university hospitals), regional hospitals, and SADTs.

Federal government financial resources cover approximately 70% of medical expenditures. The remaining 30% is supplied by the municipalities and the state.

From a neurology practice point of view, electroencephalogram testing and computed tomography scanning are currently available in medium-sized cities, but magnetic resonance imaging is performed by federal services in large cities only.

Aspects Related to Epilepsy in Brazil

Types of Seizures and Epilepsy

In Brazil, there appears to be no significant difference to developed countries in the incidence of the diverse types of epileptic seizures and syndromes.[27,44]

Etiologies

The high incidence of parasitic diseases is one of the factors that contribute to the greater prevalence of epilepsy in Brazil. Neurocysticercosis is the most common of these parasites, and it is the most frequently diagnosed cause of epilepsy in adults.[3,4,10,43,50,51] Seizures often start in childhood,[35,42] and specific clinical and computed tomography findings have been described in children.[24,30]

Malaria, when it presents with cerebral complications, may result in epilepsy. It is also a cause of febrile convulsions in children in tropical regions, in the northern part of the country.[45]

Perinatal brain damage is another factor suggested as a cause for the high incidence of epilepsy. This is possibly true in regions with inadequate prenatal care. However, Sakamoto[46] found that 14% of epilepsy cases were caused by perinatal lesions, which is no different from data collected by the Collaborative Perinatal Project of the National Institute of Neurological Diseases and Stroke in the United States.[37]

Because the incidence of motor vehicle accidents is high in Brazil, craniocerebral trauma is likely to be an important cause of epilepsy.[11] Sakamoto[46] found trauma to be the etiology of epilepsy in 3% of children and adolescents; Gorz et al.[26] found trauma to be the etiology in 13% of adolescents and adults with epilepsy.

In a country like Brazil, basic strategies for the prevention of epilepsy should include prenatal care, safe childbirth, control of infections—especially parasitic diseases—and reduction of brain injury due to trauma and stroke.

Psychosocial Aspects

Lay knowledge of epilepsy in Brazil is clearly unsatisfactory. When evaluating the knowledge of public and private school teachers and those in medical areas, Simonatto et al.[48] found it inadequate. The high rate of illiteracy and low cultural standards help perpetuate old prejudices about epilepsy. A comprehensive educational effort to inform the patients and their families about epilepsy is a basic step in successfully managing this condition.[2]

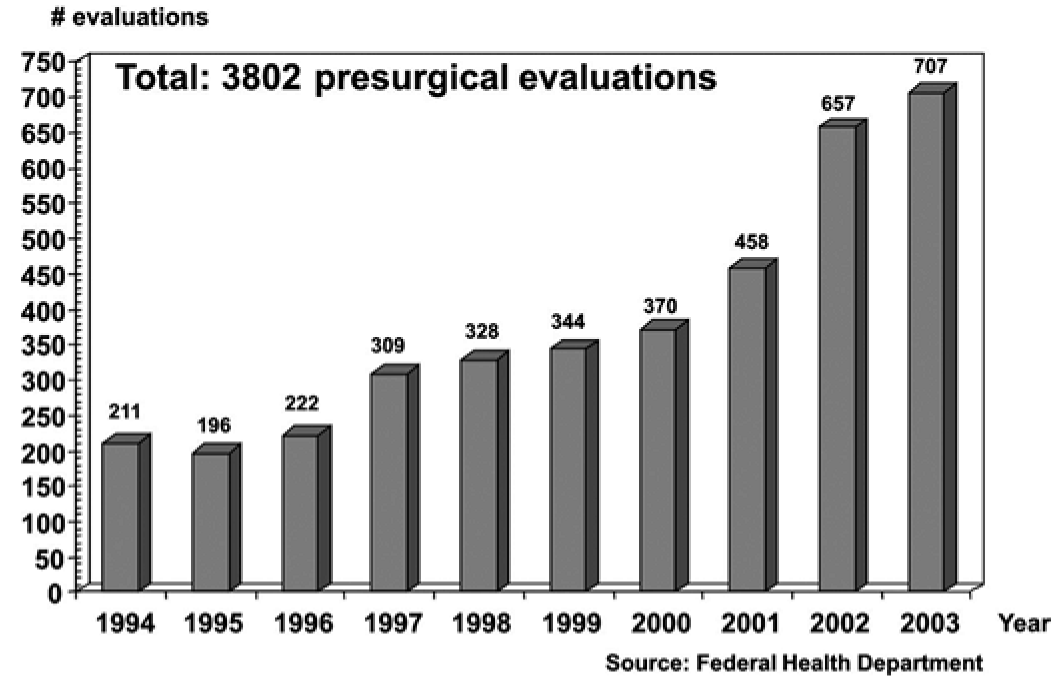

FIGURE 3. The number of presurgical evaluations registered by the Brazilian Epilepsy Program between 1994 and 2003.

Epilepsy is clearly associated with psychosocial difficul-ties.[7,21,47] Prejudice and discrimination are often worse than the seizure itself[7,36] with impact on the daily lives of people with epilepsy. According to studies carried out in Europe[7,25,52] and North America,[5,6,17] epilepsy stigma has been considered one of the most important negative factors on the quality of life of people with epilepsy. The definition of stigma in these studies[8,33] is portrayed slightly differently and, in most cases, is based on qualitative assessment expressed in proportions. Fernandes[23] has developed a scale to measure perception of stigma in epilepsy that consists of ten questions that provide a total score ranging from 0 (no stigma) to 100 (highest level of stigma). In a study carried out in Campinas, 1,850 people were interviewed and the results showed that the magnitude of stigma is different within demographics, such as gender, religion, and level of education, in an urban area. This finding is

P.2854

relevant as a reference for mass media campaigns to fight prejudice and improve social acceptance of people with epilepsy.

In southeast Brazil, Guerreiro et al.[31] evaluated the impact of epilepsy on the quality of life in 17 recently diagnosed children. The relationship between parents and children was found to be significantly altered. However, culturally and socially, the interaction of these children in school and with their families did not show significant changes after the manifestation of epilepsy.[49]

A famous Brazilian with epilepsy is the writer Machado de Assis. He is considered by some to be the most important 19th-century writer in Latin America; in Brazil, he is considered the greatest of all time. Despite having cryptogenic localization-related epilepsy with complex partial seizures of right temporal lobe origin and despite the strong prejudices existing in the second half of the last century, he made good use of his genius through writing.[29] His life serves as an example to other people with epilepsy and to those who may be prejudiced against the condition.

Specialized Centers

Considering the size of Brazil, there are few centers for the social rehabilitation of people with epilepsy. The ones that do exist have a multidisciplinary structure, are generally affiliated with a university, and are located mainly in the southern and southeastern regions of the country.

Brazilian National Epilepsy Surgery Program

Epilepsy surgery started with Niemeyer in Rio de Janeiro in the late 1950s. Indeed, he was the first to propose amygdalohippocampectomy to treat temporal lobe epilepsy and he described the technique in detail.[39] In the 1970s, São Paulo University Medical School (USP) started a surgical program, followed by the Neurological Institute at Goiânia in the 1980s. In the 1990s, three epilepsy centers joined the group: Catholic University (PUC, Porto Alegre), University of São Paulo (USP-Ribeirão Preto), and State University of Campinas (UNICAMP).

In 1994, the Federal Health Department started the National Epilepsy Program within the Program of High Complexity Medical Procedures. Some of the program's data over 10 years (1994 to 2003) in the eight approved centers are shown in Figures 3, 4, and 5.

Positive aspects of this public health policy were technical criteria for accreditation of epilepsy surgery centers, strong partnership between the Health Department and national medical societies, and a reimbursement policy granting epilepsy surgery the same status as renal transplantation. Of note are that seven of the eight epilepsy surgery centers are university institutions; presurgical investigation and surgeries are at internationally accepted standards; morbidity, mortality, and outcome figures are similar to major epilepsy surgery centers; and there is progressive development of new epilepsy surgery centers and a network of epilepsy centers with potential for collaborative research and training. The limitations observed were that the distribution of centers does not parallel demographic data; a national center for regulation of patient access is still preliminary; and there is a lack of specific policies for more complex cases (invasive procedures) and a lack of long-term planning for the expansion of new epilepsy centers. New challenges of this program include improvement of the current system for referrals of patients from less privileged regions and stimulation of greater cooperation between epilepsy surgery centers, patient care, and scientific cooperation.

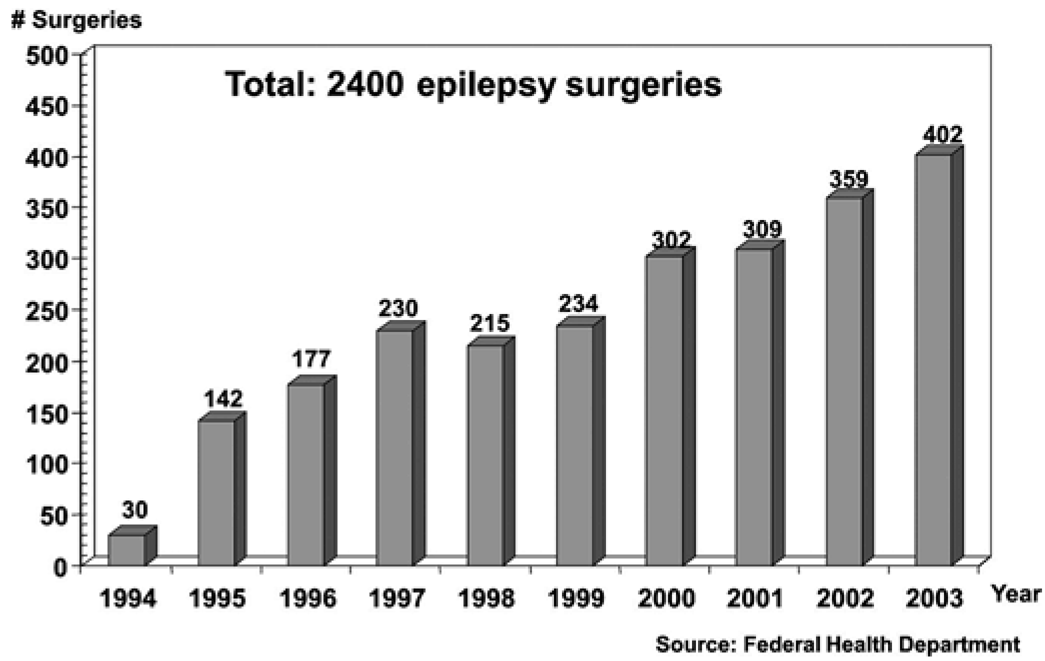

FIGURE 4. The number of epilepsy surgeries registered by the Brazilian Epilepsy Program between 1994 and 2003.

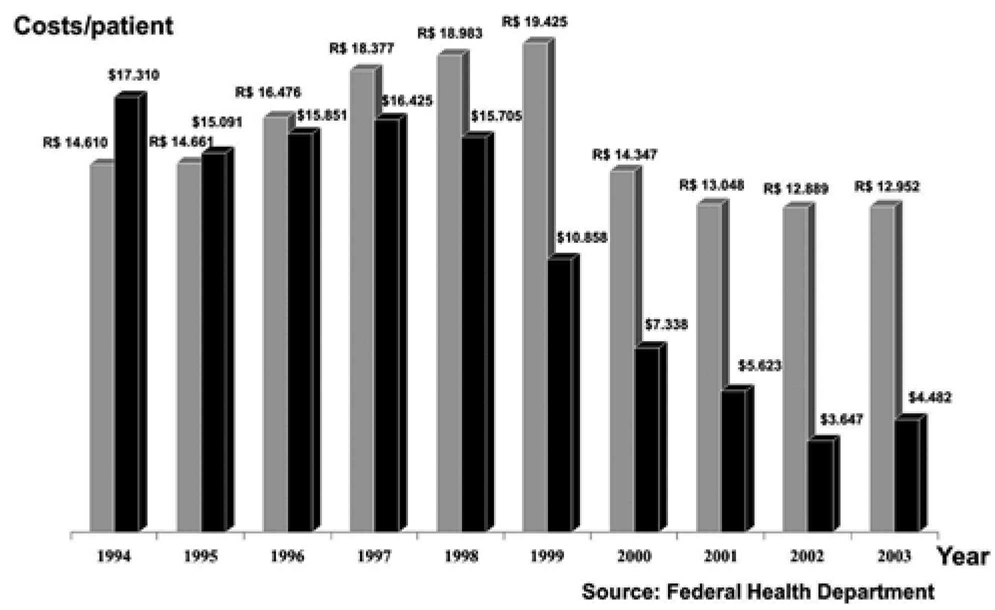

FIGURE 5. Costs per patient of the presurgical evaluation plus surgery in reais (R$) and in U.S.$ ($) between 1994 and 2003.

The Role of Societies

The Brazilian Epilepsy League plays an important role in advising the Ministry of Health on issues regarding epilepsy and in providing education to physicians. The Brazilian Epilepsy

P.2855

League sends out videos, booklets, and books to its nearly 300 members and to medical schools. It organizes scientific meetings and courses in its various regional chapters and has an annual national scientific meeting.

The National Demonstration Project on Epilepsy in Brazil has galvanized lay epilepsy associations across the country since 2002 in a joint effort to help drive epilepsy out of the shadows in Brazil.[34] The main activities are (a) the National Week of Epilepsy, which takes place in all regions of the country,[22] and (b) the National Meeting of Associations and Support Group of People with Epilepsy, where the achievements and resolutions to drive epilepsy out of the shadows are discussed.[19,20,23] These activities have been coordinated by the ASPE (Assistência à Saúde de Pacientes com Epilepsia) and EPI-Brasil (Federation of Associations of People with Epilepsy of Brazil) and represent an important step toward promoting an awareness of epilepsy, diminishing the associated stigma and improving the quality of life of people with epilepsy and their families.

Summary and Conclusions

The organization of the country's medical system for epilepsy care reflects the low socioeconomic development of the nation.

P.2856

Some factors that are causing or contributing to the high rate of epilepsy in the country are the high incidence of infectious diseases, mainly parasitic (especially neurocysticercosis); the poor quality of maternal–infant care in the low socioeconomic regions (particularly in the interior of the northeast and in the misery belts around the large cities); and the high rate of traffic accidents with resulting head trauma. Improved health care, basic education, and sanitation can greatly improve these conditions. The role of nongovernmental agencies in educating the public has produced encouraging results, although their efforts are currently limited to a few segments of society.

Basic measures should be taken to bring about a more efficient health care system. With regard to patients with epilepsy, the governmental policies related to epilepsy with referential and counterreferential centers should be reformed. Low-income patients all over the country, and not just in certain areas, should receive AEDs at no cost.

The official recognition of epilepsy surgery by the Ministry of Health is helping organize an algorithm in this increasingly complex medical care field. It is crucial that the Ministry of Health includes epilepsy in the public health priorities as proposed by International League Against Epilepsy.[34] In this setting, the World Health Organization, the International League Against Epilepsy, and the International Bureau for Epilepsy launched the Global Campaign Against Epilepsy in 1997.

Acknowledgments

The author thanks Dr. Américo C. Sakamoto, who provided data on the National Epilepsy Surgery Program, and Drs. Li Li Min, Ana L. Noronha, and Paula T. Fernandes for data related to the Demonstration Project in Brazil.

Chapter 290

Canada

Samuel Wiebe

Introduction

This monograph describes broadly the health services for epilepsy in Canada. A brief overview of the Canadian health care system provides the basis for a portrayal of services covered, challenges to epilepsy care in Canada, and specific epilepsy health care services by province.

A depiction of the Canadian geography is pertinent as this is directly relevant to health care delivery. Canada spans an area of approximately 10 million km^2, of which a substantial proportion is north of 60th parallel and in the arctic regions. Approximately 31 million people inhabit ten provinces and three territories, with a population density of 3.1 residents per km^2, one of the lowest in the American Continent. The boundaries of the vast Canadian expanse comprise the Atlantic, Pacific, and Arctic oceans. Two thirds of the population (20 million) live in metropolitan areas, most of which are located in proximity to the southern national border. The large northern areas encompassing the Yukon, Northwest Territories, and Nunavik have only 100,000 inhabitants.[7] It is readily apparent that geography poses a gargantuan challenge to equal access to health care services.

The Canadian Health Care System

The Canadian Health Care system rests on the principles enshrined in the Canada Health Act, whose tenets are equity and solidarity. Its objective is to ensure that all eligible Canadian residents have reasonable access to insured health services on a prepaid basis, without direct charges at the point of service. Canada's National Health Insurance Program consists of 13 interlocking provincial and territorial health insurance plans, all of which share certain common features and basic standards of coverage. The roles and responsibilities for Canada's health care system are shared between the federal and provincial-territorial governments. The latter are responsible for the management, organization, and delivery of health services for their residents. Essentially, each province or territory has a list of insured services covered by the national insurance program. These comprise the great majority of medically necessary physician and hospital services. There is interprovincial reciprocity of services with the exception of the province of Quebec. Physicians can refer anywhere in Canada if services are not available locally or if they are justified by complexity. There is variable coverage of medication, eye care, dental care, and allied health care services. In general, medications are not covered except in special populations, such as the elderly, disabled or unemployed, and registered natives and Inuits. Each province has a medication list whose contents vary by province. Restricted use is specified if other drugs fail. A special application is required for unlisted drugs. In jurisdictions that have drug coverage, a copayment by the patient is required. This is widely variable, ranging from the prescription cost up to a maximum yearly of $850 CDN, and then a portion of the excess in some provinces. This coverage may take income into account. A few groups have complete coverage without copayment, including children. All consults to specialists require referral by general practitioners or family doctors, and some allied health care services also require referrals.

Access to Health Care

Statistics Canada carries out national surveys that evaluate access to health care.[6] In 2003, 20% of the general population reported some difficulty accessing specialized care and 15% had some difficulty accessing diagnostic tests. The main barriers to access were long wait times for service, reported by approximately 60% of those patients who identified any type of difficulty. The health access survey also assessed the effect of waiting for specialized care. The main effect of waiting was worry or stress (60% of individuals), whereas only 20% reported worsening of health status as a result of waiting. Interestingly, people with epilepsy in rural areas report fewer barriers to health care than those in urban areas.[9] This somewhat counterintuitive finding may have two possible explanations. Epilepsy care in rural areas occurs mostly through family physicians and emergency rooms, which are more readily accessible than urban specialists with long waiting lists. Alternatively, more complex patients requiring multiple levels of health care, which are often less accessible, may migrate to urban settings. Population surveys in Canada have also shown that patients with epilepsy have a higher use of specialists, nursing, and allied health services than patients with other common chronic conditions.[9]

According to Statistics Canada and the Canadian Institute of Health Information, the ratio of population per hospital in Canada is approximately 31,000, and there is approximately one hospital per 9,260 km^2.[2] The latter varies substantially among regions and provinces, from a low of 3,000 km^2 per hospital in Ontario to a high of 450,000 km^2 per hospital in the northern territories. In general, populated provinces have more and busier hospitals that are often nearly fully occupied, whereas provinces and territories with few inhabitants have fewer hospitals per area, distributed over vast and remote geographic regions, and with more challenging access.

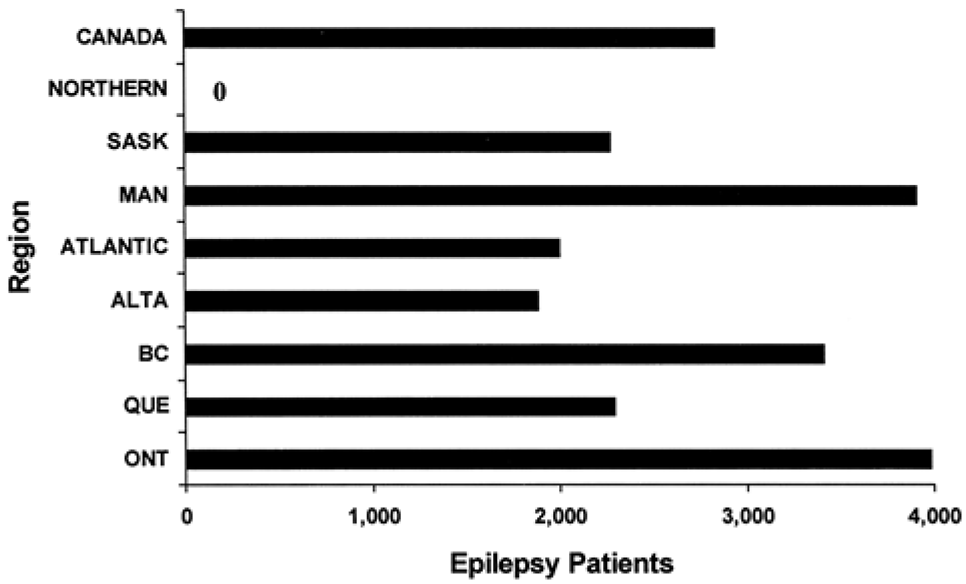

FIGURE 1. Epilepsy patients per epileptologist. In 2004, the ratio of patients with epilepsy to epilepsy neurologists varied across provinces, but with the exception of the Northern territories, it was always <4,000. Northern, Nunavut, Northwest Territories, Yukon; Sask, Saskatchewan; Man, Manitoba; Atlantic, Nova Scotia, Newfoundland & Labrador, New Brunswick, Prince Edward Island; Alta, Alberta; BC, British Columbia; Que, Quebec; Ont, Ontario. (Source: Wiebe, unpublished survey; and Tellez-Zenteno JF, Pondal-Sordo M, Matijevic S, et al. National and regional prevalence of self-reported epilepsy in Canada. *Epilepsia.* 2004;45(12):1623–1629.)

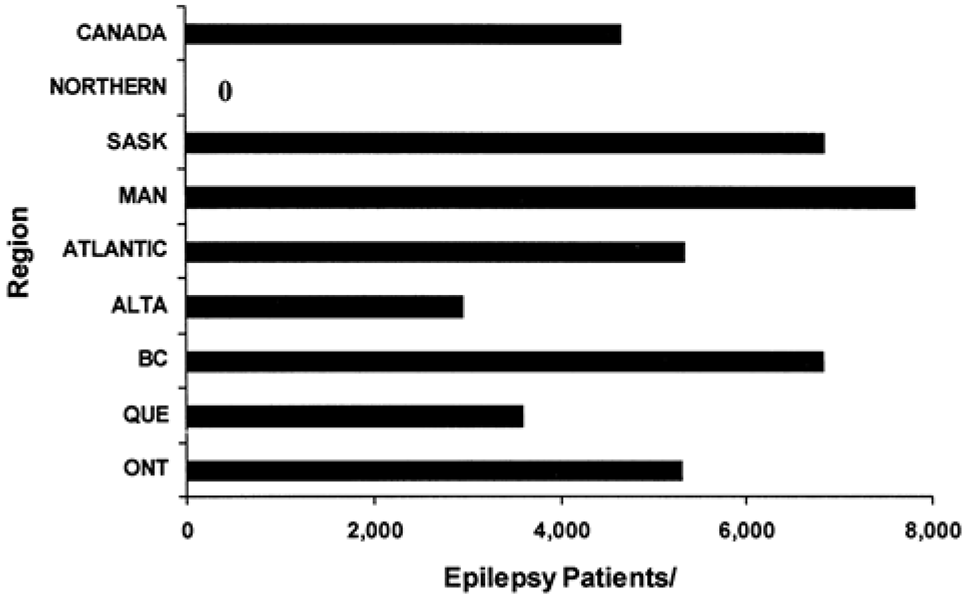

FIGURE 2. Epilepsy patients per electroencephalographic (EEG) monitoring bed. The number of patients with epilepsy per video-EEG monitored bed ranged from 2,500 to 8,000 in different provinces, and there were none in the Northern territories. Northern, Nunavut, Northwest Territories, Yukon; Sask, Saskatchewan; Man, Manitoba; Atlantic, Nova Scotia, Newfoundland & Labrador, New Brunswick, Prince Edward Island; Alta, Alberta; BC, British Columbia; Que, Quebec; Ont, Ontario. (Source: Wiebe, unpublished survey; and Tellez-Zenteno JF, Pondal-Sordo M, Matijevic S, et al. National and regional prevalence of self-reported epilepsy in Canada. *Epilepsia.* 2004;45(12):1623–1629.)

According to a 1996 survey of specialist manpower, the mean distance from a general practitioner to a neurologist was 102 km, and it was 135 km for a neurosurgeon. This is highly variable among regions. In 2002, there were 694 neurologists in Canada, resulting in a ratio of 44,700 people per neurologist. This also is highly variable among regions, ranging from zero neurologists in the three vast northern territories to 218 in Ontario, and resulting in the following population-to-neurologist ratios: British Columbia, 43,000; Alberta, 43,200; Saskatchewan/Manitoba, 74,700; Ontario, 50,100; Quebec, 33,400; and Maritime Provinces, 61,000.[1] In most provinces the ratio has decreased over time (e.g., more neurologists per population), with the exception of Saskatchewan and Manitoba, where the number of neurologists has actually decreased over the last few years.

P.2860

Epilepsy-specific Health Care Resources

The only existing Canadian study of the epidemiology of epilepsy in the general population reports a prevalence of active epilepsy of 5.6 per 1,000.[8] The prevalence of epilepsy is higher in groups with lower educational level and income, and in the unemployed. Although the prevalence of active epilepsy is fairly constant across provinces, and translates into approximately 210,000 patients with epilepsy nationally, there are minor interprovincial differences (e.g., the prevalence is somewhat lower in the Pacific than in the Atlantic provinces).[8]

The approximate ratio of epilepsy patients per neurologist in Canada is 300, based on a prevalence of epilepsy of 7 per 1,000 and a total of 694 neurologists.[1] Again, this ranges from zero in the northern territories to 245 patients per neurologist in Quebec. Bailey's national survey found that 104 (15%) neurologists in Canada reported an interest in epilepsy.[1] However, a 2004 survey by the author identified only 74 neurologists focusing in adult or pediatric epilepsy, with a provincial median of eight and a range of zero in the vast northern territories to 22 in Quebec. The ratio of adult to pediatric epileptologists in Canada is approximately 3:1, which is remarkable given that a large number of the epilepsies are of childhood onset. This survey also identified 23 neurosurgeons focusing on epilepsy surgery in Canada, with a provincial median of 3.5, ranging from zero in the north to six in Alberta. According to these data, the national ratio of patients with epilepsy per epileptologist is 2,843, the provincial median ratio is 2,300, and the range is zero in the north to 1,800 in Alberta (Fig. 1). The national ratio of patients with epilepsy per epilepsy neurosurgeon is 9,000, with a provincial median ratio of 7,000, and a range of zero neurosurgeons in the northern territories to 3,000 patients per neurosurgeon in the more abundantly served Atlantic provinces and Alberta.

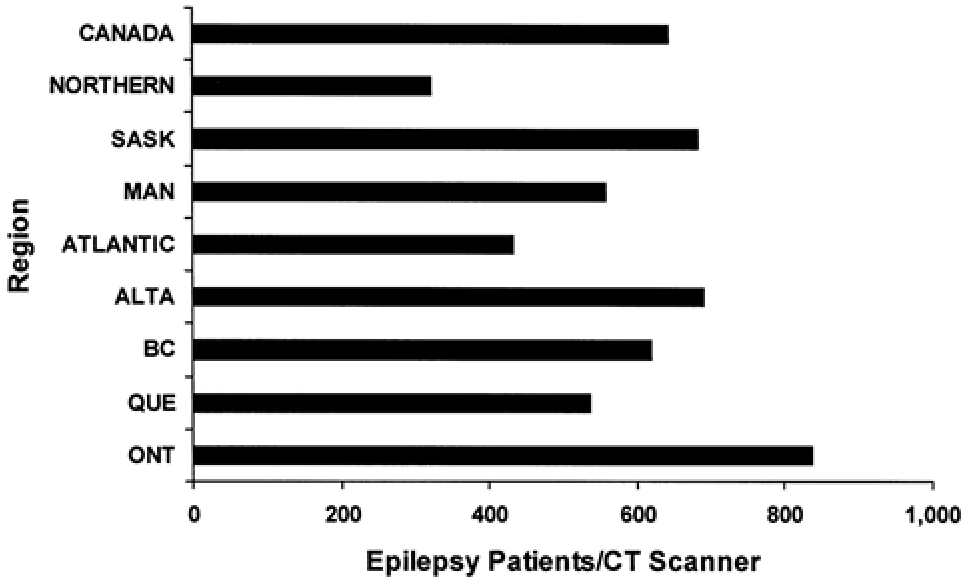

FIGURE 3. Epilepsy patients per computed tomography (CT) scanner. All Canadian provinces have CT scanners. The ratio of patients to scanner is lowest in the North because of its sparse population. Northern, Nunavut, Northwest Territories, Yukon; Sask, Saskatchewan; Man, Manitoba; Atlantic, Nova Scotia, Newfoundland & Labrador, New Brunswick, Prince Edward Island; Alta, Alberta; BC, British Columbia; Que, Quebec; Ont, Ontario. (Source: Canadian Institute for Health Information. *Medical Imaging in Canada: 2004.* Ottawa, Canada: Canadian Institutes for Health Information; 2004; and Tellez-Zenteno JF, Pondal-Sordo M, Matijevic S, et al. National and regional prevalence of self-reported epilepsy in Canada. *Epilepsia.* 2004;45(12):1623–1629.)

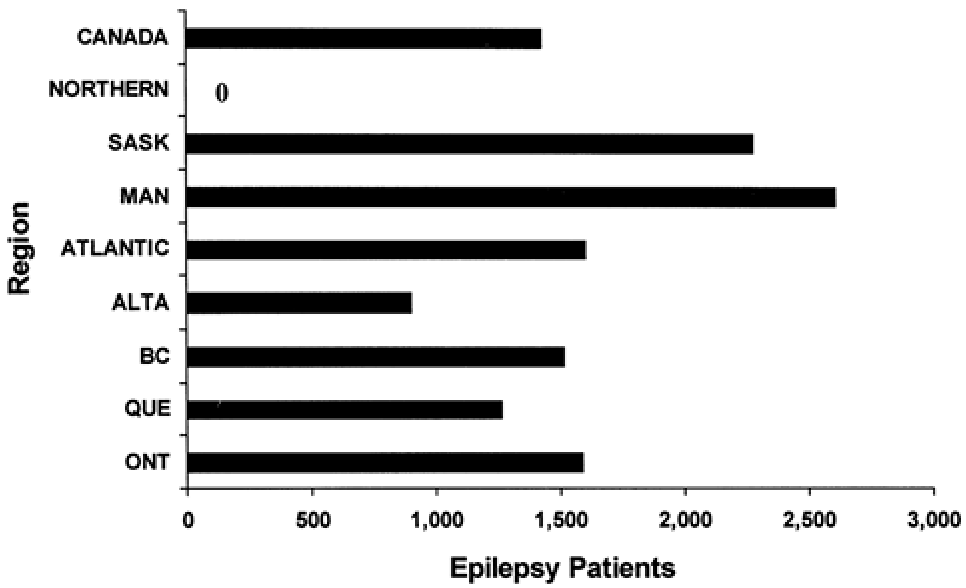

FIGURE 4. Epilepsy patients per magnetic resonance imaging (MRI) scanner. In 2004 there were 167 MRI scanners in Canada. The ratio of patients with epilepsy to MRI scanner was approximately twice that of CT scanners. There was no MRI scanner in the vast North. Northern, Nunavut, Northwest Territories, Yukon; Sask, Saskatchewan; Man, Manitoba; Atlantic, Nova Scotia, Newfoundland & Labrador, New Brunswick, Prince Edward Island; Alta, Alberta; BC, British Columbia; Que, Quebec; Ont, Ontario. (Source: Canadian Institute for Health Information. *Medical Imaging in Canada: 2004.* Ottawa, Canada: Canadian Institutes for Health Information; 2004; and Tellez-Zenteno JF, Pondal-Sordo M, Matijevic S, et al. National and regional prevalence of self-reported epilepsy in Canada. *Epilepsia.* 2004;45(12):1623–1629.)

Our 2004 survey identified approximately 45 video-electroencephalographic (V-EEG) monitoring beds in the country. This results in a national ratio of 4,600 patients with epilepsy per monitored bed, and a provincial median ratio of 5,300, ranging from zero monitored beds in the north to 3,000 patients per monitored bed in Alberta (Fig. 2). The Canadian Institute of Health Information reported a total of 326 computed tomography (CT) scanners nationally, which translates into a ratio of 645 patients with epilepsy per CT scanner, and a provincial median ratio of 600 patients with epilepsy per CT scanner (range: 325 in the northern territories to 840 in Ontario) (Fig. 3).[3] Similar sources revealed a total of 147 magnetic resonance imaging (MRI) scanners nationally, which is equivalent to a national ratio of 1,400 patients with epilepsy

per MRI scanner, and a provincial median ratio of 1,500 patients per scanner (range: zero in the North to 900 in Alberta) (Figs. 4 and 5).[3] According to the Canadian Institute of Health Information, in 2004 there were eight positron emission tomography (PET) scanners in the country.[3]

In 2003 there were approximately 17 adult epilepsy clinics and 18 pediatric epilepsy clinics in Canada. These clinics had access to a total of approximately 30 clinical psychologists or social workers and less than two dozen nurses.

Epilepsy Nurses

Best available data revealed that in 2003 in Canada there were less than two dozen nurses working part or full time in epilepsy. Furthermore, three large Canadian provinces have no access to dedicated epilepsy nurses. A recent survey conducted across Canada showed that 68% of epilepsy centers/clinics have dedicated epilepsy nurses, with a median of 1.7 nurses per epilepsy center.[5] Only 58% of centers have dedicated funding for epilepsy nurses. The role of epilepsy nurses is described in Table 1.

Antiepileptic Drugs

Most of the frequently used antiepileptic drugs (AEDs) are included in provincial drug formularies. The latter determine which drugs are available at no cost to special populations, such as the elderly, disabled, unemployed, registered Aboriginals, and Inuits. New AEDs take time to reach provincial formularies and special application can be made for these drugs. In Canada, drugs are licensed by a federal agency following a rigorous process that is similar to that of the Food and Drug Administration in the United States. At the time of this writing, the following commonly used AEDs are licensed and available for use in Canada: Phenytoin, phenobarbital, carbamazepine and carbamazepine controlled release, valproate, ethosuximide, primidone, clobazam, lorazepam, lamotrigine, topiramate, vigabatrin, levetiracetam, and oxcarbazepine. AEDs not available in Canada include zonisamide, tiagabine, and felbamate.

National Epilepsy Organizations

The Canadian League Against Epilepsy is the country's professional organization and is the national chapter of the International League Against Epilepsy. Epilepsy Canada is a national organization whose focus is on research and education, and it is the national chapter of the International Bureau for Epilepsy. The Canadian Epilepsy Alliance is a lay organization, which focuses on patient and public education and support. Regional epilepsy associations often serve the functions of epilepsy support groups and have variable degrees of interaction with epilepsy clinicians. The distribution of regional epilepsy support groups follows closely that of the population density across the country. All of the epilepsy support organizations function as not-for-profit charities.

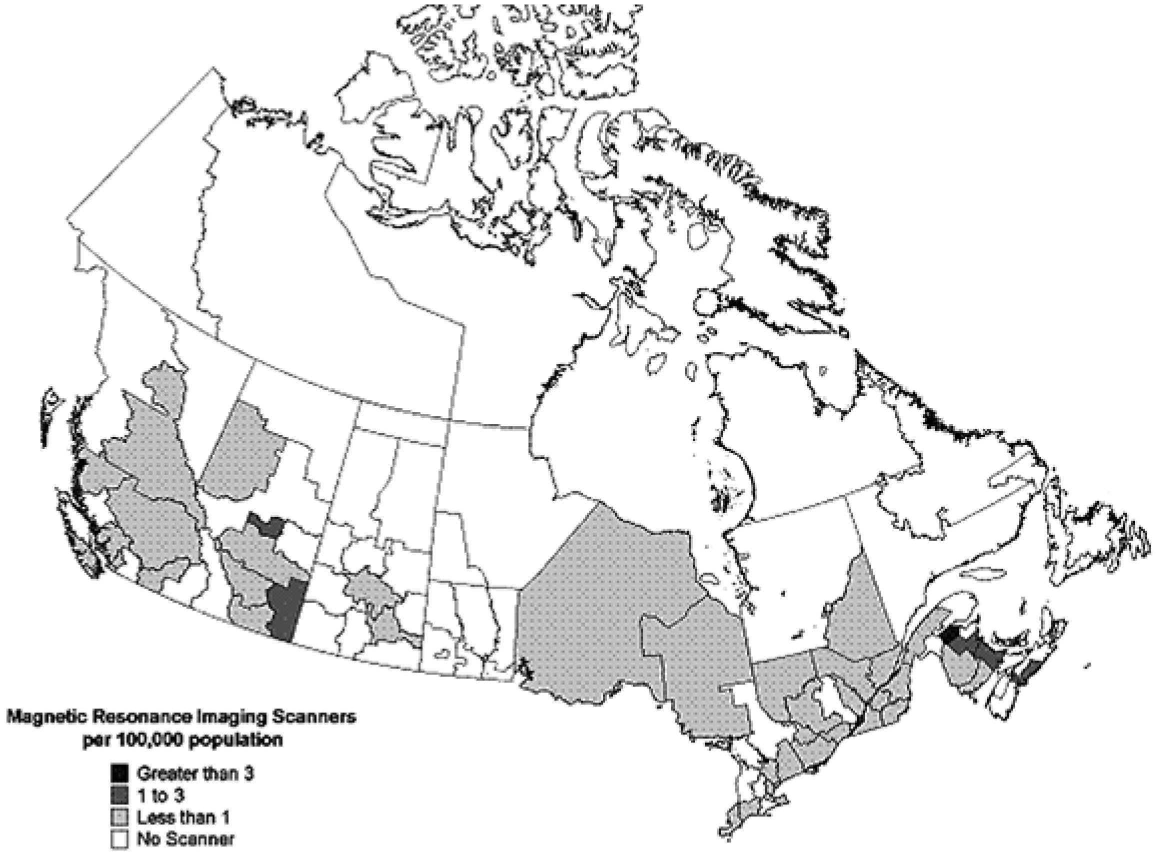

FIGURE 5. Magnetic resonance imaging (MRI) scanners per 100,000 population, 2004. Canadian map illustrating the distribution of MRI scanners in the country in 2004. Notice the distribution of scanners toward the Southern border, and also the clustering around specific large centers located in more heavily populated areas. Table 1 Epilepsy Nurses' Clinical Activities

Activity	Number (%)
Clinical education	14 (76%)
Seizure monitoring unit	12 (65%)
Presurgical evaluation (outpatient)	10 (58%)
Other patient care	15 (82%)

Patient telephone education	15 (82%)

Aboriginal Populations

Canada has the second largest aboriginal population (3.3% of the total population) after New Zealand. For comparison, the percentage of aboriginal population in Australia is 2.2% and in the United States is 1.5%. Little is known about access to health care in general and to epilepsy care in particular in aboriginal populations. However, Canadian national surveys reveal that contact with physicians or with traditional healers varies even within the aboriginal population. Aboriginals residing in urban settings have more frequent contact with physicians than those residing in rural settings. In turn, Aboriginals in the arctic regions have the least contact with physicians or traditional healers (about half as often as those in urban dwellings).[7] This is important because the aboriginal population has higher mortality rate, infant mortality, hospitalization rates, and potential years of life lost from injury than the nonaboriginal Canadian population.[4] Although the incidence and prevalence of epilepsy in aboriginal populations in Canada has not been studied, it is conceivable that lower health indices and a high rate of injuries may have an impact on epilepsy and on access to health care resources for epilepsy.

Summary and Conclusions

The Canadian health care system is based on the principles of equity and solidarity, as embodied in the Canadian Health Act, whose objectives are to ensure that all eligible Canadian residents have reasonable access to insured health services, on a prepaid basis, without direct charges at the point of service delivery. The current main barriers to care, according to Statistics Canada (2), are long waiting lists to access elective specialized care and elective diagnostic tests. Another important challenge is the enormous geographic expanse of the country, which also impacts on access to care.

The availability of epilepsy services across the country differs substantially between more and less densely populated areas, which is often a South-North gradient. Among more populated areas, there is some variability in services, especially in regards to the level of specialization, however access is generally adequate. The ratio of adult to paediatric epileptologists is approximately 3:1, which is remarkable given the large number

P.2863

of epilepsies of childhood onset. Facilities for the investigation and treatment of complex epilepsies are available throughout the country and several provinces have more than one centre. Patients can be referred across centres and across provinces throughout the country, as needed.

Most of the frequently used AEDs are included in provincial drug formularies, which determine availability at no cost to special populations such as the elderly, disabled and unemployed. There is no national insurance plan for AEDs, and each province has a different level of insurance. At the time of this writing, AEDs not marketed in Canada include zonisamide, tiagabine, piracetam, and feldamate.

Funding for research in epilepsy derives mostly from the Canadian Institutes of Health Research, which is a federal health research organization. In addition, provincial agencies have smaller opportunities to fund research in epilepsy in some areas. Canada has representative chapters from the International League Against Epilepsy and from the International Bureau for Epilepsy, with corresponding professional and lay memberships, and it is also a member of the North American Region of the International League Against Epilepsy.

Introduction

The People's Republic of China (hereinafter referred to as China) is located in East Asia and on the West Coast of the Pacific Ocean. China has 9.6 million km^2 of area and 1.3 billion of population with 56 ethnic groups. Urban population accounts for 42% of the total. The administrative division of the mainland China is 22 provinces, five autonomous regions, and four municipalities directly under the central government.

The following are some public health indicators in China: National health expenditure (2003) of $63.3 (U.S.) per capita and total of $818.7 hundred million (U.S.), which accounted for 5.6% of the gross domestic product (GDP) and 11% of the central government's expenditure allocated to health; life expectancy at birth (2000), 71, 69, and 73 years for total, male, and female, respectively; birth rate (2003), 12.29 per 1,000; death rate (2003), 6.42 per 1,000; infant mortality rate (2004), 25.5 per 1,000; maternal mortality rate (2004), 50.2 per 100,000; and mortality rate under 5 years of age (2004), 30 per 1,000 live births.

Statistics for public health resources are as follows: doctors per 1,000 inhabitants, 1.7; hospital beds per 1,000 inhabitants, 2.4; total number of health institutes in 2004, 296,492, and among them, 18,396 hospitals; and total number of health personnel in 2004, 5,353,628, and among them, 1,904,771 doctors and assistant doctors.

Since the establishment of the People's Republic of China in 1949, remarkable advances have been made in the public health system and in employment. These include the following: (a) There has been an extraordinary improvement in measures of people's health. The life expectancy at birth in 1949 was 35 years, but in 2004 it was 71.8 years. The infant mortality rate in 1949 was 200 per 1,000 live births, but in 2004 it was 25.5. The maternal mortality rate in 1949 was 1,500 per 100,000, but in 2004 it was 50.2. (b) A medical service system has been established that covers the whole nation. The three-tier healthcare system, in rural (county–township–village) and urban areas (city–district–neighborhood) has made great contributions to the improvement of people's health. (c) A medical insurance system is in development. In urban areas, there are four types of medical insurance systems: (i) "free-of-charge system," which covers about 50 million public servants, university students, etc.; (ii) basic medical insurance and (iii) supplementary medical insurance, both of which cover about 130 million workers; and (iv) commercialized insurance, which covers part of private enterprises employees. In rural areas, a new "cooperative medical service system" has just been implemented in a pilot stage, and this presently covers about 156 million farmers. (d) There has been great improvement in the prevention and control of communicable diseases. For example, deaths caused by communicable/parasitic diseases fell from first (in the 1950s) to the ninth (in 2004) place as a cause of death; smallpox, poliomyelitis, etc., have been eradicated; there has been effective control of severe acute respiratory syndrome (SARS) and avian influenza; and effective measures and networks have been put in place to control HIV/AIDS, tuberculosis, hepatitis B and schistosomiasis. (e) Remarkable improvements have been made in maternal and child healthcare. The prenatal examination rate has now reached 90%; the hospitalized delivery rate has reached 83%; and the mortality rate of children under 5 years of age has reached 29.9 per 1,000, whereas in 1949, it was 250 to 300 per 1,000.

Beginning in the late 1970s, China implemented an “open-door and reform” policy. Since then, public health work has further improved and in a number of diseases controlled. The medical service system is now under reform and the medical/health services are expanding coverage. The Chinese government has made great efforts toward the strategic goal of “health for all.”

Epilepsy was recognized and described 2,200 years ago in the oldest Chinese medical monograph *Medical Classic of the Yellow Emperor* (Huang Di Nei Jing). In China, epilepsy has long been treated by traditional Chinese medicine (TCM, meaning herbal medicine, acupuncture/moxibustion, and other folk therapies), and a long experience with epilepsy treatment has accumulated. However, the most effective control of epilepsy has resulted from modern medical practices, including surgical treatment. From the 1950s, clinical diagnosis and treatment of epilepsy in China has improved steadily, but very little research on its public health aspects occured until the 1970s.

What is described in this chapter—that is, the epidemiology, clinical neurologic diagnosis and treatment, epilepsy surgery, basic research, sociopsychological problems, rural community control programs, and TCM recognition of epilepsy in China—covers about the last three decades.

Epidemiology

Epidemiology is the study of the distribution and determinants of disease in human populations. Recently, psychosocial and economic indicators, such as quality of life and standards of care, have been incorporated into epidemiologic research, as their relationship to morbidity became evident.

There are several key difficulties in conducting epidemiologic research on epilepsy and in interpreting the epidemiologic literature.[32,47] These include:

- Variations in the definitions and classification of seizures and of epilepsies
- Poor case ascertainment due to ignorance or concealment by patients or their families, or due to the fact that some patients are not aware of having seizures
- Diagnostic imprecision, even when potential patients are identified
- Differences between studies in the age distribution of study populations, or in the place or mode of recruitment of subjects

Table 1 Prevalence Ratio and Incidence Rate of Epilepsy in China

Year	Study	Reporter	Sample population	Prevalence (per 1,000)	Incidence (per 100,000)
1981	Sichuan		426,789	4.8	35
1983	6 cities	Li	63,195	4.4	35
1985	22	Li	246,812	3.6	26

	provinces				
1992	Jiangsu	Shan	(0–14 yr)	5.9	200
2003	6 rural areas	Wang	55,616	7.0	(active 4.6)

These and other factors all limit the precision and validity of data and comparability among studies. Despite these difficulties, sufficient data are available from a number of studies

P.2866

to give a useful profile of the epidemiologic characteristics of epilepsy in China.

Prevalence Ratio

Researchers use lifetime prevalence to express the magnitude and scope of the burden of a defined disorder in the population. Point prevalence is the proportion of a defined population with a disease at a given point in time (usually the first or last day of a year). The point lifetime prevalence ratio results for epilepsy in China from some studies are shown in Table 1. We may see that the prevalence for epilepsy in China is about 4 to 6 per 1,000, which is similar to the average figure in industrialized countries. In Wang's study, patients with epilepsy who had seizures in the past year were categorized as “active epilepsy”; for those cases, the prevalence ratio was found to be 4.6 per 1,000.[41]

Incidence Rate

Incidence rate is the rate of occurrence of new cases of epilepsy in a defined population in a specified time period (usually 1 year). Table 1 also shows the incidence rates for epilepsy in China as 26 to 35 per 100,000 individuals per year.

Mortality Rate

Unfortunately in most countries epilepsy is not listed in “cause of death” statistics as an independent disease. Deaths of persons with epilepsy (PWE) are always registered as caused by the underlying disease or some other reason, such as “accident.” Reports from China showed 7.9 per 100,000 per year in urban areas and 6.9 per 100,000 per year in rural areas. The figure from China is higher than that from other countries, and this difference is not explained.[47]

In recent years, the *standardized mortality rate* (SMR) has been used in the epidemiologic literature to analyze deaths in epilepsy. These analyses show that the SMR for epilepsy patients is more than twice that for the general population. Causes of mortality include (a) underlying brain diseases, such as tumor or infection; (b) seizure-related deaths (status epilepticus; drowning, burns, or other trauma; severe aspiration or airway obstruction by food, etc.; deaths caused by habitual seizures when coexisting with cardiorespiratory disease); (c) suicide; (d) death as a consequence of medical or surgical treatment of epilepsy; and (e) sudden unexplained death in epilepsy (SUDEP), whose causes remain ill-understood.[29,47]

Research and data on SUDEP are very rare in China. From 1994 to 2004, only three papers on this topic were published, and two of them were literature reviews. Wang et al.[44] analyzed the clinical and pathologic information of seven cases of SUDEP. They found that all seven cases had edema of the brain and lungs. Some of the patients had reduction of neurons and increase of glial cells. There were no tumors or injuries. All seven died when they had a general tonic–clonic seizure. Two occurred in sleep and four had agitation or fright before death.

One hundred and twenty PWE from four provinces in China who had been part of a project, “community control of epilepsy,” in the late 1980s were followed up 5 years later. Thirteen had died. The mortality rate of this group was 2.2% per year and around 3.4 times higher than the rate in the general population. Among the 13 deceased, two (15.4%) might be categorized as SUDEP. This may be the only epidemiologic information for SUDEP in China.[40]

Distribution by Sex and Age

As reported from most of other countries, in China, the prevalence and incidence of epilepsy is more frequent in men than in women. The prevalence in men and women in urban areas is 1.3:1 and the incidence is 1.7:1; in rural areas, it is 1.1:1 and 1.4:1, respectively. These differences are probably related to the more social and physical activities of men than of women and thus more frequently risk factors and causes for epilepsy are encountered by men. For age-specific prevalence, data from China showed that it is rising with age in childhood and adolescence, then plateauing in middle age, and decreasing in old age. As for age-specific incidence, there are two peaks: in childhood and the elderly. A study from Sichuan province indicated that 80% of epilepsy occurred before 15 years of age. Cerebrovascular disease, brain tumors, and other identifiable causes are responsible for the second peak of incidence in the older age group.[23]

Table 2 Relative Frequency of Subtypes of Seizure

Subtype	China 1	China 2	Singapore	Turkey	Tanzania	United States
GS	**89.6**	**77.3**	**65.2**	**78.9**	**58**	**40**
GTCS	81	71.8	56.3	65.4	54.1	23
Absence	4.8	3.9	2.2	4.9	1	6
Other	3.8	1.6	6.7	8.6	2.9	11
PS[a]	**7.6**	**18.6**	**34.8**	**19.7**	**31.9**	**57**
SPS	4.8	4.4	2.2	7.4	0.5	21
CPS	2.8	5.9	4.5	12.3	9.2	36
PS > GS	—	8.3	28.1	—	22.2	—
Other	**2.8**	**4.1**	—	**1.2**	**10.1**	**3**

CPS, complex partial seizure; GS, generalized seizure; GTCS, generalized tonic–clonic seizure; PS, partial seizure; PS > GS, partial seizure with secondary generalization; SPS, simple partial seizure.

Table 3 Risk Factors for Idiopathic Epilepsy (Case-Control Studies in Six Cities and Rural Areas of 22 Provinces of People's Republic of China)

	6 cities		22 rural areas	
Expected risk factor	**RR**[a]	***p* <**	**RR**	***p* <**
Parents' intermarriage	—	(>0.05)	9	0.001
Epileptics in family	2.5	0.01	15.4	0.001
Previous febrile seizures	7.5	0.01	32.2	0.001
Premature or difficult labor	3.2	0.025	13	0.001
Born when mother >30 yr of age	1.5	0.05	1.4	0.025

[a]RR (relative risk) = B/C; B, case (+), control (-); C, case (-), control (+).

Subtypes of Seizures

Table 2 shows the relative frequency of subtypes of seizures reported from China and some other countries.[23] Much of the variation among countries is probably related to differences in methods of data collection, sample size, classification scheme, and certainty of clinical diagnosis. Therefore, it is difficult to compare them or draw inferences. For example, the apparent high proportions of generalized seizures in the two studies from China reflect the fact that those studies focused on convulsive seizures rather than nonconvulsive seizures.

Risk Factors

In epidemiologic studies, scientists usually use retrospective methods (typically case-control studies) to identify risk factors

P.2867

for epilepsy. For a number of practical reasons, prospective (cohort) methods, although theoretically preferable, are rarely used.

Table 3 shows the results of two case-control studies that were conducted in six cities of China in 1983 and in rural areas of 22 provinces in 1985.[23] The findings generally match those of a number of studies in other countries.[47] Many epidemiologic studies implicate genetic factors, perinatal factors, and a history of febrile seizures as risk factors for various major kinds of epilepsy, although some controversy persists.

The discovery of epilepsy genes has benefitted from the success of the Human Genome Project, a multinational endeavor that has produced detailed maps of the human chromosomes. The genes responsible for particular genetic epilepsies can now be identified and localized to specific chromosomal regions, ultimately allowing researchers to determine the structure of the encoded molecules. This requires the study of families in which several members are affected with well-characterized epilepsies. The *genetic "lesions"* responsible for idiopathic epilepsies give rise to various familial epilepsy syndromes.[3] A genetic etiology is indicated by, for example, familial incidence and frequent clinical concordance in twin studies.

In most studies, populations with *poor perinatal health care*, high incidence of premature births and head trauma during delivery, and high infant mortality are at high risk for epilepsy. The major perinatal factors include short gestation, low birth weight, prolonged labor, neonatal asphyxia, and assisted de-livery.

Febrile illness of any kind can trigger seizures in young children. About 3% of children who have *febrile convulsions* go on to develop epilepsy in later life.

Some investigations suggest that rural populations with poor health services and disadvantaged urban populations should be included in the epilepsy high-risk group: The relevant factors here are almost certainly poverty and low socio-economic status, which are themselves associated with high rates of epilepsy, as they are with so many other diseases.

Causes of Symptomatic Epilepsy

When epilepsy appears to be caused by an identifiable brain disease, it is categorized as *symptomatic epilepsy*. These causes include head injury; intracranial infection (e.g., neurocysticercosis, malaria); cerebrovascular disease; brain tumor; drugs and alcohol; carbon monoxide poisoning; and effects of ionizing radiation.

Table 4 Putative Causes of Symptomatic Epilepsy Cases in Six Chinese Cities

Putative cause	No. of cases	%
Head injury	29	47.5
Intracranial infection	15	24.6
Cerebrovascular disease	10	16.4
Intracranial tumor	2	3.3
Other	5	8.2
Total	**61**	**100.0**

Table 4 shows the results of a retrospective study in six cities of China in 1983.[3]

Prognosis and Remission

There are very few research reports on the natural history of epilepsy in China. In a survey conducted in the rural areas of 22 provinces in the 1980s, there were 904 cases of epilepsy, 417 of

P.2868

them were treated, 448 were not, and 39 were unclear. Among the untreated 448 cases, spontaneous remission rate (SRR) at 2 years was 40.4% and at 5 years was 27.4%. Studies showed that SRRs ranged from 20% to 39%. These figures are similar to what Zielinski reported (5-year remission rates of 28.6% to 30.6%).

Factors relative to the prognosis or remission rate (RR) include: (a) *Age of onset*. The highest RR was reported if onset was between 7 and 9 years old. The RR for those whose onset was before 14 years was 71%, and before 20 years, 42%. For those whose onset was before 1 year and after 40 years, the RR is low because of one increase in number of organic disorders that cause epilepsy in those age groups. (b) Seizure types: Generalized tonic–clonic seizures (GTCSs) had a higher RR (38% to 62%). (c) Frequency of seizures: Low frequency of seizures had a higher RR. More than one seizure per day had an RR of 20% to 27%, fewer than ten seizures per year had an RR of 50% to 57%, and fewer than one seizure per year had an RR of 67%. This indicates that seizure frequency before treatment is an important factor that affects prognosis, but it is an exception for absence seizures. (d) Idiopathic or symptomatic epilepsy: The former (RR of 47% to 63%) has a higher RR than the latter (RR of 24% to 27%). (e) Course of the disorder: Shorter course had a higher RR: <1 year, RR 53%; >5 years, RR 17%. (f) Neuropsychological defects: There were higher RRs if the patients were without these defects.[10,23]

The impacts of antiepileptic drug (AED) treatment on prognosis are evident. Regular treatment with AEDs may control 70% to 80% of epileptic seizures, whereas with AEDs taken irregularly the RR is similar to untreated. Good compliance with AED treatment leads to good prognosis. One study showed a 92% control rate in a compliant treatment group of children patients, but 56% in the noncompliant group. Recurrence after stopping AED treatment is a major concern of epileptologists. A report from China showed a 24% recurrence rate for 8 years after stopping AEDs, and 55% of the recurrence occurred in the first 1 years.[10]

Clinical Diagnosis and Treatment

The diagnosis and treatment of epilepsy in China has improved greatly in the past 50 years, which may be attributed to the practical efforts of neurologists/epileptologists, the development of the electroencephalography (EEG) and other diagnostic equipment and technology, and the broad international academic exchanges.[49]

Diagnosis of Epilepsy

Adequately Using the International Seizure and Epilepsy Classification to Diagnose Epilepsy

The accurate categorization and recognition of seizures and epilepsies are the foundation of correct diagnosis and further in-depth research and communication, and are also reflected in the progressive knowledge about epilepsy. The international classifications in the 1980s have been wildly used, including the Seizure Classification in 1981, the Epilepsy and Epilepsy Syndrome Classification in 1985, and its revision in 1989 proposed by the International League Against Epilepsy (ILAE). These have received common acceptance by most epileptologists. The introduction of the 1981 ILAE seizure classification into China occurred at the first National Epilepsy Conference in 1985, and it was revised somewhat to make it suitable to the practical situation in China.[37] The Chinese Classification of Epilepsy and Epilepsy Syndromes, referring to ILAE's proposal, was recommended in the seventh National Pediatric Neurology Conference in 1995.[8] The aforementioned classifications of the 1980s are now wildly used in the clinical and research work in China, as well as in research about mesial temporal lobe epilepsy and absence epilepsy, the study of the relationship between mesial temporal epilepsy and hippocampal sclerosis, and clinical observation on uncommon epilepsy syndromes, such as the acquired epileptic aphasia and West syndrome. Since the 1990s, more attention has been given to the clinical research and EEG analysis of frontal lobe epilepsy, which has complex clinical manifestations, and the recognition and diagnosis level to it has been thus much improved.

For the past few decades, much progress has been made in understanding epilepsy symptomatology, etiology, pathology, diagnosis, and treatment. The same progress can be observed in China. In 2001, the ILAE Task Force, led by Prof. Engel, proposed a new classification of epilepsy that reflected the new knowledge in epileptology and influenced the clinical practice greatly. It introduced some new concepts as “axis” in diagnosis, which was helpful to standardize the clinical diagnosis. The proposal was introduced in China soon after its publication and is now used widely.[1] There have been great changes in the classification of epileptic seizures, which rely mostly on the symptoms reflecting the relationship between the symptom and anatomic location that gives clues about the epilepsy syndrome. In addition, classification now emphasizes the psychosocial impacts on the quality of life of epileptic patients in diagnostic procedures. We found that the new proposal was not easy to use with in clinical practice because of lack of detailed explanation in some parts. Epileptic seizures and their semiology, are the core of epilepsy classification. In some degree the new classification ignores changes in high-level cortical function, for example, by excluding classification criteria based on changes in consciousness and neglecting mental manifestations, which are important features of some epileptic seizures. Furthermore, it is difficult to classify occasional seizures observed in clinical work.

The Development of the Electrophysiological Techniques

There are two key features in epilepsy: Clinical seizure and EEG manifestations. EEG is one of the most important auxiliary examinations in epilepsy diagnosis. With no doubt, the emergence of EEG is a milestone that divided the history of epilepsy diagnosis into two stages.

The first EEG machine in China was imported into the Nanjing Brain Disease Hospital in 1949 in China and used in

clinical examinations in 1951. Then a series of training courses about epilepsy and EEG were held by Feng Yingkun from the Peking Union Medical College (PUMC) Hospital. Now EEG testing is used in most hospitals in China. The international system of 10- to 20-electrode placement is used and includes both referential and bipolar recordings. Activating procedures, such as open/close eyes, hyperventilation, intermittent photic stimulation, and sedated sleep are routinely applied in most hospitals. The recording and interpretation of EEG requires expertise, but there are not yet standardized training and qualification systems for EEG technicians in China.

Mesial temporal lobe epilepsy is the most common epilepsy type. Feng Yingkun found that acupuncture pins could be used as substitutes for sphenoidal electrodes with good effect and easy acceptance.[11] There have now been more than 30,000 patients who had acupuncture pins used as sphenoidal electrodes in the PUMC Hospital.

Since the 1990s, video-EEG has been performed in many EEG labs in China. The electrocorticogram and deep electrode EEG have been used in some hospitals, which can give more information in locating the epileptogenic foci.

Other Examination Methods

In addition to electrophysiology, some new diagnostic techniques have been introduced in recent years. Imaging the hippocampus is now performed in China. Hippocampus volumetric quantitative measurement techniques are also very helpful in diagnosing and treating mesial temporal epilepsy.

The Establishment of Epilepsy Centers and Epilepsy Clinics

Since the 1990s, specialized epilepsy clinics and centers have been established in the bigger hospitals. These kinds of centers usually include neurologists, pediatric neurologists, neurosurgeons, psychiatrists and social workers. Sophisticated equipment for diagnosis is available and an operating theater equipped. Multidiscipline cooperation is the most important characteristic of such centers/clinics. They serve not only as clinical work sites, but also as sites for research, training, and public education. These centers are important developments in the prevention and control of epilepsy in China.

Drugs for Epilepsy

Medication is still the most important treatment option for patients with epilepsy. Selection of AEDs depends on the type of seizure and syndrome classification. The common AEDs used in China are valproate, carbamazepine, phenytoin, and phenobarbital. Approximately 60% to 70% of epilepsy patients can achieve remission using monotherapy. Polytherapy is chosen when patients' seizures cannot be controlled by monotherapy. We have found that side effects of rash and neutropenia occur in about 5% to 10% of patients on carbamazepine. Valproate needs careful consideration when it is used in women of child bearing age because of weight-gain and polycystic ovary syndrome effects. Phenytoin and phenobarbital have similar efficacy to carbamazepine but are no longer the first choice because of their adverse effects. However, they are still used as first-line AEDs in rural and poor regions in China. Valproate is drug of first choice in treating generalized seizure, and carbamazepine for focal seizures. Since the 1990s blood levels of AEDs have been available in big hospitals and epilepsy centers.

Since the 1990s, there have become available more than ten new AEDs on the international market, and most of them are useful in cases of intractable epilepsy. With relatively wide spectra, fewer adverse effects, fewer interactions, and better tolerance, the new AEDs offer, more choices for refractory patients. Presently, lamotrigine, topiramate, vigabatrin, gabapentin, and oxcarbazepine are available in China, and zonisamide and levetiracetam are going to be on the market soon. Most new AEDs serve as add-on drugs. The combination of lamotrigine and valproate is better for some refractory epilepsies, but skin rash has occurred.

Epilepsy Surgery: A Review

Although the trephenation opening found on a skull unearthed in Shandong province indicates that the history of surgical treatment of brain disease in China is more than 5,000 years old, modern epilepsy surgery has been available only in recent years. There is no record of epilepsy surgery in the literature or in hospitals' records before the People's Republic of China was established in 1949. The earliest record of epilepsy surgery in China may date to the 1950s to 1960s, for example, "traumatic epilepsy" written by Guosheng Duan, "hemispherectomy for West Syndrome" by Yuquan Shi, and "epilepsy surgery" by Yadu Zhao. In the following two decades, some political and social factors resulted in temporary delay in further development of epilepsy surgery.

In the late 1980s, following implementation of reform and open-door policy, scientific and technologic exchanges between China and Western developed countries resumed quickly. Advanced medical equipment and new techniques were introduced to China. A number of senior neurosurgeons restarted surgical treatment for epilepsy including anterior temporal lobe resection, callosotomy, multiple subpial transection (MST), stereotactic neurosurgery, and cerebellar stimulation. The method of lower-power electrocoagulation of eloquent areas in or adjacent to epileptogenic foci, advocated by Guoming Luan, added a new way to treat eloquent areas in epilepsy.

Localization of Epileptogenic Foci

The effectiveness of epilepsy surgery is mainly based on a precise localization of epileptogenic foci. Currently, many provincial and municipal level hospitals have electrophysiologic examination and sophisticated equipment such as CT, MRI, and even SPECT, PET, and MEG for the diagnosis of epilepsy and synthetic localization of epileptogenic foci. The introduction of MEG has improved the synthetic preoperative evaluation for epilepsy to a new stage. Furthermore, the development of electrophysiologic examination manifested not only in the noninvasion, but also in the invasion technique of using strip or grid or depth electrode. They can give further explanations about which areas have eloquent and noneloquent functions and which areas can be identified as irritating and epileptogenic areas.

The Basic Study Related to Epilepsy Surgery

In recent years, basic scientific research has made great progress, such as the epileptic nets and stereotactic atlas of epileptogenic foci and tissues around them. The various epileptic animal models made by chemical and electrical methods can help neurosurgeons prepare all kinds of operations; the electrophysiologic studies of cerebral cells and tissues can make a ground for treating the intractable epilepsy using electrostimulation methods; the chemical studies of neurosynapse and neuroreceptors in the excitable and suppressive neurotransmitters filed can theoretically support the method of cerebral tissue and neurostem cell transplantation to treat refractory epilepsy;

P.2870

the microstructure studies of epileptogenic foci such as amygdalohippocampus tissues can further expound dual epileptic pathology and its relation to postoperative effects; the neuroimaging studies such as MRI and MRS can clearly define the side and site of epileptogenic foci; and the anatomy studies of epileptic surgical approaches can increase the surgical safety coefficient and reduce the probability of postoperative complications.

The Clinical Studies of Epilepsy Surgery

Most types of epilepsy operations performed elsewhere have been successfully done in China. The number of operations has increased year by year. For example, only 1,840 epilepsy cases were reported in the first epilepsy surgery congress held in 1991, among which there were 933 cases of stereotactic ablation and only half of patients had resections with craniotomy. In the sixth congress of stereotactic and functional neurosurgery in 2004, a total of 2,077 operated cases were reported, among which there were 2,029 epilepsy cases with craniotomy treatment (more than two times the number of 13 years ago) and 48 cases with the stereotactic ablation. There were 680 cases with epileptogenic lesion and neocortical resection reported in the *Chinese Journal of Stereotactic and Functional Neurosurgery* in 2001 and 2002. By 2004, the number of reported cases of epileptogenic lesion and neocortical resection increased to 1,057. The total proportion of Engel I and II levels reached 65% to 85% among them. With regard to temporal lobe epilepsy, about 400 operations were performed each year, and the Engel levels I and II effectiveness reached 75% to 90%. Approximately 400 cases of hemispherectomy, stereotactic radiosurgery, electrostimulation, and other operations have been done each year. What is worth mentioning is that several hospitals recently used lower-power electrocoagulation to treat eloquent epilepsy, amounting to about 200 cases every year, and the proportion of Engel I and II results is around 65%. This fact indicates that the new method has obtained recognition by our domestic colleagues. The number of hospitals with epilepsy surgery capability increased every year. For example, in Beijing, three hospitals had epilepsy departments in the 1990s, whereas nine hospitals had such departments in 2005. Research on "the basic and clinical studies of intractable epilepsy surgery" has been awarded the second prize of the National Science Technology Progress Award.

Application of Neuroimaging and Gamma Knife

A number of hospitals have bought Gamma Knife equipment and begun epilepsy stereotactic radiosurgery programs. In 2004, 15 Leksell Gamma Knifes and 20 OUT-XGD rotation Gamma Knifes were available in China. However, there are still disputes about choice of treatment-site, dose, and effectiveness.

Academic exchanges on epilepsy surgery have been quite active in China in recent years. The Epilepsy Surgery Association was founded in 1990 with around 150 to 200 epilepsy surgeons as members. Several conferences and workshops on epilepsy surgery have been held in the past two decades. The National Epilepsy Surgery Workshop has been held four times since 1991, and the National Stereotactic and Functional Neurosurgery Congress has been held six times since 1987. International academic exchanges about epilepsy surgery have increased remarkably as well.

Three journals of epilepsy surgery are issued in China: *Chinese Journal of Stereotactic and Functional Neurosurgery*, *Asian Journal of Epilepsy*, and *News Letter of Epilepsy Surgery*. In the past 10 years, five monographs were published: Epilepsy Surgery, Temporal Lobe Epilepsy, Temporal Lobe Epilepsy Surgery, Neurosurgery and Epilepsy, and the second edition of Lüders' *Epilepsy Surgery*, in translation.

Basic Research on Genetics and Neurosciences

In recent years studies on the molecular basis of inherited epilepsy have been performed in China. Tang et al. reported a novel frameshift mutation of the *KCNQ2* gene, 1931delG, in a large Chinese family with benign familial neonatal convulsions (BFNC). This mutation is located in the C-terminus of *KCNQ2*, in codon 644, predicting the replacement of the last 201 amino acids with a stretch of 257 amino acids showing a completely different sequence.[36] In a Chinese family with benign familial infantile convulsions (BFICs), Xiao et al. found that it was not linked to the 19q12.1-13.1, 16p12-q12, or 2q24 loci.[50] The results indicated that BFIC showed genetic heterogeneity and the Chinese BFIC families might be mapped on another new locus.

Childhood absence epilepsy (CAE) is one of the most frequently recognized syndromes among the idiopathic generalized epilepsies (IGEs). CAE is considered a genetic disease with a possible polygenic inheritance pattern, but the genes responsible for CAE have not yet been identified. Lu et al. reported that γ-aminobutyric acid $(GABA)_A$ receptor subunit genes, *GABRA5* and *GABRB3*, may be directly involved either in the etiology of CAE in the Chinese population or in linkage disequilibrium with disease-predisposing sites.[28] Their studies suggest that the *GABBR1*, *GABRG2*, T-type calcium channel gene α (1G), and *T-STAR* might not be susceptibility genes for CAE, at least in the Chinese population studied,[7,27] whereas the T-type calcium channel gene *CACNA1H* might be a susceptibility gene to childhood absence epilepsy.[5] The mutation of G773D has been found in one other Chinese family with CAE. Ge et al. concluded that the CAE gene is transmitted with disequilibrium on locus D8S1783, and the CAE gene may be in the ECA1 area on chromosome 8q24. Heterogeneity of the CAE gene in different populations was suspected.[12]

Familial febrile convulsion (FC) is a common pediatric disorder with an obvious inherent predisposition. Qi et al. concluded that FC is linked with chromosome region 19p13.3, but not with chromosomes 6p and 8q.[31] The *CSNK1G2* gene of the region 19p13.3 appears to be a susceptibility gene for FS in the Han population of northern China.[52]

Liu et al. studied the clinical and inherent characteristics of generalized epilepsy with febrile seizures plus (GEFS+) in a large group of Chinese families. This group is screening mutations of *SCN1A, SCN1B, SCN2A*, and *GABRG2* in the Han population, and a new mutation of *SCN1A* has recently been discovered. Huang et al.

reported a GEFS+ gene mapped to 5q34 in two Chinese families and a single nucleotide polymorphism (SNP) from candidate gene *GANRA6* exon 8.[15,26]

Many laboratory facilities are dedicated to exploring the fundamental mechanisms of epilepsy, including drug resistance and the consequences of repeated seizures on brain function, by using different epilepsy models. A model with pharmacoresistent temporal lobe epilepsy features has been developed by repeated intramuscular injection of Coriaria lactone (CL),[45] an abstract from traditional herbs. This model was demonstrated with high kindling efficiency and typical behavioral and electrophysiologic manifestations. CL is reported to increase the release of glutamate and inhibit the synthesis of GABA in cultured neurons; there is also evidence from cerebrospinal fluid (CSF) of an acute CL-induced epilepsy model. In pathologic

studies on the CL model, degeneration of neurons and necrosis of astrocytes appeared widely in different cerebral areas; this was also supported by an increased BCl-2 level in neurons. During the early stage of a CL-induced seizure, an influx of extracellular Ca^{2+} has been found, indicating that Ca^{2+} signals were involved in the CL-induced seizures. One distinct feature of this model was the pharmacoresistance to AEDs, such as carbamazepine, valproate, and phenytoin. An up-regulation of P-GP-multidrug resistance 1 (MDR1) encoded protein P-170 was found in the CL model, especially in the AED-treated CL model, indicating that the mechanism underlying pharmacoresistance to AEDs was associated with overexpression of *MDR1* gene.[8] This model had been widely used in studies of epileptogenesis.

Audiogenic seizure-prone rats were also widely used as epilepsy models. The P77PMC rat has congenital audiogenic seizure (AGS). Zhang et al.[53] found that antisense oligodeoxynucleotides for *N*-methyl-D-aspartate (NMDA) receptor 1 and gap junction protein Cx32 could alleviate AGS and inhibit the frequency and amplitude of neuronal discharges in temporal cortical slices of the P77PMC rat. These results indicate that gap junction protein might play a role in the pathogenesis of epilepsy by controlling functions of electrical synapses. The DBA/2J mouse was another breed of mouse with high-intensity noise-induced audiogenic seizures. Li et al.[24] examined the gene expression profiling of AGS DBA/2J mice by using oligo-microarrays. They specifically tested the effects of Qingyangshenylycosides (QYS), abstracts from TCM, on seizure behavior and gene expression of AGS. Results showed that QYS could effectively prevent AGS and AGS-induced gene expression changes. The antiepileptic effects of some TCM were studied in other research groups. Acorus tatarinowii Schott (ATS), one of the traditional antiepileptic medicines, had been demonstrated to be able to induce sedation, decrease spontaneous activity, and possess anticonvulsive and spasmolytic action in modern pharmacologic studies. Liao et al.[25] reported that both the decoction and volatile oil extracted from ATS exhibited neuroprotection and anticonvulsive effects. Further studies on these Chinese herbs might provide clues for the development of new antiepileptic drugs.

Epileptic seizures might induce neuronal death and secondary epileptic foci. Antiepileptogenesis and neuroprotection may have clinical significance. To evaluate the long-term effects of prolonged neonatal seizures on seizure threshold and neuronal activity in the brain, Ni et al.[30] compared the immunoreactivity changes of c-Fos, NMDA receptor 2C, and $GABA_A$ in single seizure and recurrent seizure models. They found that prolonged seizures had long-term effects on seizure threshold and receptor protein expression, and recurrent seizures could cause obvious neuronal injury. Yin et al.[51] demonstrated that down-regulation of N-ethylmaleimide-sensitive fusion (NSF) protein and the loss of DA neurons were involved in mechanisms underlying the spatial learning memory deficits induced by spontaneous recurrent seizures (SRS). Nitric oxide (NO) is a readily diffusible “intercellular messenger molecule” acting to generate a cascade effect by the second messenger cyclic guanosine monophosphate (cGMP) that mediates excitotoxicity in various brain structures. Sun CK et al.[34] demonstrated that a single injection of kainate (10 mg/kg intraperitoneally) induces progressive seizures with an increased accumulation of nitrite, the stable metabolite of NO, in hippocampal homogenates of rodents, measured by the Griess reaction. L-NG-nitroarginine (NNA), an inhibitor of constitutive NO synthases (cNOS), especially neuronal NOS (nNOS), significantly enhanced the severity of kainate-induced seizures and damage in hippocampal subregions. However, administration of L-arginine (Arg), a substrate for NO synthase, unexpectedly suppressed both seizures and brain damage. The effects of NNA and Arg on kainate-induced seizures and brain damage were accompanied by appositive changes in immunoreactivity of glial fibrillary acidic protein (GFAP) and interleukin-6 in the hippocampus.

The research grants for epilepsy have been increased greatly in China in recent years. As more and more scientists have been interested in epileptology, more detailed discoveries are expected in the future.

Psychosocial Aspects of Epilepsy in China

Fear, misunderstanding, and the resulting social stigma and discrimination surrounding epilepsy often force people with this disorder "into the shadows." The social effect may vary from country to country and culture to culture, but it is clear that throughout the world the social consequences of epilepsy are often more difficult to overcome than the seizures themselves.[48]

Cross-cultural studies on epileptic patients revealed high rates of psychological and social problems.[2,18] Epileptic patients are frequently denied schooling, shunned by their peers, find it difficult to marry, and meet active employment discrimination.

In recent years, psychosocial studies on epilepsy have been performed in China. In 1988 a public awareness of epilepsy study was conducted among 1,278 respondents in Henan province. The study found that 93% of interviewees had heard of epilepsy; more than 75% knew someone with epilepsy; and almost 75% had seen someone have a seizure.[21] Furthermore, expressed negative attitudes were extensive. More than 50% of the sample said that they would object to having their children associate or play with persons with epilepsy; more than 50% also believed epileptics should not be employed in the same jobs as others. Notably, 87%, irrespective of their education level, would object to having their children marry a person with epilepsy.

In 1992, in cooperation with Dr. A. Kleinman from Harvard University, the Beijing Neurosurgical Institute conducted a psychosocial study in adult epileptic patients.[19] Forty patients with epilepsy in urban areas and 40 patients with epilepsy in rural areas were selected from the Ningxia and Shanxi provinces. The patients and their family members were interviewed together and separately during home visits by local research teams composed of neurologists who had been trained to use a semi-structured interview schedule in training workshops. The interview canvassed demographics, experiences of illness and treatment, and both family and patient perspectives on local social responses to and consequences of the illness. The interview format used open-ended questions to encourage extended responses.

Great variation exists in the public's ideas of the cause of epilepsy, ranging from heredity, head injury, possession, geomancy, poverty, and overwork to anger and fright. Patients and their family members showed a tendency to increasingly use overwork, strong effects, and a wide range of new explanations to explain why seizures continued (Table 5). Possession and head injury were less frequently named as likely causes.

Table 5 Perceived Causes of Seizures by Epileptic Patients

"Cause"	%	"Cause"	%
Anger	23%	Wrong food	5%
Possession	19%	Retribution	5%
Fright or anxiety	16%	God's will	3%
Head injury	16%	Heredity	4%
Negative geomancy	8%	Infection	3%
Poverty	8%	Congenital	1%

Overworked	8%	Others[a]	25%

[a]Includes weather change, menstruation, smoking, febrile convulsion, carbon monoxide poisoning, etc.
From Wang WZ, et al. *Chin Ment Health J.* 1995;9:129.

Table 6 Impacts of Epilepsy on Patients and Family

	Ningxia		Shanxi		Total (%)	
	Patients	Family	Patients	Family	Patients	Family
Stigma	36	38	35	23	71 (89)	61 (76)

Quality of life	34	38	29	16	63 (79)	54 (68)

From Wang WZ, Li SC, Cheng X, et al. A study on phychological and social aspects in adults with epilepsy. *Chin Ment Health J.* 1995;9:129

Table 6 shows respondents' perception of the chief effects of epilepsy on the patients. Emotional, financial, and family/marital burdens were reported to be extensive. Relations with others and overall quality of life also were strongly affected. These effects appear to be greater in rural areas. Stigma affects both the family members and the patients themselves. Most of them felt “loss of face” (conveying the embodied sense of shameful loss of moral status) and feelings of diminished self-esteem were widespread.

The Western tradition's emphasis on the subjective feeling of the afflicted individual, often viewed as isolated and forlorn, is the dominant analytic paradigm for understanding the suffering that results from serious chronic illness and disability.[20] Furthermore, suffering becomes the pain, hurt, loss, and search for meaning of a unique person who alone must bear the deep burden of his or her troubles. According to this view, suffering is a mode of social experience. The point is not to minimize the seriousness of the problems faced by individual patients with epilepsy in our study, but rather to appreciate the importance that they and their families attribute to the interpersonal, relational locus of hardship among the members of the family. Indeed, this intersubjective sensibility frequently leads family members to emphasize their own adversity as equivalent to or even greater than the patient's experience. The study focused on the concerns by the family and its members. What is most at stake in suffering is the abridgement of the family's aspirations, the threat to the life chances of its members, and the loss and hurt of the others. The result showed that suffering is as much the intersubjective experience of parents, spouses, siblings, and children as that of the patient.

For Chinese parents, the presence of a disabled child means that they are both legally and morally responsible for his or her care until that son or daughter gets married or the child dies. With marriage, the responsibility for care is shifted to the spouse and the couple's future children. Thus, there is great pressure to arrange marriage. To do so, parents try to disguise that their child has epilepsy, but if they are unable to, they will barter for a spouse with promises of an urban residence permit or employment. Illness and disability restrict the pool of potential marital partners to those who also have illness or disability and to those who are poorer, more rural, less educated, and physically less attractive. The consequences of disguise and barter are fraught with interpersonal tensions that the parents, patient, and spouse must negotiate over the long term. But to not marry is far worse: It threatens the centrality of family in Chinese society.

Many respondents believe that the financial consequences of epilepsy are serious and even ruinous. Perhaps no other aspect of social life so clearly shows the power of chronic illness to affect local worlds and reciprocally of local worlds to influence the course of illness and treatment. The current economic transformation of Chinese society marks finances as a major issue, especially in the poor regions where our study was conducted. Some farmers in our sample lived at the brink of financial catastrophe. The social welfare net of communal life is no longer

available to prevent the poorest in China from falling into extreme poverty. The economic constraints on the social course of epilepsy and other chronic illnesses often means that patients cannot afford proper treatment. The illness, in turn, transforms the economic conditions of everyday life, using up very limited reserves, creating or deepening debt, and forcing families into humiliating and often unavailing negotiations with creditors, who are also under financial pressure. The outcome is illness as the precipitant of end-stage misery. This is a powerful social consequence of illness that deserves far more attention in medical anthropology. Those who are most disadvantaged also appear to suffer the most from discrimination on account of epilepsy.

Recent research in the West challenges the idea that the stigma of epilepsy is unrelenting, and its effects always devastating. In those whose seizures are in remission, psychosocial functioning has been reported as high, with low levels of distress.[17] Public information campaigns in Western societies have improved public attitudes toward epilepsy sufferers. But the situation for epilepsy in China and other low-income regions, is extremely different and has not changed. Those with seizures routinely experience discrimination in schools, in the workplace, and in the community.

Most patients in our sample have chronic epilepsy with frequent seizures. For them and their families, the serious consequences of epilepsy are intensified by Chinese society's prioritizing of social control as the chief concern in the societal response to this and to other chronic conditions in which behavior is affected. The emphasis on social control, rather than patient rights, means that students with epilepsy may be refused to enter colleges, universities, and even middle school; people with epilepsy may not be employed, and some work units may discriminate against patients and their families who are requesting more resources for treatment.

On the other hand, overcontrol can also be viewed in a more positive light as an extreme aspect of families' routine supervision of seriously afflicted members at work, play, and home, which supports many members to participate in daily life activities while protecting them from injury. In Chinese society, institutional assistance for the disabled is largely limited to the family. Thus, the family is at once both the source of nurture and assistance but also a potential source of overcontrol.

Stigma is a moral category, yet in the Chinese context, moral blame is applied to the patient and extends to the entire family. Ideas that attribute the cause of epilepsy to bad fate, heredity, negative geomantic forces, and the malign influences of gods, ghosts, or ancestors are all accusations about the moral status of the family. Inasmuch as Chinese society turns on the individual's kinship circle and social network, families and networks that are morally compromised are perceived as ineffective and indeed actually can become so as members drop out and their social-relational power is lost. The moral status of the person is his or her face; social relations “give face” or “save face.” To “lose face” is to carry the social experience of shame into the inner experience of the body/self. The indigenous Chinese model of stigma, however, is sociosomatic and frames intersubjective delegitimation, not spoiled personal identity, as the central process. Because the person is constructed in Chinese culture as a relational self, delegitimation of the family and network is the most fundamental assault the person can experience.

Our findings revealed that epilepsy is best regarded as possessing a social course, and it results in many psychosocial problems in China, which including medical workers and governments, society should pay more attention to.

Another study on developing approaches to reducing stigma of epilepsy[16] organized by Ann Jacoby from Liverpool University, United Kingdom, supported by the National Institutes of Health, has been carried out since 2004 in China and Vietnam. Its first phase finished in June 2005, and the results were published in 2006.

Community Control Programs in Rural Areas

In 1985, the Mental Health Division of the World Health Organization (WHO) began designing a project to manage epilepsy care at a community level, because there were so many PWE in developing countries, especially in rural areas, but a lack of neurologists to treat them. With the similar situation and concern, China joined the efforts of the WHO.

In 1989 and 1993, a feasibility study on “community control of epilepsy” was conducted in China. The basic design of this project was to train village public health workers (PHWs) to use flow charts to administer phenobarbital (PB) to patients with GTCSs. Effects of treatment by village PHWs were compared with effects of treatment by neurologists. Compliance and side effects were also compared between the two groups. There were no statistical differences in the outcomes between the two treatment groups. Therefore it was suggested that the “community control of epilepsy” project was feasible in rural areas of China.[22,39]

In 1997, the WHO, in cooperation with the ILAE and the International Bureau for Epilepsy (IBE), launched the Global Campaign Against Epilepsy (GCAE).[9] As part of the GCAE's activities, a demonstration project to test the pragmatic model was set up in five locations worldwide.[33] The project, entitled Epilepsy Management at a Primary Health Level: Protocol for a Demonstration Project in the People's Republic of China, was successfully conducted in China.[42]

The Chinese project included an epidemiologic survey, an intervention trial, and an educational program in target areas. The study found that 63% of the detected people with active epilepsy (PWAE) had not received antiepileptic medication in the week before the survey (i.e., the treatment gap was 63%).[43] More than 85% of PWAE had GTCSs. Commenced from December 2001, the intervention trial was conducted including identifying patents with GTCSs, PB treatment, follow-up, and management. At the same time, education promotion activities were provided to the patients, their family numbers, and the public to broaden their scientific knowledge about epilepsy and reduce their misunderstanding and discrimination against people with epilepsy. This research involved eight counties in six provinces, with a total investigated target of 3,185,067 inhabitants. A total of 2,455 patients (1,381 males) were recruited into the study (demographic details on baseline are shown in Table 7). Duration of follow-up ranged from 1 day to 32 months (mean 20.5 months; median 25 months).

Methods

Patients with GTCSs were identified at a primary care level and provided with PB monotherapy. The starting dose was 60 mg for adults and 15 mg for children, taken once daily at nighttime, and maintenance dosage was 120 to 180 mg/day for adults and 4 to 5 mg/kg/day for children. Patients attended their local clinic every 2 weeks for the first 2 months and monthly thereafter, for dose adjustments, side effect assessment, and adherence checking, and to receive a further supply of medication. Physicians completed a follow-up form at each visit, recording seizure numbers, compliance, and side effects (using a checklist of common side effects of PB) experienced by the patients. Efficacy was evaluated from the percentage reduction in seizure frequency from baseline and as the retention of patients on treatment.

Table 7 Patient Demographics in the China Demonstration Project

Age	Mean 32.6 yr	(SD 20.7 yr)
2–14 years	268	11%
15–44 years	1544	63%
45–59 years	459	19%
≥60 years	184	7%
Age at onset	Mean 17.1 yr	(SD 14.4 yr)
Duration of epilepsy	Mean 15.5 yr	(SD 17.9 yr)
Baseline seizure frequency	Mean 35 seizures per year	

SD, standard deviation.

Table 8 Seizure Frequency after 6, 12, and 24 Months of Treatment

Change in seizure frequency from baseline	6 Months		12 Months		24 Months	
	N	%	N	%	N	%
Seizure free	919	41	644	34	347	26

Reduced by >75%	305	14	415	22	415	31
Reduced by 51%–75%	245	11	230	12	185	14
Reduced by 26%–50%	162	7	146	8	99	7
Reduced by <25%	217	10	156	8	91	7
Increased by ≥25%	369	17	306	16	187	14
Total	2,217		1,897		1,324	

Findings

Efficacy

The efficacy of PB treatment was evaluated over three periods. The first evaluation included 2,217 patients who were treated for 6 months, the second included 1,897 patients who completed 12 months treatment, and the third included 1,324 patients who completed 24 months treatment. The changes of the seizure frequency in the three periods are listed in Table 8. No evident differences in efficacy of PB treatment were observed among the study sites.

Side Effects of Phenobarbital

Over the treatment period the frequency of all side effects was reduced (Table 9). Most patients, including 189 taking at least 180 mg PB per day, experienced few side effects; only 4% and 0.3%, respectively, experienced moderate and severe side effects; and 32 patients (1%) discontinued medication because of side effects.

Adherence and Withdrawal

Tablet counting proved that over 95% of patients had good compliance to the treatment regimen at each follow-up. By the end of 24 months of treatment, adherence in those continuing in the study was estimated at almost 100%.

A total of 562 patients (23%) withdrew from the study before its completion, and 35 patients died during the study period. The causes of withdrawal are shown in Table 10. In the group who did not complete the study, the most common cause for withdrawal (28% of all withdrawals) was the subjective assumption of cure by the patients. Eighty-one individuals had increased seizure frequency of more than 50% from baseline. The reason for this “increase” needs to be further studied. Eighteen percent of those were withdrawn due to noncompliance.

The above-mentioned project was successfully implemented within the existing services in rural areas of China. It confirmed that in this setting the PB treatment protocol is feasible and that PB has high efficacy and tolerability and can help to reduce the large treatment gap. Because of this study's success the same approach has been extended to ten more locations in China and will become a national program. By September 2005, more than 10,500 individuals with GTCS epilepsy had been treated according to this protocol. This project has given hope and confidence to many PWE in China, but the work should be replicated in other countries before it can be fully recommended. Even the best intervention can only succeed when individuals and communities understand enough of the process and are able to fully participate. Furthermore, the integration of such a program into existing services is essential to ensure its sustainability. These issues should be taken into consideration in any future interventions.

Table 9 Side Effects Experienced at Different Time Points

Side effects	1–3 mo (N = 2,455) N (%)	7–12 mo (N = 2,135) N (%)	19–24 mo (N = 1,495) N (%)
Drowsiness	667 (27)	287 (13)	120 (8)
Dizziness	320 (13)	182 (9)	81 (5)
Headache	185 (8)	108 (5)	41 (3)
Ataxia	182 (7)	87 (4)	30 (2)
Anxiety	154 (6)	94 (4)	31 (2)
Hyperactivity	51 (2)	37 (2)	13 (1)
Gastrointestinal complaints	347 (14)	192 (9)	55 (4)
Skin rash	81 (3)	34 (2)	13 (1)
Others	69 (3)	27 (1)	14 (1)

Table 10 Causes of Withdrawal

Withdrawal causes	Patient numbers (%)
Patient perception of "cure"	169 (28)
Noncompliance with regimen	104 (18)
Perception of inefficacy	97 (16)
Lost to follow-up	53 (9)

Migrated from study area	38 (6)
Death	35 (6)
Side effects	32 (5)
Others	69 (12)
Total	597 (100)

Traditional Chinese Medicine and Epilepsy

Knowledge of Epilepsy in Traditional Chinese

In traditional Chinese medicine (TCM), epilepsy belongs to the diagnosis "Xian Bing" and is also called "Yang Dian Feng" (goat stroke). It refers to a seizure caused by organic and mental injury, which results in the loss of spirit control. The etiology of epilepsy is due to congenital and acquired factors, especially mental factors. Congenital factors refer to heredity dysfunction, pregnancy disturbance, and bad gift of embryo. It was said in the TCM classical book *Plain Questions* that "epilepsy of baby after birth come[s] from the outside shock, which frightens the mother and cause[s] Qi stasis." Huo You Xin Shu, another pediatrics book of China noted the following: "An overmuch taking in of sour-salty food or mental disturbance of the mother may interfere [with] the embryo and cause epilepsy." Acquired factors include external pathologic factors such as abnormal diet and mental status, injury, and brain parasites. Stroke may also cause epilepsy.

Pathologic Pivots

Generally, deficiency of the liver, kidney, and spleen, which will cause internal wind, phlegm, and blood stagnation, is the basis of epilepsy.

Seizure Stage

Abnormal circulation of Qi is the pathologic pivot of epilepsy in seizure stage. Every kind of Qi in TCM has its own principle of circulation. If any type of Qi is circulating the wrong way, a reverse flow of Qi will attack and clog the openings of the brain, resulting in dizziness, twitching, or coma.

Truce Stage

Mild epilepsy may have a truce of months or years, while a severe epilepsy may have a truce of only minutes. The truce only means a temporary dissipation of evils, but a recurrence is expectable at any time because of the existence of pathologic factors.

Convalescence Stage

In this stage, epilepsy may stop for more than 3 years. Three outcomes are accessible in this stage: Healing, because of the elimination of pathologic factors and rectification of organic functions; recurrence, only in special conditions such as infections, brain injuries, overeating, fatigue, and menstruation, but with organic function coming back normal; and no recovery of the organs can be expected, especially brain, liver, and kidney.

Treatment in Traditional Chinese Medicine

Treatment Principles

Alerting the consciousness in seizure stage, reinforcing the deficiency, expelling evils in truce and convalescence stages should be the treatment principle. To expel the evils, we should clear the phlegm and repress the internal wind. To reinforce deficiency, we should nourish the spleen, liver, and kidney and calm the heart.

Various TCM therapies are available as medicine, acupuncture and moxibustion, massage, diet, and psychological therapy. For medicinal treatment, we have patent medicine and syndrome-differentiating medicine. For acupuncture, we have body, auricle, and scalp acupuncture. Thread imbedding and fascia cutting are also introduced on the basis of acupuncture.

P.2876

Recent Development of Treatment on Epilepsy in Traditional Chinese Medicine[4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35]

Pharmacologic Treatment

The controlled clinical trials of the fixed TCM prescriptions for epilepsy treatment developed recently were carried out in China.

Extracts of Chinese Medicine

Extracts of Chinese medicine for epilepsy, which proved to be effective, has been paid more and more attention these days. Distilling of effective ingredients from herbs may help us to better understand their chemical structure and structure activity relationship so that further synthesizing and developing work of new medications can be done. The effective ingredients in some herbs now can already be affirmed, and the mechanism research are now being undertaken.

Nonpharmacological Treatment

Acupuncture and Medicine.

Acupuncture is effective economically and harmless for the treatment of epilepsy. Acupuncture combined with medicine proved to be clinically effective in research comparing traditional acupuncture and scalp acupuncture, electroacupuncture, thread imbedding, and acuinjection.

Summary and Conclusions

There are approximately 9 million people with epilepsy in the People's Republic of China, including 6 million people with active epilepsy. Moreover, there are an additional 0.4 million new cases each year. A survey suggests that nearly 65% of these patients do not receive appropriate medical treatment. In China, epilepsy has been treated by TCM in a long history. Beginning in the 1950s, the clinical diagnosis and treatment of epilepsy made substantial progress. Epidemiology, clinical neurologic diagnosis and treatment, epilepsy surgery, basic research, sociopsychological problems, rural community control programs, and TCM recognition of epilepsy in China have progressed greatly in recent years.

Chapter 292

Germany

Margarete Pfäfflin

Rupprecht Thorbecke

Introduction

The German social welfare system was introduced between 1883 and 1889 by Chancellor Bismarck in an attempt to maintain his authoritative rule by outmaneuvering the rising social democratic movement. This system, which has survived several political eras—the Kaiserreich, the Weimar Republic, and National Socialism—was created to insure general life risks. State legislation on health insurance was passed in 1883, on state accident insurance in 1884, and on old-age and pension insurance in 1889. In 1927, this system was supplemented by legislation on unemployment insurance (including job-creating measures). Subsequent to the increasing number of senior citizens, a fifth pillar of welfare, the nursing insuring act, was enacted in 1994. Currently, more than 90% of the 82 million inhabitants of Germany are covered by the state-provided social welfare system in regard to sickness, accidents at the workplace, occupational disease, disability, unemployment, nursing needs, and motherhood.[9]

Objectives of German Social Welfare

The principles of state-provided social welfare are listed as follows:

1. Compulsory membership. All adults with incomes below a certain level (3.375 € per month in 2002) must join. Family members (children, spouses) without income are covered as well. Professionals and people with incomes above this level may opt for the social insurance system or obtain private insurance.
2. Solidarity. Payment depends on one's income; services of social welfare depend on one's needs. Everyone receives the same services, independent of premium, health risks, gender, or age. Public pension plans and unemployment insurance are related to former income level and the length of time insured.
3. Principally, health insurance is financed through the members. Nevertheless, insurance fees are divided (e.g., between employers and employees, between pensioners and the state pension insurance). Low-income groups like students pay a fixed fee. With the exception of state accident insurance, which is paid solely by the employers, each person pays around half of the premium. Because the level of the premium is related to income, the basis of the social welfare system is determined by the sum of all wages. The state subsidizes some of the insurance plans.
4. Social welfare insurance plans are self-governing public corporations under federal supervision. Their boards are composed of elected delegates equally representing employers and employees. Numerous organizations back up the insurance plans. However, all are controlled by state health legislation. Unemployment insurance has only one supporting organization, the federal labor office.

The tasks of different insurance plans partially overlap, which can lead to conflicts with respect to responsibility for measures. Who pays is determined by who has the financial risk in case the measure fails. State pension or unemployment insurance is responsible for vocational rehabilitation; state pension or health insurance is responsible for "medical" (functional) rehabilitation. Apart from this, health insurance covers medical treatment. This "division of responsibility" has strings attached. Vocational training, for example, cannot be started during medical treatment or medical rehabilitation, even though this would be advantageous from the patient's point of view. Therefore, comprehensive care relies on the voluntary cooperation of health professionals beyond the limits of administration.

Community welfare completes the system of social welfare. It is founded on the principle of communal welfare, which existed long before Bismarck. Under this plan, persons who are not able to make their own living, who are unemployed (for more than 1 year, currently), and who are not covered by health insurance can ask for income support or welfare. Social welfare is financed primarily by community taxes. The number of people on welfare is determined mainly by employment opportunities. In the past 20 years this number has grown threefold.

Private Insurance Plans

Individuals with incomes above a certain limit can obtain private insurance. Private insurance plans charge according to the covered services. Age, gender, health risks, and chronic illnesses influence the level of premium an individual is charged. Private insurers can reject applicants if the insurance risk is assessed as being too high. About 10% of the population had private health insurance in 2003.[9] Persons with epilepsy who cannot insure themselves in the state health insurance system (e.g., self-employed persons, lawyers, and physicians) may have difficulty finding private health insurance. If they are accepted by a private company, they often have to pay high risk premiums or the insurance plan does not include epilepsy as a covered condition. For persons with epilepsy, private accident insurance plans and disability insurance are especially difficult to obtain. Among 236 privately insured patients with epilepsy, none was able to obtain disability insurance.[10]

State Health Care

State Health Insurance: Budget Organization and Development

Originally, state health insurance was established to guarantee medical care and help avoid loss of income due to sickness. Since 1970, members of the state health insurance system generally receive sickness benefits for 6 weeks. In 2003, more than 72 million inhabitants were insured by state health

P.2880

insurance.[9] Of these, about 30% were covered as noncontributing family members, and 22% were pensioners paying minimal contribution. During the past 20 years, the income from premiums has increased at a far slower rate than the expenditure. Although the average membership rate changed from 8.4% to 14% of salary, expenditure increases continuously, especially expenditure on hospital treatment, which increases every year between 1% and 3%.[2,9] Hospital expenditure accounts for one third of all health care expenditures.

In 1993, a law was passed to keep the increase in expenditures equal to that of the income premium. Expenditure has decreased as a result, but not enough. Therefore, numerous laws have been passed to control expenditures. This process is ongoing. Financial barriers between hospital treatment and primary care are partially torn down through “integrative care” such as disease management plans and managed care programs. Administration has blown up to a great extent, not to the advantage of patent care. Insurance plans independent from employment and wages are in discussion. As a result, the idea of the welfare state is being questioned, with some suggesting that state health insurance should be limited to standard treatment, and optional treatment should be paid for privately. Already, since about 8 years, an increasing amount of health care services has to be paid by the patients themselves in addition to the reimbursements of the insurance.

Health Services

Germany has a high density of medical care services, albeit one that is unevenly distributed between urban and rural areas. In 2003, there was one physician for every 370 inhabitants and one hospital bed for every 150 inhabitants, which is a decrease of about 20% within the last 15 years. Of about 300,000 physicians, 41% worked in hospitals, 3% in rehabilitation units, 42% in solo practice, and 13% in scientific institutions, administration, and federal health services (institutions that control epidemics with measures such as vaccinations and hygiene). When a patient decides to be treated, he or she has free choice among doctors in private practice (general practitioners and specialists, e.g., neurologists) who are contractors of health insurance plans. Often the proximity of a practice or the waiting period rather than the quality of treatment is decisive in determining a patient's choice. Doctors in own practice may refer patients to hospitals or to outpatient treatment units at hospitals. The ratio between doctors in hospitals and nonmedical staff members (e.g., nurses, technical staff members, midwives, social workers, psychologists, pharmacists) was 1:7.5 in 2003.[9]

The basic idea of the German health system is that the doctor provides treatment and advice. Newly, therapeutic psychologists in solo practice are included in the treatment service and refunded by the insurance plans comparable to physicians. Despite this rather physician-centered approach, nonmedical health-related services outside the hospitals have expanded greatly during the past 100 years. Such services include advice centers established by churches and welfare associations and health-related services developed outside the state health systems. These services as a rule are either free of charge for the clients (e.g., advice centers of churches or of the state) or clients can use the service at their own expense (e.g., physiotherapy or psychotherapy in solo practice). Reimbursement by the state health insurance for nonmedical health-related services is possible, as an exception, and often requires bureaucratic procedures.[1] Thus, comprehensive care is affected sometimes by a lack of funding but more often by a lack of communication and competition for patients.

Primary Care

Primary care in Germany does not have as clear a structure as it does in other countries, such as the United Kingdom. There are general practitioners and pediatricians in solo practice,

specialists or consultants (such as neurologists and internists) in solo practice, and specialists in hospital outpatient clinics. The latter depend on permits given by health insurance and physicians organizations. Apart from university clinics, these are only given in exceptional cases. Outpatient clinics may offer comprehensive care because professionals other than doctors, who are employed in the affiliated hospital, may be called on for their services (e.g., neuropsychologists or social workers). However, these additional services are not always refunded by the patient's insurance. There are no clear rules with respect to treatment of specific diseases. Thus, a general practitioner, an internist, or a neurologist might treat a person with epilepsy.

The structure of primary care is negotiated by doctors' organizations and health insurance providers. Arrangements include the guarantee of medical care in a certain region, guarantee of 24-hour availability, and a basic set of covered services. Physicians prescribe medications, confirm a patient's inability to work, and refer patients to specialists or hospitals. Medical treatment in regard to necessity, implementation, and correct calculation is scrutinized. Economic efficiency is evaluated by the doctors' organizations and health insurance providers, as is compensation. Services of physicians are calculated by evaluating every service. Because of the current law that establishes the formula that costs may not increase more than basic wages, physicians working harder get less for their services than before.[1]

Hospital Treatment

Hospitals are one of the oldest services provided. Although their purpose has not changed over the years, their equipment, size, and specialization have. In 2003 hospitals numbered 2,197, of which 373 had a special department for neurology.[9] Hospitals are financed by a dual system. Capital costs for investment are paid through the public budget, and current costs for treatment are paid by the patients, usually through the state health insurance plans. Until 1992, hospitals had cost-based charges. Since then, hospitals have received a budget that is linked to basic wages. Now a complicated account and contract system is instated, which will mean that hospitals are managed more like businesses. Competition between hospitals leads to fusions of hospitals, closing down of smaller houses, and reduction of the number of hospital beds. The financial frames are set through the German version of the DRG system (diagnose related groups). Patients with high nursing needs (e.g., the elderly or chronically ill persons, including persons with epilepsy) may then become unattractive to hospitals. The average hospital stay has shortened from 14.0 days in 1991 to 8.9 days in 2003, and capacity utilization from 84.1% in 1991 to 77.6% in 2003.[9]

Table 1 Patients with Epilepsy per Group of Physicians in Solo Practice and per Year

Physicians	No. of physicians	No. of epilepsy patients		Percentile		
		M +	SD	25%	50%	75%
Neurologists	4,000	48.19	57.45	10	30	65
General practitioners	61,916	4.83	4.68	2	4	6
Pediatricians	6,000	14.45	29.05	3	7	15

M, mean; SD, standard deviation.

Care for Persons with Epilepsy

Care for Children

Primary Care

As a rule, children with epilepsy in Germany are treated by pediatricians. Newly, a number of pediatric neurologists in solo practice have organized themselves. The list of pediatric neurologists sums up to 107 pediatric neurologists in solo practice. In larger cities only with several pediatricians in solo practice, one usually concentrates on epilepsy, and children with seizures can be referred to him or her by his or her colleagues. Children in Germany have the right to nine medical checkups in the first 6 years of life; more than 90% of families take part in these checkups. After the checkups, a doctor may order nonmedical treatment such as psychological therapy and diagnostics, speech therapy, or psychomotor exercises.

The pediatrician can refer children to a pediatric neurologist who works in an outpatient clinic or a medical center. In Germany there are around 170 pediatric outpatient clinics, of which 103 additionally specialized in epilepsy (in 2004). These specialized outpatient clinics usually have access to psychologists, social workers, physiotherapists, and other specialists, of whom quite a few have expertise in epilepsy. Education of staff members in epilepsy is one of the most important issues now. Nonmedical professionals can attend courses to acquire an additional expertise in epileptology certified through the German chapter of the International League Against Epilepsy (ILAE). Therefore, expertise in pediatric (as well as in adult) epilepsy is growing. The pediatrician in solo practice may also refer a child requiring sophisticated treatment to a hospital specializing in pediatric neurology. There are about 200 such departments in Germany; every outpatient clinic for children with epilepsy is affiliated with one of these.

A pediatrician is more likely to refer a child with epilepsy (especially one with complicated epilepsy) to a colleague with expertise in epilepsy at one of the above-mentioned centers if he or she has already established a good working relationship. Referral to such a center ensures that the pediatrician is expanding the patients' treatment options.

Primary care for children in Germany is, with a few exceptions, sufficient and of good quality. A child's development can be closely tracked through the medical checkup system. Somatic illnesses are usually recognized early. Some problems remain, however. It is often not easy to find the level of specialized care adequate to a patient's needs, and persistence is required. Parents may have to test several options before finding the right one. Pediatricians often misjudge the level of development in children with complicated types of epilepsy, falsely assuring concerned parents that nothing is wrong. When children are finally referred to specialized care, they have often experienced delays in diagnosis and treatment of secondary problems.

Hospital Treatment

Children with febrile or afebrile seizures are usually transferred to the pediatric department of the nearest general hospital or to the nearest pediatric neurology department of a university hospital.[3] Diagnosis and proposal for treatment are offered to the pediatrician in solo practice. Children with more complicated forms of epilepsy, including refractory seizures, are transferred to the hospital again and again. Only if treatment is unsuccessful over a long period of time is a child referred to one of five specialized centers for epilepsy. Regular children's hospitals usually do not have the resources to treat complicated types of epilepsy. They lack the experience in helping parents cope with changes in medication, during which children may have more frequent seizures, and also lack expertise in psychosocial problems accompanying difficult-to-treat epilepsies. Staff members in epilepsy centers, in which medical treatment, psychosocial counseling, and special education are offered, usually believe that early referral prevents delays in achieving optimal treatment.

Children can be treated in all of the five epilepsy centers for children in Germany. The centers provide specialized treatment including epilepsy surgery, neuropsychological assessments, counseling for parents, and educational advice. For adolescents, guidance in vocational training is offered. The Bethel Epilepsy Center is one of the most important referral centers for epilepsy surgery in children in Europe. It is *the* referral center for the very young age group in the German-speaking countries. Epilepsy centers also function as advisory centers, transferring their expertise in treatment and rehabilitation into the home communities of the patients. They also serve as educational centers for medical and nonmedical personnel.

Centers for Medical Rehabilitation

There are five rehabilitative centers for children and adolescents with neurologic diseases. They follow a comprehensive approach with the aims to integrate children into school and into professional education. They teach skills to prepare them for independent living. Apart from medical treatment they offer physiotherapy, speech therapy, (neuro-)psychological treatment, counseling, and special work-preparatory courses. All centers have broad experience with children with epilepsy.

Table 2 Hospital Treatment in 2000

	No. of cases	No. of days hospitalized	Days per case
Total	17,313,222 (100%)	65,821,972 (100%)	9.0
Epilepsy	128,698 (0.74%)	1,312,720 (0.84%)	10.2

Included are all cases with the main diagnosis epilepsy (G40 and G41, International classification of Diseases and Related Health Problems (ICD) version 10, WHO); http://www.who.int/classifications/en/

Care for Adults

Primary Care for Adults

In Germany little is known about primary care for adults with epilepsy. To remedy this, a widespread survey has been performed.[6] Results show that an average of four to five patients with epilepsy consulted 1 of about 62,000 family doctors per year (Table 1). After the first seizure, in most cases it is the family doctor who is asked for advice and who establishes a diagnosis. Frequently this doctor refers the patient to a neurologist for confirmation of diagnosis, electroencephalography (EEG), and initial treatment. The neurologist usually refers

the patient back to the primary care physician or tries to establish a consulting arrangement. In Germany there are about 4,000 neurologists in solo practice who care for 50% to 60% of patients with epilepsy, the remaining being treated by general practitioners or pediatricians. Within the group of neurologists in solo practice, about 12% concentrate on epilepsy, treating a higher number of patients with epilepsy. They do have a special qualification in the treatment and counseling of persons with epilepsy. Their qualification is certified by the German chapter of the ILAE. The German chapter of the ILAE has established guidelines for the treatment of persons with epilepsy in solo practice specializing in epilepsy treatment. Because of this development, the standard of care for persons with epilepsy has improved in Germany.

The German chapter of the ILAE established guidelines for diagnosis and treatment of epilepsy, which take the position that a division of labor should be established within a multilevel service system. Up to now, the expertise in a multilevel system of care has not been used systematically by physicians or patients. Patients move frequently between family doctors and neurologists. Only a few are treated in outpatient clinics or specialized centers.

In 2005 there were 38 outpatient clinics for adolescents and adults with epilepsy. These clinics have access to EEG and video-EEG, and most of them to computed tomography (CT) and magnetic resonance imaging (MRI). The average waiting period for a first appointment is 1 to 3 months. All outpatient clinics have access to a social worker, who in the some cases has a specialized training in epilepsy. In the last 10 years the social workers have been offered advanced training, and they form a network to support each other in specialized questions. Brochures, leaflets, and Internet information have been developed for patients' service. Problems of prime importance are occupational in nature. About 50% of adult patients with seizures are faced with considerable job problems. They are unemployed, prematurely retired, or employed below their qualifications. Epilepsy was cited as the reason for an inability to work in about half of the cases seen in the outpatient clinic of the Epilepsy Center Bethel in 2003.

Hospital Treatment

The number of hospital treatments and the average length of stay are generally viewed as excessive in Germany (Table 2). Many persons who have seizures with loss of consciousness or body control are admitted to the hospital even when they carry a note stating that no help is necessary. This is because people who witness a seizure may feel that they are providing assistance by taking the person to a hospital. A person who is admitted to a hospital usually has to stay at least 1 night for observation. In theory, patients can leave the hospital on their own volition, but most do not.

In Germany there are eight specialized epilepsy centers, which provide the highest level of care for adults with epilepsy. All these centers provide diagnosis and treatment for in- and outpatients, as well as research and education. Among them four centers have specialized in epilepsy surgery, and three have specialized in social and vocational rehabilitation. The Epilepsy Center Bethel is the only center that combines all functions.[7]

Centers for Medical Rehabilitation

Three centers for medical rehabilitation exist in Germany currently, the first being launched in 1997.[8] Their main aim is to ameliorate the psychological, social, and vocational consequences of epilepsy. All three are run on an inpatient basis. They are funded mainly by the state pension insurances with the aim to reduce early disability in patients with epilepsy. Early retirement in epilepsy patients is prominent and very costly. An evaluation study has shown that such centers are effective in improving quality of life and reducing the frequency of hospital stays and unemployment in those treated.

Summary and Conclusions

The future of epilepsy treatment in Germany is hopeful, although there are several problems to be overcome. The German chapter of the ILAE together with voluntary epilepsy organizations has developed standards of care for persons with epilepsy. The underlying philosophy emphasizes the need for comprehensive care for people with epilepsy apart from high-standard medical treatment counseling and support for the various psychiatric and social difficulties often associated with epilepsy. There are standards for physicians as well as for allied health professionals specializing in epileptology ("Zertifikat Epilepsie plus," "Zusatzausbildung Epilepsie"), and there is an ongoing demonstration project for the development of the qualification of an "epilepsy nurse." A standard for outpatient clinics concentrating on epilepsy ("Anfallsambulanzen") has been established for a while, and in 2000 standards for private practices specializing in the care of persons with epilepsy ("Schwerpunktpraxen") were decided. The German chapter of the ILAE enforces these standards by certifying persons and/or institutions for fulfilling them and publishing their addresses. As of the writing of this paper a standard of "epilepsy centers" proposed by the German chapter of the ILAE is under discussion.

Standards for treatment and care including rehabilitation will become even more important as citizens from the European Union can ask for treatment in various European countries. It is important to include self-help groups in the process of developing these standards because they have the most comprehensive perspective and can act without financial dependency.

Information on epilepsy for the general public, for nonmedical professionals (e.g., teachers, facilitators, personnel from rehabilitation or counseling centers), and for persons with epilepsy and their families is produced by the German chapter of the ILAE, by the German Epilepsy Foundation ("Stiftung Michael"), by national self-help organizations

("Deutsche Epilepsievereinigung," "Epilepsie-Bundes-Elternverband"), and regional self-support groups. One shortcoming in epilepsy information is that it is not developed on a systematic base. In consequence, there are gaps and the quality of information differs highly. There are numerous efforts to use the various possibilities of the Internet for epilepsy information.

Since the end of the 1990s there have been strong efforts to develop patient education programs for adults and children with epilepsy and their families. About 1,500 adult persons with epilepsy are educated with the MOSES program.[4] A version of the program for children and their parents has been ready for administration in the routine medical practice since 2005.[5]

Because counseling and support for psychosocial problems are most often provided by institutions outside the medical systems, various efforts are now under way to bind services closer together to create comprehensive epilepsy networks. Such efforts have been done in Bavaria, North Rhine-Westphalia, and Berlin. Networks serve three functions: First, they facilitate the transfer of new knowledge and experience and reduce competition. Second, they increase the number of referrals (e.g., for early evaluation for surgical treatment or for rehabilitation interventions). A promising development in this field is the installation of specific counseling centers for epilepsy with the function of public education, counseling of schools or other institutions, and individual counseling of persons with epilepsy. Such centers, in which a social worker specialized in epileptology is always present and sometimes also a psychologist, exist in various federal states (e.g., Bavaria, Hessian, Lower Saxony, North Rhine-Westfalia, and Saxony), and hopefully will also be installed in more states.

The most urgent problems in care for people with epilepsy are the following:

- Referring patients much earlier to the most competent institutions and specialized centers
- Developing epilepsy networks for comprehensive care for persons with epilepsy
- Educating and hence empowering more adults and children with epilepsy and their relatives because in the coming structures of our health system, it is even more the patients' responsibility to obtain adequate
- Maintaining specialized epilepsy centers or comparable institutions (even under economic strain) that are experienced in treatment and counseling of patients with difficult-to-treat epilepsy and psychosocial problems.

Chapter 293

India

Satish Jain

P. Satish Chandra

Introduction

India is the second most populated country in the world with majority of population being rural. Although the economy has been growing at a rapid pace, the per capita expenditure on health, family welfare, water supply and sanitation in recent years has been dismally low. The health services provided by the government are totally free or highly subsidized for the poor and needy. The rapidly emerging private health sector with health insurance facilities is affordable to only a small section of the population.

It is estimated that with a population of more than 1 billion, there are about 6–10 million people living with epilepsy in India, accounting for nearly one fifth of the global burden. The challenge of meeting the needs of the people with epilepsy in a developing country like India is a daunting task for every one involved in the planning and delivery of health care. In a country like India with diverse cultures, castes and low literacy; various myths and misconceptions about epilepsy that exist among the people further add to the societal disease burden and treatment gap. Developing countries such as India need to develop alternative strategies to reach out to the needy people living with epilepsy in different parts of such a vast country. The best approach in a country like India with limited resources for health-care would be to encourage “private-public participation.” There is an urgent need to have a separate National Epilepsy Control Programme (NECP) in countries like India. In order to be successful, the proposed NECP must be an initiative of the government and should work in collaboration with the health care providers in the private sector and non-governmental organizations.

Demographic and Socioeconomic Indicators

India is the largest country in the Southeast Asian Region of the World Health Organization (WHO) with an estimated population of more than 1 billion living in an area of 3287.3 thousand km^2 with the population density being 325 per km^2. The majority of the population is rural, with only 27.8% living in urban areas. India has 35 states and union territories accounting for 593 districts, 5,161 towns, and 593,643 inhabited villages as of March 31, 2001.[8] The majority of the population as per the 1991 Census was young, with 37.8% being in the 0- to 14-year and 55.5% in 15- to 59-year age group. The national literacy rate for 2001 was 65.5%, with males (75.96%) having a better literacy rate as compared to females (54.28%).

The combined national crude birth rate for 2002 as per the sample registration system of the Registrar General of India was 25.0, the crude death rate being 8.1 and the natural growth rate of 16.9 per 1,000 population. The average annual exponential growth rate of the population is calculated to be 1.96%. The gross per capita net national product at current price for 2003–2004 was estimated to be about U.S. $463 (INR 20860, 1 U.S.$ = INR 45.00). Only 3.97% of the total expenditure in the budget was allocated to the Health, Family Welfare, and Indian System of Medicine and Homeopathy (ISM & H) for the 10th 5-year plan (2002 to 2007). The per capita expenditure on health, family welfare, water supply, and sanitation during 2002–2007 will be about US $2.53 per year.[8]

Basic Structure of Health Care Delivery System in India

The primary and secondary health care in the government sector is delivered through a vast network of subcenters (SCs; one SC for about 5,000 population and manned by health workers); primary health centers (PHCs; one PHC for 30,000 to 50,000 population); and taluk hospitals/community health centers (CHCs; one CHC for 100,000 population) that are under the administrative control of district hospitals (DHs; one DH for 1.5 to 2 million population). The tertiary health care is provided by hospitals attached to medical colleges, apex institutions, and super-specialized centers. Government health services are totally free/highly subsidized for the poor and needy. A rapidly emerging private health sector, in the absence of government health insurance to the majority, is affordable to only a small section of the population. Though allopathy (modern medicine) takes care of the majority, traditional systems of medicine also are widely used in the country.[6]

There were 189 medical colleges (during 2000–2001) and 185 dental colleges (2003–2004) imparting education and health care facilities in the modern system of medicine. In addition, there were 431 colleges providing training and health care facilities in the ISM&H, with the maximum being in Ayurveda (209) followed by homeopathy (180), Unanai (36), and Siddha (six). There were 15,393 hospitals as of January 1, 2002, with 914,543 hospital beds (of all types) accounting for 89 hospital beds per 100,000 population. In addition to the hospitals, there were 137,311 SCs, 22,842 PHCs, and 3,043 CHCs on March 31, 2001. There were 605,800 medical doctors registered with the Medical Council of India as of December 31, 2002, at the rate of 59 doctors per 100,000 population. In addition, 839,862 nurses and midwives were registered with the Nursing Council of India as of March 31, 2003.[8]

While the primary and secondary health care facilities may at the most provide only the basic health care, some of the private and government hospitals and institutions now are providing “state of the art” facilities often at a fraction of the cost that needs to be paid in the hospitals in the developed nations. Although still not adequate, there has been a phenomenal growth in the health care sector in the last few years, especially in the private sector. The private health insurance agencies also have begun to play a role in the country, though not in a big way. Distribution of these health care facilities leaves much to be desired, and despite the fact that many parts of the country may still be without adequate health care facilities, medical tourism is projected to be a major revenue-earning industry in the next few years.

Mental Health Care in India

India being a land of contrasts, mental health care is provided by a multitude of trained and untrained personnel that include neurologists, neurosurgeons, psychiatrists, physicians, pediatricians, those trained in the ISM&H, and a large number of health and non–health care personnel (registered and unregistered medical practitioners, religious heads, and even faith healers). In urban areas for most people with epilepsy who receive treatment, the expert care is provided mainly by the neurologists and neurosurgeons, though primary care is delivered by family physicians, pediatricians, and internal medicine experts.

Specialist Resources

The challenge of meeting the needs of people with epilepsy in a developing country like India is a daunting task for everyone involved in the planning and delivery of health care. The limited resources and lack of adequate trained manpower complicates the problem further. At present there are about 800 trained neurologists and 1,300 to 1,500 trained neurosurgeons in the country. The paradox of a country like India is that as per the president-elect of the Association for Indo-American Neurologists, there are 600 to 700 neurologists of Indian origin in the United States (personal communication).

A high-powered committee set up by government of India, the Technology, Information, Forecasting, and Assessment Council (TIFAC), examined the technology and manpower requirement for the year 2020. The needs in the discipline of neurology were also assessed by the TIFAC. Assuming even a modest ratio of one neurologist for 200,000 population as against 8,000 in Italy and 18,000 to 50,000 in the United Sates, India would require ≥5,000 neurologists as against the present strength of <1,000 neurologists. Even if a hundred trained neurologists were to be added to the pool annually, giving allowance for outward movement from the country, it would take at least half a century to achieve the goal. A further confounding problem is the distribution of neurologists, because major proportions gravitate to metropolitan cities and big towns, leaving almost 70% of the population in the rural areas deprived of specialists' care. Thus, there is an urgent need to reconsider and conceptualize alternative strategies to organize services at the peripheral, regional, and apex levels, as recommended by the TIFAC.[6]

Magnitude of the Epilepsy Problem in India

Many studies based on well-accepted methods, valid screening and diagnostic tools, and case confirmation methods have been conducted to identify epilepsy in the community in an inexpensive way in different parts of India. Population-based neuroepidemiologic studies conducted in different regions have shown that epilepsy constitutes nearly a third of all neurologic disorders. The prevalence of epilepsy varies from 2.5 to 11.9 per 1,000 population.[2,3,5,6,7,9,10,11,12,13,14] In the Bangalore Urban Rural Neuroepidemiological (BURN) survey, a task force project supported by the Indian Council of Medical Research (ICMR) covering a population of 102,557, a prevalence rate of 8.8 per 1,000 population was observed, with the rate in rural communities (11.9) being twice that of urban areas (5.5). Epilepsy was found to be the second leading neurologic problem in both urban and rural populations, next only to vascular headache.[7] Based on these data and information emanating from various studies, it is estimated that in India (with a population of more than 1 billion), there are about 6 to 10 million people living with epilepsy, accounting for nearly one fifth of the global burden.[2,3,5,6,7,9,10,11,12,13,14] Though most of the epidemiologic studies in India estimated prevalence of epilepsy, one study from Yelandur has provided incidence data.[10] Accordingly, 50 new cases per 100,000 population are added annually, giving an additional burden of 500,000 new-onset epilepsy cases every year in India.

Burden of epilepsy as estimated using disability adjusted life years (DALYs) accounts for 1% of the total burden of disease in the world, excluding that due to social stigma and isolation, which is highly prevalent in India and might account for a much higher disease burden. In a country like India with a diverse culture, caste, and low literacy, various myths and misconceptions exist about epilepsy among the people, which further adds to the treatment gap. The treatment gap in epilepsy ranges between 38% and 80%. The lowest figure is from Kerala, which has a high literacy rate and health-conscious people. The BURN data have demonstrated that even in urban areas, the treatment gap is as high as 50%. This large treatment gap is due to multiple factors, including lack of awareness about epilepsy among the people; social stigma; reluctance to accept the diagnosis; improper distribution of the available medical facilities, especially among rural, tribal, and hilly areas of the country; and availability and/or affordability of the long term antiepilepsy drug treatment.[6]

Delivery of Epilepsy Care in India

In India, with its population of more than 1 billion, a dismally low trained neurologist ratio of 1 in 1,250,000, and a very high epilepsy burden, primary care physicians, general practitioners, pediatricians, and psychiatrists provide 60% to 70% of epilepsy care. Hence, it is imperative that developing countries such as India develop alternative strategies to reach out to the needy people living with epilepsy in different parts of such a vast country. Various models of delivery of epilepsy care have been tried and are in practice. Brief accounts of the same are given below.

Satellite Clinic Model

The National Institute of Mental Health & Neuro Sciences (NIMHANS), Bangalore, has developed a satellite clinic model (SCM), which has been implemented for more than two decades, since 1982. This model is successful in delivering neurologic and psychiatric care to the rural community—an example of joint collaborative work between governmental and nongovernmental agency. The NIMHANS provides expert panels; local governmental agencies along with nongovernmental organizations (NGOs) such as the Lions or Rotary conduct the service camps on a “fixed day at fixed place” every month. This approach results in the delivery of expert care at the patient's doorstep.

Epilepsy accounts for 40% to 50% of all the neuropsychiatric patients seen in these camps. The NIMHANS caters to five places located within a 50- to 100-km radius, on 5 fixed days every month. More than 150 to 300 people attend each camp. First-line standard antiepileptic drugs such as phenobarbital, phenytoin, carbamazepine, and valproate are provided free to needy patients and simple medical records are maintained to follow these individuals. The camps are coupled with awareness campaigns about common neurologic disorders such as stroke, epilepsy, and mental retardation through the NGOs using both electronic and print media. Over the last two decades

thousands of people made use of this satellite clinic model and have benefited from these camps.

Community Health Center Model

The NIMHANS has also developed another model called the "community health center model" to take care of the patients at the community level in the urban areas in Bangalore. CHCs covering a population of 50,000 to 100,000 work in close liaison with medical colleges. There are nearly 200 medical colleges in India that look after the CHCs via their preventive and social medicine departments. The services of medical colleges and CHCs can be used to look after the epilepsy patients in their jurisdiction and also for the distribution of first-line antiepileptic drugs to the needy. The paramedical staff attached to these CHCs maintains health records. The epilepsy patients can be treated and followed up by this trained workforce at the patient's doorstep. The CHCs also have their mobile health care units reaching out to remote villages and far-flung, unreached areas. It has been demonstrated that the community health center model is successful in reaching out to the people at their doorsteps.

District Epilepsy Care Model

The "epilepsy control program" through a district model was developed by the NIMHANS, Bangalore, with the support of the WHO (SEARO) through the Ministry of Health, Government of India. This was implemented between 1999 and 2001. The program has three main objectives:

1. It would sensitize state health administrators regarding epilepsy as a public health problem.
2. It would train district medical officers in the delivery of epilepsy care. The trained doctors could further train other PHC medical officers.
3. "Nodal neurologists" at the state level would coordinate with these district medical officers to sustain this program.

Districts are used for health care delivery in this model since they have the advantage of being an independent administrative unit. The district medical officer (DMO) is the administrative head that implements and monitors various national health programs at district levels. In addition, all health programs at PHCs and Taluks come under jurisdiction of the district. Districts as models for mental health care have already been successfully implemented in India. There are 593 districts with an average population of 1.5 to 2 million people in each district.

The essential step in the district model is training of DMOs. The internal medicine experts/pediatricians /psychiatrists can also be included in the training of the trainer's program. Training is focused on (a) identification of epilepsy, (b) diagnosis, (c) treatment, (d) counseling, (e) psychosocial aspects of epilepsy, and (f) legal aspects of epilepsy. Training is done using training modules, audiovisual aids, and lectures that also include demonstration of practical aspects of managing acute emergencies in epilepsy. Evaluation of the training course is done using pre- and posttraining questionnaires. The training courses need to be followed by periodic workshops. These medical officers would subsequently train other primary health center doctors and also coordinate with the nodal neurologists. Programs of this nature require support from the government and NGOs in getting an uninterrupted free supply of antiepileptic drugs, maintenance of simple medical records, maintenance of epilepsy diaries, and regular follow-up from the patients. This model has also been successfully tested during the 3-year period by the NIMHANS.

Fortis Epilepsy Control Program Model

The Fortis group of hospitals is a part of the Fortis health care that is fast emerging as a leader in the delivery of health care in the private sector in India. As a part of its commitment to provide affordable health care at the community level, the Fortis Epilepsy Control Program (FECP) was launched on November 18, 2005, with an aim to provide some treatment to those with epilepsy who receive no treatment at all at the community level.

As part of the FECP, 18 practicing doctors from different parts of the state of Uttar Pradesh (UP) and the National Capital Region (NCR) with at least an MBBS degree were invited and trained on November 17, 2005 (the

World Epilepsy Day) at Fortis Hospital, NOIDA, to detect grand mal seizures using the protocol prepared under the guidance of the WHO-SEARO.[1] The trained doctors started treating only those patients diagnosed to have grand mal seizures in the area of their practice from January 1, 2006. The doctors trained have been told to exclude and not to treat patients below the age of 10 years and above the age of 60 years; those having any other seizure type or multiple seizure types (probably an epilepsy syndrome); women with a potential to have children or pregnant women; those having serious medical illnesses like hepatic or renal disease; those with known allergies to antiepileptic drugs; and those having any abnormality on neurologic examination like focal deficits and evidence of raised intracranial tension. All patients to be included for treatment under the FECP will be made aware and offered the choice of investigations like electroencephalography, computed tomography scan, or magnetic resonance imaging scan of the brain.

Those epilepsy patients with grand mal seizures selected for treatment will be treated with tablets of Phenytal (100 mg phenytoin and 30 mg phenobarbitone), two tablets once a day at bedtime for an average adult. The participating doctors will provide these tablets to all patients at the nominal cost of about Re 1 per day for two tablets (about U.S. $2 per 3 months of medicinal supply). A complete database of patients with all contact details will be maintained by the treating doctors. The patients included in the treatment plan will be followed up at regular intervals, preferably every month specifically for seizure control and any adverse effects of antiepileptic drugs. Any patient having problems due to poor seizure control or side effects of drugs or any other problem will be referred for an “expert opinion” to Fortis Hospital at NOIDA or any other tertiary care hospital. Neurologists from the Fortis Advanced Centre for Epilepsy, NOIDA, will periodically visit the participating doctor's clinic to review the work being done.

In the first phase, 18 doctors trained are participating in the FECP. During the second phase the plan is to enroll more doctors practicing in 10 to 15 neighboring districts. In the third phase, the program will be extended to all other districts of UP and NCR and also to neighboring states, depending on the resources.

The models outlined above are not exclusive but complementary to one another and will be able to “reach the unreached” with regard to epilepsy.

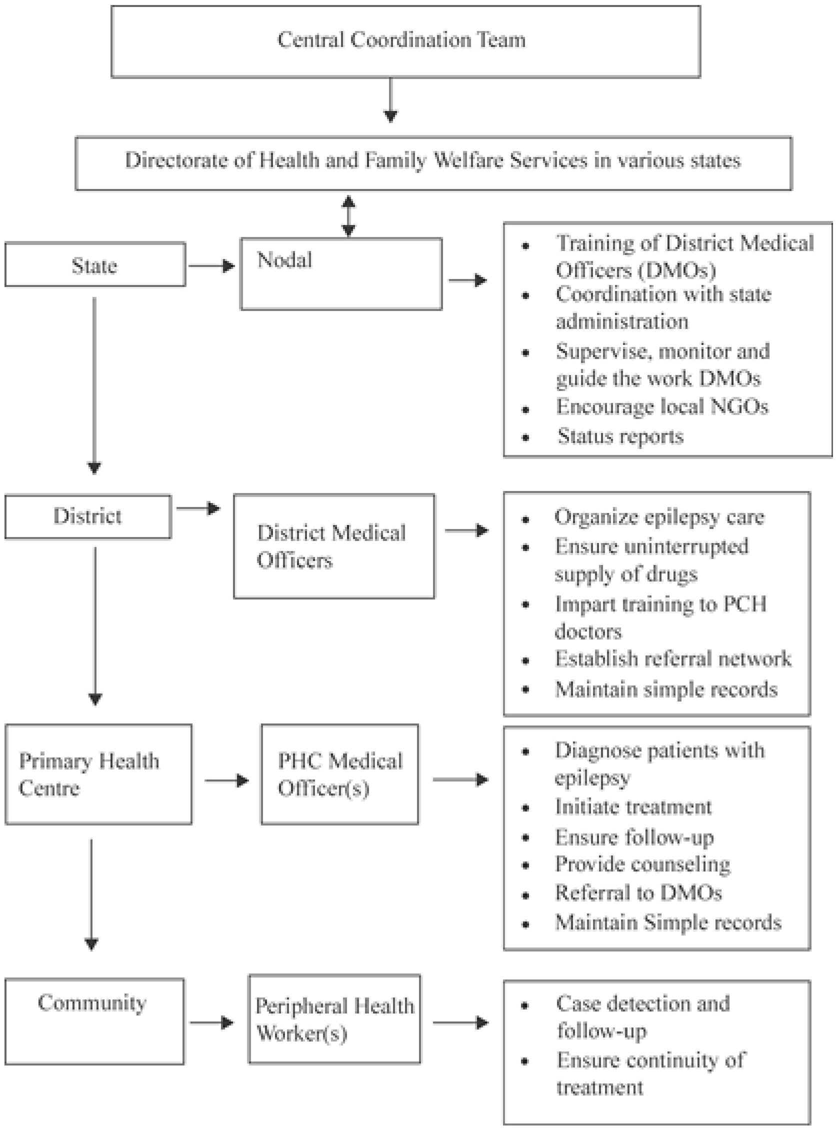

FIGURE 1. National Epilepsy Control Programme: action plan. (Adapted from Gourie-Devi M, Satishchandra P, Gururaj G. Epilepsy control program in India: a district model. *Epilepsia.* 2003;44[Suppl 1]:58–62.)

National Epilepsy Control Program (NECP)

Launch of the WHO/International League Against Epilepsy (ILAE)/International Bureau of Epilepsy (IBE) joint initiative of the "Global Campaign Against Epilepsy" in 1997[4] has given impetus to start a similar National Epilepsy Control Program

P.2888

in India. This needs to be implemented all around the country with the following objectives:

1. To provide accessible and affordable health care to all people living with epilepsy, particularly to the people living in rural and far-flung areas and vulnerable sections of the society
2. To have joint participation of community and nongovernmental agencies in the delivery of comprehensive epilepsy care to people living with epilepsy
3. To ensure integration of people with epilepsy in various spheres of activity through psychosocial and vocational rehabilitation
4. To reduce the prevalence rate of epilepsy in the community by reducing the birth injuries and controlling

parasitic diseases (neurocysticercosis) and other neuroinfections and road traffic accidents

5. To create and improve awareness among the people about epilepsy

The proposed action plan of the National Epilepsy Control Program is given in FIGURE 1. It is proposed to have one national epilepsy center, which will be linked to four or five regional epilepsy centers in different parts of the country to coordinate with state level centers. To achieve the goal of the National Epilepsy Control Program, the Indian Epilepsy Association (IEA), Indian Epilepsy Society (IES), and other nongovernmental agencies need to actively participate together with the main focus being on improving awareness about epilepsy and providing comprehensive epilepsy care to the people with epilepsy. This can be achieved with the "center to periphery" or "periphery to center" approach. The proposed National Epilepsy Control Program should preferably be a separate program. It could also be integrated into an appropriate ongoing vertical national health program in India for easy implementation.

Summary and Conclusions

India is a land of contrasts. Until recently the ever-increasing population was proving to be a major handicap for the national growth. The availability of a large trained workforce (as a result of the large population) has changed the apparent "disadvantage" into a big national "advantage." Today, India's economy is rapidly growing and is matched by that of China only. The India growth story has just gotten bigger and better. For the first time, India has emerged stronger on the global investment radar in 2005, overtaking even the most developed economies of the world. India today is one of the most attractive foreign direct investment destinations in the world.

Despite being home to about one fifth of the entire world's population with epilepsy and a rapidly improving economy, there is no national epilepsy control program in India. This is perhaps the right time for the governmental heath planning authorities to take note of the situation and take some

remedial steps. There is an urgent need to have a separate NECP in India. Clubbing the epilepsy control program with the National Mental Health Program in India is likely to have serious implications with regard to increased societal stigma. Such a step could be a retrograde action in view of the Global Campaign Against Epilepsy that aims to bring "epilepsy out of the shadows." The best approach in a country like India with limited resources for health care would be to encourage "private–public participation." The models adopted by the NIMHANS and the Fortis group have the potential to be applied at the national level with support from the government in collaboration with the health care providers in the private sector and nongovernmental organizations. There are costs for doing all of this, but the costs of not doing this are perhaps much higher.

Chapter 294

Japan

E. Ann Yeh

Masakazu Seino

Introduction

In 1994, Japanese government officials introduced a new vision of social welfare for the 21st century.[8] Central to this vision was the issue of how to handle problems that stem from the growing population of elderly individuals, many of whom will soon become disabled and utilize health care services to a greater degree than their younger counterparts. These concerns are not limited to the elderly, but extend to all disabled individuals. How these people will be cared for and who will be responsible for their care are questions that need to be addressed.

With these concerns in mind, this chapter examines the current health care policies of the Japanese government, beginning with a review of health insurance in Japan. A discussion of national health care spending follows, along with a description of the organization and distribution of health care personnel. Health care services available to individuals with epilepsy are examined, with special reference to medical specialists treating epilepsy in Japan. The chapter concludes with a brief discussion of the contradictions inherent in current government policy.

Health Insurance

The health insurance system of Japan currently operates on the basic premise that all individuals should have access to affordable health care. However, the original impetus of the government for establishing a health insurance system was not the provision of affordable medical care, but rather the maintenance of a strong workforce. It was but one element of government efforts at nation building in the early 20th century.[4] In 1960, the year that universal health care was instituted, 94.2% of the population of Japan was covered by health insurance. Since then, the proportion of insured individuals has increased annually. In 2002, virtually 100% of the Japanese population was covered by health insurance.[10] Health insurance in Japan is of two main types: Employee insurance (60.3%) and National Health Insurance (NHI) (39.7%). Benefits include compensation for clinical visits and drugs.[5]

Employee Insurance

The number of individuals covered by employee insurance (either as a principal policy holder or as a dependent of a policy holder) grew from 48.5% of the population in 1960 to 60.3% of the population in 2002. There are four distinct categories of employee insurance: Government-managed insurance (46.9% of the total number of employee insurance policy holders), large enterprise insurance (40.0%), mutual aid associations (12.8%), and seamen's insurance (0.3%). Insurance premiums of approximately 8.6% of an employee's salary are deducted monthly. At present, 70% of the medical costs of both policy holders and their dependents are covered, while 80% of medical costs for children younger than 3 years of age and 90% of costs for individuals older than 70 years of age are covered.[5]

National Health Insurance

NHI was established in 1938. In 1960, health insurance coverage through NHI was extended to all residents of Japan not eligible for employee insurance—self-employed individuals, students, farmers, unemployed individuals, and part-time workers, among others. Benefits under NHI are far less comprehensive than those available under employee insurance; 70% of medical costs are covered. Premiums are scaled to income and assets, with an average household yearly payment of 163,842 yen. This amounted to 2.8% of the average national income in 2002. In 1984, a pensioner's plan was introduced that increased benefits for retired persons to 80% of all hospital costs and 70% of outpatient costs of policy holders and to 80% of the hospital costs of dependents. In 2002, approximately 50,297,000 people, or 39.7% of the population of Japan, were insured through NHI.[5]

Payment for Hospital Services: Epilepsy and the General Population

According to a 2002 patient survey, on any given day in Japan, an estimated 7,929,000 people were either hospitalized or used outpatient services. Of these patients, 60.3% were covered by employee insurance (split almost evenly between policy holders [30.1%] and dependents [30.2%], and 39.7% by NHI).[9]

The proportions of types of health insurance used in medical consultations related to epilepsy differ somewhat. According to estimates by the Ministry of Health, Labor and Welfare (MHLW), 38% of visits by patients with epilepsy were paid for with NHI. In addition, although employee insurance was used by almost the same proportion of individuals (11.2%) as in the general population (10.7%), insurance for dependents with epilepsy was used with greater frequency (22.5%). As with the general population (1.8%), there were no clinical visits related to epilepsy that were paid for in full by patients. Health services for 9.2% of patients with epilepsy were paid for through publicly funded Medicaid (Seikatsu Hogo Hou) and through other public funds. These numbers are significantly higher than the proportion estimated for all hospital patients (0.5% under the Mental Health Act, 7.5% under the Social Welfare Act, and 6.1% through other public funds).[10]

These figures indicate that a significantly higher proportion of individuals visiting clinics and hospitals for problems related to epilepsy are self-employed or unemployed and receive some sort of public assistance. The relatively higher numbers of patients using insurance for dependents can be explained partially by the large proportion of people <25 years of age using hospital services for problems related to epilepsy (see Specialists Treating Epilepsy).

P.2892

Budget Organization and Development

National spending on health care in Japan has increased rapidly since 1954, the year the Ministry of Health and Welfare (MHW) began keeping such records.[5] That year, health care spending equaled 215.2 billion yen (1.871 billion U.S. dollars at the 2005 exchange rate of 115 yen per dollar). Medical costs in Japan have increased in tandem with the standard of living and national income. They have remained at approximately 5% to 6% of national income since 1975, ranging from 5.22% in 1975 to 6.42% in 1987.[3] In 2002, 31.1 trillion yen, or 8.58% of the national income, was spent on health care.[5] Normal births, medical checkups and public health measures, costs of prosthetic devices, and costs related to nursing homes are not included in these figures,[5] nor are costs related to research.[4]

Health care spending as a proportion of national income appears to be low compared with the United States (13.9% in 2001), France (9.4%), Canada (9.4%), and Germany (10.8%).[3] However, according to the Organization for Economic Cooperation and Development (OECD), spending in Japan is underestimated by about 25% because figures do not account for spending in categories included in other national estimates.[12] Even with the added 25%, the figures for Japan are low compared with these countries. With respect to the gross national product (GNP), health care spending in Japan, which was 7.4% of the GNP in 1998, was lower than that of countries such as the United States and France.[5]

Sources of payment for health care range from insurance (employee insurance and NHI) (44.9% of total), the Geriatric Act (34.37%), patient payments (15.3%), and government-sponsored plans (including welfare and the Mental Health Act, and others) (5.5%) (2002 figures).[3]

Regarding the sources of money spent on health care, in 2002, 51.7% came from insurance premiums, a figure that has risen steadily from 45.8% in 1954. Spending from public sources has risen from 16% in 1954; the current rate is 33% (25.1% from federal and 7.9% from regional sources). Patient payments account for 15.3%, and 0.2% comes from other sources.[3]

Whereas in 1955 10.2% of all medical payments came from Medicaid (Iryou Hogo/Seikatsu Hogo), the amount has dropped steadily and was 0.8% in 2002. In addition, medical costs borne by patients not using insurance dropped from 20.7% in 1955 to 1.3% in 2002. Employee insurance covered 60.3% of health care, and NHI covered 39.7% in 2002, proportions roughly equivalent to the relative number of individuals insured under these categories.[5]

Organization of Hospitals, Physicians, and Health Care Workers

Hospitals and Clinics

Medical facilities in Japan (excluding dental facilities) totaled 966,044 in 2002. They are organized into hospitals having more than 20 beds (9,280) and clinics with fewer than 20 beds (86,764).[a]

Most of the facilities fall into one of five major categories, representing ownership: Individual ownership (10.4%); medical juridical persons (nonprofit organizations) (Iryou Houjin) (60.2%); public medical facilities (15.0%); National (3.7%); and employee insurance groups (1%) in 2002. Privately owned clinics and hospitals make up the overwhelming majority of medical facilities, and as the government does not regulate their distribution, the concentration of facilities in different prefectures varies widely. In 2002, the average number of general hospitals was 6.7 per 100,000 people in Japan.[5,b]

In 2002, Japan had one of the highest proportions of medical beds per capita in the world: 1,573 per 100,000 people, which is comparable to Iceland (1,670 per 100,000), Sweden (1,480 per 100,000), and Norway (1,500 per 100,000). The proportion is about twice that of Canada (778 per 100,000) and almost three times that of the United States (586 per 100,000). The percentage of filled hospital beds in Japan was estimated to be 85.3% of general hospital beds and 93.2% of psychiatric beds in 2001.[5]

There were about 1,646,000 hospital beds in 2002 in Japan, with 1,372 general hospital beds per 100,000 people. Of all beds in hospitals with >200 beds, 54% were located in hospitals run by medical juridical persons, 21% in hospitals run by local, and 6% in hospitals run by federal government. As with hospitals, great discrepancies in numbers of beds exist from prefecture to prefecture. The prefecture with the highest concentration of hospital beds, Kagoshima Prefecture, had 2,081 beds per 100,000 people, while the lowest, Saitama Prefecture, had 878 beds per 100,000 people in 2002.[5]

Medical and paramedical services (including physician services and occupational/physical/speech therapies, laboratory testing, and some nursing services) are billed on a fee-for-service basis, with prices for services and drugs regulated by governmental bodies.

Decisions concerning changes in billing rates are highly political. From the mid-20th century to the present, members of the Japanese Medical Association (JMA), the majority of whom operate private clinics, have been extremely powerful in shaping billing decisions, such that current billing decidedly favors clinicians in private practice.[4] In the early 1960s, the JMA was able to bring about an increase in compensation for services by refusing to cooperate with certain public health measures. A second effect of the JMA's lobbying has been that responsibility for chronic, costly health problems has been shifted to the state.

Because physicians working in clinics do not usually have admitting privileges in hospitals, much duplication and fragmentation of medical services takes place in Japan.[4] Referral is only sometimes practiced: According to the MHLW 2002 survey of patients, the majority of patients visiting outpatient services (93.2%) and who were hospitalized (55.2%) did not receive referrals from staff at other hospitals or clinics.[10] The government is attempting to change this practice. Starting in 1988, patients were required to receive referrals to utilize the services of specially designated tertiary care centers. Patients who do not receive referrals to the centers cannot use their health insurance for the first consultation they receive there.

Outpatient services are used with greater frequency in Japan than in the United States. The number of outpatient visits per capita in Japan was more than twice that of the United States in 1996 (16.0 vs. 5.8).[12] On an average day in 2002, 6,478,000

P.2893

people, or 5.1% of the general population, visited a hospital or clinic for an outpatient consultation, and 1,451,000 people, or 1.1% of the population, were hospitalized (41.8% in general beds, 17.4% in psychiatric beds, 31.9% in long-term care beds, and the remainder in nursing beds and beds devoted to the care of specific diseases).[10]

Although a relatively small proportion of the population in Japan is admitted to hospitals, Japan has an average length of hospital stay of 37.9 days (24.0 days in general hospital beds, 195 days in rehabilitation hospital beds, and 385.7 days in psychiatric hospital beds).[5] This is just twice the 1998 U.S. average of 20.4 days (7.8 days in acute care hospitals).[11] The staff-to-patient ratio in general hospitals in Japan is low, with an average of 103.3 staff members per 100 beds (including 11.2 physicians, 31.4 nurses, 14.7 assistant nurses, 0.4 occupational therapists, 1.0 physical therapists, and 3.1 technicians). The ratio is even lower at psychiatric hospitals, with an average of 53.2 staff members per 100 beds (including 2.7 physicians, 13.0 nurses, and 14.5 assistant nurses).[5]

Although the staff-to-patient ratio is low in hospitals, technologic apparatus is more readily available in Japan than in other countries.[4] In 1999, 10,693 Japanese medical facilities had either whole-body or head-only computed tomography (CT) scanners. All of the country's 2,938 magnetic resonance imaging (MRI) scanners were located in hospitals.[5]

Physicians

The number of physicians in Japan has nearly doubled since the early 1970s, when the government began its campaign to increase the number of physicians to 150 per 100,000 people. In 2002, there were 255,792 licensed physicians in Japan, or approximately 200 physicians for every 100,000 people.[5] Most physicians in Japan are specialists, the greatest concentration of whom are internists (30.6%), followed by surgeons (10.1%) and pediatricians (5.8%).[5] Because there are almost no general practice physicians in Japan, internists often act as primary care generalists; over one third of all hospital consultations on a given day in 2003 were estimated to be with internists, and 91.3% of all hospitals in Japan had internists on staff.[c] By comparison, 9.7% of all hospital consultations were conducted by surgeons and 66.8% of all general hospitals had surgeons on staff. In general hospitals 4.3% of all consultations were performed by pediatricians and 40.8% of all general hospitals had pediatricians on staff.[5]

Physicians are plentiful in more densely populated areas in Japan. There are, however, regional differences in the distribution of physicians. Saitama prefecture, for example, has the lowest physician-to-population ratio (121.8 per 100,000 people), while Tokushima prefecture has the highest physician-to-population ratio (258 per 10,000 people) in the country.[5]

Services for Epilepsy in Japan

The MHLW estimates that on an average day 26,900 people with epilepsy received treatment at clinics and hospitals around the country in 2002. These visits constituted 0.34% of all clinical encounters.[d] Of the consultations related to epilepsy, approximately 72.5% were outpatient visits. The number of hospitalized patients with epilepsy has decreased over the years, with hospitalized patients with epilepsy totaling 8,997 in 1994, 8,332 in 1996, and 7,400 in 2002.[7,10]

The number of consultations related to epilepsy has risen together with the total estimated number of medical consultations. Estimated figures for all medical consultations between 1984 and 2002 show a decrease in inpatient consultations and a slow rise in outpatient consultations. The number of outpatient consultations for epilepsy increased more significantly than outpatient visits in general, with a rise from 172,000 in the 1980s to 195,000 in the mid-1990s. Ninety-eight to 99% of hospitalizations for patients with epilepsy in any given year began in the previous year.[7,10]

According to MHLW estimates, all hospitalizations and most outpatient consultations related to epilepsy take place in hospitals.[10] The number of patients who received referrals from other hospitals or clinics in 2002 was 55.2% for inpatients and 93.9% for outpatients. The rapid increase in the number of referrals in the 1990s can be attributed to a newly introduced health insurance system that provides physicians with incentives for issuing referrals. Those patients who first visit hospitals or clinics without referrals issued by previous physicians must pay their fees out of pocket. Insurance companies will not cover these visits.

Hospitalizations for individuals with epilepsy represent approximately 0.5% of hospitalizations for all problems. Hospital stays are long, averaging 122.0 days—far longer than the national average of 44.9 days.[10] As with the national average, the average number of days that patients with epilepsy are hospitalized varies greatly from institution to institution. The shortest average length of stay is at company hospitals (14 days). Hospitalizations for epilepsy in other types of hospitals (e.g., nonprofit or public) are similar in length (approximately 16.1 days). The longest average hospitalization for epilepsy is in psychiatric hospitals (688.1 days).[9]

The number of beds in a hospital also determines the length of a hospital stay. In hospitals with between 200 and 699 beds, average stays for problems related to epilepsy range from 131.3 to 254.4 days. In facilities with 20 to 49 beds, epilepsy patients stay an average of 12 days. In 1990, more than half (53%) of the hospitalizations for epilepsy in Japan were estimated to have lasted longer than 5 years. Seventy-three percent of these had lasted longer than 10 years.[9]

Specialists Treating Epilepsy

Although in North America people with epilepsy receive treatment primarily from neurologists or pediatricians, and in some cases general practitioners or family doctors, in Japan neuropsychiatrists and pediatricians are primarily responsible for the treatment of epilepsy. Other specialists who treat epilepsy in significant numbers in Japan are neurologic internists and neurosurgeons. Because internists often act as generalists, they see a significant number of epilepsy patients—10.5% of all cases. Most of these are outpatient visits that are split almost evenly between hospitals and private clinics. Epilepsy cases make up only a small percentage (0.2%) of the total number of cases seen by internists. A small number of consultations for epilepsy are carried out by surgeons (0.9%) and pediatric surgeons (0.3%).[9]

Neuropsychiatrists receive training in areas that in North America would fall under the specialties of psychiatry or neurology. Consequently, they treat conditions that are categorized in North America as psychiatric (i.e., schizophrenia, depression) or neurologic (i.e., stroke, epilepsy, cerebral palsy).[10] Most neuropsychiatrists (92.4%) practice in hospitals. The remaining 7.6% either have their own private clinics or are employees of small clinics.[2]

According to estimates of the MHLW, approximately 50.1% of patients receiving treatment for epilepsy are seen by neuropsychiatrists. Most of these consultations take place in hospitals (93.9%), and the majorities are inpatient consultations (64%). In 1990, 3.6% of all psychiatric consultations were estimated to be related to epilepsy.[9]

In the 1970s, a new specialty was introduced in Japan—neurologic internal medicine. Specialists in this area make up only a small fraction of all practicing physicians (1.3%). Most neurologic internists are hospital based. They conduct an estimated 3.7% of all medical consultations for epilepsy, which make up approximately 3.3% of their total consultations. In 1990, all consultations were hospital based, and most (75%) were outpatient consultations.

In 1990, children under 15 years of age comprised 23.3% of all patients seen for problems related to epilepsy in Japan. An estimated 24.8% of all medical consultations related to epilepsy were treated by pediatricians.[9] Although most pediatricians are hospital based (68.9%), 20% have their own clinics. However, almost all pediatricians treating epilepsy are employed by hospitals (89%). Of all pediatric consultations related to epilepsy, 91% take place through outpatient services.[9]

Finally, although surgery for epilepsy is not performed frequently in Japan (fewer than 500 cases in 2002), neurosurgeons treat a significant number of people with epilepsy—approximately 10% of the total. These consultations make up about 2.8% of the total number of clinical consultations with neurosurgeons and, for the most part, are outpatient, hospital-based appointments (80.0%). Most neurosurgeons (99%) are hospital employees. They made up 2.5% of all physicians in 2002.[10]

Although most people being treated for epilepsy appear to be covered by health insurance, several additional costs may burden individuals with epilepsy. Travel costs to specialized clinics, particularly for individuals with chronic health problems who must visit them frequently, are often prohibitive.

Because epilepsy in and of itself has only recently been recognized by the government as a disability, subsidized transportation was not provided in the past for people with epilepsy unless the individual also had severe mental disabilities, psychiatric problems, or physical disabilities.[e] This changed in 1995, when epilepsy was included in the Comprehensive Welfare Act for Individuals with Disabilities (Sougou Shougaisha Fukuski Hou), which awarded disability certificates (techou) based on an individual's degree of impairment with respect to daily living and degree of seizure frequency and severity. Financial burdens on individuals with severe disabilities have presumably been reduced by this act. However, individuals who must be accompanied by a parent or friend to doctors' appointments incur even greater costs that are not subsidized by the government.

Finally, people who have been given a diagnosis of active epilepsy are prohibited from driving in Japan, unless the length of time they have been seizure free exceeds 2 years. Thus, many people with epilepsy must rely on friends, family, or public transportation to get to their appointments. These barriers constitute perhaps the greatest obstacles to the utilization of hospital services for people with epilepsy.

Summary and Conclusions

Health care in contemporary Japan operates on the fundamental assumption that all residents should have access to medical services of some sort. However, policies are not blind to an individual's “social contribution,” a concept that originated in the early 20th century. This concept linked work with the right to health care. A two-tiered health insurance system continues to exist. It provides full-time company employees with health care benefits that are equivalent to those provided via NHI to the unemployed and people with part-time employment. Premiums for inclusion in NHI are scaled to income and assets. However, payment for medical services is not scaled to income. This therefore constitutes an additional barrier to access to health care for the unemployed and underemployed.

Individuals who are chronically ill, such as those with epilepsy, are most likely to be unemployed or working part time. One result of current policy is that these individuals are therefore more likely to incur larger personal health care bills per hospital visit than the average patient. Individuals with epilepsy who utilize health care services in Japan are far more likely than the average patient to be holders of NHI or to be dependents of policyholders of employee health insurance. When hospitalized, their stays are longer than the national average for all health problems—both chronic and acute. Individuals with epilepsy also incur larger-than-average bills for repeated outpatient visits and long-term drug therapy.

Contemporary political talk in Japan idealizes the concept of welfare, promoting the creation of a society that accommodates individuals who do not necessarily fit into narrow standards of “normalcy.” However, these idealistic visions are not realized in current health policy. Indeed, current policy simply reinforces the notion that productive ability is equivalent to social worth and that the valid contributions to society arise entirely through full-time employment. Unless this message is replaced with a more flexible idea of what constitutes valid social contributions, current policy may actually prevent the realization of the government's much touted social “vision.”

Chapter 295

Nigeria

Bolanle Adamolekun

Introduction

Nigeria is a federation of 36 states and a federal capital territory, with a land mass of almost 1 million km^2. With a population estimated at 128 million in 2005, it is Africa's most populous country. The prevalence of epilepsy in Nigeria varies from 0.53% in areas with well-developed primary health care services to 3.7% in the rural areas with poor health care infrastructures.[2] About 70% of the total population live in the rural areas.

Children under 15 years constitute 48% of the total population.[12] Peak age-specific prevalence rates for epilepsy occur in the first and second decades.[13]

The Development of Health Care Services in Nigeria

Traditional Medicine

Traditional medicine may be defined as the sum total of all knowledge and practices used in the prevention, diagnosis, and therapy of physical or mental illnesses and relying exclusively on practical experience and observations handed down from generation to generation, whether orally or written.[2]

Traditional medicine has evolved over centuries as the indigenous health care system in Nigeria. Genuine indigenous health care practices are usually based on the cultural and religious beliefs of the people. In a multiethnic country like Nigeria with over 250 ethnic groups, there are expectedly some variations in the system of traditional medicine, with each variant being strongly bound to the local ethnic culture and beliefs. However, common to all the variants of traditional medicine are dualist explanations of the etiology of illness in natural and supernatural terms and the therapeutic use of herbs and magico-religious rituals.

Nigeria has more traditional healers than Western-trained doctors. Although traditional medicine is well known to be a popular option for Nigerians, official government involvement has been minimal, being generally limited to sponsorship of conferences on traditional medicine and programs for the training of traditional birth attendants.[16]

The only legal reference to traditional medicine was in the Medical and Dental practitioners' decree of 1988, where the government referred to a traditional healer as "any person acknowledged by the members generally of the community to which he belongs as having been trained in a system of therapeutic medicine traditionally in use in that community." This definition appeared to leave the accreditation of traditional healers to the community. Government boards of traditional medicine were set up first in Lagos in 1981, and subsequently in other states with the purpose of accreditation and attestation of bona fide traditional healers, in response to the endemic problem of infiltration by charlatans. Recently, the Federal Ministry of Health has announced plans to produce a draft traditional medicine policy for Nigeria.

Members or leaders of some of the numerous churches and mosques in Nigeria practice faith healing. They are not officially recognized or funded at any of the three tiers of government because of the constitutional secularity of the Nigerian State, but nevertheless enjoy wide patronage.

Conventional Medicine

Conventional health care services in Nigeria evolved out of the medical services of the British colonial army. The army medical service, initially meant only for its members and dependents, began to provide medical services to government employees and their dependents following the integration of the army with the colonial administration after the Second World War, and later to the public living near such facilities. The colonial government started off the present system of conventional health services with a network of rural dispensaries and maternity homes to which rural health centers and hospitals were subsequently added.

The first national policy on health care services was introduced as part of the 1946–1956 development plan in the colonial era. The second and third development plans included revisions of this national health policy, with the third (1975–1980) containing a provision for primary health care.

The current national health policy[8] was launched in 1989, and provided for a three-tier schedule of responsibilities of the federal, state, and local governments. Under this system, the delivery of primary health care is the responsibility of local governments, while the state governments are responsible for the delivery of secondary health care and the federal government for tertiary health care. This schedule of responsibilities is coordinated by the Federal Ministry of Health. The National Primary Health Care Development Agency (NPHCDA), formed in 1992, is responsible for the delivery of primary health care services and the construction of the new health centers. It establishes and trains local development committees to manage local health care.

Although both traditional and conventional health services form a plural system of health care, they remain functionally unrelated in any way. There are no official avenues for referral between the two systems.

Health Care Financing and Expenditure

Revenue

Government health services are financed from the consolidated revenue fund. There are no special taxes or levies for generating funds for health care. The Western regional government had introduced government lotteries in 1955 and legislated[10]

P.2896

that all monies received from the sale of tickets be paid into a medical development fund. However, this effort was eventually discouraged by poor receipts.

The nonexistence of a special health fund, tax, or levy and the relatively low fees paid by patients for health services have resulted in a widening gap between expenditure and resources. For example, most states devote up to 10% of their total annual budget to health services, whereas their annual health revenue usually constitutes <1% of the health budget. In federal teaching hospitals, internally generated revenue accounts for only 5% to 8% of the total annual expenditure.

In order to reduce the burden of the provision of health finances on the three tiers of government, a National Health Insurance scheme was launched in 2005. Federal government workers constitute the first core group to be covered by the pilot phase of the program. The program will later be extended to the organized private sector, but is unlikely to cover the majority of Nigerians, who are either self-employed or work for small enterprises.

Cost recovery through revolving funds is consistent with the national policy, which states that users shall pay for curative services but preventive services shall be subsidized.[8] A seed fund is provided to purchase a good stock of drugs and other consumables employed in medical care. Subsequently, further replenishment of stocks is provided for by sales. Provision is made for losses, exemptions, inflation, and overheads by adding 5% to 20% of the actual cost to the amount charged to the patient. The revolving fund scheme has been quite successful in many teaching hospitals.

Expenditure

In 2002, the Nigerian public health expenditure as a percentage of the gross domestic product (GDP) was 1.2%, while the private health expenditure as a percentage of the GDP was 3.5%. State governments devote between 5% and 10% of their total annual budget to health care, while local governments spend 10% to 15%.

Government medical care is labor intensive. For example, 70% to 90% of each federal teaching hospital's annual budget is spent on salaries and emoluments, leaving little for health care services and drugs.

The concept of "managed care" is practiced by all public and private companies and corporations who are obliged by law to provide free health care for their workers and their dependents. The companies enter into contracts with selected private hospital groups as health care providers, or provide limited cash reimbursements for medical expenses purchased by employees in the private health sector. The financial expenditure on health by companies is not usually made explicit in company financial statements, but the contribution to health care by this private sector financing of health is quite substantial, given the number of companies that offer this service and the large number of workers and relatives covered.

Public and institutional spending on health probably constitutes <30% of the total health expenditure in Nigeria. The majority of expenditure is by private individuals who purchase care as needed in private for-profit clinics and hospitals. These clinics and hospitals are commonly regarded as providing prompter, more courteous, and more efficient services.

Acutely ill patients receive substantial financial support from the immediate and extended families, which mitigates considerably the overall costs of health care to the patient and makes it possible for such patients to have access to health care that may otherwise be out of reach from pecuniary constraints. However, this family support tends to wane over time in patients with illnesses requiring chronic therapy, such as epilepsy.

Organization of Health Care Services

Numeric Strength and Distribution of Health Care Personnel

Doctors

Nigeria attained the recommended doctor-to-population ratio of 1:8,000 in 1982. In 1993, the ratio was 1:4,379, with wide variations between different states.[12] The 1991 doctor-to-population ratio varied from 1:1,614 in urban and affluent Lagos state to 1:114,069 in Katsina state and to 1:235,827 in Jigawa state with a low level of urbanization and weak economic infrastructures. In general, doctors tend to cluster in urban areas, avoiding rural and economically depressed areas, as is the case elsewhere in the world.

There were about 110 specialists in the clinical neurosciences practicing in Nigeria in 2004. These include 75 psychiatrists, 10 neurosurgeons, and about 25 neurologists.

Nurses

Registered nurses and midwives constitute the largest trained workforce in the health care system, with a nurse-to-population ratio of 1:655. They are also much more evenly spread between and within the states than doctors.

Community Health Workers

Community health officers are drawn from the cadres of public health nurses, community health supervisors, nursing sisters, or rural health superintendents and undergo a special 1-year training program in community health. They are the most senior community health workers.

Community health supervisors are drawn from the cadres of community health assistants, staff nurses, or rural health inspectors and undergo a special 1-year training program in community health.

Community health extension workers are responsible for the direct supervision of volunteer village health workers and spend 80% of their working time in the community. In 1993, the community health worker-to-population ratio was 1:2,166.

Primary Health Care

Traditional Medicine

There are some 200,000 traditional healers in Nigeria.[7] These include specialists such as herbalists, bone setters, traditional birth attendants, and those occupied with simple surgery, mental diseases, and therapeutic occultism.[16] Herbal medicine is the most widely practiced specialty of traditional medicine among Africans. There are also general practitioners who are competent in more than one form of therapy but are not specialized in any.

Herbal Therapy

The traditional mode of treatment of seizures commonly involves consultations with traditional deities in the supernatural world by the rendition of incantations or metaphors, combined with the administration of herbal remedies. The herbal remedies are commonly mixtures of plants with anticonvulsant, antipyretic, or antibacterial activity.

One traditional herbal remedy for generalized convulsions in Western Nigeria is the fruits of *Tetrapleura Tetraptera* Taub and the leaves of *Nicotiana Tabacum* Linn. These plants contain *Scopoletin* and its methyl derivative, *Scoparone,* which have been shown to protect against leptazol-induced convulsions.[1] However, the plants are sometimes extracted into a concoction containing cow's urine or local gin before administration. This concoction has a prolonged hypoglycemic effect, and is known to cause permanent cerebral damage in children.[15]

The health-seeking behavior of patients with epilepsy suggests a strong preference for traditional herbal medicine over conventional medicine, especially in the rural areas. For instance, all of 101 freshly screened patients with epilepsy in a community-based survey in Igbo-Ora, Western Nigeria, had been treated with herbal remedies, while only four (3.9%) were receiving conventional antiepileptic drug therapy.[13] This is particularly remarkable because the village being surveyed had good primary health care facilities, which had been functioning several years prior to the survey.

Spiritual Therapy

Epilepsy is often regarded as a manifestation of visitation of the devil, the effect of witchcraft, or the revenge of an aggrieved ancestral spirit.[14] The management of epilepsy is therefore commonly assumed to be in the domain of spiritual healers who hold out the attractive promise of a complete cure of epilepsy by magico-spiritual therapies. These elaborate therapies include ritual dances, incantations, propitiatory rites, and exorcism. They may take up considerable time, effort, and money, but are of considerable psychotherapeutic value to the patients in view of the deep-rooted beliefs about the supernatural etiology of epilepsy.

An emerging group of spiritual healers are the Islamic and Christian faith healers, who combine the basic concepts of their religions with superstitious customs and practices. They promise an instant and complete cure for epilepsy by exorcism and provide for the psychological needs of their adherents.

Traditional herbal medicine appears to be more popular for epilepsy care than spiritual therapy. Of 265 epileptic patients who have used alternative forms of therapy prior to seeking hospital treatment in one study,[3] 47% had used traditional medicine, 20.4% had used spiritual healing, while the rest had combined both treatments. However, after initiation of drug therapy in hospitals, more than two thirds of patients who had earlier used spiritual therapy tended to continue such therapy, compared with 14.6% of patients who had used traditional herbal medicine. This implies a stronger perception of continuing psychological benefit from spiritual therapy.

Eighty-six percent of patients who chose alternative medicine as their first level of care were influenced to do so by relatives, friends, and neighbors.[3] Most patients with epilepsy reporting for the first time in a conventional hospital facility would have spent between 1 and 5 years in traditional or spiritual therapy before reporting to the hospital. Thus, the intervention of these alternative practitioners often delays the arrival of patients at centers where more adequate therapy may be available.

Government Primary Care Services

The primary health care services of the national health system are provided by the local governments, their combined primary health care clinics, and health center facilities constituting 50% of all health establishments in Nigeria.[12] These facilities are well spread out in rural areas and indeed are often the only access to conventional health care for people domiciled in those areas. Government primary health care is provided at two levels:

1. The Village Health Service is provided by volunteer village health workers under the control and supervision of village health committees.
2. The District Health Center serves as a referral point for the Village Health Service. Services are provided at this level by community health officers, supervisors, and community health extension workers.

The national mental health policy calls for the integration of mental health into the national primary health care program. "Mental health" was used in this context to include the care of major psychosis, epilepsy, mental retardation, and dementia.

Therefore, mental health has been incorporated as the ninth component of primary health care. Standing orders on mental health for community workers have been developed. The orders for the junior community health extension workers at the village level[6] requires that cases of epilepsy be referred to the health center, but kept on the risk register and followed up. Accordingly, there are no antiepileptic drugs on the official drugs list for the village dispensary. The official standing orders for community health officers, supervisors, and assistants working at the district health center,[5] however, only requires the workers to treat acute seizures with paraldehyde or diazepam and to refer suspected cases of epilepsy to the general hospital.

The government primary health care workers are thus not officially required or trained to make a diagnosis of epilepsy or administer drug therapy to patients with epilepsy. Accordingly, most health centers do not have patients with epilepsy on their registers.

General Medical Practitioners

Individuals and private groups own 30.5% of all health establishments in Nigeria. These profit-orientated private health facilities are most often manned by single medical doctors in a solo practice. Some of these doctors are specialists by training, but in practice are general practitioners seeing all cases.

Private hospitals and clinics are most concentrated in the urban areas where they are largely responsible for the availability of health facilities to 75% of the urban Nigerian population within 4 km of their residences.[12] Only 35% of rural dwellers have similar access.

As there are no fee-for-service schemes or other incentives to encourage the participation of private practitioners in government primary care services, they are largely autonomous of the government. Many private hospitals have retainerships with companies and corporations for the primary care of their staff and dependents.

However, most workers will not disclose their history of epilepsy to their employers because of fears about job discrimination[4] and will therefore tend to avoid utilizing health services provided by their employers.

Most cases of epilepsy in urban areas are probably diagnosed and treated by general practitioners in private hospitals and in the general outpatient departments (GOPD) of tertiary hospitals, particularly partial seizures and absences, which are often poorly recognized by nonmedical health care workers.

Secondary Health Care

State governments are responsible for secondary health care. The state general hospitals where secondary care is provided make up 11.6% of all the health establishments in Nigeria. The hospitals serve as a referral center for the district health centers. There is a plan for each local government area to have a general hospital. There are currently 451 general hospitals for the 589 local governments in Nigeria.

P.2898

The general hospitals have outpatient departments run by general practitioners. The hospitals are also expected to have a full complement of curative care, with specialists in medicine, pediatrics, surgery, and obstetrics. While this complement is often attained in urban general hospitals, it is an exception in general hospitals located in the rural areas. Most rural general hospitals have a single general practitioner to provide services. These may sometimes be young medical doctors on national youth service.

In those where specialist physicians and pediatricians are available, the general hospitals serve as the first level of access to specialist care for patients with epilepsy. The patients are usually referred from private clinics in the catchment area and from the hospitals' own general outpatients department. There are no neurologists at the general hospital level.

There is a full range of routine antiepileptic drugs in the essential drugs list at the secondary care level. Of these, phenobarbitone and phenytoin are readily affordable, but carbamazepine and sodium valproate are more expensive. There are no facilities for therapeutic drug monitoring of serum levels of antiepileptic drugs. There are also no facilities for electroencephalography (EEG) in these hospitals; patients requiring EEG are referred to the teaching hospitals with neurologic services.

There is an increasing number of well-equipped private hospitals in the urban centers that provide a full complement of secondary health care services.

Tertiary Health Care

There are 12 neuropsychiatric hospitals and 25 teaching hospitals in Nigeria. The neuropsychiatric hospitals are run by psychiatrists, while epilepsy care in the teaching hospitals is provided by neurologists, psychiatrists, pediatricians, and internists. Access to epilepsy care in the tertiary centers is by referral from general practitioners in private hospitals and the outpatients departments of the tertiary hospitals.

All the teaching hospitals have neurologic units with facilities for EEG and computed tomography scan. One of these, the University College Hospital, Ibadan, was designated as a center for excellence in neurosciences by the federal government in 1986. Six teaching hospitals have facilities for magnetic resonance imaging. Most routine antiepileptic drugs are available but the newer antiepileptic medications are prohibitively expensive. There are no special centers for epilepsy care in Nigeria.

Summary and Conclusions

Young adults living in rural areas constitute the majority of Nigerians with epilepsy. There is evidence that the majority of them are receiving traditional therapy rather than conventional antiepileptic drug therapy, even in areas where there are well-established and otherwise efficient primary health care facilities. This preference for traditional medicine has been documented to cause delays of up to 5 years before many patients with epilepsy reach centers where they can be better treated.

A review of the standing orders for epilepsy care at the primary health care level in Nigeria showed that the community health workers are not motivated or trained to treat patients with epilepsy. Nigerians have been shown to demonstrate a pragmatic, efficacy-testing health-seeking behavior for any particular complaint[9,11]; decisions on choice of care depend on, among other things, whether the health care facility in question has a reputation for alleviating such complaints. In order to demonstrate the efficacy of conventional antiepileptic drug therapy in the rural areas, there is a need to fully integrate the management of epilepsy into the national primary health care programs along the lines suggested by the World Health Organization in 1990.[17]

The development of efficient tertiary epilepsy care in Nigeria is hampered by the small numbers of specialists in the clinical neurosciences and by poor funding.

Abdul Aziz Al Semari

Introduction

Although the Kingdom of Saudi Arabia comprises the largest area of the Arabic peninsula southwest of Asia, it continues to provide high standards in health care. Medical technology is continually upgraded. One of the first initiatives of King Abdul Aziz Al Saud, the founder of modern Saudi Arabia, was to improve health care facilities and to provide free medical treatment to all citizens and to pilgrims who travel to Mecca.[10,11]

The report of the World Health Organization (WHO) in 2006[17] shows that the total population of Saudi Arabia is 24,573,000. Life expectancy at birth is 59.8 years for males and 62.9 years for females. Child mortality per 1,000 is 29 for males and 24 for females. Adult mortality per 1,000 is 196 for males and 120 for females.[17] Saudi Arabia's health care achievements now match those of many developed countries. Saudi Arabians are no longer required to travel abroad to get specialized medical treatment. The country has the facilities to train physicians, nurses, and other medical personnel to staff the infrastructures of the Saudi health care system, which extends today to most remote communities in the country (Table 1). The government of Saudi Arabia continues to provide massive support to existing health projects in order to ensure that health services are accessible to all people at all levels.[9,12]

The Saudi health system has developed strategies to achieve the following objectives[9,12]:

1. Identification and treatments of patients
2. Delivery of preventive medicine
3. Improvement of diagnostic facilities
4. Improvement of treatment modalities
5. Optimum clinical and social follow-up of patients with chronic diseases
6. Availability of high-standard tertiary care centers for expert evaluation of complicated patients
7. Improvement of health education

The Saudi health system faces several challenges[9,12]:

1. Limited epidemiologic studies
2. Large mass of inhabited land
3. Diversity of living environments in urban and rural areas
4. Rapidly proliferating numbers of national and expatriate inhabitants

To overcome these challenges, the Saudi health system developed four phases of planning with shifts, changes in priorities, and overtime organizational arrangements. The proliferation of the health system within a short period of time had brought into focus several health-planning issues such as coordination, health information systems, and the need for establishing national bodies for health planning and accreditation. To achieve the objectives of the Saudi health system, the Kingdom organized the delivery of health care into several levels.[9,12]

Primary Care

This service is defined as the health care provided by primary care physicians evaluating patients. In Saudi Arabia, the primary care centers are distributed evenly in the country to include variable urban and rural regions. All major health sectors provide primary care centers in the country, but the Ministry of Health (MOH) remains the largest health sector providing primary health care in Saudi Arabia through a number of hospitals and polyclinics established at a standard design to match the numbers and needs of the population served (Table 2).[6,8,12,13]

Primary care physicians can refer patients to a higher level of health service according to their needs.[6,8,12,13]

Secondary Care

This level comprises most of the general hospitals in Saudi Arabia, and the Ministry of Health represents almost 63% of hospital beds in Saudi Arabia, followed by other hospitals (Table 2). Physicians practicing at this level can refer patients to tertiary care hospitals as needed. The Ministry of Defense and Aviation operates a medical evacuation program consisting of assigned equipped executive jets and helicopter aircrafts with flight physicians and nurses to transport patients to tertiary care centers.

Tertiary Care and Specialized Centers

In Saudi Arabia, a number of tertiary care hospitals are available and receive patients with complex medical conditions from different regions of the country. These centers provide advanced facilities for diagnosis and management of various medical and surgical disorders under the supervision of highly trained medical experts. Some of these centers are world famous for referrals, teaching, and research such as the King Faisal Specialist Hospital and Research Center and the Riyadh Military Hospital.

Major health care–providing sectors include government and private hospitals. Governmental sectors include the Ministry of Health, the Ministry of Defense and Aviation, the Ministry of Interior, the National Guard, University Hospitals, the King Faisal Specialist Hospital and Research Center, and the general organization for social insurance hospitals. The private sector hospitals provide a vital contribution to health service and have expanded dramatically over the past decade; there are a number of these hospitals and clinics in Saudi Arabia.[8]

Table 1 Labor Force in Health Services

Epilepsy Health Services in Saudi Arabia

Epilepsy is a major neurologic disorder in Saudi Arabia. The incidence and prevalence of epilepsy in Saudi Arabia are

P.2900

underestimated. Head trauma due to road traffic accidents remain a major etiology of epilepsy in Saudi Arabia due to the high rate of road traffic accidents. Other etiologies of epilepsy in Saudi Arabia include cerebrovascular diseases, trauma, central nervous system infections, and developmental and genetic disorders. There is a significant reduction in prenatal injury as an etiology of epilepsy due to advanced obstetric and pediatric care.[2,3,4,5,7,14,15,16] Epileptic patients in Saudi Arabia can be treated by primary care physicians, pediatricians, and internists, but more often they are referred to adult and pediatric neurologists in major cities of the country. Facilities for digital electroencephalography (EEG) and neuroimaging with computed tomography (CT) scans or magnetic resonance imaging (MRI) are available in general hospitals distributed throughout the country.

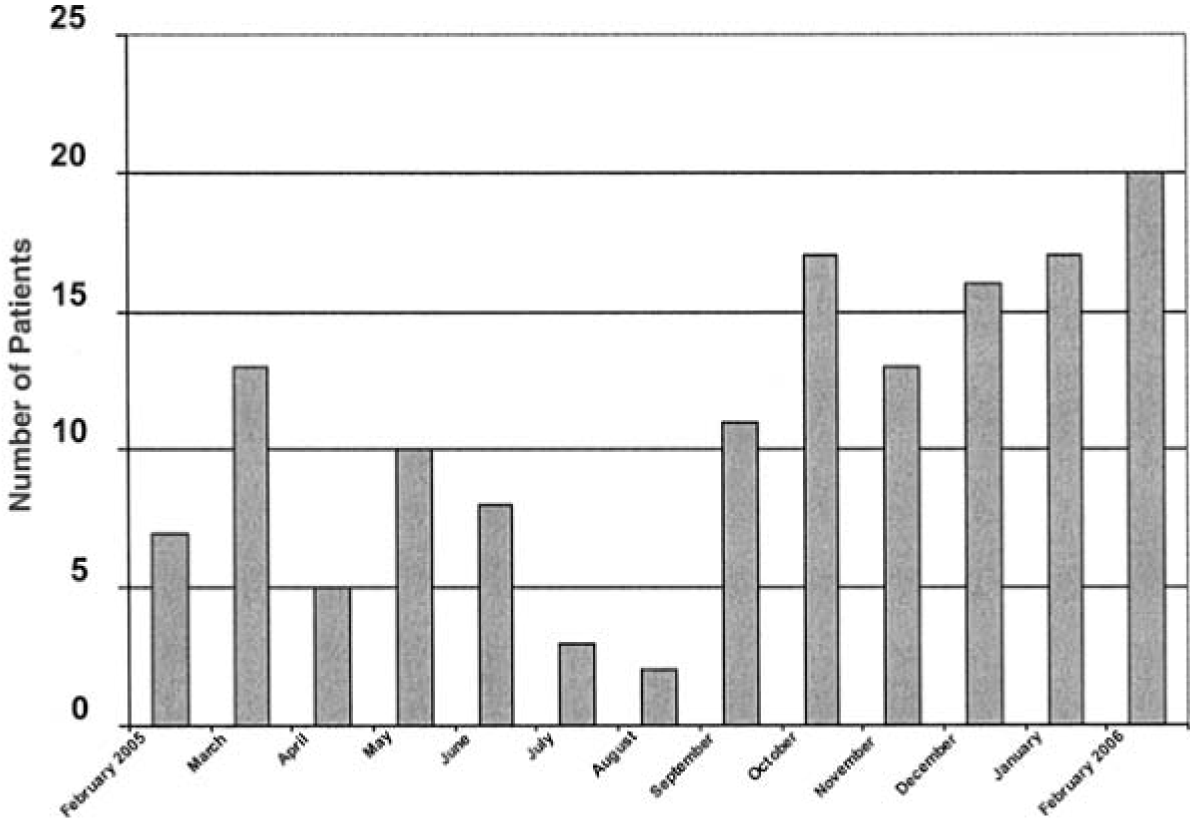

FIGURE 1. Epilepsy monitoring unit admissions (February 2005–present).

Antiepileptic drugs are widely available in Saudi Arabia in different formulations. Traditional antiepileptic drugs include phenytoin, phenobarbitone, primidone, carbamazepine, sodium valproate, ethosuximide, and clonazepam.[1,3] New antiepileptic drugs such as vigabatrin, lamotrigine, topiramate, oxcarbamazepine, gabapentin, and levetiracetam are available in major hospitals and pharmacies. Carbamazepine remains the most common antiepileptic drug prescribed. Patients with unclassified epilepsy or those with intractable epilepsies are referred to tertiary care epilepsy centers for further evaluation and management. Epilepsy centers have advanced structural and functional neuroimaging techniques and facilities for video-EEG monitoring. Trained epileptologists and neurosurgeons supervising investigations of epileptic patients in those centers are available in Riyadh and Jeddah. The largest and oldest epilepsy center in Saudi Arabia is in the King Faisal Specialist Hospital in Riyadh. The second largest epilepsy center is in the Riyadh Military Hospital. More recently, additional units have been introduced at the King Faisal Specialist Hospital in Jeddah, the National Guard Hospital in Riyadh, and the King Faisal University Hospital in Dammam. Facilities for

video-EEG monitoring are also available in the private sector hospitals such as the Saudi German and Erfan Bagedo hospitals in Jeddah. The numbers of advanced epilepsy units are expected to rise in Saudi Arabia, with increasing numbers of trained national epileptologists and epilepsy surgeons returning to Saudi Arabia after finishing their scholarships. The following section provides an overview of the two largest epilepsy comprehensive programs established in Saudi Arabia.

The Comprehensive Epilepsy Program of the King Faisal Specialist Hospital and Research Center

The comprehensive epilepsy program was established in the year 1998 at the King Faisal Specialist Hospital and Research Center. The major aims of this program are to treat the referred patients medically and surgically in specialized adult and pediatric epilepsy clinics, by adult and pediatric epileptologists, neurophysiologists, and neuropsychologists. The majority of approved antiepileptic medications are available. The existing epilepsy monitoring unit has the capacity to monitor five patients at one time for surgical evaluation and classification. The patients who are admitted for surgical management are discussed during a weekly epilepsy conference. Wada tests, subdural EEG recordings, and electrocorticography are performed routinely. Figures 1,2,3,4,5 and Table 3 show data on admissions, surgical procedures, and outcome. Programs for deep brain stimulation and ketogenic diet are being developed to treat refractory cases of epilepsy.

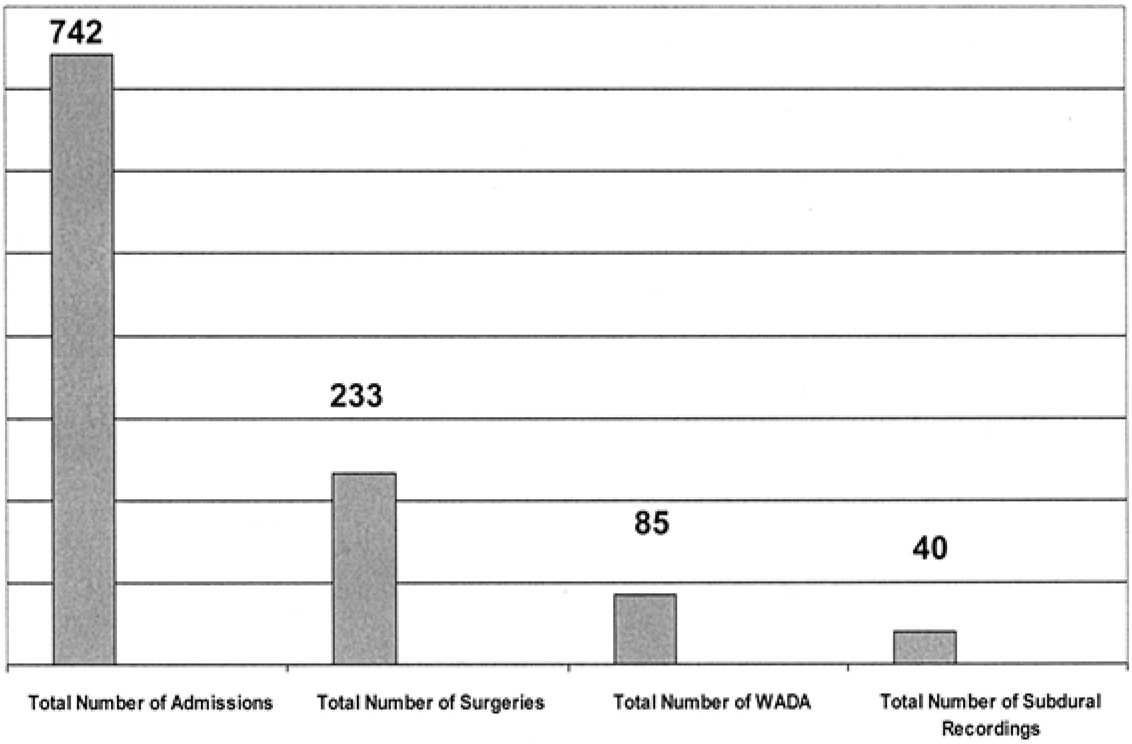

FIGURE 2. Epilepsy monitoring unit statistics.

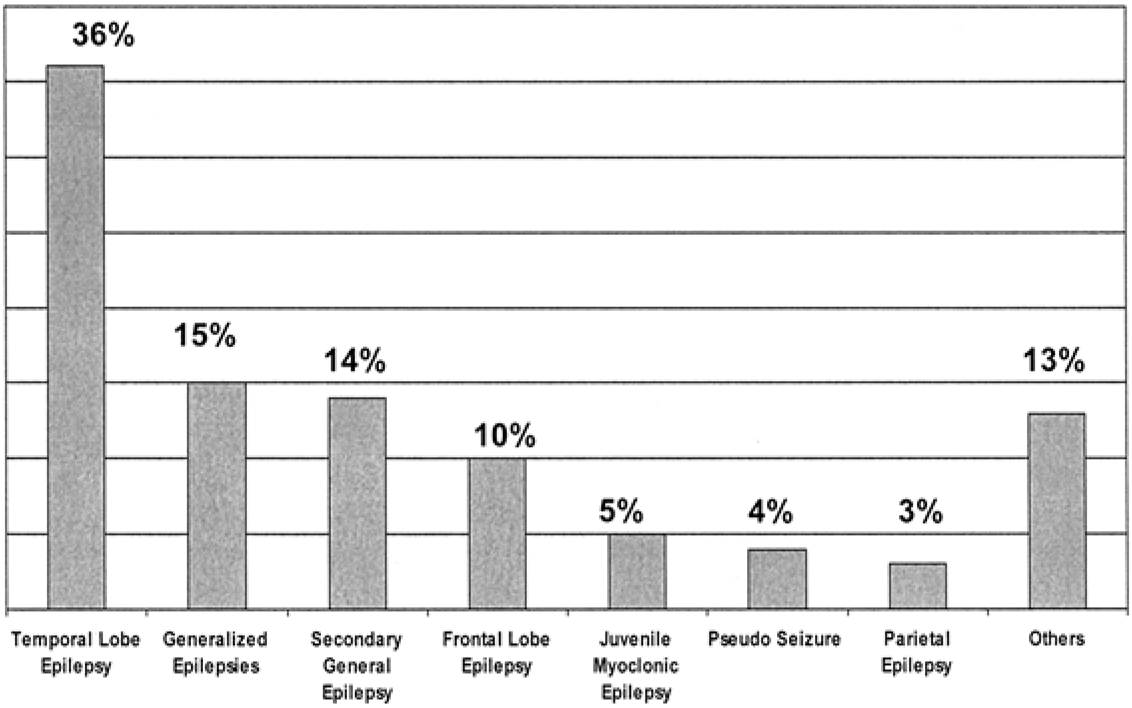

FIGURE 3. Diagnosis based on distribution of epilepsy cases.

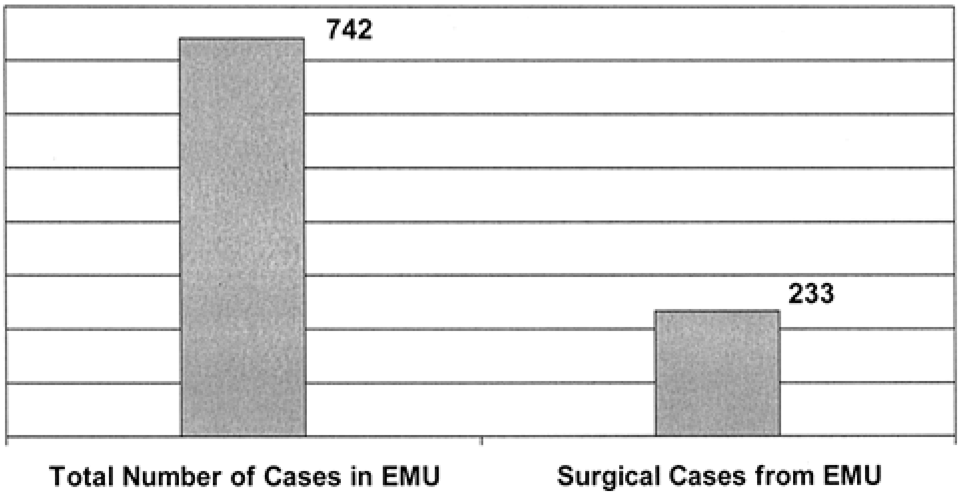

FIGURE 4. Epilepsy monitoring unit (EMU) admissions and surgical cases.

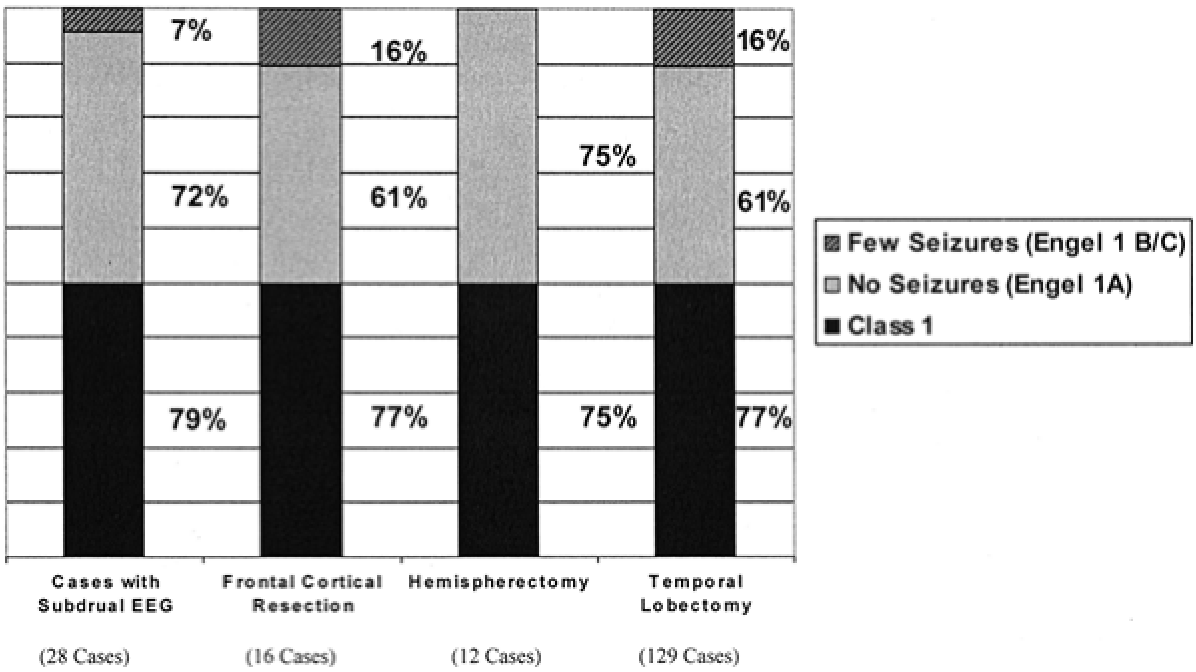

FIGURE 5. First-year outcome by surgical procedure. EEG, electroencephalogram.

An epilepsy registry has been established, and it is the first of its kind in the Kingdom of Saudi Arabia, thus serving as a resource to improve the understanding of epilepsy and to assess the magnitude and impact of this disorder on the society. The major goals of the epilepsy program are to treat the referred patients and collect, analyze, and disseminate accurate and timely data pertaining to their demographics, medical history of risk factors, type of disease, treatment, and outcome to health care providers and researchers. It is hoped that this will also serve as a model for the establishment of a Kingdom-wide registry for this disease.

The neurophysiology technologists training program was developed in 2002. Its objectives are to train and graduate skilled technicians to perform a quality service in the neurophysiology laboratory, and to provide the society with a role model of a well-trained neurophysiology technologist (Fig. 6).

The Epilepsy Comprehensive Program at Riyadh Military Hospital

This epilepsy program was introduced in January 1998 and is the second largest referral program for advanced epilepsy management in the Kingdom of Saudi Arabia. Adult and pediatric epileptic patients are referred to the epilepsy comprehensive program at the Riyadh Military Hospital from all military hospitals as well as from other governmental and private hospitals in all regions of the Kingdom of Saudi Arabia. Through special arrangements, referrals from the Arabic Gulf region and the Middle East can be seen in the Riyadh Military Hospital. The epilepsy comprehensive program receives 15 to 20 new epileptic patients per month in the outpatient clinics,

P.2902

evaluates ten epileptic patients per month in the epilepsy monitoring unit, and provides long-term video-EEG monitoring for ten patients per month. A total of 1,500 active epilepsy patients are followed by the comprehensive epilepsy program (Fig. 7).

The epilepsy program has two adult epileptologists, two pediatric neurologists, two neurophysiologists, two neuropsychologists, one epilepsy surgeon, and two neuroradiologists, in addition to a number of trained neurophysiology technologists and full-time nurses.

Services of the Epilepsy Comprehensive Program at Riyadh Military Hospital

Diagnosis of Epilepsy

Military and nonmilitary personnel are referred for evaluation of episodes of loss of consciousness. A comprehensive workup of high-resolution MRI scans of the brain,

P.2903

21-electrode digital EEGs, and long-term video-EEG monitoring is performed. Cardiac workup including echocardiography, 24- and 72-hour electrocardiography (ECG) Holter monitoring, advanced electrophysiologic tests of the heart, and other relevant tests are also included in the workup.

A wide variety of epileptic syndromes and nonepileptic conditions such as pseudoseizures, neurocardiac syncope, and other diagnoses are entertained in the epilepsy unit (Table 4).

Medical Management of Epilepsy

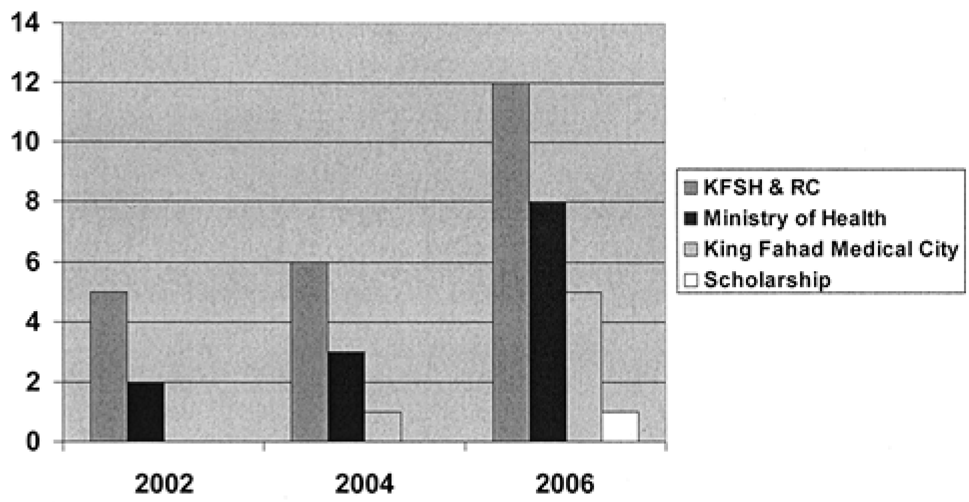
Newly diagnosed epileptic patients and epileptic patients not responding to standard antiepileptic drugs are referred to the epilepsy comprehensive program for medical management or adjustment of antiepileptic drugs. In addition to the standard antiepileptic drugs such as phenytoin, carbamazepine, valproate, ethosuximide, phenobarbitone, and primidone, new antiepileptic drugs are available. These include lamotrigine, topiramate, gabapentin, and levetiracetam.

Surgical Management of Epilepsy

A presurgical workup is performed on patients with intractable epilepsies. This include a detailed history and physical examination of the patients; blood investigations including antiepileptic drug levels; 21-channel digital interictal awake, asleep, and sleep-deprived EEG; full neuropsychological and psychological evaluation; and long-term video-EEG monitoring for 5 to 7 days using scalp EEG electrodes with zygomatic (Zg1, Zg2) or sphenoidal electrodes (Sph1, Sph2). The patient is monitored to capture three to five events and to perform ictal single photon emission tomography (SPECT) scans. Additional presurgical tests are performed as needed such as interictal SPECT scans, interictal positron emission tomography-^{18}F-fluorodeoxyglucose (PET-FDG) scans, and functional MRI for language and memory lateralization and motor function mapping. Nonselective intracarotid amobarbital test function (Wada test) in epilepsy surgery patients remains the standard tool to lateralize memory and language at the epilepsy comprehensive program. Recently, propofol replaced amobarbital in the Wada test due to the unavailability of the amobarbital.

Table 3 Surgical Outcome by Surgical Procedure

Surgical procedure	Total Surgical cases	Followed case	Seizure free	
			Cases	Percent
Parietal cortical resection	4	2	1	50%
Parieto-occipital lesionectomy	2	2	2	100%
Multiple subpial transection	1	1	1	100%



Year	Number of Trainees	Number of Graduates
2002	5	5
2004	7	6
2006	12	…

FIGURE 6. Neurophysiology technology training program. KFSH & RC, King Faisal Specialist Hospital and Research Center.

A reasonable number of epilepsy surgeries are performed yearly (Table 5). Decisions and plans for epilepsy surgery for each patient take place after finishing the full presurgical workup and discussing the presurgical data at the weekly epilepsy surgery meeting attended by the epilepsy team. Further plans for epilepsy surgery are made in the meeting. The most common intractable epilepsy encountered is temporal lobe epilepsy with hippocampal sclerosis as the most common surgical substrate. The most common epilepsy surgical procedure is anterior temporal lobectomy. Other epilepsy surgical procedures, such as lesionectomies for foreign tissue lesions such as vascular malformations, tumors, and focal cortical dysplasias, are performed. Functional hemispherectomy for diffuse unilateral hemispheric lesions is performed. Facilities for intraoperative monitoring methods such as electrocorticography, cortical stimulations, and somatosensory-evoked potentials for mapping of the motor cortex and other eloquent regions are available. Surgical outcome of lesional epilepsy surgery is comparable to the international literature (Table 6). No epilepsy surgery for nonlesional epilepsy has been performed yet due to technical limitations. Other palliative surgical procedures for intractable epilepsy can be performed at the epilepsy comprehensive program. The first implantation of vagal nerve stimulation in the Kingdom of Saudi Arabia was performed at the epilepsy comprehensive program in 1998 for three patients with intractable epilepsy. Vagal nerve stimulation as a treatment modality for intractable epilepsy at the epilepsy comprehensive program remains restricted for very selective patients.

Epilepsy Registry Data

Locally registered data of 1,000 active epileptic patients are available, which include demographic, clinical, EEG, and MRI data as well as seizure and epilepsy classification according to the International League Against Epilepsy (ILAE) classification.

Women and the Epilepsy Program

Women with epilepsy at different ages are referred to the specialized epilepsy clinics for counseling and follow-up.

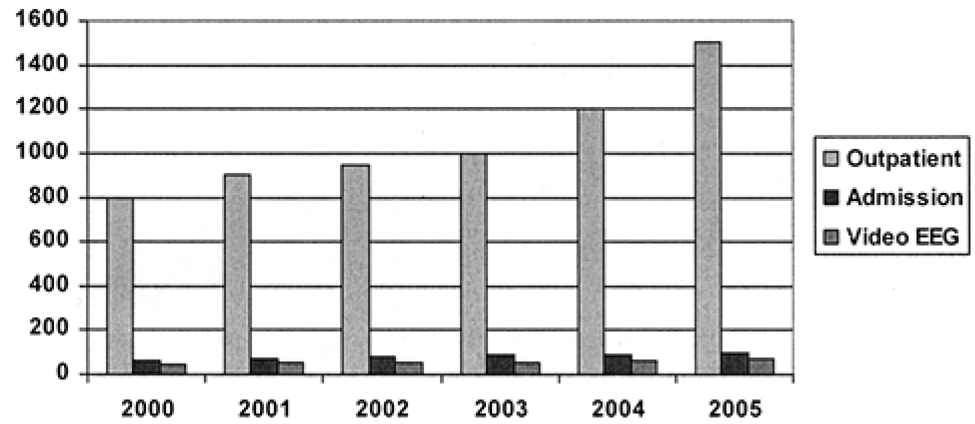


FIGURE 7. Annual statistics of the epilepsy program (2000–2005). EEG, electroencephalogram.

Table 4 Diagnoses at the Comprehensive Epilepsy Program (2002–2005)

Diagnoses	Mean age (yr)	Gender		Total
		Male	Female	
Generalized epilepsy	25	17	30	47 pt (20%)
Partial epilepsy	38	70	60	130 pt (60%)

Pseudo seizure	35	5	30	35 pt (15%)
Others	30	20	3	23 pt (5%)

Newly diagnosed epileptic young and elderly women are referred to the epilepsy program for the choice of appropriate antiepileptic drugs according to their diagnoses, ages, and comorbid conditions such as menstrual irregularities, osteoporosis, etc. Epileptic women of childbearing age are referred to the specialized epilepsy clinic for pre-pregnancy counseling, choice of contraceptive pills, and comprehensive follow-up during the pregnancy delivery and postpartum periods.

Epilepsy Training

The epilepsy comprehensive program provides regular biannual courses on basic and practical epileptology for nurses, technologists, and other health providers interested in epilepsy. These courses are limited to the hospital staff. In addition, neurology and neurosurgery board residents rotate for a 2-month period during their training in the epilepsy unit to learn basic epileptology related to their specialties.

Epilepsy Education and Training

Due to the small number of trained epileptologists and epilepsy surgeons in Saudi Arabia, the government of Saudi Arabia in general and the Saudi neuroscience society in particular encourage young neurologists and neurosurgeons to pursue higher training in epileptology and epilepsy surgery, respectively.

Through fully sponsored governmental scholarships, national neurologists and neurosurgeons are sent to the most prestigious European and North American epilepsy centers to pursue their subspecialty training and to gain the highest level of expertise in epilepsy. Internationally recognized epilepsy centers and programs in Europe and North America receive neurology and neurosurgery graduates on a regular basis. In addition, the government of Saudi Arabia provides local and international scientific scholarships for paramedical personnel to obtain higher training in their fields.

Major epilepsy centers in Saudi Arabia provide limited medical training in epileptology for the neurology and neurosurgery residents. In addition, high-standard training programs are available locally for nurses and neurophysiology technicians. Regular scientific activities include the full-day annual Saudi epilepsy meeting under the annual Saudi neuroscience symposium and regular half-day workshops, lectures, and seminars for neurologists, neurosurgeons, physicians, board residents, and paramedical staff. Every two years a 2-day Saudi epilepsy course takes place in collaboration with the regional commission of the ILAE and the International Bureau of Epilepsy.

Collaborative clinical and research projects take place regularly between the Saudi epilepsy centers and international recognized epilepsy centers with regular visits from international epileptologists and epilepsy surgeons to the epilepsy centers in Saudi Arabia. The Saudi chapter of the ILAE and the Saudi chapter of the International Bureau of Epilepsy represent the scientific body that supervises all academic epilepsy activities in Saudi Arabia. Regular scientific epilepsy papers and abstracts are presented in local, regional, and international neuroscience and epileptology conferences.

Patient Education in Epilepsy

Lay knowledge of epilepsy is unsatisfactory in Saudi Arabia. Despite the improved standards of general education in the Kingdom, significant misunderstanding and social stigma of epilepsy remain in Saudi Arabia.

Table 5 Epilepsy Surgery at the Riyadh Military Hospital (November

1998–June 2006)

Year	Temporal surgery	Extratemporal surgery	Total
1998	1	—	1
1999	10	4	14
2000	12	2	14
2001	8	2	10
2002	8	4	12
2003	13	4	17
2004	10	4	14
2005	8	4	12
2006	3	3	6
Total	73	27	100

Table 6 Surgical Outcome at the Riyadh Military Hospital

	Temporal		Extratemporal	
Surgical outcome	n	%	n	%
Engel I	55	75%	19	70%
Engel II	15	21%	5	19%
Engel III	2	3%	2	7%
Engel IV	1	1%	1	4%

Many patients believe in traditional medicine in the form of herbal or spiritual therapies. Other patients avoid medical management to avoid psychosocial stigma. Despite advanced medical and surgical standards in the management of epilepsy in Saudi Arabia, patient education has remained significantly retarded for a long time. The King Faisal Specialist Hospital and Research Center in Riyadh took the first step toward a comprehensive educational program for patients and the

public by forming the Epilepsy Support and Information Center (ESIC).

Epilepsy Support and Information Center

The ESIC is a community volunteer group affiliated with the comprehensive epilepsy program at the King Faisal Specialist Hospital and Research Center in Riyadh composed of both community volunteers and medical professionals. The center is dedicated to dispersing information about and understanding of epilepsy in Saudi Arabia and the International Arab Community. ESIC's mission is to promote increased awareness, understanding, and acceptance of epilepsy. Other epilepsy centers and ministries of health are organizing a collaborative patient support group with ESIC to improve epilepsy patient education in Saudi Arabia. ESIC endeavors to promote epilepsy health education and support for individuals with epilepsy and their families through the publication and nationwide distribution of printed materials on epilepsy.

List of Publications

The following is a list of ESIC's publications:

- Questions and Answers about Epilepsy
- Febrile Seizures
- Epilepsy and Children
- Advice on Raising a Child with Epilepsy
- Epilepsy Medications and Epilepsy
- Myth and Misunderstanding about Epilepsy
- Epilepsy and Education: The Role of the Teacher (Booklet)
- Epilepsy and Pregnancy (Booklet)
- Questions and Answers about Epilepsy (Booklet)
- Adil and Epilepsy (Children's Story Booklet)
- Epilepsy Information Fact Sheet
- 12 Antiepileptic Drug Wallet Cards

Patient Information Lectures and Conferences

ESIC offers six public information lectures and three public epilepsy conferences.

Website

The ESIC has established the first comprehensive epilepsy Internet Website (www.epilepsyinarabic.com) in the Arabic language. Visitors to the site contact us on a regular basis through e-mail and ESIC receives regular online requests for Arabic language brochures from many countries, including Saudi Arabia and the other Gulf States, Libya, Jordan, Syria, Egypt, Morocco, Spain, Britain, and the United States, to name a few.

Family Festival for Epilepsy Awareness

To date, the ESIC has organized five annual Family Festivals for Epilepsy Awareness. The sixth annual Family Festival is planned for November 2007.

Teacher Awareness Program

To date, the ESIC has organized ten half-day Teacher Awareness Conferences at schools, universities, and government rehabilitation centers in Saudi Arabia.

Epilepsy News/Media Campaign

In May 2006, the ESIC distributed a four-page Epilepsy Public Information Fact Sheet with basic facts and information about epilepsy. The fact sheet was distributed Kingdom-wide as an insert in the Al-Riyadh Daily National Newspaper. Total distribution was 140,000 newspapers nationwide.

P.2907

Epilepsy Workshops for Health Care Professionals

To promote enhanced medical care and strengthen the medical emergency response to epilepsy, the ESIC organizes regular accredited full-day epilepsy workshops for primary health care professionals. To date, the ESIC has organized three epilepsy workshops. The last workshop was held March 12, 2005 and was organized in cooperation with the Saudi Arabian Ministry of Health.

Research

To highlight the societal impact of epilepsy and the needs of individuals with epilepsy to national health care planners, the ESIC is cooperating with the King Faisal Specialist Hospital and Research Center comprehensive epilepsy program to provide support and assistance in the establishment of a National Epilepsy Registry. The ESIC is also involved in an ongoing research survey aimed at determining the predominant societal attitudes and general level of knowledge about epilepsy in Saudi Arabia.

Awards

In 2001, the ESIC received the internationally recognized Initiative Prize from the Arab Gulf Funding for United Nations Program. The prize, received in the UN offices in Geneva Switzerland, consisted of a trophy and a $40,000 grant.

International Involvement

The ESIC has been a full chapter member of the International Bureau for Epilepsy since 2001, and has participated in the Eastern Mediterranean Epilepsy Task Force and in the drafting of the Eastern Mediterranean Declaration on Epilepsy in Cairo, Egypt.

Summary and Conclusions

Epilepsy is a common neurologic disorder in Saudi Arabia. Delivery of health services in general and of epilepsy in particular in Saudi Arabia is done at the primary care, then secondary care, then tertiary care levels. Despite the rapid proliferation of the population of Saudi Arabia, the advanced epilepsy centers with epilepsy surgery services remain confined to few centers and hospitals with limited capacities. Therefore, the official recognition of the increasing demands on more national epilepsy monitoring units and epilepsy surgical programs should be included in the main health-planning strategies toincrease epilepsy monitoring beds and to advance neurophysiologic and neuroimaging techniques in Saudi Arabia to the highest international standards. Epidemiologic studies are limited on epilepsy in Saudi Arabia. Therefore, national multicenter epidemiologic surveys should be launched to verify the magnitude and demands of epilepsy as a health problem in Saudi Arabia. National multicenter registries for epilepsy patients, pregnancy, and antiepileptic drugs and epilepsy surgery data should be initiated to achieve a better understanding of epilepsy in Saudi Arabia. Patient education of epilepsy is limited; therefore, all efforts should unify to overcome local misconceptions about epilepsy and improve general understanding of epilepsy. General national and local guidelines are needed for various epilepsy-related issues such as driving and pregnancy. Education about epilepsy in the elderly should be generated and approved by higher authorities to reduce morbidity and mortality of epilepsy. Education on epilepsy for health professionals should be optimized to organize a structured algorithm in the management of epilepsy in Saudi Arabia.

Chapter 297

Senegal

Amadou Gallo Diop

Ibrahima Pierre Ndiaye

Introduction

Epilepsy is one the most common neurologic diseases in outpatient and inpatient health management in Senegal, West Africa. It is the same situation in the majority of African and many developing countries, where it constitutes a major public health care problem.[11] From newborns to teenagers, childhood are the most stressed group due to several causes of epilepsy including perinatal problems, febrile convulsions, cerebral malaria, and consanguinity, which is a genetic factor.[1,19,22]

Such as in the majority of African countries, the cultural environment is a limiting factor for early diagnosis and treatment of seizures. Interpreted as a subnatural affliction, epilepsy is mainly managed by traditional healers, reducing the chance for Senegalese people living with seizures to benefit from modern drugs and better opportunities to become seizure free. A heavy burden is generated, leading to school withdrawal, nonemployment, and other social discriminations.

Overview of the Country

Senegal is a Western African country of 196,722 km^2. It is surrounded by Mauritania (at north), Guinea and Guinea-Bissau (at south), Mali (at east), and the Atlantic Ocean (at west). Gambia Republic is situated inside Senegal. Forty-five percent of the population is younger than 15 years old; 53.5% of the population is female, and 52% of the population is rural. The increasing rate for the general population is 2.6% per year. The population of Senegal is estimated to be near 12 million (Table 1). The general life expectancy is estimated at 54 years for males and 58 years for females. The infantile mortality rate is estimated to be 58 of 1,000 births.

The mean population density is estimated at 54 inhabitants per km^2, but it is very disparate: 3,659 inhabitants per km^2 are living in the capital city Dakar region, versus eight inhabitants per km^2 for the region of Tambacounda in the southeastern region, which represents 30% of the surface of the country. This situation can be explained by the large surface of this region, the low-wealth environment, and its aridity. Sixteen ethnic and language clusters are defined, but the main ethnic group and most spoken language is *Wolof*. It is important to be aware of this diversity because it may be considered in any information and education program, because of specific social and cultural values that are correlated to each. The rate of illiteracy is 43% of 15- to 24-year-old males and 62% of 15- to 24-year-old females. Ninety-two percent of the people in Senegal are Muslim.

Senegal is composed of 11 regions. Regions are divided in departments, themselves divided into districts, then into rural communities. These structures are led, respectively, by governors, prefects, and rural community presidents. Cities are led by a mayor. In their intervention domains are included health in coordination with the ministry of health, education, environment, urbanism, agriculture, youth, sport, and art craft.

Senegal is a low-economy country. The gross national product per inhabitant is estimated to be U.S. $480. The economy is mainly based on exploitation of phosphate, fishing, tourism, and agriculture.

General Data on the Health System

Health Organization and General Data

Senegal guarantees in its constitution that health is a right of every citizen and the duty of the state to provide. The medical and health systems are inherited from French colonization. A recent law is trying to organize traditional medicine, but one can guess how difficult it is to do so because of the secrecy surrounding this mystic and intrafamilial legacy. Despite this legislation, total or partial health insurance or coverage is a reality for about one third of the population represented by public and private workers and their families. The remaining two thirds remain in an informal sector, financing their health fees through their own or indirect supports. The health system is structured like a pyramid constituted from the base to the top by health post (for villages and rural communities), health center (inside cities), regional hospital, and two university hospitals. This represents the following (Table 2):

- 11 medical regions (led by the regional head doctor)
- 56 health districts (with one or more doctors and paramedical staff)
- 59 health centers (with nurses and midwives)
- 813 health posts (with nurses)
- 37 private Catholic health posts located in the suburban area of Dakar

The geographic accessibility to a health structure is theoretically 1.2 km for Dakar's patients, versus 16.2, 12.9, 11.0, and 10.3 km for the regions of Tambacounda, Louga, Saint-Louis, and Kolda, respectively.

In the context of the African continent, Senegal has a very low prevalence rate of HIV/AIDS infection: 0.8%. Heterosexual transmission is the major route. Since the early beginning of the AIDS pandemic, a strong policy of information, prevention, and caring has been developed. Reported AIDS cases increased progressively and remain stable now, estimated to be about 45,000 people. This tendency is attributed to Senegal's initiative of access to free antiretroviral drugs since 1996.

Table 1 Socioeconomic, Demographic, and Health Indicator Data about Senegal

Population, total	11.9 million
Population growth (annual %)	2.4
Life expectancy at birth, total (yr)	56.1
Fertility rate, total (births per woman)	4.8
Mortality rate, infant (per 1,000 live births)	77.6
Mortality rate, under 5 yr (per 1,000)	136.6
Births attended by skilled health staff (% of total)	57.8

Malnutrition prevalence, weight for age (% of children under 5)	22.7
Immunization, measles (% of children aged 12–23 months)	57.0
Prevalence of HIV, total (% of population aged 15–49)	0.9
Primary completion rate, total (% of relevant age group)	45.2
School enrollment, primary (% gross)	76.0
School enrollment, secondary (% gross)	19.4
School enrollment, tertiary (% gross)	4.9
Ratio of girls to boys in primary and secondary education (%)	89.8
Literacy rate, adult total (% of people aged 15 and above)	39.3

Total	22	56	59	813

Health Financing

The health annual budget roses to 9% of the global government budget since 2002. But 65% of the budget of the Ministry of Health is dedicated to pay salaries. There is a decreasing participation of the government financing of health and an increase in the population participation. Thirty percent of

P.2910

credit and expenses are done in the capital region of Dakar. Other sources of finances include development partners and local communities. They contribute in building, training, salary, and daily expenses. But it is difficult to determine their exact contributions. City administrations are also contributing in the health expenses, drugs, and maintenance. Armed forces and police also participate in health expenses of their personnel and families.

Health Personnel

Representing the health personnel are 649 (public and private) doctors and 3,287 paramedical staff (midwives, private nurses, and health agents) (Table 3). The mean general doctor-to-population ratio in Senegal is one doctor for 18,300 inhabitants, one midwife per 6,124 reproductive women and 0- to 4-year-old children, and one nurse for 4,570 inhabitants. The World Health Organization (WHO) recommends one doctor for 5,000 to 10,000 people, one midwife for 300 people, and one nurse for 300 people. There is a wide disparity: 90% of specialized doctors are concentrated in Dakar, the capital. The Dakar region has more than 50% of doctors, pharmacies, surgeons, nurses, and midwives. The national ratio is 11,163 inhabitants per health post. This is not so far from what WHO recommends (10,000 inhabitants).

Excluding two psychiatrists (one at North, one at South), the rest of the neuroscience personnel resides in Dakar: 15 public and two private neurologists, three private and 11 public psychiatrists, and six public neurosurgeons. Postgraduating diplomas in Psychiatry, Neurosurgery, and Neurology have existed in Senegal since 1993, 1998, and 2000, respectively.

Neurologists

Seventeen neurologists were identified in Senegal in 2007, among them eight professors (three with PhDs) and two private. All public-sector neurologists practice in the capital city of Dakar, where the unique service of Neurology of the University Hospital is located. The ratio of one neurologist for 700,000 people, far from the recommended WHO rate of one for 50,000 people, is one the best in the intertropical area of Africa, where the ratio ranges from one neurologist for 1 to 4 million people. This reality demonstrates the strong need to cooperate with psychiatrists, neurosurgeons, general practitioners, pediatricians, and public health staff.

Table 3 Health Personnel Data in Senegal

Physicians (number)	649
Physicians (density per 1,000 population)	0.06
- Including neurologists	17
- Including psychiatrists	14
- Including neurosurgeons	6
Nurses (number)	3,287
Nurses (density per 1,000 population)	0.32
Dentists (number)	97
Dentists (density per 1,000 population)	0.01
Pharmacists (number)	85
Pharmacists (density per 1,000 population)	0.01
Public and environmental health workers (number)	705
Public and environmental health workers (density per 1,000 population)	0.07

Lab technicians (density per 1,000 population)	0.01
Other health workers (number)	704
Other health workers (density per 1,000 population)	0.07
Health management and support workers (number)	564
Health management and support workers (density per 1,000 population)	0.05

Epilepsy in Senegal

Epidemiology

The mean national prevalence rate of epilepsy in Senegal was estimated to be 3.1% in 1970,[4,5] then 8.3% in 1986.[19] Different epidemiologic research has stressed the very different disparities from one region to another. In the suburban area near Dakar, Pikine, characterized by promiscuity and problems of hygiene and water supply, the prevalence was estimated at 12% in 1989.[23] A survey conducted in the same area during the demonstration project of the Global Campaign Against Epilepsy revealed a prevalence rate of 14%.[21] It has been remarked that when there is a good concentration of health

P.2911

personnel, the rate decreases. This is the case in Saint-Louis (1.9%), the former capital of Senegal, or in Niakhar (3.1%), a village where a hepatitis project is conducted with constant medical visits for the surveillance.[18]

No incidence studies have been conducted, but there is, as described elsewhere, a dramatic presence of epilepsy among children and the elderly.[13] When the results are analyzed regarding age, it is clear that childhood is the most affected group.[2] Epilepsy is the first cause of hospitalization among young patients (16.1% to 32%) in the different hospitals of Dakar.[1,18,22] Among them, 7.46% have been hospitalized for status epilepticus, which is a real problem of public health with a high risk for vital prognosis.[15] Surveys conducted in schools revealed that the mean prevalence rate is 21% in different schools in Dakar and Thies (the second city 75 km from Dakar). The rate is 2.6% in Saint-Louis among 6- to 15-year-old alumni.[2] The question is, Does this reflect a true reality due to the good ratio of health personnel to population? Or is it related to a possible withdrawal of epileptic children from school by their parents and/or teachers because of a frequent cultural allegation of "risk of contamination" to the rest of the classroom?[20]

Concerning the elderly, it has been also demonstrated that the incidence within this group is progressively becoming higher after 50 in Senegal as soon as the life expectancy progressively raises.[14] A prospective follow-up of a group of pregnant epileptic women with a prevalence rate of 1.05% revealed no difference in the occurrence of fetal development versus the nonepileptic group.[16]

The Etiologic Factors

The difficulty to investigate every epilepsy case contributes to enormous bias for the precision of etiologies. Many existing factors can lead to epileptic conditions. It is assumable that leading causes described worldwide and especially in developing countries may be considered in Senegal as well as in other African countries, including pregnancy problems (53% of pregnancies are nonmedically assisted, leading to a possible cause in 10% to 60% of epilepsy due to bad perinatal environment or ischemia from prolonged delivery), febrile convulsions, infections, and febrile diarrhea in children under 5 years old.[11] Bacterial meningitis, cerebral malaria, and other encephalitis were found in 7% to 19% in a hospital study conducted in Senegal. Furthermore, in Senegal, 43% of marriages are celebrated within the (large) family, entertaining the consanguinity and favoring expression of potential genetic epilepsy. A close intrafamilial relation between genitors is reported in 7% to 50% of surveyed people with epilepsy.[3] In the population ever so, vascular factors are reported in 68%, before infections, cerebral tumors, and metabolic factors including diabetes.[6,10]

Diagnosis and investigation of epilepsy in Senegal benefit from a limited number of specialists (the ratio is 1 for 700,000 people, versus 1 for 50,000 people as recommended by the WHO), as described above. In 2007, the available material is composed of six public and five private computed tomography (CT) scans and six public and four private electroencephalograms (EEGs) and two public and two private magnetic resonance imaging (MRI).

Sociocultural Representation

In many developing countries it is estimated that 80% of people with epilepsy are not treated with modern medications. The large majority of Senegalese patients living in rural areas are not consulting modern medical centers. Part of the reason could be geographic and/or economic related to the difficulty of access to health care structures. In a survey conducted in the suburban area of the capital city, Dakar, it has been demonstrated that 35% were taking antiepileptic drugs (AEDs) only, 41% associated them with traditional means, 11% took only traditional means, and 13% were not taking anything. The treatment gap (related to modern AED treatment) was consequently estimated to be 23.3%. But this is just the visible part of the iceberg.[21] The hidden and major part is related to the fact that epilepsy is considered a subnatural affliction and must be managed by traditional healers.[17] In the Senegalese culture, seizures are the manifestation of strong spirits involving the body and shaking it. The various definitions in local language reflect a basic knowledge of epileptic presentations. Some seizures could be considered as a positive but too powerful spirit.[12] In most instances traditional healing is the first treatment sought. In some countries, the traditional belief systems endorse discrimination against people with the condition, leading to their exclusion from mainstream society and restrictions on their accessing basic human and civil rights. However, the role of traditional healing should not be completely discredited as in many instances the person with epilepsy obtains a degree of secondary benefit from this form of intervention in the way of reassurance and emotional support. Efforts should be made to integrate traditional and Western interventions in a way that provides a range of services offering holistic support and care for the person with epilepsy and his or her family.[9] These would include advice, counseling, social support, school-to-work transitioning, job creation and training, rehabilitation, and community integration. The challenge is how to conciliate conflicting convictions that guide the traditional and scientific treatment concepts.[24]

Available Antiepileptic Drugs and Diagnostic Facilities in Senegal

The antiepileptic drugs available in Senegal and the cost of a month's worth of tablets in private pharmacies and in generic public forms are indicated in U.S. dollars (at the rate of December 2006) in Table 4.

P.2912

Table 4 Antiepileptic Drugs Available in Senegal

Drug	Strength	Public price[a]	Generic price[a]
Phenobarbitone	10 mg	1	0.4
Phenobarbitone	50 mg	1.02	0.4
Phenobarbitone	100 mg	1.24	0.6
Carbamazepine	200 mg	8.7	NA
Carbamazepine	SR 200 mg	14	NA
Carbamazepine	SR 400 mg	16.5	NA
Ethosuximide	NA	NA	NA
Phenytoin	100 mg	3.18	NA
Valproate	200 mg	9.3	NA
Valproate	500 mg	14.5	NA
Valproate	SR 500 mg	17	NA

Clonazepam	2 mg	9.5	NA
Diazepam	10 mg	7.9	NA
Diazepam	5 mg	6.7	1.24

NA, not available.

Primary health care centers can have all forms of phenobarbitone, phenytoin, and intravenous diazepam. In Dakar's pharmacies and in the capital of the nine other regions, one can find all the drugs cited above. A new generation of AEDs and brand new drugs and intravenous valproate and phenytoin are not available in Senegal.

The Role of the Senegalese League Against Epilepsy

The situation described above led to the creation in 1995 of the Senegalese League Against Epilepsy. Its originality is that this International League Against Epilepsy (ILAE)/International Bureau for Epilepsy (IBE) chapter gathers patients, families, and health and social workers and volunteers, with the purpose to improve the knowledge, awareness, and management of epilepsy.

The Senegalese League Against Epilepsy (SLAE) plays an important role in advising the Ministry of Health on issues regarding epilepsy and in providing education to physicians. The SLAE has created videos, leaflets, surveillance books for patients, training and guideline booklets for health personnel, and posters and T-shirts for public advertising. It organizes scientific meetings and courses in its various regional chapters.

Selected as a site of the Global Campaign Against Epilepsy (GCAE) Demonstration Project on Epilepsy, Senegal had conducted an epidemiologic survey about epilepsy quality care and KAP (Knowledge, Attitude, and Practice) evaluation among the general population and health personnel. These public health operational research projects led to concrete interventions deducted from the results. A weekly epilepsy consultation has been set up since then in the suburban area of the capital city of Dakar. Five regional branches have been installed with training and local care activities. The location of the unique neurology service in Dakar and the research results led to the concept of "Caravan for Epilepsy." It consists of a 3-day intervention: Day 1: Arrival of the neurosciences team, meeting with administrative and health leaders, and media talk show on epilepsy. Day 2: Full-day training course with general practitioners and paramedical staff, while some members of the team meet with schools, women associations, and social workers. Day 3: Full-day consultation of patients coming from villages and small cities surrounding the main regional city and informed about this mission by the day 1 radio talk show. If indicated, some patients can be investigated with a portable EEG. Intensive information and education programs are continually conducted via TV, radio, newspapers, and public conferences on epilepsy. A group of traditional healers of the region of Dakar has benefited also from a training program on epilepsy to develop a better collaboration between modern and traditional medicine, which is utilized by the very large majority of people with epilepsy in Senegal and Africa, whatever their instruction level, residence, and concomitant modern health management.

Summary and Conclusions

Describing Senegal realities reflects and summarizes the very common situation of epilepsy in developing countries of the sub-Saharan part of Africa. The management of public health has been dominated since the introduction of modern medicine in Africa via French colonization, many centuries ago. The leading infectious diseases masked the real incidence of nontransmissible disorders, including neurologic ones. Many factors cause a high rate of epilepsy in the country: The high incidence of infectious diseases, the poor quality of maternal–infant care in this low socioeconomic country, consanguineous marriages, and delayed diagnosis and management of tumoral and traumatic causes. Nowadays, more consideration is progressively given to nontransmissible diseases. Many cultural factors maintain epilepsy in the shadows and lead to a dramatic treatment gap. Improved and delocalized epilepsy health care, communication with the different segments of the population, basic education, and intensive training of doctors and paramedical staff, coordinated by a league against epilepsy, raise awareness and begin to give optimism to the improvement of epilepsy management quality and reduction of personal burden and condition of people living with epilepsy. The war will take a long time to win, but step by step, an encouraging and sustainable effort can lead to more success stories for epilepsy in African developing countries such as Senegal.

Chapter 298

United Kingdom

Stephen W. Brown

Frank M. C. Besag

Introduction

In 1911 a National Health Insurance Scheme was introduced in the United Kingdom that allowed low-paid workers (but not their families) access to primary health care. This was the first intervention by a British government in the area of general health care delivery. There was interest in taking matters further, and at the end of World War I an election pledge to establish a general health service was made by Lloyd George's coalition. A Consultative Council on Medical and Allied Services was set up, headed by the King's physician, Sir Bertrand Dawson (1864–1945, later Viscount Dawson of Penn), which produced an interim report in 1920. This discussion document suggested a framework for a comprehensive service emphasizing primary care and preventive medicine while defining the roles of secondary and tertiary services, in the event no action was taken and there was no further report. However, the philosophy and ideas of the Dawson Report were to influence the development of the National Health Service as World War II drew to a close more than 20 years later.

Development of the Present System

Shortly after the outbreak of World War II, the national government in Britain, which included representatives of all main political parties, asked Sir William Beveridge (1879–1963), an economist and master of University College Oxford, to chair an interdepartmental committee on the coordination of the Social Services. This was not expected to be completed until after the war, but the report entitled *Social Insurance and Allied Services* was published in 1942, some 18 months after the work started. It proposed a comprehensive social insurance scheme covering the whole population without income limit. The government response, with other pressing priorities, was initially low key, but the report sold 70,000 copies in 4 days and was popular with the public. An understanding then emerged that with the coming of peace a health care service for the nation would be established, free at the point of entry and financed by national taxation, based on a White Paper of 1944. This policy would be carried out by whichever party won the first postwar general election. In 1945, the Labour Party assumed power between the German and Japanese surrenders. Acts of Parliament in 1946 (covering England and Wales) and in 1947 (Scotland) were passed, and the National Health Service (NHS) was inaugurated on July 5, 1948.

The National Health Service Act (1946) defined ministerial responsibility for establishment in England and Wales of "a comprehensive health service designed to secure improvement in the physical and mental health of the people and the prevention, diagnosis and treatment of illness for that purpose.… Service so provided shall be free of charge.…" Responsibility for ushering in the new age fell on the Labour politician Aneurin Bevan (1897–1960), who was the Minister for Health and Housing. There was initial resistance from the medical profession, but Bevan proved an able negotiator, and in his own words overcame doctors' objections by "filling their mouths with gold." Bevan believed that access to free medical care would improve ordinary people's health to the extent that there would be economic benefits, and in particular that the cost of the new NHS would fall with time as the rate of disease was reduced. This thinking was fortunately not enshrined in statute as history proved him completely wrong. Meanwhile private practice was allowed alongside and within the NHS.

Between 1948 and 1974 the NHS consisted of three main branches: Public health services, which were the responsibility of local government; the hospital-based services; and the primary care service in which family practitioners (general practitioners [GPs]) worked. Difficulties in planning and coordinating services led to considerable consultation and debate between 1968 and 1972, and in 1974 a major reorganization created three administrative tiers—at Regional, Area, and District levels—that sought to overcome these problems. This unfortunately proved bureaucratically inefficient, and in 1982, following a Royal Commission report, the middle tier of Area Health Authorities was abolished.

Up to this point stages in the development of the service were a consequence of consultation and forward planning that took place under governments of both main political parties, and the broad policy was bipartisan. From the mid-1980s onward the Conservative government began to introduce changes that deviated from this consensus. In 1985 the NHS was placed under a management board chaired by its own chief executive, accountable to but with some autonomy from the government Department of Health and Social Security. In the late 1980s the NHS was subjected to a private review by the government, after which a major change in its mode of operating was devised. Against concerted opposition from all those relevant professional bodies who expressed an opinion, as well as from other political parties, an amending act was passed in 1991, and a new, reformed NHS appeared on April 1, 1992.

The main changes reflected the adoption of an internal market strategy. This meant that the old District Health Authorities were allocated a grant based on their individual population needs, to purchase health services from provider units such as hospitals. Provider units were given the opportunity to become self-governing trusts, in competition with each other, obtaining their income from purchasing authorities by selling services to them. Doctors working in primary care were allowed (and encouraged) to take responsibility for managing their own budgets for purchasing secondary services (known as GP Fundholders). This controversial purchaser/provider split appeared to lay the foundation for an increase in the establishment of managerial, accounting, and general administrative staff, with a power shift away from health professionals. Some rationalization was attempted by a drastic reduction in the number of Regional Health Authorities in 1994, together with partial devolving of planning to the periphery. At the time of writing, virtually all provider units have self-governing Trust status, while the commissioning of most services is a function

P.2916

of locality-based Primary Care Trusts. These came about after the Labour Party won the 1997 election with a policy pledge to abolish the internal market of the NHS and to remove the perceived unfair advantage of the fund-holding primary care sector over the non–fund-holding sector. The years since then have seen a series of rapid changes in structure, characterized by the increasing devolution of service commissioning to the primary care level, and a downscaling of the influence of the old Regional Offices, which were eventually abolished. This also happened against a background of devolution of government to Welsh, Scottish, and Northern Irish Assemblies, producing different NHS structures with subtle differences in four jurisdictions. Total spending on health by the government has substantially increased, but not surprisingly some of this has been required to finance the structural reforms and monitoring apparatus that have had to be introduced. In England and Wales recommended treatment guidelines for NHS use are drawn up by a quasi-autonomous government-funded organization, originally called the National Institute for Clinical Excellence, later expanded to the National Institute for Health and Clinical Excellence, but always known by its acronym, NICE. This describes itself as "the independent organization responsible for providing national guidance on the promotion of good health and the prevention and treatment of ill health." NICE also appraises health technologies, including drugs, to make recommendations for use within the NHS based on cost effectiveness, with the economic modeling emphasizing cost to the NHS rather than cost to society as a whole—an approach that has led to considerable criticism; it remains to be seen whether this narrow approach will survive. Nevertheless, NHS organizations in England and Wales are required to audit their practice against NICE guidance, and a degree of performance management is dependent on this. NICE produced comprehensive epilepsy management guidelines in October 2004.[13] In Scotland, some of the equivalent functions of NICE are performed by the Scottish Intercollegiate Guideline Network (SIGN), which produced updated epilepsy guidelines in June 2004.[16] There are some subtle differences in emphasis, which if followed closely could lead to different care pathways being followed by people with epilepsy in the United Kingdom depending on where they live, though whether this is important only time will tell. Both NICE and SIGN guidelines may be accessed through the Internet at www.nice.org.uk and www.sign.ac.uk, respectively. One consequence of current policy is the setting of various clinical and managerial targets (e.g., waiting times) that contribute to performance management of NHS organizations. An early attempt at this in England by a previous government was the publication in 1992 of *The Health of the Nation.*[7] Inclusions and exclusions in this document are somewhat arbitrary. Targets for reduction in HIV and suicide are included, despite the relatively small numbers in England of those affected by HIV and the fact that suicide statistics depend on quality control of coroner's courts. Epilepsy was not mentioned. Later, epilepsy came to move further up the governmental agenda. One of the key influences in this was the National Sentinel Clinical Audit of Epilepsy-related Death, published in 2002.[10] This came about after intensive lobbying of the government by the voluntary sector, and its influence on service development has been significant. The government was moved to produce an Action Plan for epilepsy service improvement, which, although criticized heavily by the voluntary sector and by epilepsy specialists, nevertheless raised the profile of epilepsy considerably.[3] Indeed, much direct representation to government about epilepsy services has been through charitable and voluntary groups, such as the British Epilepsy Association (now called Epilepsy Action), the National Society for Epilepsy, and the Joint Epilepsy Council of Great Britain and Ireland. In the United Kingdom these nonprofit organizations are called charities. In 1994 the government tacitly opposed a Disabled Rights Bill and met with much lobbying and criticism from groups advocating rights for the disabled and from consumer groups. Shortly afterward, the Charity Commission, the government-appointed body that regulates the activities of charities (some of which had been highly critical of the government's failure to support the bill), issued firm guidelines that seemed at first effectively to stop charities from future involvement in political lobbying, unless they were willing to risk losing their charitable status.[6] This advice was subsequently revised.[5] The government then brought forward separate legislation on disability rights, the Disability Discrimination Act, which came into law in 1997.

Budget Organization and Development

National Government

The NHS is financed by taxation. Responsibility for setting and allocating the NHS budget for the United Kingdom lies with the central government. In England this is the responsibility of a politician, the Secretary of State for Health, who heads a ministry, the Department of Health. In Scotland, Wales, and Northern Ireland health issues are the responsibility of different government departments, belonging to the devolved parliamentary assemblies in Scotland, Wales, and, when it is sitting, Northern Ireland.

For the purposes of health administration England was previously divided into a number of Regions, each with a population of approximately 5 million, with strategic overview provided by an NHS Executive Regional outpost, which has replaced the old Regional Health Authority. Each Region contained a number of Health Authorities (HAs), with populations of approximately 250,000 each. NHS Regional outposts were broadly responsible for strategic planning within their areas, but details of service provision were decided and carried out at District level. The process of peripheral devolvement has seen the abolition of Regional outposts and of the old Health Authorities, to be replaced in England by smaller Strategic Health Authorities (SHAs) and Primary Care Trusts (PCTs). At the time of writing there is speculation that many PCTs may be forced to merge for economic and strategic reasons, and SHAs may also combine to larger organizations, which might effectively bring back the old District/Regional boundaries, the process therefore turning full circle within a few years. Not surprisingly many who work in the service find it difficult to embrace these sorts of changes with the same enthusiasm as the politicians.

Board members of NHS organizations are currently appointed by the Secretary of State. There are proposals that may allow some local election to boards in the future, but this has yet to be implemented. Currently PCTs (and to a lesser extent SHAs) in England and their equivalent bodies in other jurisdictions are the authorities with responsibility for purchasing health services on behalf of the community, with funding from central government, the level being fixed by population size and type.

The purchasing authorities, as defined earlier, may contract with health providers such as hospitals, ambulance services, and so on, which are organized as self-governing trusts. There is also the option to purchase from the private sector, so that the public and private sectors become less demarcated.

Table 1 Proportion of Gross Domestic Product (%) Spent on Health

	1980	1987
United States	9.2	11.2
Sweden	9.5	9.0
Canada	7.4	8.6
France	7.6	8.6
Netherlands	8.2	8.5
Austria	7.9	8.4
Germany	7.9	8.2

State Provincial Government

Provincial (local) government below the level of the four jurisdictions (England, Scotland, Wales, Northern Ireland) has

P.2917

no direct role in the United Kingdom as far as health care is concerned. However, local government is responsible for the organization of social services and for the provision of children's education. Therefore long-term care, which can be construed as a social services responsibility, has to be considered in this way, and the special educational needs of children with epilepsy have to be assessed and provided for at this level. Because of this split, opportunities arise for budget holders to attempt to shift financial responsibility away from their own areas, although officially cooperation between different agencies is encouraged.

Insurance Company/Health Schemes by Budget

Since the NHS was founded there has always been a small but flourishing private sector. Only 11% of people have private health insurance.[15] The NHS has traditionally been regarded as superior in emergency care and, until recently, in provision for chronic illness. The private sector offers shorter waiting times for nonurgent surgical procedures, better access to some investigations (especially magnetic resonance imaging), and a more discrete, personalized service.

Finances

In 1987 the United Kingdom spent 6.1% of its gross domestic product (GDP) on health. At first this appears to compare unfavorably with some other industrialized countries (Table 1).

Until 1980 the NHS budget had been increasing by about 4% per year, after inflation. From 1980 to 1986 this rate of increase slowed to 1%, although it increased again after 1986. The slowing of growth in income between 1980 and 1986 was consistent with government policy to increase efficiency in the public sector and to limit public spending. This meant that in 1986 the gap between actual and expected budget was £3.53 billion, a shortfall of nearly 20%. However, increased spending after 1986 had largely closed this gap by 1992. The usual explanation for the discrepancy between GDP spent on health in the United Kingdom and other countries is that the nationalized health system spends less on administration, and so overall costs are kept low. This was especially apparent in the spending squeeze between 1980 and 1986, although evidence from other countries suggests that policy attempts to improve efficiency may have the opposite effect.[18]

Control of Expenditure by Different Segments

At the National Level

The total NHS budget is set after Treasury negotiation each year, and decided by the Cabinet. The Secretary of State for Health has the responsibility of making the case in Cabinet for appropriate funding in the context of total government budget, competing with other departments such as education or defense.

In the past, budgets for the main parts of hospital services were then devolved to Regional Health Authorities. Since the complex and changing reforms of the last 10 years, the trend has been toward establishing local health commissioning organizations such as PCTs, which are allocated funds according to a formula based on local population demographics.

People who have private health insurance are still most likely to use the NHS for primary care by choice. Where contact with hospital-based services is concerned, insurers may be reluctant to provide coverage for expensive or long-term treatment, so these are likely to be met from NHS resources too.

Organization of Physicians

Primary Care

Nurse Practitioners

Epilepsy specialist nurses started appearing as a distinct group in the United Kingdom in the early 1990s. The first appointments came mainly from the charitable sector (the David Lewis Centre, in Manchester, and the National Society for Epilepsy, in London), although NHS funding was involved in an innovative community-based scheme established in Doncaster in Yorkshire.[17] These nurse practitioners bring an added dimension of counseling skills to the clinical team and are able to provide more time to answer patients' questions than physicians. They also assist in liaison between primary and secondary care services, and can supervise previously prescribed changes of medication, thus freeing up the time of doctors. There is now a professional body that sets standards, the Epilepsy Specialist Nurses Association.[8] A major impetus to the development of the specialty has been provided by the British Epilepsy Association (BEA) in collaboration with industrial sponsorship to provide pump-priming finance for the establishment of a number of new posts around the United Kingdom starting in 1995. This project, launched in BEA's 45th anniversary year, is known as the Sapphire Nurses Programme, and represents a potentially major change in the mode of service delivery.

P.2918

It did not come about by project planning in the NHS, despite published evidence of efficacy of such a service[8] and despite the much-vaunted sensitivity of the NHS reforms to local needs. As in other areas of epilepsy provision in the United Kingdom, the main thrust has come from the voluntary, charitable sector. However, in 1995 the result of raised consumer expectations, pressure from the charitable sector, and interest from within the Department of Health (DOH) combined so that the DOH sponsored a number of pilot projects, mainly in the primary care arena, referred to as the Epilepsy Initiative. Matters altered considerably after the change of government in 1997, and current NICE guidance endorses the value of epilepsy specialist nursing. There are also opportunities for specialist nurses to become prescribers of medication within agreed treatment protocols, although this has yet to have a significant impact in epilepsy.

General Practitioners and Family Practice

In the United Kingdom it is unlikely that antiepileptic drug treatment would be initiated solely by a general practitioner. Where patients present with suspected epilepsy, the primary care physician will virtually always obtain an opinion from a specialist. The United Kingdom has relatively fewer neurologists per capita than other European or North American countries, and so the specialist opinion may be obtained from a general physician (internist) or general pediatrician. Recent data suggest that initiation of treatment for children is carried out by general pediatricians in about 55% of cases, whereas for adults, neurologists initiate treatment in about 66%.[14] The vast majority will be seen in the public (NHS) sector by physicians working in hospital practice. After initial investigation and treatment, most patients are referred back to their GPs for longer-term follow-up.

GPs are mainly organized into partnerships that may be based in health centers providing total primary care services for populations of 12,000 to 20,000 (with six to 10 GPs). A significant number work in smaller partnerships, and there are a few single-handed practitioners. GP partnerships typically employ primary care nurses and other allied professionals. At present in the United Kingdom there is no established model that is equivalent to the polyclinic or multispecialty clinic seen in some other countries, although some areas have commenced a pilot scheme for Primary Care Resource Centres that may fulfill some of these functions, and there is encouragement for the development of specialist GPs (GPSIs—GPs with a Special Interest) in various therapeutic areas and opportunities for this to develop in epilepsy.

GPs have the responsibility to provide all primary care medical services to the whole population registered with them, and so all GPs have a responsibility for epilepsy. Similarly, virtually all people with epilepsy are registered with GPs, although for many the involvement with treatment consists of little more than obtaining repeat prescriptions for antiepileptic drugs. About 20% of patients continue to see hospital physicians.

General Pediatricians and General Physicians (Internists)

General pediatricians and general physicians are hospital-based practitioners. Within the hospital setting there is an increasing trend to specialization, so that a district general hospital will have a group of general physicians that will include some with special interests in cardiology, endocrinology, gastroenterology, and so on. Where there is no staff neurologist, one of the general physicians may take this on as a special interest and will therefore have a broad responsibility for epilepsy. However, it is likely that all general physicians will see some patients with epilepsy, and all will take turns at receiving urgent admissions of patients with epilepsy from accident and emergency departments.

The percentage of the different specialists (other than neurologists) who see epilepsy patients regularly is shown in Table 2.[9]

Table 2 Medical Practitioners Who See Epilepsy Patients Regularly

	Percentage of specialists seeing specialty patients with epilepsy
General medicine (internists)	56
Psychiatrists	20
Pediatricians	80
Gerontologists	73

Neurologists

In the early 1990s the United Kingdom had about 300 trained career neurologists, approximately the same number as Denmark, a country with one-tenth the population. There has been a tendency until recently for neurologic practice to be most concentrated in teaching hospitals. However, the specialty is set for expansion. It is likely that neurologists in the NHS will be concentrated in neuroscience centers, each serving a population of 1.5 to 2.5 million, along with neurosurgeons and neurophysiology services. District hospitals serving much smaller catchments within the neuroscience center areas will obtain neurologic services from the center, on a hub-and-spoke principle. Private practice neurology exists and frequently shares facilities with the NHS service.

Referrals to neurology services will typically be made by GPs or hospital-based physicians. Self-referral is not the usual pattern in the NHS, and is unusual even in the private sector. The main barrier to access is the shortage of neurologists, with the waiting list for nonurgent outpatient appointments varying across the country from 2 to 92 weeks in 1993.[9] Reducing waiting list times such as this has been a high priority of the Labour Government, and it is alleged that the maximum time has been considerably reduced. Data for 2004 suggested that of 84,290 referrals for outpatient neurology consultations in England, only 384 (0.46%) had to wait more than 21 weeks to be seen.[12]

Epilepsy Centers

The term *epilepsy center* has two different meanings in the United Kingdom. It may refer to a residential facility owned and administered by a nonprofit organization specializing in epilepsy, or it may refer to a specialist unit within an NHS neuroscience center. The former typically have close links with the latter, so that there is some integration of service. For example, Chalfont Centre, a residential facility in rural Buckinghamshire run by the nonprofit National Society for Epilepsy, forms part of a service provided also by the National Hospital for Neurology and Neurosurgery in London.

The availability of epilepsy services in different parts of the United Kingdom is a reflection of both the enthusiasm of different local physicians and the local public profile of consumer groups and nonprofit organizations. Epilepsy surgery programs are currently well established at nine major NHS neuroscience centers in the United Kingdom, with several others in

development. There are at least four multidisciplinary residential assessment units for adults and two for children, all mainly within the independent nonprofit sector, and there are a larger number of NHS neuroscience centers with specialist hospital-based assessment facilities. The total number of specialist outpatient clinics known to the British Epilepsy Association had increased to 59.[2] The reasons for this increase and the reason why there continues to be a slow but sustained improvement in epilepsy services include:

- New antiepileptic drug licenses and increased activity by the pharmaceutical industry to sponsor continuing medical education, thereby raising awareness among professionals
- Increased consumer expectations and demands
- The BEA Sapphire Nursing scheme (see earlier)
- Continued lobbying from nonprofit organizations, in particular resulting in the National Sentinel Audit of Epilepsy-related Death, the government Action Plan, and the issuing of epilepsy guidance by NICE

As a recognition of and in response to the preceding, the NHS published an Executive Letter (EL 95/120) early in 1996[1] drawing the attention of purchasers and providers to the potential for developing epilepsy services, to the role of voluntary organizations, and to how epilepsy relates to the priorities for service development in the NHS. Needless to say, the voluntary organizations carefully monitored the response and carried out some research into its effectiveness.[4]

Summary and Conclusions

The British National Health Service was established in 1948 as a publicly funded service, free to the consumer at the point of access. Private medical practice continues to exist alongside the state sector, but a large majority of citizens use the NHS exclusively for the services that it provides.

Rising costs and the need to establish more effective management caused the government to introduce a number of structural changes, characterized in the 1980s by the establishment of the NHS Executive and in the 1990s by the introduction of an internal market with a purchaser/provider split. A new government was elected in May 1997, which has reversed some but not all these changes and introduced some new ones.

The priorities for the NHS include (among others) an increasing focus on primary care, the effective use of resources, and working with service users and caregivers.

Neurology as a medical specialty was traditionally more diagnostic than therapeutic, and much of the treatment of common neurologic conditions was carried out by general physicians. Epilepsy services therefore tended not to develop exclusively in neurology departments, and indeed have often been supported by the charitable (nonprofit or voluntary) sector. Consequently, epilepsy services remained fragmentary, variable in quality, and difficult for the consumer to find. A number of factors have contributed to an improved outlook, including a greater commitment to develop neuroscience services, greater consumer empowerment, and development of innovative service models, including enhanced primary care liaison and the use of specialist nursing. Nonprofit organizations representing views of service users and professionals, such as the Epilepsy Action (British Epilepsy Association) and the National Society for Epilepsy, have played an important part in establishing epilepsy on the health planning agenda, and these organizations will continue to fulfill this role.

Chapter 299

United States

Robert J. Gumnit

Introduction

The organization of health care in the United States has undergone major changes in recent years. In this chapter, the historical background is presented, after which the organization of health care as it exists in 2006 is outlined.

Historical Background

Health care in the United States was initially provided by generalist physicians. During the colonial era, they graduated largely from the medical schools of Great Britain. By the time of the Revolutionary War (1776), however, some physicians in the United States developed expertise in certain areas and were considered specialists. Medical schools were established in the United States along with the earliest universities and tended to follow the Scottish model. Under the Constitution, regulation of medical practice in the United States is relegated to the individual states. As a result, each state has its own licensing authority. During the 19th century, the quality of training and care varied widely, and fraudulent claims to medical training were frequently made. This was particularly a problem in rural areas of the western states.

By the time of the Civil War (1861), specialization in neurology had developed, and some of the earliest research in neurologic disease was done at that time. The specialties of neurology and psychiatry were closely intertwined from the earliest days of the medical system.

At the beginning of the 20th century, under the aegis of a charitable foundation, a study of medical education in the United States was carried out (the Flexner report), and a revolution occurred. A national accreditation authority for medical schools was established, and medical schools were reorganized more along the lines of the German system. Training in basic science was required of all students, and organized clinical training began. Still, up to the beginning of World War II (1939), the overwhelming majority of physicians were in primary care, and specialty care was available only in major cities and in association with university schools of medicine.

The end of World War II, the creation of the GI Bill of Rights, and the establishment of federal subsidies for medical insurance, research, and education produced a second revolution. Large numbers of physicians were trained, many more medical schools were established, and specialty training in the form of residencies became the norm. State licensing authorities no longer permitted physicians to practice after only a single year of postgraduate training (internship), and formal residencies and accreditation boards were created in all specialties, including family practice.

Large numbers of dollars flowed into the health care system as health insurance became a fringe benefit provided by nearly all large employers. Health insurance was readily available for purchase by individuals, and the federal government began subsidizing health care for the poor and elderly.

Levels of Care

Nonetheless, today, the United States, despite its enormous wealth, fails to provide for the basic health needs of a large part of its population. It has more levels of care than any other major industrialized country.

Level 1: Provisions for the Very Poor, Whether or Not They Are Homeless

The very poor have no money and no health insurance. Historically, they depended on charitable acts of individual physicians. As practices became more highly organized, and the poor became more concentrated in inner cities, finding access to charity care became increasingly more difficult. The federal government provided large amounts of money to hospitals for capital expansion and modernization under the Hill-Burton Act of 1946. A subsequent law required any hospital that received Hill-Burton funds to provide emergency care to all coming to its emergency department, whether or not they could pay. This was the final safety net, but provided only for the most obvious emergencies. However, the educational needs of physicians in training and the sense of local responsibility on the part of cities and counties has led to a system of county hospitals with outpatient facilities of varying completeness. Some of these are now being closed because of fiscal constraints.

Level 2: Medicaid

From 1966 to 1996, the federal government provided money to the states under Title XIX of the Social Security Act. This provided matching funds to the states to care for sick children, mothers of minor children, and the disabled. Strict federal guidelines were enforced. This broad mandate became eroded during the 1990s. The programs of the individual states now have more variability, and the ability of the poor to choose their own physicians is once again becoming compromised.

Level 3: Medicare

In 1965, the federal government initiated the Medicare program (Title XVIII) to provide health insurance for the elderly. Anyone over the age of 65 is eligible. This is a complicated act that provides for inpatient hospital care (Part A). Hospital care is primarily paid for by the federal government, with deductibles and copayments by patients. Voluntary premium payments by eligible patients, with some support from the federal government, provide funding for outpatient hospital care and physician care (Part B).

The payments from both Title XVIII and Title XIX are far below community standards and stress the physician segment more than the hospital segment of the health care system. In January 2006, Medical Part D was implemented, providing for

a benefit to assist in the purchase of pharmaceuticals. This law (and its regulations) is extraordinarily complicated, depends upon a multitude of competing private plans, and is partially needs based. Early implementation was poorly planned, and many patients were denied needed medicines. It is too soon to know how this program will eventually develop.

Level 4: Private Insurance

Individuals were able to buy hospitalization insurance beginning in the early 1930s. A few people were able to purchase physician insurance also. The wage freezes imposed at the time of World War II were circumvented by employers and unions that agreed to purchase health insurance for employees. The cost of insurance was not subject to the wage freeze. These payments started a major industry in the United States—private health insurance. For many years, private health insurance was of the indemnity type. Any service prescribed by a physician and provided by a licensed practitioner or facility was covered. To this extent, it was analogous to the collision insurance that one buys for an automobile. The great majority of the people in the United States are still covered by insurance that is purchased by an employer. However, insurance has become increasingly expensive because of increased demand, increased costs, the complexity of medical treatment, and the failure to obey market forces. A major effort to control costs by setting up large bureaucratic organizations to provide medical service took place in the 1990s. These schemes are called *health maintenance organizations* (*HMOs*), *preferred provider organizations* (*PPOs*), *independent practice organizations* (*IPOs*), or *physician-hospital organizations* (*PHOs*). Over time, the restrictive nature of the HMOs lost favor, and most employers provide some form of PPOs. This type of plan offers more choice of physician to the patient.

Level 5: Indemnity Insurance and Private Payments

Where it still exists, traditional indemnity insurance permits unlimited access to medical and hospital care. Increasingly, certain services are no longer available, because managed care organizations will not purchase them and there are too few indemnity patients to sustain them.

The policy of the Bush administration (2000–2008) is to shift cost and responsibility to the individual patient. Tax-exempt Medical Savings Accounts are now being promoted heavily. Higher deductibles and copayment requirements are becoming burdensome.

Thus, it is extremely difficult in the United States to understand how decisions are made with respect to health care expenditures. They are made by many different groups at many different levels, in many different locations. The United States has failed to initiate a nationwide health care system and relies instead on competition within the marketplace and multiple individual decisions. As the major sources of money become restricted (national, state, and employer), an increasing portion of the money spent on health care comes from individual persons.

Organization of Physicians for Primary Care

In the United States, primary care is largely provided by family practitioners, although increasing numbers of nurse practitioners and physician assistants are being used. The general practitioner who also performs surgery and obstetrics is a dying breed, and the average family practice physician refers most surgical cases to specialists.

Family practitioners are found throughout the United States. Only a few are left in solo practice; most practice together in single-specialty groups that in some areas comprise as many as 30 or 40 people. Others work in large family practice departments of multispecialty clinics. From the standpoint of epilepsy care, most patients with epilepsy receive care from primary care physicians (although in urban areas, many patients are also followed routinely by a neurologist).

In the United States, primary care is also often provided by pediatricians and internists. Internists who subspecialize are known as *cardiologists* or *rheumatologists*, for example. They tend to practice in small, single-specialty groups or in departments of multispecialty clinics. The average internist or pediatrician sees no more patients with epilepsy than the average family practitioner. The average primary care physician cares for between five and ten patients with epilepsy. Pediatricians and internists tend to be located in urban areas, including smaller cities with as few as 10,000 to 20,000 people.

There are roughly 750,000 licensed physicians in the United States and only 12,000 neurologists. Most neurologists practice in large urban areas or in association with medical schools. Very few are in solo practice; most are in single-specialty groups or in departments of multispecialty clinics.

In the United States, many people seek out neurologic care directly, although the majority is still referred by primary care physicians. With the development of managed care organizations of various sorts, new barriers have been created to specialty access for people with epilepsy. In addition to the problems of distribution and distance, barriers exist to accessing a neurologist (or any other specialist) without a referral from a primary care physician.

In the United States, primary care physicians frequently admit a patient to a hospital and call a neurologist in consultation. This is in contrast to what occurs in many other countries, where the patient is referred to a hospital group or a neurologist, who then takes on the primary responsibility for hospital care.

Excellent comprehensive epilepsy centers are available throughout the United States (see Chapter 302).

It is important to note that, in the United States, a license to practice medicine is generic. There is no legal restriction to physicians' describing themselves as specialists in any area. Control over quality is a function of hospital staff privileges. In this way, physicians in major hospitals cannot practice in an area for which they have not had appropriate residency training; specific privileges are granted, and these may often relate to something as narrow as whether or not a lumbar puncture can be performed.

However, what takes place in an individual physician's office is completely unregulated. This allows innovative, less expensive treatments to be provided by highly ethical physicians. It also allows opportunities for misrepresentation and less than ideal treatment by others.

Summary and Conclusions

The United States has at least five different levels of care, largely driven by economics and barriers erected against those with pre-existing physical conditions. The relatively unregulated practice of medicine and the fact that the license to practice medicine is generic leads to wide disparities in quality of care.

Chapter 300

Zambia

Gretchen L. Birbeck

Ellie Kalichi

Introduction

In 2000, epilepsy accounted for 0.5% of the global burden of disease,[22] and appreciation for epilepsy as a public health problem is growing as the full range of medical, psychological, social, and economic morbidities associated with the condition are being recognized and quantified.[20] Use of such measures as the disability-adjusted life year (DALY) to more fully capture the burden of nonfatal, chronic diseases has played an important role in placing epilepsy on the public health agenda in many regions. Of the approximately 50 million people with epilepsy, over 80% reside in developing countries, and less than 10% of these individuals are receiving treatment.[30] A very productive collaboration, The Global Campaign Against Epilepsy, has evolved between the World Health Organization (WHO), International Bureau for Epilepsy (IBE), and the International League Against Epilepsy (ILAE).[14] This consortium's work is aimed at reducing the treatment gap, decreasing the social and physical burden of epilepsy, educating health care personnel, dispelling stigma, and providing support for prevention of epilepsy. These efforts are laudable, but these international efforts rely on individual health care providers working in developing countries to seek and/or accept the role of advocate and push forward the agenda of improving the lives of people epilepsy within their own community, city, country, or region.

No “how to” manual is available to describe the process whereby one would begin to improve epilepsy care for a population. Epilepsy texts typically provide advice on individual case management and sometimes provide guidance on the resources and organization necessary to develop an Epilepsy Surgery Center. Undoubtedly, there are many ways in which a motivated neurologist could approach such a mission, and the most appropriate tactics will vary greatly depending on the physicians' expertise, available time, the burden of disease he faces, the resources and organization of the existing health care system, the local beliefs surrounding epilepsy, and more. Nevertheless, it may prove useful for physicians who have the opportunity and inclination to provide epilepsy care in less developed regions to learn about experiences elsewhere.

The Chikankata Epilepsy Care Team (ECT), located in a rural region of Zambia's Southern Province, has been providing care to a large population of people with epilepsy since 2000. The ECT came into existence after efforts to understand the burden of epilepsy in the region in 1994 eventually resulted in local support (both community- and hospital-based) for the development of such a team. The ECT has since played a significant role in country-wide programs aimed at decreasing epilepsy-associated stigma and narrowing the treatment gap. This chapter provides an overview of our perspective on how care providers “in the trenches” might undertake efforts locally to improve epilepsy care, and goes on to describe the potential to expand such work to a national level under the right circumstances. We will also discuss other “success stories” we've encountered or learned about in the literature.

Barriers to Epilepsy Care in Less Developed Regions

Epilepsy care provision in less developed regions is negatively influenced by several factors (Table 1).

Barriers to care for people in less developed settings are complex, multifactorial, and depend on economic, social, and cultural factors usually considered outside the realm of medicine. Yet, failure to recognize and address these barriers in the organization of health services delivery as well as in the approach to individual patient care will doom any attempts one makes to provide care to such vulnerable populations.

Consider the role that local health beliefs may play in determining whether a person with epilepsy is *ever* brought to your attention for care. Given the often violent and entirely unpredictable nature of seizures, these events are frequently interpreted as the result of supernatural or spiritual forces. As such, even people who would seek care at a health center for a fever or cough may take their seizure-related problems to a traditional or evangelical healer. Health care providers, who may have little formal education and no training in epilepsy, may hold similar beliefs regarding seizures that occur outside of acute infections. Only educational programs aimed at first-line health care providers and case-finding endeavors in the community will overcome these problems.

Table 1 Barriers to Epilepsy Care Delivery in Less Developed Regions[25]

Barrier	Example
Health beliefs[4]	People with epilepsy and their families perceive seizures as a supernatural or spiritual problem and therefore care is sought from traditional or evangelical healers. Health care workers may hold supernatural or spiritual beliefs regarding the etiology of seizures.
Lack of available services[10,31]	Health care providers and facilities may be either geographically or financially unavailable to many people with epilepsy.
Health care worker limitations[6,10]	May have no training in the diagnosis and treatment of epilepsy. May not be allowed to prescribe anticonvulsants. May not have recourse to refer patients for physician-level care. May have only a few minutes to spend with each patient.
Lack of physicians	Too few physicians, with most in the private sector
Lack of diagnostic resources	No recourse to neuroimaging, EEG, or basic laboratory services.
Lack of treatment resources	Few treatment options if first-line medications fail or aren't tolerated. Even first-line agents may not be available in some regions.
Stigma[2]	Fear of drawing further attention to the seizures may result in an unwillingness to seek care. Health care workers may avoid providing care to people with epilepsy, given fears of stigma by association, particularly in regions where contagion beliefs regarding epilepsy care common.
Lack of social support[2,3,7]	Devalued persons with epilepsy may not have sufficient social supports to seek care consistently.

Even if someone wishes to seek medical care for their seizure disorder, medical services may not be accessible. Health care centers offering even first-line anticonvulsants may be either prohibitively expensive or too geographically distant from the person's home to be a feasible source of care. Primary health care centers, usually staffed with nonphysician care providers, are often supplied with only the most basic medications, so that even if the health care provider is able to diagnose the condition and knows what treatment is needed, the treatment may not be available. These barriers are only exacerbated by the continuing brain drain. Physicians from regions such as Africa are leaving developing regions in droves as a consequence of the poor working and social conditions in the home country and the wealthy, aging West's need for a larger pool of health care providers. Finally, epilepsy-associated stigma further may decimate the social capital of the person suffering from epilepsy, making it even more difficult for them to garner the community support needed to seek care. For example, women with epilepsy in Zambia often lack the usual male protector, having been largely abandoned by their families. Therefore, these women are particularly vulnerable to sexual assault if they travel alone. So, although most Zambian women can safely seek medical care alone or accompanied only by their children, this is not true for women with epilepsy, who need an adult to travel with them. The barriers to care listed in Table 1 are certainly not exhaustive, and each setting undoubtedly offers unique barriers. These can only be appreciated if one develops a dialogue with experienced, empathetic health care providers,

P.2924

community leaders, and most of all people with epilepsy who are actively struggling with the barriers.

Data Gathering

Developing or expanding epilepsy care services requires careful planning and input from stakeholders in the health care system. As neurologists, we may simply assume this is a reasonable health care priority. However, this is not always a safe assumption. Recognize that any program must eventually be self-sustaining. And therefore, the program must have enough value to warrant eventual support within a system that is probably chronically underfunded and that encompasses many other competing health care needs. Eventually, any investment in epilepsy care entails a lost opportunity to invest in some other aspect of care. One must ask the key question: Is epilepsy a significant enough problem in this community, given the other health burdens present, to warrant long-term investment?

This is not a trivial question. But before taking the issue to key stakeholders, some objective data is required to assess the true burden of the disease in the population. The most obvious measure of the epilepsy burden in a population is the prevalence of epilepsy. Standard methods have been described that are ideal for epidemiologic purposes.[19] But the burden of epilepsy cannot be captured in a simple prevalence number. One must consider a far broader range of epilepsy-related morbidity and mortality to appreciate and express the full burden of disease (Table 2).

Formal studies to quantify the burden of disease may offer some academic currency and open doors to extramural funding opportunities. But even simple, hospital-based studies may offer data and insights into the burden of disease in a region sufficient to guide decision-making regarding resource allocation. For example, if your hospital has a busy burn center, consider a study to determine the proportion of burn victims who were burned during a seizure. If the number is substantial, then resources presently allocated to the burn center might be partially directed to epilepsy care, with the goal of burn preventions. Improving epilepsy care has been associated with a decrease in severe burns in some regions.

Table 2 Measures of Epilepsy Morbidity and Mortality

Aspect	Measure
Epidemiologic	Prevalence* Incidence Treatment gap
Health-related quality of life	KENQOL[27] SF-36[9] WHOQOL[23]

Functional status	DALY[11] Karnofsky score
Epilepsy-related physical morbidity	Burns Drowning Fractures
Social morbidity (largely mediated by stigma)	Loss of educational opportunities Loss of marital opportunities
Economic morbidity	Related to lack of education Incapacity to work due to social or physical disability

*Consider age-specific prevalence, given the impact of loss of work-related productivity in young adults.

Small, hospital-based studies can yield important information. In the Chikankata catchment area, anecdotal experiences suggested that a substantial burden of neurologic disease was going unrecognized even in the inpatient setting. By conducting a hospital-based, systematic period prevalence study (which had virtually no cost in addition to the time invested by a senior neurology resident), we were able to determine that 10% of hospital admissions were primarily related to a neurologic disorder, and that neurology patients consumed almost one-third of the intensive care unit bed-days.[5] These data allowed those of us interested in expanding neurologic services to capture the attention of hospital administration, which had previously considered neurologic diseases to be esoteric problems irrelevant

in a large rural bush hospital. Among all the conditions identified, epilepsy appeared to be one that was particularly under-recognized and undertreated. We were then able to leverage matching funds from the administration to conduct a door-to-door survey to determine the prevalence of epilepsy in the region. We found that, although our catchment area of 65,000 people had only 32 individuals with epilepsy registered at the hospital's chronic disease registry, more than 1,000 people with epilepsy eventually came forward for treatment.[8] This deluge of previously under-recognized disease treatable with medications generally available and by existing health care workers allowed us to establish local support for the development of an epilepsy care team.

Involving Key Stakeholders

If, after consideration of the full range of epilepsy-related morbidity and mortality in the region of interest, epilepsy appears to be a significant public health problem, further plans to develop or expand neurologic services should only be undertaken in consultation with relevant stakeholders. Only if individuals who are part of the health care system *and* potential recipients of services are part of the process of service development will those services be appropriate for the circumstances and environment. See Table 3 for considerations of who potential stakeholders might be; this is not a comprehensive list.

Table 3 Stakeholders to Consult when Developing Epilepsy Care Services

Entity	Example

Health care providers[16]	Physicians Clinical officers Nurses Community health workers Traditional birth attendants
Other healers[1,13]	Traditional healers Evangelical healers
Administrators	Hospital administrators Nursing directors Local representatives of the ministry of health Pharmacy directors Medical records personnel
Community leaders	Headmen Elected community representatives Elders Church leaders Respected businessmen or -women
People effected by epilepsy[21]	People with epilepsy Parents of children with epilepsy Family members of people with epilepsy
Other important social entities	Clerics Teachers Employers Police

The importance of persuading these stakeholders to guide the priorities of any evolving epilepsy care program cannot be overestimated. For any program to thrive in a sustainable fashion, many different groups must have a vested interest in the well-being of the program, and the program must be developed in a way that recognizes the most urgent problems at hand. A shared partnership with the community may entail delaying or even abandoning one's own academic interests (e.g., an EEG monitoring unit) for something recognized as more important from the community's perspective (e.g., a community-based care program). If an evolving program can offer what is most needed from the stakeholders' perspective, opportunities usually become available to pursue more academic interests, but these interests must be put in perspective. Even if outside funding is available to support the more academic and/or research-oriented questions, research programs that fail to take into consideration the needs of the community will eventually flounder and/or engender suspicion and animosity in the community under study.

Traditional healers are perhaps one of the most critical groups of stakeholders frequently ignored when health system planning is undertaken in developing countries.[1] Historically, the relationship between traditional healers and physicians has been one of animosity and criticism. However, traditional healers play an important social role, even if their treatments offer little therapeutic benefit (and that has not been formally studied in most instances). In developing regions, physicians and traditional healers witness each others' iatrogenic complications and failures on an almost daily basis. Given that most people with epilepsy in developing countries seek care from healers at least initially and often exclusively, we must work to develop more interactive and collaborative relationships with these care providers if we wish to reduce the treatment gap in areas with the greatest need.

As physicians, most of us have received little training and have even less experience in developing working relationships with such a diverse group of individuals. This is doubly compounded if the physician in question is an expatriate or non-native health care provider. Serious consideration should be given to soliciting assistance from more experienced individuals. Consider the value of involving a sociologist, anthropologist, or health services researcher as you engage key stakeholders. Good intentions for meaningful exchange can be entirely lost if the venue or circumstance for a meeting inadvertently offend or imply a lack of respect for those involved. There may be reasons to meet with some stakeholders separately. And the

P.2926

need to avoid proselytizing is critical. The goal is not to convince stakeholders of your perspective, but to gather theirs.

Care Plans

Once health care delivery priorities have been established in a region, one must consider how to deliver those services. This entails consideration of the actual plan for health care providers' interactions with patients as well as developing algorithms for individual care plans. In resource-limited settings, it is neither feasible nor desirable to anticipate that epilepsy care will be primarily provided by a neurologist. It may not even be possible to expect physician-level input into epilepsy care for the vast majority of patients. The skill and training level of the care provider who will diagnose and then provide chronic treatment to people with epilepsy must be determined by the existing capacity of the health care system. It is essential element to assure that health care providers who are likely to initially encounter people with epilepsy and/or people with epilepsy-related injuries are capable of recognizing the condition when they encounter it. Whether these individuals then go on to treat the condition or refer to someone with more expertise will depend on the geographic and fiscal feasibility of such a referral system. Initial programs for expanding epilepsy care may need to focus on expanding the diagnostic skills of health care providers on the front line and streamlining the referral process when they encounter someone with epilepsy.[12,18,24,26,28,30]

Once stable treatment regimens are established for patients, their care should be transferred back to the health care provider most financially and geographically accessible to them, if they are to be expected to maintain adherence to drug therapy over the long term. Clear, written communications to the health care provider who will assume care of the patient is critical. Epilepsy educational materials for physicians and clinical officers in developing regions are available at low-cost through several routes.[15,17]

Although algorithms for health care provision are not popular in much of the developed world, such clearly delineated and simplified care plans are often critical for health care provision in developing regions, where resources and health care expertise are limited. As much as possible, such epilepsy care algorithms should be evidence-based. When an evidence-base is lacking, expert opinion should be acquired. Ideally, an expert panel should be consulted if an epilepsy care algorithms is being developed that will be applied to a large population. E-mail and Internet access have improved substantially in the past few years, and establishing such an expert panel may now be possible with a minimum of fiscal resources. One must not neglect the importance of including local experts who function within the health care system of interest. Critical aspects of routine nursing and pharmacy practices may be inadvertently ignored if only outside opinions are sought. Key stakeholders (purchasers of medications for the public health care system, hospital administration) must also be included in this process.

Many developing regions may only be able to offer phenobarbitone to the majority of people with epilepsy. If second-line agents are not routinely available, some rational process should be put into place to determine criteria whereby people are placed on second-line agents. Inevitably, a two-tiered system will be in place in most health care systems in which people with resources can purchase drugs within the private sector. But within the public health system, medical criteria should determine the allocation of drugs with limited availability. Predetermined criteria for placing patients on a second- or third-line agent will assist health care providers in decision-making and assure some social equity. Unfortunately, within the private sector, inappropriate utilization of complex drug regimens may be unavoidable.[29]

Table 4 Potential Sources for Additional Revenues and Resources

Source	Approach
Clinical revenues	An allocated day or half-day for private-pay patients, with revenues directed to the upgrade of clinical service.
Churches or philanthropies in wealthier countries	Fundraising when you are abroad or encouraging visitors who become familiar with your operation to do the same on returning

	home
Local businesses	Approach local businesses for support.
Educational grants	Seek funding through educational grants: www.cos.com www.grantsnet.com www.WFNeurology.org
Research grants	Seek funding through research grants: www.cos.com www.grantsnet.com www.wellcome.ac.uk www.nih.gov
International collaborations	Contact researchers conducting studies of interest to you: www.ilae.epilepsy.org www.ibe-epilepsy.org

Acquiring Resources

Developing, enhancing, or expanding neurologic service in a less developed environment goes beyond simply working as a clinician in a one-on-one patient interaction. Services must include clinical care, infrastructural development of the health system, efforts at outreach, education for health care providers and the lay public, and research. Because the limited budgets of developing countries cannot even sustain the essentials for basic care, optimal expansion of neurologic services will require accessing resources beyond those available through public health funds, although partnership with the appropriate health authorities and appropriate allocations for neurologic disorders should be sought. Many options for accessing additional resources exist for those keen clinicians and/or administrator willing to explore these routes (Table 4).

Developing relationships with clinicians and organizations outside your own region or country can serve as a great source of intellectual stimulation and often results in productive collaborations that benefit both parties. Clinicians from developed regions with an interest in working in less developed regions often struggle to make appropriate contacts and identify opportunities to offer their services. The same is true of researchers. Fostering these relationships at every level will help to build bridges that can lead to future opportunities for expanding neurologic care.

P.2927

In terms of accessing resources for a growing epilepsy care program, consider clinical revenue streams. Where neurologic expertise is limited and concentrated in academic medical centers, private patients are often willing to pay substantial sums to avoid long waits and queues. Although such services shouldn't be offered to the extent that it is detrimental to publicly available services, setting aside some time for such private patients and applying the resulting revenues to care expansion is one option. Where civil servant salaries are quite low, academic specialists may already provide private services to augment their own salaries to a reasonable level. Consider then that visiting volunteer specialists who do not have work permits might be able to provide services in exchange for donations or other services. Or, possibly, such visitors may assist in the established private clinics, with the additional revenues being directed to expansion of epilepsy care services.

Visiting clinicians and interested individuals who become familiar with your program's goals may also serve as fundraisers and advocates. Developing a simple printed brochure that outlines your activities, goals, and fund-raiser campaign and that can be given out freely may help encapsulate your work in a marketable way. Such materials may even be provided to private patients and representatives of local businesses with philanthropic tendencies.

Funding opportunities for educational and research programs can serve as an important source of revenue for building infrastructure, hiring staff, and purchasing equipment. If one has Internet access, several search engines are quite helpful at identifying potential funding sources. Also, make certain to make inquiries to your local, regional and national medical programs. If you do not have experience writing proposals, this may be another opportunity for collaborations with international colleagues. For example, if you read an article describing research that interests you, consider contacting the investigators. Contact information, usually including an e-mail address, is provided in most journal articles. Never doubt that your expertise, experience, interests, and environment offer a great deal to potential collaborators.

Summary and Conclusions

The global burden of epilepsy is concentrated in resources poor regions with limited healthcare services. Substantial socioeconomic issues impact the quality of care and quality of life for people with epilepsy, particularly in developing regions. To improve epilepsy care delivery, it is imperative to understand the barriers to care delivery and care-seeking in the local environments and develop pragmatic approaches to overcoming these barriers. Accessing resources for optimizing care can be facilitated by acquiring data regarding the magnitude and consequences of epilepsy as well as the potential cost-effectiveness of treatment. Data dissemination and education of policy makers is paramount. Collaborative partnerships to develop local priorities for care and research require meaningful exchange between clinicians, researchers and key stakeholders. For successful and sustainable programs, community representatives must be included in such endeavors. Unique partnerships between clinicians and scientists in developed and less developed regions will be required to tackle the global problem of epilepsy in resource-poor regions where ~80% of people with epilepsy reside.

Chapter 301

Comparison of Different Systems and the Burden of Epilepsy

Matilde Leonardi

Chong Tin Tan

Introduction

The aim of this chapter is to compare information and data collected on epilepsy around the world and to find a means of comparing them so as to produce indications for further work.

Several authors in the preceding chapters have highlighted the national situation on epilepsy and epilepsy care. However, despite differences, it is important to define ways to overcome these discrepancies and to note the advancement of care and research that could enhance the care of people with epilepsy worldwide.

The past 10 years have been important for progress in epilepsy care, and many initiatives and much research have contributed to raise a lot of attention on the burden of epilepsy.

The Main Pillars for Change in the Field of Epilepsy

Although some traditional epidemiologic data reported in the chapters in this section do not show major changes in epilepsy course, several factors are contributing to change in the care and course of epilepsy worldwide. The main pillars for change could be identified in the following factors: (a) the Global Burden of Disease study and all the research done in the field of summary measures of the population's health; (b) the World Health Organization (WHO), International Bureau for Epilepsy (IBE), and International League Against Epilepsy (ILAE) Campaign on Epilepsy, with the publication of detailed information in the WHO Atlas on Epilepsy in 2005; (c) the publication of the International Classification of Functioning, Disability, and Health (ICF) classification in 2001 and the shift from diagnosis alone to functioning and disability approach to health; and (d) the increasing attention on innovative methodologies to collect information for policy decision making. All these factors will be analyzed here so as to provide a means for future work at the country as well at international level.

The Burden of Epilepsy and the Global Burden of Disease

The Global Burden of Disease (GBD) 2000 study was carried out by the World Bank in collaboration with the WHO and the Harvard School of Public Health. Three main goals were addressed: To provide information about nonfatal health outcomes, to develop unbiased epidemiologic assessment for major disorders, and to quantify the burden of diseases with a measure that could also be used for cost-effectiveness analysis. The GBS study provided the true magnitude of the long underestimated impact of neurologic disorders. With mortality indicators alone, mental and neurologic disorders have never been ranked in the top ten priority list of public health significance. Demographic changes and epidemiologic transition, as well as changes in family structure, are projecting the burden due to neurologic and psychiatric disorders to increase up to 15% of the global disease burden.[15]

There is a growing need to combine information on mortality and nonfatal health outcomes to represent the health of a population that reflects health expectancies and health gaps. Summary health measures can be used for comparing the health status of different populations and health of populations at different points of time, and for balancing priorities between fatal and nonfatal outcomes. These are measures that combine information on mortality and nonfatal health outcomes to represent the health of a particular population as a single number. The GBD study provided the DALY (Disability Adjusted Life Year), a measure that added disability to mortality in the evaluation of the burden of diseases. The allocation of limited resources for health care should be based on the relative importance (or burden) of different conditions to the health of the nation. Mortality as major public health indicator has had the effect of limiting the attention given to highly prevalent, seriously disabling but nonfatal disorders. Use of traditional measurement methods has led, in fact, to a serious underestimation of the relative importance of neurologic disorders worldwide, because they rarely cause death and because several of them produce severe and long-term disability but not death. The number of deaths does not take into consideration the nonfatal outcome of illness, and prevalence rates do not take into consideration the severity and duration of disability produced by a disease. There is also increasing attention being given to the shift from communicable diseases to chronic, noncommunicable diseases: The so-called "epidemiologic transition," which is also related to the increase of life expectancy.

Diagnosis alone does not predict service needs, length of hospitalization, level of care, or functional outcomes. The occurrence of a disorder is not an accurate predictor of receipt of disability benefits, work performance, return to work, or likelihood of social integration. This means that if we use a medical classification of diagnosis alone (e.g., the International Classification of Diseases [ICD]) or the ILAE classification, we will not have the information we need for health planning and management purposes. Neurologic disorders contribute substantially to the overall disease burden of developed and developing societies, but this is generally underestimated by the public health community.[27]

Epilepsy is one of the most common serious disorders of the brain, affecting about 50 million people worldwide. Epilepsy accounts for 1% of the global burden of disease; 80% of the

burden of epilepsy is in the developing world, where in some areas 80% to 90% of people with epilepsy receive no treatment at all.[30] It is clear that epilepsy is a major public health problem and that it is important to assess its burden as well its cost to persons and to societies so that health care priorities can be set in a rational way. To highlight differences, we analyzed common epidemiologic data as also reported in previous chapters and through literature assessment.

As stated in *Epilepsy: Out of the Shadows* background booklet, "The suffering and the disability caused by the disease are physical and psychosocial, is bringing a huge burden to people with epilepsy, their families and society at large."[9]

The burden of epilepsy is also strongly associated with significant psychological and social consequences for everyday living. This has been clearly highlighted in the previous chapters of this section. People with hidden disabilities such as epilepsy are among the most vulnerable in any society. While their vulnerability may be partly attributed to the disorder itself, the particular stigma associated with epilepsy brings a susceptibility of its own. Stigmatization leads to discrimination, and people with epilepsy experience prejudicial and discriminatory behavior in many spheres of life and across many cultures.[31]

People with epilepsy experience violations and restrictions of both their civil and human rights. Civil rights violations, such as unequal access to health and life insurance or prejudicial weighting of health insurance provisions; withholding of the right to obtain a driving licence; and limitations to the right to enter particular occupations, certain legal agreements, and in some parts of the world even marriage, are severely aggravated by epilepsy. Discrimination against people with epilepsy in the workplace and in respect of access is not uncommon for many. Violations of human rights are often more subtle and include social ostracism, being overlooked for promotion at work, and denial of the right to participate in many of the social activities taken for granted by others in the community. For example, ineligibility for a driving licence frequently imposes restrictions on social participation and choice of employment.[31]

The World Health Organization–International Bureau for Epilepsy–International League Against Epilepsy Global Campaign Against Epilepsy

The problems related to provision of care and treatment of people with epilepsy are too complex to be solved by individual organizations; therefore, the three leading international organizations working in the field of epilepsy (the WHO, IBE, and ILAE) joined forces to create the Global Campaign Against Epilepsy. The campaign aims to provide better information about epilepsy and its consequences and to assist governments and those concerned with epilepsy to reduce the burden of the disorders. More than 90 countries worldwide have been involved in the campaign.[31]

Regional conferences have been organized in all WHO regions to raise awareness on the public health impact of epilepsy, and a questionnaire was developed in order to make an inventory of country resources for epilepsy worldwide. Regional reports were developed and the main result of this effort was the publication in 2005 of the *Atlas of Epilepsy Care in the World*. The Global Campaign also had some demonstration projects that consisted of assisting countries in the development of their national epilepsy programs. Much of the information about data comparability on epilepsy has been collected in the *Atlas,* and this chapter summarizes some of the main results.[30] This initiative and its results could be considered another pillar to analyze information on epilepsy from different countries in a different way. The results of the WHO/IBE/ILAE Campaign allow a detailed evaluation of differences between developed and developing countries in several epilepsy indicators.

Comparison of Different Systems: Underlying Factors for Regional Differences and Salient Findings

Epidemiologic indicators needed to construct the diagram of each disease are several and can be listed as prevalence, incidence, mean age of onset, course, natural history, duration, severity breakdown, mortality, and impact of treatment. These indicators are the starting point for data comparison as well as for highlighting information gaps. Salient findings on incidence, prevalence, treatment gap, and socioeconomic data are reported in this chapter as they are crucial to highlighting country differences in the field of epilepsy. While data on incidence, prevalence, and treatment gap are available in several publications and are also reported in this section in detail, it is important to also report here some of the data that have been recently published in the WHO *Atlas*[30] that cover a broader spectrum of items and that are a useful indicator of epilepsy burden and care worldwide.

The Prevalence of Epilepsy

The number of people with epilepsy is high in most regions of the world, and 43,704,000 people with epilepsy are reported from 108 countries covering 85.4% of the world population. The mean number of people with epilepsy varies across regions: The prevalence per 1,000 population is 8.93 from 105 responding countries. It is 12.59 and 11.29 in the Americas and Africa, respectively, 9.97 in WHO South East Asia, 9.4 in the Eastern Mediterranean, 8.23 in Europe, and 3.66 in the Western Pacific.[30] The mean number of people with epilepsy per 1,000 population ranges from 7.99 in the high-income countries to 9.5 in the low-income countries.[6,7] The overall prevalence of epilepsy ranges from 2.7 to 41 per 1,000 population, though in the majority of reports the rate of active epilepsy is in the range 4 to 8 per 1,000.[8] The prevalence of active epilepsy is generally lower in industrialized countries than in developing countries, which may reflect a lower prevalence of selected risk factors. In industrialized countries, the prevalence of epilepsy is lower in infancy and tends to increase thereafter, with the highest rate occurring in elderly people.[8] Where available, age-specific prevalence rates of lifetime and active epilepsy from developing countries tend to be higher in the second (254 vs. 148 per 1,000) and third decades of life (94 vs. 145 per 1,000).[1] The differences between industrialized and developing countries may be mostly explained by the differing distribution of the risk factors and by the shorter life expectancy in the latter. Prevalence of epilepsy, as incidence, tends to be higher in men. Socioeconomic background has been found to affect the frequency of epilepsy reports in both industrialized and developing countries, in which prevalence rates have been shown to be greater in the rural compared with the urban context or in the lower compared with the higher socioeconomic classes.[17]

The Incidence of Epilepsy

The annual incidence of unprovoked seizure is 33 to 198 per 100,000, and the incidence of epilepsy is 23 to 190 per

P.2931

100,000.[10] The overall incidence of epilepsy in Europe and North America ranges from 24 and 53 per 100,000 per year, respectively. In studies from Africa and South America, the peak incidence of epilepsy occurs in young adults, and the dramatic increase in incidence in the elderly has not been identified. It's similar to the patterns of incidence, and therefore risks for epilepsy are different in these populations.

The incidence in children is eventually higher and even more variable, ranging from 25 to 840 per 100,000 per year, most of the differences being explained by the differing populations at risk and by the study design. In developing countries, the incidence of the disease is higher than that in industrialized countries and is up to 190 per 100,000 (the higher incidence of epilepsy may also be explained by the different structure of the populations at risk, which is characterized by a predominant distribution of young individuals and a short life expectancy).

In industrialized countries, epilepsy tends to affect mostly the individuals at the two extremes of the age spectrum. The peak in the elderly is not detected in developing countries, where the disease peaks in the 10- to 20-year-old age group.[1] The incidence of epilepsy and unprovoked seizure has been reported to be higher in men than in women in both industrialized and developing countries.[30]

The incidence of epilepsy is higher in the lower socioeconomic classes. This assumption is supported by the comparison between industrialized and developing countries and by the comparison, within the same population, of people of different ethnic origin.[21]

Several recent studies provide incidence from developing countries. An incidence of epilepsy that is considerably higher than that reported in industrialized countries (114 per 100,000 person-years) has been reported from rural area of Chile.[11] A study in Tanzania reported the incidence of epilepsy to be 77 per 100,000. These data are three times the incidence reported in industrialized countries in which similar definitions have been used.[18] In studies in France and Rochester, Minnesota, at least half of newly occurring afebrile seizures do not fulfil criteria for epilepsy. Nonetheless, the incidence of epilepsy may likely be higher in developing countries then in industrialized countries.[8]

Treatment of Epilepsy: Gaps and Services

Worldwide, the proportion of patients with epilepsy who at any given time remain untreated is large, and is greater than 80% in most low-income countries.[19]

The size of this treatment gap reflects either a failure to identify cases or a failure to deliver treatment. In most situations, however, both factors will apply. Inadequate case finding and treatment have various causes, some of which are specific to low-income countries. They include people's attitudes and beliefs, government health policies and priorities (or the lack of them), treatment costs and drug availability, and the attitude, knowledge, and practice of health workers.[31]

Although most epileptic syndromes cannot be prevented, epilepsy can be treated effectively in the majority of cases. The most common treatment is medication, but brain surgery and, very rarely, vagal nerve stimulation may be used as alternatives in some patients failing to achieve seizure control by medication.[4] Therapeutic drug monitoring is available in 45.1% in Africa, 54.6% in the Western Pacific, 55.6% in WHO South East Asia, 85.7% in the Eastern Mediterranean, 93.3% in Europe, and 95.8% in the Americas. Neuropsychological services are available in 37% of low-income countries. Such facilities are present in 88.6% of high-income countries.[30] In developing countries there is often also limited access to antiepileptic drugs (AEDs), particularly new AEDs; irregular supply of drugs; and poor access to investigations such as electroencephalographic (EEG), computed tomography (CT) brain scan, magnetic resonance imaging (MRI), therapeutic drug monitoring, long-term video-EEG monitoring, and single photon emission computed tomography (SPECT). The patients often have to pay for the medications and investigations out of pocket, which can be astronomical when compare with the family income.

There is also a relative lack of use of epilepsy surgery. In 25% to 30% of people with epilepsy the seizure cannot be controlled with drugs. Epilepsy surgery is a safe and effective alternative treatment in selected cases. Investment in epilepsy surgery centers, even in the poorest regions, could greatly reduce the economic and human burden of epilepsy. There is a marked treatment gap with respect to epilepsy surgery, however, even in industrialized countries. In a survey of epilepsy surgery in Asia, 80% of surgery was done in Japan and South Korea, although the two countries account for less than 10% of the Asian populations surveyed.[12]

Epilepsy surgery is not available in 88.6% in Africa, 68.2% in the Western Pacific, 66.7% in WHO South East Asia, 50% in the Americas and the Eastern Mediterranean, and 33.3% in Europe. Epilepsy surgery is not available in 87% of low-income countries. The facility for epilepsy surgery is also absent in 34.3% of high-income countries.[30]

Epilepsy Care and Health Professionals

It is difficult to quantify the number of medical professionals involved predominantly in epilepsy care. The figures reported in WHO's *Atlas* are based on best estimates by the respondents. Information about the distribution of the medical professionals in countries is not available, but the majority is likely to be concentrated in urban areas. The median number of neurologic nurses per 1,000,000 population in Europe involved in epilepsy care is 0.7 for low-income countries; it is 1.7 for higher middle-income and 1.1% for high-income countries. The median number of neurologic nurses per 1,000,000 population is 1.9 in Europe and 0.3 in WHO South East Asia.

No facility for training in epileptology exists in countries in WHO South East Asia, while such facilities exists in only 2.6% of the countries in Africa, 6.7% in the Eastern Mediterranean, 17.4% in the Western Pacific, 20.8% in the Americas, and 31.8% in Europe. Few studies report the number of health professionals devoted to epilepsy in many of the developing countries. As is the case in Nigeria, the primary care is manned by medical assistants who do not have the medications or skills in managing epilepsy. At the tertiary care level, there is scarcity of neurologists, even more so pediatric neurologists, and epileptologists. This is worse for regions outside the big cities and for public patients. For example, there are only 25 neurologists and 10 neurosurgeons in Nigeria, with 128 million people (see Chapter 295). All 15 neurologists practicing in the public health sector in Senegal, with 12 million people, are in the capital city of Dakar (see Chapter 297). In India, only 10% of the medical workers are employed by the government.[16] The lack of trained specialists and medical facilities needs to be seen in the context of severe deficiencies in health delivery that apply not only to epilepsy, but also to the whole range of medical conditions. Training medical and paramedical personnel and providing the necessary investigatory and treatment facilities will require tremendous effort and financial expenditures and will take time to achieve. A lack of involvement of paramedical professionals such as neuropsychologists, specialist nurses, occupational therapists, and educators in the care of epilepsy has also been noted in the epilepsy care of the East.[20] Nonscientific concepts of causes and treatment of epilepsy are common. For

example, in Nigeria, dualist natural and supernatural terms to explain illness are prevalent, with traditional herbal remedy strongly preferred over conventional antiepileptic drugs in the rural areas (see Chapter 296). A significant proportion of countries does not have professional or patient-based epilepsy societies. Even when these are present, they are often limited to large urban centers. For example, a nationwide epilepsy society for both professionals and patients was formed in China only in 2005. With limited resources, research is of low priority, with limited data related to epilepsy.

Socioeconomic Burden and Costs of Epilepsy

The lack of uniformity in the available studies on the cost of illness of epilepsy makes it difficult to compare cost figures from different studies. Some findings, however, can be summarized.

Many socioeconomic factors underlie the differences in care of epilepsy between the developed and developing countries. A low level of general education and high illiteracy is seen in some developing countries. For example, in India, the national literacy rate in 2001 was 65.5%, and 54.3% for females (see Chapter 294). The limited government resources generally are made worse by medical care being considered low priority by some governments. For example, Indian state budgets allocate only 2.3% of their money to health care.[16] The per capita expenditure on health, family welfare, water supply, and sanitation during 2002 to 2007 is about U.S. $2.53 per year (see Chapter 294). As such, in many developing countries, the government-subsidized health care is limited to hospital bed stay and medical consultation. Medications, surgery, and investigations are borne by the patients directly. Various disability benefits enjoyed by the developed countries are also not available. Difficulties of transport and communication in the remote area posing problems to access to modern health care facilities are also common. Nongovernmental organizations that play a crucial role in public health and awareness raising are rare in many parts of the world.

These differences are reflected in many aspects of health care structure and management of epilepsy in developing countries. It is thus not surprising that a large treatment gap for epilepsy has been reported in many developing countries, particularly the rural areas, with a large number of undiagnosed and untreated patients. For example, the treatment gap for China was 63%.[24]

Economic assessments of the national burden of epilepsy have been conducted in a number of high-income countries[2] and in India, all of which have clearly shown the significant economic implications the disorder has in terms of health care service needs, premature mortality, and lost work productivity. The Indian study calculated that the total cost per case of these disease consequences for epilepsy amounted to U.S. $344 per year (equivalent to 88% of average income per capita) and the total cost for the estimated 5 million cases in India was equivalent to 0.5% of the gross national product.[23]

As part of a wider WHO cost-effectiveness work program,[22] information has been generated concerning the amount of burden averted by the current or scaled-up use of treatment with AEDs, together with estimates of cost and cost effectiveness. Effectiveness was expressed in terms of DALYs averted and costs were expressed in international dollars. Compared with a “do-nothing” scenario (i.e., the untreated natural history of epilepsy), results from nine developing epidemiologic subregions suggest that extending AED treatment coverage to 50% of primary epilepsy cases would avert 150 to 650 DALYs per million population (equivalent to 13% to 40% of the current burden), at an annual cost per case of international $55 to $192. Older first-line AEDs (phenobarbitone, phenytoin) were most cost effective on account of their similar efficacy but lower acquisition cost (International $800 to $2,000 for each DALY averted). In all nine developing regions, the cost of securing one extra healthy year of life was less than average per capita income. Extending coverage further to 80% or even 95% of the target population would evidently avert more of burden still, and would remain an efficient strategy despite the large-scale investment in manpower, training, and drug supply/distribution that would be required to implement such a program.[31]

In Europe, a separate budget for epilepsy care and services is present in only 6.4% of the responding countries. Private insurance and private foundations constitute only 1.9% and 1%, respectively, of the primary method of financing. While social insurance is the primary method of financing in 55.6% and 56% of higher middle-income and high-income countries, respectively, none of the low-income countries employs it as the primary method of financing. A study by Ekman and Forsgren on the cost of epilepsy in Europe allowed one to see regional differences and provided an estimate of the economic burden of epilepsy.[4]

Functioning and Disability in Epilepsy and the International Classification of Functioning, Disability, and Health Classification

As shown, the knowledge about prevalence, incidence, socio-economic burden, and prognosis of epilepsy is still limited because of the methodologic weakness of many studies. Data on epilepsy, as well as on several other neuropsychiatric disorders, are still scarce in many parts of the world and inconsistent because of the sampling frames and how samples are defined.

Uncertainty about the prevalence distribution as well as about the variation of severity of epilepsy reflects the limitation of instruments for classifying it in a comparable manner across populations and the limitations in the information available to classify, beyond the diagnostic classification, the severity and, mostly, the disability of the disorder.[15]

Up-to-date international comparable data about functioning and disability are simply not available. The primary reason for this is that different countries, for different purposes, define disability differently. As a recent European Commission study on definition of disability in Europe has shown, data on disability are not consistently gathered because some countries define disability in terms of performance levels in employment or other social activities. In the employment sector specifically, for example, coordinated policy across Europe has been undermined by the inability to collect comparable data about rates of disability and employment.[5] As a rule, disability population surveys focus on a limited number of functional domains (e.g., activities of daily living [ADLs]) and ask questions about a limited number of impairments, making it difficult to identify new and emerging populations of persons with disabilities, such as, for example, those associated with HIV, depression, and substance use disorders. Furthermore, often a priori and arbitrary thresholds for identifying impairments are provided, without any evidence of prevalence levels. Finally, disability surveys ask questions that are not easily or directly linked to data from population health surveys, so there is no obvious way of linking health conditions, such as diseases or injuries, to impairments, nor to identify the role of environmental factors in limiting, or expanding, levels of participation across the range of normal activities. It is clear that at the moment, it is almost impossible

to evaluate the impact of either demographic changes (such as aging) or social change (such as new legislation, policy change, or changes in lifestyles) on disability.[13]

Though there are international disability data gathering efforts by OECD and UNSTAT, these efforts merely reproduce the same wide disparity in the prevalence rates of disability across countries and regions, created by a lack of a common framework and methodology for defining disability.

The WHO has for several years been aware of this widespread problem of data comparability both in health and disability statistics. Following its mandate for producing standards for international data comparability in the health area, the WHO began as early as 1974 to supplement its ICD International Statistical Classification of Diseases and Related Health Problems[26] with a companion classification of functioning and disability, the International Classification of Impairments, Disability, and Handicap (ICIDH).[25] This classification underwent a revision process that lasted several years. After extensive international field testing, the final version of the International Classification of Functioning, Disability, and Health was endorsed by the World Health Assembly in May 2001. The World Health Organization's ICF has been accepted by 191 countries as the international standard to describe and measure health and disability.[29] The ICF is the product of decades of research, refinement, and testing in an international collaborative setting. Both as a model for structuring health and disability information and as a classification and coding tool for collecting this information, ICF fills the gap in our understanding of disability and its dimensions, causes, and prevalence.

The International Statistical Classification of Diseases and Related Health Problems (ICD-10) and the ICF are the two classifications that currently make up the WHO Family of International Classifications (WHO-FIC).

In the evaluation of differences between countries in the field of epilepsy, the presence of the ICF could be considered as a crucial pillar for a change in perspective. The methodology that ICF proposes to overcome data gaps in epilepsy is a shift from diagnosis alone to functioning and disability.

Disability is a multidimensional phenomenon arising out of an interaction between the individual's health status and the physical and social environment. Disability data, and the instruments to measure them, must reflect this biopsychosocial model of disability. Valid and reliable information are essential to design, implement, or evaluate policies and legislation to combat discrimination and promote social integration and participation and to enhance opportunities.

Data currently being collected, nationally and internationally, embody conceptual confusions, inconsistencies, and ambiguities about disability and the relationship between health conditions, impairments, and environmental factors. What we lack is the knowledge about the level of functioning and disability. The ICF provides the framework for documenting the interaction between health status and environmental features, and the differential distribution of disability among different groups in different contexts.

There is no better conceptual model for the measurement of the types and prevalence of impairments that offers a holistic conception of disability suitable for data collection, clinical measurement, and social policy. Using the ICF framework, the WHO estimates that as much as 500 million healthy life years are lost each year due to disability associated with health conditions. This is more than half the years that are lost annually due to premature death. The ICF provides a common measure about this immense problem and makes possible to collect those vital data in a consistent and internationally comparable manner.

ICF defines disability as "difficulty in functioning at the body, person or societal levels, in one or more life domains, as experienced by an individual with a health condition in interaction with contextual factors." The ICF definition is inclusive of all aspects of disability, captures the interactive dynamic of disability, and acknowledges the equally important contribution of health conditions and environmental factors to disability. In fact, the ICF provides the framework for documenting the interaction between health status and environmental features, and therefore the differential distribution of disability among different groups in different contexts.[13]

This definition includes all aspects of disability, highlights the interactive dynamic nature of disability, and acknowledges the equally important roles of the person's state of health and environmental factors in the production and mediation of the disability experience.

The model described in the ICF will assist in the prediction and understanding of changes in the prevalence and differential distribution of impairments; assess the impact of social, political, demographic, cultural, and environmental factors in the production of disability; and support policy developments for achieving an improved quality of life and equal opportunities for people with disabilities.

Since its endorsement by the World Health Assembly in 2001, the ICF has been applied in a variety of settings at the national and international level and has been translated into 40 languages. ICF-based health and disability surveys have been conducted in many countries worldwide. From these data, population norms can be generated for estimating disability prevalence. At a national level, ICF0-based data sets and questionnaires for census and surveys are being used by numerous countries including Spain, Australia, Canada, Chile, China, Indonesia, Namibia, Nicaragua, and South Africa. Several countries have started the process of streamlining their health and social information standards and legislation within the ICF framework. Development and piloting of ICF-based indicators and reporting systems for use in rehabilitation, home care, age care, and disability evaluation are ongoing in Germany, Italy, Sweden, the Netherlands, the United Kingdom, Australia, Canada, Colombia, India, Mexico, and the United States.

The ICF sets out an internationally comparable language of all dimensions of human functioning at the *body, person, and societal levels*. Difficulties of functioning at the body level, or impairments, can therefore be conceptually and operationally distinguished from difficulties of functioning at the person or societal levels (activity limitations and participation restrictions). The ICF's model of disability is interactive—combining the best of the so-called medical and social models into a fully integrated model. The ICF also contains a classification of environmental factors, that is, the physical, social, and attitudinal factors that, as barriers, contribute to the creation of impairments, activity limitations, and participation restrictions, or as facilitators increase or extend levels of functioning at the body, person, or societal levels. The classification of environmental factors makes it possible, for the first time, to identify, assess, and measure the impact of a person's environment on his or her levels of disability. The underlying theory of the ICF is based on two important principles that directly affect measurement strategies:

1. The principle that disability is a common, indeed universal feature of the human condition, not the mark of a social minority group (universalism)
2. Functioning and disability, both at the population and individual levels, are *continuous* phenomena, matters of "more or less" rather than strict dichotomous categories

Taken together, these principles entail that the measurement of disability must arise from a determination of the range of functioning across all domains, rather than a priori from either self-identification or by allocation into categories merely by the presence of certain bodily impairments such as blindness, deafness, mental retardation, or paralysis.

In the ICF Environmental Factors classification, all discriminatory behaviors and attitudes are included, making it possible for the first time to include questions in surveys and other information-gathering instruments on environmental barriers and facilitators using a common framework that will then make data comparisons more feasible and practical. This might be very relevant for epilepsy because, as previously reported, stigma is still a major issue both in developed and developing countries.

These data can then be compared across countries, populations, and age groups. In addition, the effects of these behaviors and attitudes on individuals' levels of participation can be measured and interventions designed.

Policy Makers and Epilepsy

As stated in the previous edition of this book, although the political, economic, and social changes that are occurring globally take many different forms, and although rapid changes in health care delivery are under way in many countries, there is clearly a convergence of ideas toward the fact that health care is part of the glue that holds each society and the international community together, a social good that should be available to all people on the basis of needs.[14] There is a strong interest among policy makers in monitoring the impact of health care measures, reforms, and other interventions by using common cost-effective measures.

The information that health and disability policy makers require—for developing summary measures and other analytic tools for measuring health, which in turn assist in the tasks of proposing and implementing policies and monitoring the performance of policies for subsequent revision—cover at least the following range of data points: Basic prevalence data about diseases and injuries; data about impairments and capacity levels associated with health conditions; data about actual performance levels; data about the presence of environmental barriers and facilitators (as defined and classified in the ICF), and the extent to which these affect observed performance levels.

All these diverse data could not possibly be collected in a single survey or questionnaire, or at least one that could feasibly be put into the field. More plausibly, one can imagine a range of surveys—both on health issues but also on broader social issues such as health determinants, employment, and other social factors—that are coordinated by a common conception of health and disability, and that altogether could collect a substantial portion of these data. Of course, for most countries of the world, even this approach is far beyond available resources. This is leading, then, to the question that is the object of this chapter: What is the state of the art of collecting basic information about epilepsy, the prevalence of its impairments, and their relationship to health outcomes (however construed) on the one hand, and the burden and quality-of-life assessments on the other hand? The interest here has been not merely in listing only what has been done to date, but, more generally, in highlighting the underlying concepts used and the unresolved issues that researchers have faced, either successfully or not, and are facing.

Differences between developed and developing countries are still large; however, there is an increasing recognition that reducing the incidence and severity of disability due to a disease in the population involves modifying the social and physical environment as well as enhancing the level of functioning of the person.

Designed to meet these growing needs, the ICF has potential uses in many sectors, and it is expected that in the future functioning data might allow a better comparison between countries on the burden of the disease and might serve the needs of policy making to improve the quality of life of people with epilepsy worldwide.[15]

Summary and Conclusions

This chapter summarized some of the salient findings developed in recent years that allow one to move toward new features in data comparison on epilepsy. Disability data, recently published in the Global Burden of Disease study, allow broader comparability in epilepsy, due to the characteristics of the disease. Traditional epidemiologic information has been supported by a full range of data that are useful for policy development.

The WHO/IBE/ILAE Global Campaign focused on the importance of awareness for filling the gap between developed and developing countries and provided the international community with the *Atlas on Epilepsy* that is showing the path for further work and research.

Finally, after the publication in 2001 of the ICF, it became clear that information about the levels of functioning across all areas of life is essential data for policy purposes. Medical diagnostic data alone do not predict health service needs, length of hospitalization, or level of care required, and the presence of a disease is not an accurate predictor of receipt of disability benefits, work performance, return to work potential, or likelihood of social integration or any other important goal for disability policy that is based on human rights. What is missing are data about the full, lived experience of health, which includes functioning and disability.

Intervention costing, in terms of outlines defined by levels of functioning, will in turn open the door to protocols for comparing the cost-effectiveness of interventions aimed at the individuals (medication, rehabilitation, training) as opposed to those aimed at the environment (e.g., normative, architectural, accessibility, fighting stigma).

One of the most difficult, yet most important, decisions in all areas of disability policy is whether resources are better spent in increasing the functioning levels of the person or in making the environment more accessible and accommodating. In a sense, all of disability policy depends on this incredibly difficult decision. Without reliable and relevant data, however, these decisions are not based on evidence. The overall human rights goals of equality and full participation are not served, and never will be served, without this information. In this sense, the ICF is the most important of all human rights instruments for persons with disabilities.

The ICF in the field of epilepsy can therefore be used to capture and structure holistic and multidimensional data about human functioning for a wide variety of uses, including population surveys, administrative data collection, and clinical assessment. Properly used, it can help us to understand the relationship between impairments and environmental factors that together determine levels of participation in education, employment, and all areas of social involvement.

Only when disability data are collected at the population level in terms of the ICF model of disability will this evidence be available. It is only then that data collected will be relevant to the relationship between environmental, political, social, and cultural factors and the occurrence of impairments. This is a clear indication for future new research in the field of epilepsy.

Chapter 302

Comprehensive Epilepsy Programs—United States

Robert J. Gumnit

Introduction

The difference between a specialty epilepsy clinic and a comprehensive epilepsy program (CEP) is highlighted in this section. CEPs are different from epilepsy centers. Epilepsy centers can be places for the long-term residential treatment of people with seizures, or they can be places where a patient goes for specialized treatment. Specialized centers for the long-term care of people with epilepsy have essentially disappeared from the United States. When patients with epilepsy require long-term care, it is usually because of associated conditions: Severe brain damage, severe psychiatric problems, or mental retardation. Patients with epilepsy who have these conditions are usually cared for in residential centers or small residential programs whose treatment is directed at the primary problem causing the disability.

In the best sense of the term, a CEP is one in which a multispecialty team (physicians, psychologists, nurses, social workers, and specialized technical help) is brought together to provide an organized approach to the management of people with complex problems related to epilepsy.[1]

There is no organization in the United States that accredits a specialized epilepsy center or a CEP (although efforts are underway to establish one). Any physician with any training can print up stationery that says "Comprehensive Epilepsy Program," mount a sign on the door, and go into business. There are documented cases of physicians without specialized training doing just that. CEPs in the United States vary greatly in quality and organization.

Historical Development

CEPs were originally developed under the aegis of the United States Public Health Service as part of the so-called 314(e) program in the early 1960s. One of the first was established in 1964, at the St. Paul Ramsey Hospital in St. Paul, Minnesota, and evolved into what is now called *MINCEP Epilepsy Care*. In that sense, the MINCEP program is the oldest in the United States. Nonetheless, major university centers devoted to specialized treatment (but without the full, comprehensive approach of medical, surgical, educational, psychologic, social, and community organization) have been in existence for many years.

The National Association of Epilepsy Centers (NAEC) was established in 1986 to help with the development of CEPs. A recent survey indicates that more than 130 places in the United States refer to themselves as *epilepsy centers*. Some of these consist of no more than a single neurologist with a particular interest in epilepsy. Others are CEPs in the fullest sense. The NAEC has published guidelines for classifying epilepsy centers and for the services to be rendered. Member centers (there were 116 in 2007) self-designate and affirm that they meet these guidelines. For more information, consult www.naec-epilepsy.org.

Mechanisms of Referral

In accordance with the free-market economy underlying health care in the United States, patients historically have been able to reach a CEP by a variety of routes. Some are referred by a neurologist, others by primary care physicians. Some learn about a center from social agencies, and others from friends and neighbors.

With the development of managed care organizations, many patients may no longer have free access to a CEP. They may be restricted to one with which the organization has a contract, or the organization may resist any referral at all. Furthermore, the amount paid for care is set by the individual health plan or insurance company. In some cases (certain state medical assistance programs, for example), the amount is so small that the specialized center cannot afford to provide the necessary treatment.

Location of Centers

Some major urban centers in the United States do not have a comprehensive program. Others have two or more. (Los Angeles has nine groups claiming to be CEPs!) In general, it takes a population base of at least 2 to 3 million to support a CEP. In the case of uncommon conditions (e.g., extratemporal lesions requiring subdural arrays, Landau-Kleffner syndrome), a much larger population is necessary if a center is to develop a reasonable experience.

Nearly all comprehensive programs are associated directly or indirectly with major medical centers, and usually medical schools as well. Because of the unique structure of the U.S. health care system, it is possible for a major medical center to exist in a small, rural community and draw patients from many miles around.

Leadership and Staffing

The leadership and staffing of CEPs vary enormously. The major centers are headed by epileptologists with national reputations, have several physicians who specialize in epilepsy on staff, and provide a full range of support services (psychiatry, psychology, neuropsychology, social work, video-electroencephalographic monitoring). Centers in a developmental phase or those that merely aspire to the name may have far fewer resources.

A lack of uniformity exists among centers in regard to programs, size, and funding. Some centers serve only a few

P.2938

patients, whereas others perform several hundred evaluations a year.

Funding

Centers in general are funded on a fee-for-service basis. Some centers offer medical services as a loss leader so as to generate a high volume of surgical cases. Others try not to get involved in the long-term medical management of patients and seek only to evaluate and operate on patients who need simple types of surgery. This latter approach can be criticized as “skimming the cream.” For a CEP to survive on a long-term basis, it must earn a sufficient profit by caring for a high volume of routine cases in order to subsidize the care of patients with the most complicated problems.

When the center is part of a large organization, bureaucratic imperatives drive the funding (the regular operating budget as well as capital investment). When the center is free-standing in private practice, ensuring the growth of the center and meeting the needs of patients take priority.

Barriers to Access

In the United States, various barriers to access to care exist. Many people who are poor or totally disabled do not have adequate access to health care. Financial barriers are a major issue. Indeed, this is compounded by the tendency of many physicians to treat some patients unsuccessfully until they are so disabled that they lose their jobs and health insurance, then they turn such patients over to public charity.

A second barrier is ignorance. Many patients are unaware of the existence of comprehensive programs despite the best effort of lay organizations and the centers themselves to educate the public. Many primary care physicians are ignorant of their existence as well, and do not know how or when to refer a patient.

Reluctance to refer can also be a major problem. Pride and refusal to admit that someone else may be able to do something that they cannot do exists among physicians everywhere in the world. In a fee-for-service environment that is under stress because of a reduced number of patients with indemnity insurance, the financial implications of making a referral come into play as well. If the patient is covered by a managed care organization, even if the physician wants to refer, the organization may be unwilling to spend the money.

Many patients are reluctant to travel for care. Some people will journey to the ends of the earth to see a physician with marginally better credentials. Other patients are unwilling to travel across town to consult a physician at a highly specialized center. For patients with epilepsy, travel may be difficult and presents a particular problem.

Perhaps the biggest barrier is the sense of hopelessness that develops in many patients who have had uncontrolled seizures for years. After a while, they simply lose their ability to cope and cease to seek better care.

Competing voices in the marketplace also may serve as a barrier to reaching a CEP. Religious healers and practitioners of alternative medical philosophies (homeopathy, naturopathy, food fads) all create a clamor.

Nonetheless, many fine CEPs exist throughout the United States, and most can find some way to help a patient obtain the care needed if only the patient will apply for help.

Summary and Conclusions

The quality of epilepsy care in the United States varies broadly, and CEPs vary widely in quality and distribution. Frequently, socioeconomic factors are a major impediment to patients seeking appropriate help.

Chapter 303

Comprehensive Epilepsy Programs—Norway*

Svein I. Johannessen

Karl O. Nakken

Introduction

In Norway, with a population of about 4.5 million people, only one specialized center for epilepsy exists. It is designated as a national center of competence in epileptology and comprehensive epilepsy service. Being an institution with nationwide responsibilities, its role in the National Health Service system and its program for activities are defined by the Department of Health and endorsed by the Norwegian Parliament.*

National CentER for Epilepsy—historical background

At the end of the 19th century, in Kristiania (now Oslo), the deacons established a home for people with epilepsy. In 1910, they bought a farm in Sandvika, 15 kilometers outside Oslo, where they established a nursing home for the residential care of 64 patients with chronic epilepsy. Dr. Monrad Krohn, professor of neurology at the National Hospital (Rikshospitalet) in Oslo was the first medical supervisor. The deacons were inspired by the epilepsy colonies, which at that time had been established in some European countries, including Denmark and Germany.

In 1924, the institution was donated to the State, which for many years ran it as a nursing home/farm for people with severe epilepsy. To the extent possible, the residents took part in the farm work. In 1954, thanks to a donation from the Norwegian Red Cross, a new unit was built for temporary service to 36 children with epilepsy. The new medical director, Dr. Georg F. Henriksen, specializing in neurology, psychiatry, and clinical neurophysiology, had been trained in epileptology in the United States and Canada.

During Dr. Henriksen's tenure (1954–1974), the National Nursing Home for Epileptics developed into the National Hospital for Epileptics with 184 beds: 36 for children, 34 for residential care, and the rest for adolescents and adults with difficult-to-treat epilepsy. The patients were admitted from all over Norway to be diagnosed and treated by a multiprofessional staff of about 150. Most patients had not only epilepsy, but also considerable additional problems, such as mental retardation, psychiatric and behavioral disturbances, and neurologic deficits.

In 1974, Dr. Yngve Løyning, a specialist in neurology and clinical neurophysiology, succeeded Dr. Henriksen. In 1975, the institution was renamed the National Center for Epilepsy (Statens Senter for Epilepsi [SSE]), reflecting its development into a multiprofessional comprehensive service center in epileptology. Residential care was abandoned in 1980.

Epilepsy surgery was introduced in Norway by professor Kristian Kristiansen at the Department of Neurosurgery at Oslo City Hospital (Ullevål) in 1949. He had his training at professor Wilder Penfield's department in Montreal, and Kristiansen was for many years the only Norwegian surgeon who performed epilepsy surgery. In 1976, epilepsy surgery was transferred to the National Hospital (Rikshospitalet) in Oslo. In 1992, the Norwegian Health Authorities decided to centralize this resource-intensive service. Selection of candidates for epilepsy surgery, preoperative investigations, and postoperative follow-up and rehabilitation would take place at the National Center for Epilepsy, whereas neuroradiologic investigations, intracarotid amobarbital (Wada) tests, and diagnostic and therapeutic surgery would be performed at the National Hospital.

In 1971, Norwegian Health Authorities planned to establish additional epilepsy centers in association with the university hospitals in the western, mid, and northern parts of Norway. The center in Sandvika was supposed to serve the southeastern part of the country, increasing its number of beds to 308 (including 92 for residential care) and the number of employees to 340. However, over the next years, it became evident that the additional centers would not be built because (a) the neurologic and pediatric epilepsy service had improved considerably throughout the country, making the need for more centers questionable; (b) the authorities decided that patients in need of permanent care should be treated in their local counties; (c) the economy in all regions had become weaker; and (d) the capacity at the center in Sandvika had improved, owing to the fact that the duration of stays at the center had decreased dramatically. The center would continue its nationwide service with fewer, rather than more beds, provided the staff was increased.

In 2005, the center had 25 buildings, occupying 21,000 m^2 of the 400,000 m^2 land area. There are 87 beds and about 300 employees.

Despite the continuous improvement of medical and psychosocial epilepsy service in Norway, the need for internal and external comprehensive service from the center in Sandvika is still increasing. The average yearly admission of inpatients over the past 30 years (1975–2005) has increased more than fivefold. During the same time, the number of beds was reduced from 183 to 87. This intensification has led to a marked reduction in average length of stay at the center, from 150 days to 17 days.

In the last few years, the center in Sandvika has been designated as a competence center for severely disabled patients with epilepsy, including those with mental retardation, tuberous sclerosis, and autism.

Development of the Norwegian Health-Care System

Regionalized Service

Since 1976, the system for health service in Norway, as in the other Scandinavian countries, has been regionalized. The intention is that each of the five health regions should have the resources to provide its population with most of the medical and psychosocial service needed. Some of the regional hospitals have supraregional or nationwide service functions, which are often resource-intensive and mostly intended for small groups of patients.

In addition, special institutions with supraregional or nationwide service functions exist for special groups of patients: Those with rare diseases or syndromes, those requiring particularly resource-demanding or multiprofessional services (e.g., drug-resistant epilepsies, cerebral palsy, multiple sclerosis), or those with different ailments in need of the same service (e.g., various physical deficits requiring rehabilitation).

Service Levels

Medical and psychosocial service is provided at four levels of increasing competence: In the local district, in the counties, in the regions at university hospitals, and in the special institutions or centers. The goal is to treat patients at the lowest possible service level as close to their own district as possible. A primary care physician, who calls in other professionals as consultants when needed, coordinates all service. Although rehabilitation teams are available in the counties, a complete multiprofessional staff providing the integrated, comprehensive service necessary for patients with difficult-to-treat epilepsy is established at a national epilepsy center at the fourth service level only.

Mechanisms of Referral

According to the outlined service principles, patients with epilepsy should have access to service on all four levels, depending on the severity and complexity of their condition. In Norway, it is recommended that all patients with epilepsy be referred to a specialist in pediatrics or neurology (depending on the age of the patient) to clarify the diagnosis, etiology, and type of seizures and epilepsy, as well as to initiate, change, or terminate antiepileptic drug (AED) treatment. The general practitioner should monitor the patient's AED treatment according to seizure control, side effects, and serum concentrations. The specialist should be available for consultation and renewed investigation when needed. Only those with drug-resistant seizures are referred to the National Center for Epilepsy. The number of referrals is restricted for economic reasons. The expenses are covered by the health regions, which require an approval by a specialist at the local hospital.

Barriers to Care

The service system does not impose any barriers to necessary care except the economic barriers for use of service outside the county (i.e., in the regional hospitals and epilepsy center). However, the numbers of pediatricians and neurologists are not sufficient in all parts of the country to give patients with epilepsy access to a specialist as soon as needed. Rehabilitation teams often do not have the capacity or competence to deal with psychosocial problems associated with seizures.

National Center for Epilepsy

Geographic Location

The National Center for Epilepsy is located just outside Oslo, which is located in the southeast end of the elongated country. The location causes some difficulties for the follow-up of patients and communication with health personnel in distant parts of the country. This is one of the reasons why we at the center in Sandvika (belonging to Health Region South) have advocated establishment of local epilepsy centers in the other four health regions (Health Region East-, West-, Mid-, and North Norway).

For many years, the center has collaborated closely with the National Hospital in Oslo, where neuroradiologic investigations and surgical interventions are performed.

Leadership and Staffing

In 2002, the epilepsy center became a part of the National Hospital. In 2005, great organizational changes took place within the health service in the Oslo area. The Norwegian Radium Hospital (specialized in cancer treatment) was merged with the National Hospital (Rikshospitalet University Hospital) and organized into eight clinics. The National Center for Epilepsy became a part of the Division of Clinical Neuroscience, which also comprises Departments of Neurology, Neurosurgery, as well as Psychosomatic Medicine. The center no longer has a director of its own, but is now under the medical leadership of the Division of Clinical Neuroscience.

Employees at the center for the time being, nearly 300, represent the necessary disciplines for addressing the various problems of the patients. The staff includes 23 physicians who cover neurology, pediatrics, clinical neurophysiology, and psychiatry, and one clinical pharmacologist. Of these, eight are interns training for any of these specialities. There are nine clinical neuropsychologists, three social workers, six vocational therapists, five physiotherapists, and 13 laboratory technicians. In addition, there are about 100 nurses, of whom many have subspecialized in epileptology and/or psychiatry. The nurses are key persons in the epilepsy education offered to all our patients, and the importance of having structured epilepsy nursing for improved quality of life has recently been documented.[4] The center has its own elementary and secondary school, with 18 specially trained educators, including speech therapists.

Services Available

The service offered by the center is established in accordance with the objectives decided upon by the Health Authorities and the Norwegian Parliament. These include service to inpatients and outpatients, consultative assistance to health professionals and others dealing with patients with epilepsy, education of students and health professionals, information to relevant groups in the society, and distribution of results from clinical research.

Internal Service

Patients are admitted to the center for seizures of an unclear nature or difficult-to-treat seizures, for evaluation of surgical treatment, for postoperative controls, and for psychosocial problems related to the epilepsy or epilepsy treatment. Many

P.2941

patients have multiple medical problems, often with complex causes. Several are in need of family therapy and/or of habilitation and rehabilitation. Most patients profit from a multiprofessional comprehensive service, and some participate in group therapy.

For inpatients, the center has separate wards for children (n = 32), 1 to 14 years of age, as well as for adolescents and adults without mental retardation (n = 34), with slight retardation (n = 14), and with severe retardation (n = 7). Other units are designated for intensive monitoring (n = 5; n = 10 from 2006), vocational observation and training, physiotherapy, and leisure activities. There are as well laboratories for clinical chemistry/clinical pharmacology, clinical neurophysiology, and clinical neuropsychology. The school has a capacity for about 40 children. The center has housing facilities for relatives and guests.

The center also accommodates national centers of competence-related diagnostic groups, such as tuberous sclerosis, autism, and learning disability with epilepsy.

Between 30 and 40 patients undergo epilepsy surgery every year, mostly resective surgery. Analyses of the outcome and its prediction factors have been presented.[1,3] Every year, about 15 drug-resistant patients who were found unsuitable for surgery are offered vagal nerve stimulation.[8]

External Services

External service offered at the center includes preadmission assessment; postdischarge follow-up by long-distance communication and outpatient clinical and laboratory service, visiting service to some residents with learning disabilities, nationwide consultative service to health professionals and authorities, graduate and postgraduate educational service to health personnel and school teachers, and supervision of students in different health professions.

In Norway, two nursing homes are available for patients with severe epilepsy (Kure and Røysumtunet). Physicians from the center serve these two institutions through visits on a regular basis.

Number of Patients Served

In 2004, 1,413 patients were admitted to the National Center for Epilepsy. Their average stay was 16.9 days (1 day–4 months). The number of admissions is increasing slightly year by year. The average waiting time before admission was 110 days. In 2004, about 200 patients were evaluated for epilepsy surgery, but only about 35 of them were actually operated. The need for epilepsy surgery is estimated to be about 50 patients per year.[6]

About 1,400 patients, both children and adults, are admitted to the outpatient clinic for approximately 2,000 consultations per year. Among these, about 50 patients participate in drug trials.

At the Department of Clinical Chemistry/Clinical Pharmacology, about 45,000 blood samples from in- and outpatients were analyzed in 2004, mainly to determine serum concentrations of AEDs.

At the Department of Clinical Neurophysiology, 4,176 recordings were performed in 2004, both standard electroencephalogram and combined video and telemetry, 100 evoked potential studies, 100 electromyograms, and about 20 ictal single-photon emission computed tomograms (SPECT) were recorded.

The Department of Neuropsychology performs about 110 general neuropsychological assessments (including personality inventories) per year, 40 preoperative assessments (including Wada tests), 35 postoperative assessments, 20 online evaluations of cognitive effects of interictal EEG disturbances, and about 15 functional magnetic resonance image (fMRI) scans.

Funding

Funding of Health Service

A part of the salaries of all employees in Norway are taxed to fund the National Health Security System. This tax covers all the expenses for all health service and social service, except for a small amount paid by the patient for service from outpatient clinics and private practitioners. Thus, the health regions offer service to patients in hospitals and institutions from funds allocated by the government.

Barriers to Care

Finances

Because the health regions are underfinanced, the use of service outside the regions is decreasing. This is a concern for special institutions like the epilepsy center. Fortunately, so far, the admissions to the center have not been reduced.

Ignorance

The existence of the epilepsy center is well known to most patients with epilepsy, their relatives, and health care and social service personnel. However, the benefits of comprehensive service, and particularly of surgical treatment, are not sufficiently known. Thus, many patients are referred too late, often when psychosocial problems have become fixed and irreversible.

Research

In recent years, research activities have been pursued in the following fields: Clinical pharmacokinetics of AEDs, evaluation and monitoring of AED treatment, clinical trials of new AEDs in phase III and IV, epilepsy surgery, intensive observation and differential diagnoses of episodic brain dysfunctions, automatic detection and quantification of epileptiform EEG discharges, neuropsychological testing of performance in relation to epileptiform activity, physical fitness and physical exercise in relation to epilepsy,[7] the influence of drug treatment on psychosocial functioning, genetic aspects of epilepsy, analyses of comprehensive service needs,[5] and benefit evaluation of the center service.

Future Epilepsy Service

In 1995, Health Region West established high-level medical services to patients with epilepsy at the Departments of Pediatrics and Neurology at Haukeland University Hospital in Bergen. In Health Region North, a comprehensive epilepsy service has for some years been planned at the Department of Neurology at Tromsø University Hospital, but is not yet realized.

However, in Health Region Mid-Norway no plans exist to establish a unit for patients who need to stay for a longer time than is possible in ordinary hospital wards. Therefore, patients requiring comprehensive service will continue to be referred to the National Center for Epilepsy in Sandvika.

In 1981, the National Center for Epilepsy presented a plan for its future service based on analyses of service needs. We renewed our recommendation to establish similar centers in the

other health regions. Whether such centers will be realized is open to the gravest doubt and, until further notice, the present center will need 100 beds for a nationwide inpatient service, with a corresponding level of sufficient staffing.

Summary and Conclusions

The views from the Norwegian Center for Epilepsy can be summarized as follows:

A person with newly diagnosed epilepsy may face long-lasting problems including seizure susceptibility, drug-related side effects, and the psychosocial burden. Fortunately, most patients have minor problems, but all patients will be in need of some comprehensive service.

Ideally, comprehensive service should be provided at all service levels. Those specialists in pediatrics or neurology who establish the diagnosis of epilepsy and initiate drug therapy should cooperate closely with the local general practitioner, nurse, social worker, and, if necessary, school teachers and a psychologist. According to the patients' requirements, information should be given to all those involved. The patient should be informed about the Norwegian Epilepsy Association (and its local branch) and about other sources of epilepsy information. At the regional hospital, a multidisciplinary team at the Departments of Pediatrics and Neurology provides comprehensive service.

About 30% of patients with epilepsy will be in need of comprehensive service from a specialized center or unit, where they can stay for a longer time than in ordinary hospital wards. At such epilepsy centers/units, they will be offered integrated multidisciplinary services, including physical, social, and vocational habilitation and rehabilitation and, if required, patients can attend school. To meet these demands in an optimal way, an epilepsy center should cover a population of about 1 million, thus serving about 2,500 patients with severe epilepsy.[2]

Ideally, in each Health Region, an epilepsy center/unit for long-term comprehensive service should be established, preferably in close collaboration with the regional hospital.

In a small country like Norway, epilepsy surgery should be coordinated from, and centralized to, one epilepsy center and one collaborating regional hospital. Patients with severe epilepsy and considerable comorbidities may not be able to take care of themselves. Earlier, many of these patients lived in big central institutions. In 1991, such institutions were closed in Norway, and today many of these patients are living in small, local, sheltered homes. In addition to the local comprehensive service, these patients should be followed-up on a regular basis by an epileptologist from the nearest epilepsy center/unit, and be admitted for a temporary stay when necessary.

Chapter 304

Comprehensive Epilepsy Programs—Japan

Masakazu Seino

E. Ann Yeh

Introduction

Epidemiologic studies of epilepsy, which are indispensable to estimate the magnitude of a problem, are limited in Japan. A 1-day population-based survey of children under the age of 13 years, conducted in Okayama Prefecture in 1999, showed the prevalence rate of seizure disorders to be 8.9 per 1,000 population (2,222 per 250,997). When febrile seizures and other single provoked seizures and acute symptomatic seizures were excluded (848 cases), the rate was 5.5 per 1,000.[14] The figures are comparable with those in the United States and Europe.[5] According to a 1-day survey done by the Ministry of Health in 2002, on the estimated number of patients with epilepsy whose medical fees were subsidized by any one of the governmental health insurance systems, 74,000 patients were hospitalized and 195,000 patients visited outpatient clinics.[7]

The issue of medically refractory epilepsy is a topic of special significance in epilepsy treatment. A series of nationwide surveys was carried out to establish the number of people with refractory epilepsy in Japan. People with refractory epilepsy were defined as those with an increase or no change in seizure frequency despite at least 3 years of intensive medical treatment at either a university hospital or a specialized center. The number of patients identified in these surveys as having refractory epilepsy was over 100,000. Most of these patients also had multiple neurologic and psychosocial problems. Of patients 15 years of age or younger, 13.5% were found to have medically refractory epilepsy,[15] and the epilepsy of 25.3% of patients over 16 years of age was medically refractory.[13]

In Japan, epilepsy patients were treated by psychiatrists until 1950s. For this reason, mental hospitals are the final stop for individuals with most refractory and disabling epilepsy. *The Handbook for Mental Health and Hygiene* reported, in 2002, that 4,243 (1.3%) of 330,050 patients institutionalized in mental hospitals in Japan on a long-term basis had intractable seizures in addition to personality and psychiatric disorders or mental disabilities.[8] The number of patients with epilepsy who were admitted to mental hospitals has decreased markedly over the past decade. The numbers have dropped yearly since 1995. Between 1995 and 1997, respectively, 8,997, 8,574, and 8,332 patients with epilepsy were hospitalized in mental hospitals in Japan. This decrease in numbers of hospitalized patients presumably represents improvements in epilepsy care in general in Japan.[1]

Historical Development

In a 1966 article, Wada[20] noted that Japan's progress in the scientific aspects of epileptology was on par with that of North America and Europe, although Japan lagged behind in its support of comprehensive medical services for epilepsy. Unlike the nations of North America and Europe, where custodial facilities for people with epilepsy and other disabilities were established in the middle of the 19th century,[2,3] state-sponsored institutional care for people with disabilities was not introduced in Japan until the mid 20th century. Legislation for the creation of institutions for individuals with severe mental disabilities was introduced in 1959. This legislation was established only after the state was pressured by lay people and professionals to take responsibility for the support for individuals with severe disabilities. Thus, although the influential 1969 Reid

Report[2] was shelved for lack of funding and political will in Great Britain,[18] its recommendations concerning the general care and management of patients with epilepsy, as well as for the creation of special epilepsy centers, were welcomed with great enthusiasm by Japanese professionals.

Although the need for establishing comprehensive multidisciplinary treatment programs for people with epilepsy in Japan was advocated by Nakata as early as 1966,[12] it was only in the 1970s that a special center for the treatment of epilepsy was established.[19] Inspired by the Reid Report,[2] the Japanese Ministry of Health and Welfare decided in 1975 to convert a tuberculosis hospital located in Shizuoka into a special center for epilepsy.[23] The center was defined as an integrated organization from which delivery of the following services would be possible: (a) long-term, longitudinal care of individuals with epilepsy from infancy through adolescence to adulthood; (b) multidisciplinary team treatment by neurologists, pediatricians, neurosurgeons, psychiatrists, nurses, and comedical personnel; (c) occupational therapy and rehabilitation activities; and (d) training and research in epileptology. In addition, during the 1980s and 1990s, several governmental sanatoriums Tokyo, Kyoto, Niigata, and Yamagata converted their neurology/psychiatry clinics into epilepsy assessment centers. The total number of these converted beds was approximately 250 in 2005.

The National Epilepsy Center in Shizuoka, Japan

The remainder of this chapter is devoted to a description of the current therapeutic activities and demographic features of the National Epilepsy Center in Shizuoka, based on statistics from 1975 to 2002. From 1975 to 2001, a total of 22,950 new patients with epilepsy visited our Center. The number of patients younger than 15 years of age has deceased since the mid 1980s, whereas the number of patients older than 15 years of age has gradually increased. The electroencephalogram (EEG) was the most frequently performed clinical investigation. A total of 187,600 EEGs was performed between 1975 and 2001.

Geographic Distribution of Outpatients

A total of 1,451 new patients visited the center's ambulatory services in 2003, including 27% from Shizuoka Prefecture

(where the center is located) and 31% from adjacent prefectures situated between Tokyo and Nagoya (about 200 km away, or a 1-hour trip by bullet train from Shizuoka). The remaining lived in areas beyond the Tokyo and Nagoya metropolitan areas.

Geographic Distribution of Inpatients

The center has four wards for patients with epilepsy. There are 100 beds in the two adult wards and another 100 beds in the two wards for children. On average, 178.1 inpatients/day were hospitalized at the center in 2002. Patients come from every prefecture in Japan. Approximately a quarter of the inpatients are residents of Shizuoka Prefecture. The other patients come from other parts of Japan.

Age Distribution

The age of new outpatients ranged from 1 month to 76 years. The mean age was 18.5 years. Forty-five percent were under the age of 15, and 55% were over the age of 15 years. The age of inpatients ranged from 1 month to 62 years, also with a mean age of 18.5 years.

Patient Referrals to the Outpatient Clinic

The center is an officially recognized tertiary center for epilepsy in Japan. Based on statistics from 1991, 79% of outpatients were referred to the center by other physicians. Pediatricians made 37% of the referrals, neurosurgeons 8%, neurologic internists 8%, and general practitioners 7%. Twenty-one percent of the outpatients visited the center without referrals, of whom 8% were without diagnosis or treatment.

The government is attempting to decrease the number of patient self-referrals. Since 1988, under the Standard for Special Medical Treatment Act, patients have been required to receive referrals to utilize the services of specially designated tertiary care centers. Patients who do not receive referrals to the centers cannot use their health insurance for the first consultation they receive there.

The Diagnosis of Epileptic Syndromes and Epilepsies in 100 Consecutive Inpatients in 2002

The diagnosis of epileptic syndromes and epilepsies in 100 consecutive inpatients in 2002 was as follows: Syndrome identified in 39%, syndrome probable in 19%, other epilepsies in 32%, and nonepilepsy in 10%. Of the 39 patients whose syndromic diagnosis was definite, temporal lobe epilepsy was found in 21, frontal lobe epilepsy in eight, occipital lobe epilepsy in four, West syndrome in two, juvenile myoclonic epilepsy in one, and epilepsy with grand mal on awakening in one. Of the 19 patients whose syndromal diagnosis was probable but not definite, frontal lobe epilepsy was diagnosed in eight, occipital lobe epilepsy in four, temporal lobe epilepsy in three, progressive myoclonus epilepsy in two, familial adult myoclonic epilepsy in one, and Doose syndrome in one.

Of another cohort of 659 of the center's outpatients, 349 (53%) were followed for 3 years at the center's ambulatory services; 310 (47%) were sent back to the referring physicians. Treatment outcomes, expressed by rate of reduction in seizure frequency at 3-year follow-up compared with baseline, were as follows: Complete seizure freedom in 121 patients (35%), greater than 75% reduction in seizure frequency in 76 (22%), and greater than 50% reduction in 58 (17%). In other words, seizure frequency was reduced by at least 50% in almost 75% of outpatients treated at the National Epilepsy Center.[15]

Length of Admission of Inpatients

In 1998, the mean duration of admission was 123 days. One obvious reason for the long hospitalizations is that most of the center's inpatients have seizures that are extremely difficult to control, and because hospitalizations are fairly inexpensive, neither staff physicians nor patients and their families have much incentive to keep stays short. However, more complex social reasons exist. Most of the adult patients who are hospitalized at the center say they would like the treatment they receive to help them lead "normal" lives—lives during the course of which they could work, marry, have children, and so on. Because there are major restrictions on the employment (and thus economic independence and marriage) of individuals with epilepsy in Japan, the only way that many patients imagine this ideal can be realized is through full seizure control. These hopes are often nearly impossible to meet. One result has been long hospitalizations.

Epilepsy Surgery

Seven hundred and thirty nine patients have undergone epilepsy surgery at the center since 1982. Decisions regarding surgeries are made by a multidisciplinary team. Twenty-nine percent of the surgery candidates underwent presurgical evaluations with long-term intracranial EEG-video monitoring. Radiographic surveys, computed tomography (CT), magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT), and magnetoencephalography (MEG) were also used in the presurgical evaluations. Outcomes of 100 patients who underwent temporal lobe surgery and were followed for more than 2 years were as good as or better than results reported for Europe and North America.[10] After a mean follow-up of 8.0 years, 80.5% of 425 patients receiving temporal lobe surgery had seizure outcomes falling into Engel's Class I. Sixty-two percent of 140 extratemporal cases were classified as Engel's Class I after a mean 6.2-year follow-up.[11]

Mihara concluded that resective surgery provides sustained, positive benefits with a high likelihood for seizure freedom (80%) for most medically refractory patients with discrete lesions. In patients without a clear MRI lesion who underwent extra-temporal lobe resection, however, Engel's class I to II was achieved in less than 50% of patients. High-resolution MRI should be performed early in all patients with partial seizures.[11]

Table 1 Comprehensive classification of people with epilepsy

Group 1: People with epilepsy who (a) have had no seizures for 5 years or longer, (b) do not have associated (physical, intellectual, psychiatric) disabilities, and (c) can do all types of work except for that involving heavy lifting.

Group 2: People with epilepsy who have had no seizures for 3 years, and are able to do certain types of work, even if their associated disabilities are taken into account.
Group 3: People with epilepsy who have been seizure-free for less than 3 years, and who are employable even if hazards caused by seizures and interictal disabilities are taken into account.
Group 4: People with epilepsy who are having several seizures a month or even fewer. The seizures may cause hazards. These individuals are employable only in sheltered situations.
Group 5: People with epilepsy who are having several seizures a week or even fewer. Their seizures cause hazards. These individuals are unable to support themselves because of interictal disabilities, and are therefore in need of occasional help from others.
Group 6: People with epilepsy who are having several seizures a day or more (in some cases, fewer), and are entirely unable to care for themselves and always in need of help from others.

From Yagi and Onuma, ref. 21.

Finances in 2002

The National Epilepsy Center operates under the auspices of the Ministry of Health and Welfare of Japan. All income from medical services is considered governmental income, and the hospital's annual budget is issued by the Ministry independently. The approximate income in 2002 was 4.11 billion Yen, while total expenditures amounted to 4.05 billion Yen. (For the sake of conversion, about 115 Japanese Yen were equivalent to 1 U.S. dollar in 2006.) Thus, the hospital operated at a surplus of 1.6% in 2002, whereas the hospital has operated at a yearly deficit of 10% for the past 10 years.

Severity of Epilepsy and Comprehensive Classification

In 1986, Yagi and Onuma[17] introduced a system to classify individuals with epilepsy according to their ictal and interictal levels of disability. The system was designed to evaluate levels of need for health and special services. The six levels of this classification system are summarized in Table 1.

In this classification system, ratings are based not only on patients' inherent seizure types and frequencies, but also on the severity of seizure-related disabilities. For example, higher ratings are given to seizures that (a) cause abrupt falls and injury, (b) are accompanied by prolonged impairment of consciousness including automatisms, and (c) result in immobility, even if consciousness is not impaired. In a survey of 542 outpatients at the center, the breakdown was as follows: Group 1, 8%; group 2, 16%; group 3, 38%; group 4, 22%; group 5, 11%; and group 6, 4%.

Patients classified in groups 1 through 3 (63%) can be managed as outpatients and, in principle, are employable, whereas those in groups 4 and 5 (33%) have been subjected to short- or long-term hospital admissions, depending on the severity of their seizures. Patient classifications are subject to change. For example, a patient in group 4 whose hospital stay is shorter than expected might be shifted up to group 3, and a patient in group 5 whose condition worsens may be moved down to group 6.

Rehabilitation and "Habilitation"

The Reid Report envisaged special centers as being concerned with medical care and rehabilitation, with the ultimate goal of returning people with epilepsy to a normal life in the community. It specified the need for facilities for people with severe epilepsy—individuals whose seizures cannot be adequately controlled and who require long-term accommodation. According to the report, the needs of these patients must be recognized as being different from those of the long-stay resident who is institutionalized for other reasons (mainly custodial care).[2]

With respect to the needs of these patients, Grant argues that specialized services are necessary for individuals "…whose seizures cannot be effectively controlled, and those who require medical supervision under everyday living conditions or in a working setting."[4] These patients would fall into groups 5 and 6 in the comprehensive classification system described above.

Patients who fall into groups 3 and 4 in the system would most nearly approximate the group that Laidlaw and Laidlaw[9] describe as "…people with epilepsy who very nearly but not quite can manage on their own, who are employable, but break down under external environment stresses, who, given just a little bit of support, can be most successful."

In Europe, proposals for the creation of special centers were specifically aimed at the deinstitutionalization of individuals with epilepsy.[2] However, during the years following the North American and European movements for deinstitutionalization, critics have made it clear that deinstitutionalization in itself does not offer a more "humane" solution than institutionalization,[19] and that it must be accompanied by alternatives other than the street and soup kitchens. It is also clear that supportive, residential environments can be of benefit to some individuals. Finally, it is the opinion of the first author (M.S.) of this chapter, based on more than 30 years of experience at the Center, that residential care is necessary for a limited number of individuals who have severe, frequent seizures and intellectual or behavioral problems. The authors suggest that this type of residential care for people with epilepsy be based on a goal of "habilitation"—the provision of schooling (for children) and care (for adults) in livable and supportive environments, rather than on the primary goal of "rehabilitation"—the accommodation of individuals to society. These goals do not conflict with, and indeed may be integrated easily with, the goals of current community care plans.[13]

Summary and Conclusions

Over one million people in Japan have epilepsy. One-tenth of them have medically intractable seizures. Most of these individuals have concomitant physical and/or intellectual disabilities.

P.2946

Although the need for comprehensive services for epilepsy was established before 1975, it was only in 1975 that the Japanese Ministry of Health decided to convert a tuberculosis hospital into a special center for epilepsy. Our experience over the past 30 years at the National Epilepsy Center in Shizuoka suggests that treatment can improve seizure control in approximately two-thirds of patients. Outcomes for patients who underwent epilepsy surgery were as good as or better than results reported for North America and Europe. The management of epilepsy should be oriented toward seizure control, psychological well-being, and social rehabilitation. To satisfy these goals, it is imperative that different types of health care professionals come together to form multidisciplinary treatment teams. However, in Japan, only a small number of these multidisciplinary teams have been established. Furthermore, the need for residential care for individuals who have severe disabilities related to epilepsy must be addressed. This type of residential care should be oriented toward "habilitation"—the provision of schooling and care in livable and supportive environments—rather than the goal of "rehabilitation"—the accommodation of individuals to normal life in the community.

Chapter 305

Residential Epilepsy Centers—United Kingdom

Frank M. C. Besag

Stephen W. Brown

Introduction

The term *epilepsy center* is used to denote two different situations in the United Kingdom: (a) a collection of professionals specializing in epilepsy and offering different aspects of service at a specified geographical site or area and (b) residential centers for children or adults with epilepsy that offer short- to medium-term assessments, longer-term placements, or both. There are two main types of residential centers, sometimes existing together at one site: The adult centers and the epilepsy special schools.

It might be argued that a comprehensive "epilepsy center" should comprise a group of hospital-based professionals, including physicians who specialize in epilepsy neurosurgery and neuroimaging, in close proximity to a residential center that can offer longer-term assessments or indefinite care in selected cases.

Historical Development

A major change in attitude has occurred, from the earlier concept of an "epileptic colony" to that of a residential center that has strong community links and emphasizes preparation for living within society. This contrasts sharply with the image of an "asylum" that either protects the individual with epilepsy from the community or protects the community from the person with epilepsy; neither of these aims would be considered acceptable in current practice.

It is interesting to note that the early residential centers were actually referred to as "colonies," for example, the Lingfield Colony and the Chalfont Colony. Both these centers have changed their names to reflect the change in attitude.

The history of epilepsy centers in Europe seems to be relatively short. The monks at the priory of St. Valentine at Rufach in Alsace provided a "hospice for epileptics" at the end of the 15th century. The Bishop of Wurzburg started a home for people with epilepsy in 1773. In the United Kingdom, the National Hospital for the Paralyzed and Epileptic opened in Queen Square, London, in 1860. The Lingfield Colony (now The National Centre for Young People with Epilepsy) was founded in 1898 by a group of Christian people who had been inspired by Pastor Friedrich von Bodelschwingh. This man had taken over the center at Bethel near Bielefeld, Germany, in 1872, 5 years after it had been established. Subsequently, The Chalfont Centre was founded in Buckinghamshire in 1894, and the David Lewis Centre in Cheshire was opened in 1904. The Park Hospital in Oxford later provided medium-term residential assessments for children with epilepsy, and Bootham Park Hospital in York has provided specialist services, primarily for adults. St. Elizabeth's School and Home at Much Hadham in Hertfordshire and the Meath Home in Surrey initially provided only for female patients but now accept patients of both sexes. The Quarriers Homes in Scotland also have a long tradition of providing residential care for adults with epilepsy.

What is the role for these epilepsy centers in a country with an advanced system of medical care, in which the emphasis is on moving services out into the community? People with epilepsy certainly should lead lives that are as normal as possible and, for most, this implies that they should be living in the community. However, there are two situations in which the epilepsy center may play a role. The first of these is for short- or medium-term assessment and treatment. If there is real diagnostic doubt that cannot reasonably be resolved by the hospital services, it may be appropriate to use the specialist residential center to clarify the diagnosis. The center may also be used for complex, protracted changes in antiepileptic drugs, particularly if a significant risk for status epilepticus is involved. The second situation arises when longer-term placement is needed for a very small proportion of people with epilepsy whose needs cannot reasonably be fulfilled using resources available in the community. The number of people with epilepsy in this category has, appropriately, diminished steadily over recent years, both because of better treatment and because of changing attitudes.

Reasons for Referral

Some of the possible reasons for referral to a residential center are listed in Tables 1 and 2. It is not simply the presence of these factors but the degree to which they hamper satisfactory management that is likely to determine whether the epilepsy center must play a role or not. The possible reasons for referral have been discussed in detail elsewhere.[2,3]

Location of Centers

It is mandatory that a specialist epilepsy center have a team of doctors, other caregivers, educational specialists, psychologists, physiotherapists, occupational therapists, and speech therapists if it is to provide a full range of services. This necessarily implies that, to be viable, the center has to be of a reasonable size and have a moderately large number of residents at any one time. An alternative would be for the center to share facilities with other establishments. In practice, the centers tend to be moderately large, and consequently they are relatively few in number across the country. The geographical location may not be very convenient. The Winterton Report[7] on services for people with epilepsy recommended that two new special assessment centers be set up, partly to reduce the distances patients have to travel. This document referred to earlier reports

P.2948

by Morgan and Kurtz[5] and Reid,[6] which stated that "special centres should be provided for those people with epilepsy whose management presents particular problems,"[5] and "the evidence is of a continuing number of young adults, both males and females, requiring a period of inpatient treatment during which they can be observed by trained staff, investigated and started on remedial programmes of treatment—special centres should, therefore, be seen to have a continuing role."[5] In the current financial climate, however, it seems unlikely that additional centers will be initiated. It might be argued that the centers should be placed closer to large populations. For historical reasons, they have tended to be placed in rather rural situations, because they were founded at a time when close links with the local community were not considered to be essential. There was no particular reason why a "colony" needed to be near a heavily populated region. The current philosophy of facilitating close links with the community, however, implies that the centers should ideally be closer to the communities they serve.

Table 1 Reasons for referral

Difficult epilepsy
Other medical problems
Cognitive problems
Behavioral problems
Peer group problems
Family and social problems
Psychiatric problems
Multiple problems

Table 2 Features of difficult epilepsy

Frequent seizures
Injury during seizures
Risk for status epilepticus
Variable seizure frequency
Postictal problems
Problems with antiepileptic drugs
Inadequate control
Difficult-to-recognize epilepsy

Relation to Medical Centers

Notwithstanding the historical reasons for the epilepsy centers being located away from major cities, a clear need exists for them to have very close links with major hospitals. In practice, because the United Kingdom is not very large, it is possible for the centers to be in semirural areas and yet to be relatively close to major hospitals capable of providing specialist services, such as magnetic resonance imaging and neurosurgery.

Leadership and Staffing

Currently, a very healthy trend exists for the residential special centers to be led by professionals who have an international standing in the field of epilepsy. The implication is that they adopt the approach of providing high-quality service, making full use of the multidisciplinary team.

Services Available

Uniformity Among Epilepsy Residential Centers

If it is accepted that the centers should provide a high-quality, specialist, tertiary referral service, it is essential that they have a full range of therapists, as already indicated. It is also essential that they have links with the appropriate hospital-based investigational and neurosurgical treatment facilities. It could certainly be argued that sophisticated encephalographic (EEG) and video-EEG monitoring should be mandatory at such centers. In the United Kingdom, these services are available at most of the centers, but there is the occasional notable exception. In the United States[4] and Australia,[1] attempts have been made to set minimal standards, but no such consensus has yet emerged in Europe.

Number of Patients Served

Only a very small proportion of people with epilepsy require the services of a residential center. However, the individuals who need these services tend to be the more difficult and demanding patients who would, in any case, require much in the way of resources for their needs to be met. Placement in a specialist residential center may be a very efficient way of fulfilling their needs, particularly if the outcome is a beneficial review of drug therapy or a successful referral for neurosurgery.

Funding

In the past, most residents at the special centers have been sponsored by the local authority of their home area. At least for placements in which the department of education plays a role, there appears to be a current trend away from funding by local authorities to a more centralized form of control through the so-called quasi-autonomous nongovernment organizations (QANGOS). In some cases, this may imply that funding is more easily available. However, it is difficult for a central funding agency to have a good appreciation of the needs of individual patients.

There is also an increasing trend to multiagency funding, with, for example, the district health authority and educational and social services all having to contribute toward the payment. This seems to be based on the naïve concept that greater cooperation will be fostered between the actual agencies providing longer-term care. In practice, it often adds to administrative costs and, worse still, delays or jeopardizes placements because of interagency disputes.

Barriers to Access

The families of patients with epilepsy may be faced with a dilemma if they consider that referral to a center represents some failure, on their part, to provide a caring environment. In these circumstances, there is a role for wise professional counsel based on decisions concerning what really is best for the individual with epilepsy.

Professionals may be reluctant to refer because they may view referral as an admission of defeat or because the admission may draw on limited budgets.

The person with epilepsy may also resist referral for a number of reasons, including feelings of hopelessness. What is the point of a further disruption to life if it will not achieve anything? There may also be an understandable fear of changing from the “disabled” role, with its apparent certainties of care, to the less certain role of increasing independence if control of the epilepsy improves. Support of the peer group, both within the center and subsequently through local epilepsy action groups, can be invaluable in this regard.

Comprehensive Epilepsy Programs

Recognition is growing of the need to coordinate all services: Hospital-based services, residential centers, outpatient clinics, and community outreach services. Relatively few groups of professionals anywhere in the world offer this type of comprehensive service. The need has been recognized in the United Kingdom, but much further development is required.

Summary and Conclusions

An unfortunate tendency has emerged to leave referral to specialist services until very late, with the result that the patient's life is disrupted in a major way by epilepsy. Late referral may also be associated with increasing difficulties in treatment. Rather than viewing the epilepsy center as a repository for the long-term care of “hopeless” cases, future emphasis should ideally be on early referral and a much higher volume throughput of cases, with intensive medium-term assessment, investigation, presurgical preparation, and postsurgical rehabilitation as appropriate. Above all, the current trend for preparing patients with epilepsy for life outside the residential establishment should be developed further, either through discharge into the community or through part-time involvement in the community for those who continue to require longer-term residential placement.

Chapter 306

Comprehensive Epilepsy Centers—The Netherlands

Harry Meinardi

Albert P. Aldenkamp

Introduction

In the first edition of this handbook, a description of specialized care for epilepsy reflected a rather stable period of health care in The Netherlands. Recent rapid developments in the fields of science, communication, and accessibility with simultaneous changes in demography, and economy however, clash and obstruct the implementation of theoretically feasible improvements in health care. Although most of the objectives of specialized care for people with epilepsy presented in the previous edition are still valid, some must be adapted to present-day requirements. Because this chapter is rewritten during a period in which many of the changes are still in the making, some uncertainties about the future situation are unavoidable.

The objective of special centers for epilepsy are still in essence to (a) offer intramural and extramural care to individuals with epilepsy within the framework of available facilities or facilities to be created in accordance with new developments and knowledge, and (b) promote the control of epilepsy.

Care comprises several elements, including diagnosis, rehabilitation, and temporary or long-term residential care. *Diagnosis*—the examination, observation, and evaluation of the symptoms and signs of disease and the psychic and social functioning of the patient in order to plan assistance—includes one or all of the following:

- Recommendations for the patient and the patient's family, including presentation of all treatment possibilities (drug treatment, diet, surgery, neuro-stimulation, psychological treatment)
- Recommendations for other health care providers to manage or supplement assistance
- A program for continued support by intramural or extramural facilities of the specialized center

Rehabilitation, the second aspect of care, is the integrated treatment of disordered physical, psychic, and social functioning. Finally, as the third element of care, an important precondition for temporary or prolonged residential care is the *verification that the specialized center is the most appropriate provision within the Dutch health care system for the referred patient*.

The second major objective of the specialized epilepsy care center is to promote the control of epilepsy in general by developing conditions that guarantee optimal physical, psychic, and social well-being for people with epilepsy, or that prevent the development of epilepsy. This can be achieved through:

- Research
- Public education
- Assistance of authorities responsible for health care and welfare on a regional, national, and international level

At present, society considers persons with epilepsy and their relatives to be responsible for the management of their own health. In other words, the patient is no longer comparable to a passenger who boards a ship to be transported to his destination. Rather, he has become a private ship's captain, who rents a ship and crew and takes over command, only consulting a trained pilot when the waters get treacherous.

In addition, the cost of illness is usually paid by insurance companies, which feel entitled to make patient care decisions on their behalf. This is exemplified by the way health services presently are paid for based on *diagnosis-treatment combinations.*

Historical Development

In a general article on specialized centers for epilepsy, Meinardi and Pachlatko[4] reviewed the history of some of these centers. The oldest specialized center is reputedly the hospice of St. Valentine in Rufach, France. Although the institution is still there, it no longer functions as a hospice for people with epilepsy. This chapter concentrates on specialized centers in The Netherlands.

Specialized centers for epilepsy in The Netherlands play an important role, both scientifically and with regard to patient care. In 1985, Meinardi[3] described the various theses on epilepsy published in The Netherlands since Prince William the Silent offered a university to Leyden in 1575, in recognition of the city's important contribution to the liberation of The Netherlands from despotic Spanish rule. During the years 1955 to 1985, more than a quarter of these theses were produced by the staff of specialized centers for epilepsy.

The first specialized center for epilepsy in The Netherlands was founded on January 26, 1882, in Haarlem, in the Western part of The Netherlands. The society created to enable the development of a hospital for people with epilepsy originated as part of the so-called *Reveille movement*. This movement was started by well-to-do citizens who wanted to put their Christian principles into practice. Years passed before a specialized center was established. The owner and director of a Deaconesses' Hospice in Haarlem, Lady Teding van Berkhout, was approached several times with a request to admit people with epilepsy. This request was usually rejected, and patients were referred to a psychiatric hospital. Finally, two girls were admitted in 1879, but the experiment was a failure. One of the girls was taken by coach to Bielefeld. In that German city, in 1867, the reverend Von Bodelschwingh had started a specialized center for patients with epilepsy. This experience was decisive; with the help of some friends and allies, the Christian Society for the Care of People with Falling Sickness (the Christian Society) was established, and a small building on the grounds of Lady Teding van Berkhout's home was opened for girls with epilepsy, partly supported by staff from her Deaconesses' Hospice. At first, six girls were admitted, but the pressure for appropriate care for people with epilepsy was such that soon other buildings had to be bought to accommodate

P.2952

an increasing number of patients. In 1885, the mansion “Meer en Bosch” was acquired. For many years, the name “Meer en Bosch” was used as *pars pro toto* for all activities of the specialized center.

In 1966, the national regulations regarding the financing of health care made it desirable to put the facilities of the Christian Society into separate foundations. The new name, Instituut voor Epilepsiebestrijding (Institute for the Fight Against Epilepsy), was for public relations considerations expanded to include the names of the major campuses of the institute, “Meer en Bosch” and “De Cruquiushoeve.” These campuses, in Heemstede and nearby Vijfhuizen, comprise a total area of 155 acres. Early in the 20th century, outpatient centers were created in parts of The Netherlands too remote for patients to make a one-day consultation with doctors at the major epilepsy centers. These outpatient facilities served for the intake of new patients and after-care for those who could go home after successful reduction or complete suppression of their seizures. During the 1980s, experiments started to expand the services of the outpatient units. Two so-called *Polimides* were created that used the technical developments of portable electroencephalogram (EEG)-machines and automatic video-registration linked with a piezo-electric seizure detection device to observe patients in their home situation and thus reduce the need for hospitalization in the epilepsy center. Finally, during the years 1988 to 1992, the political trend of paying more attention to consumer needs resulted in a decision to require the Instituut voor Epilepsiebestrijding to build an annex for 80 patients in the northeastern region of The Netherlands. In particular, parents of children with epilepsy had protested to the Ministry of Health that, when intramural tertiary care was needed, they had no other option but to go to a specialized center either in the south or the west of The Netherlands. Permission to build a new epilepsy center was constrained by an order of the government not to increase the total number of beds in the specialized centers for epilepsy. In consultation with the three centers in Breda, Heeze, and Heemstede, it was decided that the Instituut voor Epilepsiebestrijding would transfer some of its capacity to Zwolle. This new center opened in October 1999. The name of the organization now responsible for the centers in Heemstede and Zwolle and nine outpatient clinics in a circle of strategic towns north of the Rhine was changed into Stichting Epilepsie Instellingen Nederland (SEIN). Presently, the intramural capacity of the centers in Heemstede and Zwolle is 600 beds, of which 440 are designated for residential (long-term) care, while facilities in the nine consultation centers North of the Rhine care for 9,278 outpatients.

Only relatively recently has Dutch society ceased to be subdivided along ecclesiastical lines. It is therefore not surprising that, following the successful establishment of a Protestant Christian institution, a secular society against falling sickness was established in 1902, and in 1920, a home for Catholic men with epilepsy. The former had as one of its leaders Dr. L. J. J. Muskens, cofounder of the International League Against Epilepsy (ILAE). In 1902, this group it opened a hospital for people with epilepsy in Amsterdam. The catholic center was established in the South in Geldrop. It was not until the 1960s (although the initiative dates from 1953), that a residential center for women was established adjacent to the home for Catholic men. This new center also provided advanced intramural medical care to both men and women. These two organizations gradually merged into the Epilepsy Center Kempenhaeghe in Heeze, near Geldrop; it has an intramural capacity of 525 beds and also outpatient departments in five different cities that care for 3,869 outpatients.

Several interesting phenomena relating to the social forces that affect health provision can be observed in the development of epilepsy services in The Netherlands. The Hospital Muskens built in Amsterdam near the Municipal University Hospital was closed in 1986. Factors contributing to its closure were the impossibility of expanding the building, because costs of building in the center of Amsterdam were prohibitive. So, when specialized centers for epilepsy began to engage in rehabilitation and provide sheltered workshops for their patients, Amsterdam had to default. Furthermore, the neighboring University Hospital was very much in need of referrals of other patients with chronic illnesses in addition to epilepsy. Willy-nilly, these referrals were accepted, and thus the advantages of a specialized center for epilepsy were lost.

Another interesting development was that, as late as the 1960s, a new, small Catholic epilepsy center comprising 132 beds, named Hans Berger Kliniek, was started in Breda. This facility presently also cares for 2,000 patients via outpatient departments in four cities. This center in Breda was started mainly because of the rapid emptying of a large sanatorium for tuberculosis patients in that city. The decreased need for care of patients with respiratory disorders was compensated for by establishing departments of epileptology, cardiac surgery, and child psychiatry. However, at the end of the 20th century, it became government policy to merge smaller hospitals with only a few specialties with larger, more general hospitals. Although the special center for epilepsy remained an independent foundation, it had to move its facilities to a general hospital, the AMPHIA in Breda. Its intramural capacity was reduced to 56 beds, with an additional four beds for day care. To achieve a situation similar to the SEIN-managed centers in Heemstede and Zwolle, a merger between Kempenhaeghe and the Hans Berger Kliniek has recently been established.

Although hospitals had to merge in order to increase in size, residential facilities for the long-term care of persons with epilepsy, psychiatric patients, or the mentally handicapped were stimulated to reduce their size. In the Heemstede epilepsy center, but especially in the Southern epilepsy center Kempenhaeghe, developments started to change chronic intramural care. Whereas in the past all facilities were on the campus of the epilepsy centers, this changed to smaller community houses in the surrounding communities, with services provided by the epilepsy center.

In yet another development, the university hospital of Maastricht in the south of The Netherlands has chosen epilepsy as one of its priorities for patient care and research and is cooperating with the epilepsy center Kempenhaeghe. Negotiations aiming at a similar type of cooperation are ongoing between SEIN and the Christian University Hospital in Amsterdam. In both university hospitals, units for epilepsy surgery are in development. Epilepsy surgery is also continuing in the university hospital of Utrecht, where modern epilepsy surgery was initiated during the 1970s.

Although beyond the scope of this chapter to detail, all Special Centers for Epilepsy provide, on request, incidental and regular consultations in homes and institutions for mentally handicapped patients. Among the persons cared for in these establishments, 20% to 30% may have epilepsy, with a rather high prevalence of refractory epilepsies: Among 172 patients with epilepsy on optimal treatment in a home for the mentally retarded, 61 (35%) were seizure-free, whereas at the other extreme, 23 (13%) had a seizure frequency between several per week and daily.[5]

In summary, the three specialized epilepsy centers located in Heemstede/Zwolle, Heeze/Breda, and their outpatient clinics in Heemstede, Amsterdam, Leeuwarden, Groningen, Zwolle, Enschede, Nijmegen, Heeze, Sittard, Arnhem, Utrecht, Breda, Terneuzen, Goes, Rotterdam, and The Hague, make specialized care for people with refractory epilepsy available in

16 areas, each serving approximately 1 million of the 16 million inhabitants of The Netherlands.

Mechanisms of Referral

The specialized centers for epilepsy in The Netherlands must be viewed against the background of health services in that country. In The Netherlands, 16.3 million people inhabit an area of 34,000 square kilometers. One general practitioner is available for every 2,350 inhabitants, and one neurologist for every 22,500 inhabitants. There are 3,015,704 children younger than 14 years old and, for many of them, specialist care is provided by pediatricians. One pediatrician is available for every 2,500 children below the age of 14.

In 2006, a new Health Insurance Act was implemented. Its impact on care for persons with epilepsy can not yet be fully estimated. Under this Act, all Dutch citizens, irrespective of income, must buy a basic package of health insurance. The government has established a list of conditions that must be covered by the basic package. The costs may vary according to the contracts that insurance companies establish with health care providers on the one hand and their clients on the other. The cost will not depend on the age or health of the client. This is made possible through a compensation fund that will reimburse those insurance companies with a higher-than-average proportion of high-risk clients who present extra costs. Once a year, the client can reconsider whether to stay with the same insurance company or switch to one that he expects will better suit his needs. The new Health Insurance Act stipulates that a Netherlands Care Authority be established that will supervise proper execution of the law; it also is mandated with stimulating competition and, where no competition is possible, setting budgets and tariffs for hospitals. (The Netherlands Care Authority absorbs and replaces the present Board for Statutory Control of Health Care Insurances as well as the Board for Health Care Tariffs.)

Many health care items previously covered under the compulsory insurance scheme for low-income people (<31,000 Euro annual income, or those on welfare) are now excluded from basic coverage. Additional insurance to cover these items can be purchased, but is not obligatory.

Consultation with a general practitioner by a person registered as his patient is free of charge. Concomitantly, how insurance companies pay for other services rendered to their clients has drastically changed. A system of diagnosis-treatment combinations has been developed, with input from all parties concerned. Cost elements known to be associated with a particular diagnosis—for example complex partial seizures or appendicitis—are averaged and shown on the bill whether or not all these elements have been utilized for the particular patient named on the bill, such as anesthesia or surgery. How these changes will affect services for people with epilepsy is difficult to predict. An important problem still under debate concerns financing for research needed to optimize diagnosis and treatment. Although special centers for epilepsy in The Netherlands do not have academic hospital status, in the past, the Heemstede center did have permission to include the cost of research personnel in its fees, a practice that has not yet been approved under the new regulations.

An increasing number of neurologists are employed by the hospitals where they practice. Their income is independent of the number of patients seen, or the number of interventions offered. Others are in private practice and have contracts with hospitals for the facilities provided. There are 725 registered neurologists in The Netherlands. There are 90 general hospitals, 85 psychiatric hospitals, ten hospitals for special categories (e.g., three for epilepsy), and ten University hospitals (in all, 22 teaching hospitals). The problem with epilepsy care and the development of a nationwide network of outpatient clinics manned by the staff of specialized centers for epilepsy is rooted in the incompatibility of the needs of teaching hospitals and the quality of care requested by patients with long-term illnesses such as epilepsy. In particular, long-term patients become discouraged by the frequent rotation of the junior physicians directly responsible for their care. In The Netherlands, specialized centers for epilepsy started as hospices at the end of the 19th and beginning of the 20th century. Although located in a semi-rural area, SEIN (Meer en Bosch-de Cruquiushoeve) is surrounded by four universities at distances of 20, 25, 35, and 60 kilometers. It was therefore easy for its staff to keep up with the latest scientific developments and often to take the lead in research. Because epilepsy patients could obtain high-quality care without having to cope with the continuous turnover of physicians inherent in a teaching hospital, they preferred to avoid the university hospitals. As a consequence, interest in epilepsy at the universities slackened, with subsequent deleterious effects on the ability of their graduates to treat patients with chronic epilepsy. In recent years, closer ties have developed between the special centers and university hospitals, Consultative collaboration aimed at the education of neurologic residents has been established between SEIN and the university hospitals of Utrecht, Rotterdam, Amsterdam, and Groningen, and between Kempenhaeghe and the Universities of Nymegen and Maastricht. Both centers offer a short internship to neurologists in training. Furthermore, SEIN has links with the Free University of Amsterdam and is considering moving its short-term care facilities and part of its laboratories to a site adjacent to the Hospital of this University. Kempenhaeghe has established a link with Maastricht University.

The insurance companies cooperated in the development of a nationwide network for tertiary epilepsy care by permitting referrals from neurologists to epileptologists, even though epileptology is not a registered specialty. This was facilitated by the inclusion of epilepsy centers as a special category of hospitals in the law covering hospital provisions. As mentioned, the intramural capacity is presently 1,337 beds, spread over four locations. Furthermore, a network of 17 outpatient clinics is maintained by the specialized centers and cares for 12,300 of the estimated 96,000 people with active epilepsy in The Netherlands.

The epilepsy centers once employed neuropsychiatrists. From the early 1970s on, specialization as a neuropsychiatrist was no longer possible; only the constituent specializations of neurology and psychiatry were thenceforth registered. The medical staff of the epilepsy centers was subsequently selected from neurologists and supplemented with clinical psychologists.

In The Netherlands, epilepsy centers are in fact autonomous organizations, with sometimes divergent interests. However, through the national epilepsy organizations such as the Dutch branch of the ILAE and an umbrella organization (the National Epilepsy Fund), they keep in close contact and work to keep their policies—and, in particular, their relations with the government—consistent.

Funding

The possibility of achieving one's objectives is determined by the means available. A specialized center, like all other health care facilities in The Netherlands, is financed by the fees the insurance companies pay for the services rendered. Because the health insurance premium has a pronounced influence on the national economy, tariffs and the services considered acceptable were negotiated on a national level by the Central

Bureau Tariffs Health Care. The state, insurance companies, and health care providers participated in these negotiations. Only after intensive negotiations were most, but not all, financial consequences of the objectives of Special Centers for Epilepsy accepted. In particular, the provision of psychotherapy on an outpatient basis was rejected on the assumption that other existing institutions could serve that purpose. Unfortunately, a lack of familiarity with specific, epilepsy-related factors has repeatedly caused attempts to assist patients along these lines to go wrong. The full impact of The Netherlands Care Authority cannot yet be estimated.

Not all costs for rehabilitation are paid for by health insurance. To reintegrate people with epilepsy who, because of seizures (and often overprotection) have lost or never acquired job experience, the Instituut voor Epilepsiebestrijding was permitted to open a sheltered workshop with the financial assistance of the Ministry of Social Affairs. This was also motivated by the reluctance of the regular regional sheltered workshops to accept people with epilepsy. Because the cost of maintenance of sheltered workshops was increasingly a problem for the government, negotiations were started during the 1990s to terminate the special arrangement with epilepsy centers and refer patients for rehabilitation to the regional sheltered workshops. Interestingly, a few years after this had been achieved, the regional workshops moved from Haarlem to a location immediately adjacent to the campus of the SEIN in Heemstede, which reflects a further removal of the discrimination between persons with epilepsy and persons with other handicaps.

Similarly, the Ministry of Education finances schools on the campuses of the epilepsy centers. Although, according to their charter, the schools were originally established for "children with epilepsy," in the 1980s this was changed to "special schools for the multiply handicapped." This implies that, in addition to epilepsy, another handicap should be present—most often mental retardation. Hospitalized children with normal intelligence and no physical handicap may attend the schools, but the costs are not reimbursed, and therefore the number of children in this category remains small. The Ministry of Education does finance outreach by staff of the schools at the epilepsy centers to other schools, which receive advice on how to manage pupils with epilepsy.

Neurosurgery for Epilepsy

In the budget of the Instituut voor Epilepsiebestrijding, a small amount had been made available for research by the Central Bureau Tariffs Health Care. Fortunately, the Christian Society, which formally is no longer connected with the epilepsy centers, does provide financial support for research and development and for recreational facilities for long-term patients. In the period from 1989 to 1993, a 3-year project was cofunded with the government to establish the optimal protocol for functional neurosurgery for patients with epilepsy. Functional neurosurgery for epilepsy in The Netherlands started in 1971 as a collaborative undertaking of the University Hospital at Utrecht and the Instituut voor Epilepsiebestrijding, the latter being responsible for the presurgical analysis, and in particular the monitoring of patients in whom intracranial electrodes have been placed for detailed analysis. Before any final decision to operate, a counsel, The Dutch Epilepsy Surgery Program, in which all major groups concerned with patients with intractable epilepsy participate, reviews the findings. As of 2005, patients go for presurgical analysis to Heeze or Heemstede. After receiving a verdict from the Dutch Epilepsy Surgery Program, epilepsy surgery still mainly takes place in Utrecht, but now is also being performed at the Free University in Amsterdam and at Maastricht University.

The Christian Society has also funded a project to investigate whether the provision of long-term monitoring facilities on an outpatient basis, including monitoring at home, could effectively make intramural observation redundant. Based on its findings, diagnostic and counseling services at home have been greatly expanded. However, during the late 1990s, the Christian Society has also spent some of its funds assisting SEIN to reorganize, thus reducing its ability to support research.

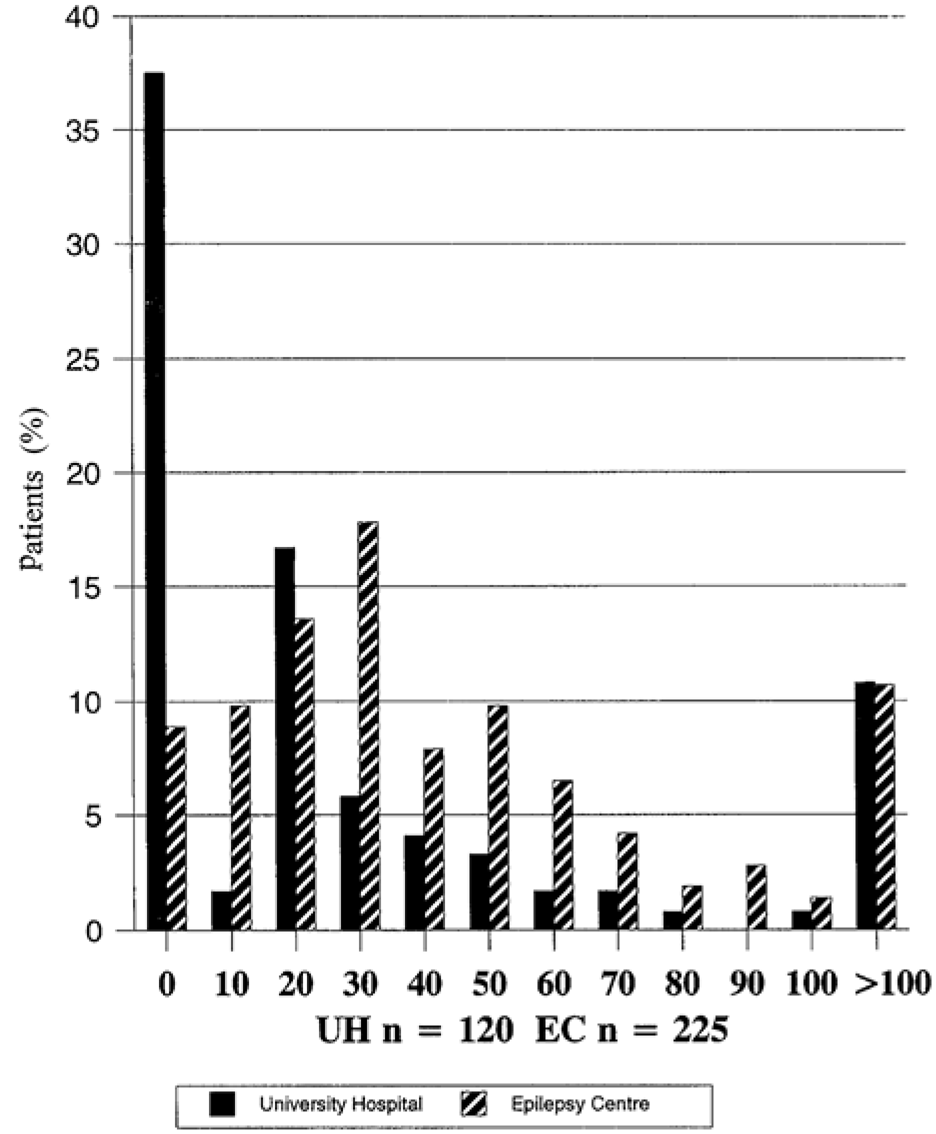
On a national level, research grants for epilepsy are provided annually by the National Epilepsy Fund, which derives its income from charity and legacies. These grants are, however, not restricted for use by the specialized centers. The Christian Society initiated providing monies for an endowed chair in epileptology, which, after prolonged deliberations by the departments of neurology of the Dutch universities, was finally established in 1984, at the University of Nymegen.

After the retirement of the first chair-holder in 2000, this chair was moved to the Free University of Amsterdam. Nij-megen appointed at its own expense a new professor of epileptology; however, this chair will not be continued after his retirement, which is due in 2006. In recent years, the National Epilepsy Fund has established two additional chairs for epileptology at the Universities of Utrecht and Maastricht.

Tertiary Versus Secondary Care

Two articles[2,7] have been published by the Nymegen department of epileptology comparing treatment and outcome in a secondary and tertiary epilepsy care outpatient facility. To compare the two facilities, several characteristics were considered that might influence the course of epilepsy. These were age, gender, type of seizure, duration of epilepsy type, and strength of medication. The strength of medication was determined by the ratio of the prescribed daily dose to the defined daily dose (PDD/DDD ratio). The DDD is the assumed average recommended adult dose for the major indication for prescribing the drug, and it is the unit of comparison recommended by the World Health Organization (WHO) Drug Utilization Research Group.[5] The PDD is the dose actually prescribed for the individual patient. Also, the following indexes have been determined on a clinimetric basis:

- Index of Seizures (IS), indicating seizure type and frequency
- Seizure Activity Index (SA), which modifies the IS to include seizure severity
- Neurotoxicity Index (NTX)
- Systemic Toxicity Index (STX)
- Composite Index of Impairments (CII), reflecting all treatment-related impairments, that is, paroxysmal impairments (seizures) caused by the disorder being treated and drug-induced impairments or adverse effects of treatment (CII = SA + NTX + STX)



Univ	37.5	1.7	16.7	5.8	4.1	3.3	1.7	1.7	0.8	0	0.8	10.8
Epil	8.9	9.8	13.6	17.8	7.9	9.8	6.5	4.2	1.9	2.8	1.4	10.7

FIGURE 1. Distribution of the CII (abscissa) for the UH (n = 120) and the EC (n = 225). *White bars*, university clinic; *shaded bars*, epilepsy center.

These indexes have been extensively described in previous publications.[1,6] Parameters of other effects, such as psychosocial and occupational impacts caused by disabilities and handicaps, were not included.

In the first part of these studies, patients were examined who regularly visited the outpatient departments of the University Hospital in Nymegen (UH), or the outpatient departments of the Instituut voor Epilepsiebestrijding in Utrecht and

P.2955

Heemstede (EC), literally cross-secting The Netherlands. Selection criteria were as follows:

- Patient files should be well documented, including an accurate history and adequate neurophysiologic data for a firm diagnosis. The patient should have well-defined types of seizures according to the International Classification of the ILAE.
- No factors should be present that might be considered to complicate the evaluation process. These factors included progressive brain disorders, obvious noncompliance in drug use or seizure registration,

pseudoseizures, and severe mental retardation.

When the data of 120 patients from the UH and 225 from the EC were analyzed, it became clear that there was no significant difference in sex or age between the two groups. However, a significant difference was noted in duration of epilepsy. The median duration of epilepsy was 20 years for the EC group and 10 years for the UH group ($p = 0.0001$). The groups were also different with respect to seizure types. At the UH, a higher percentage of patients had primarily generalized tonic–clonic seizures (45.8% vs. 11.6% for the EC; $p < 0.001$), whereas at the EC, a higher percentage of patients had secondarily generalized tonic–clonic seizures, although the difference was not significantly different (16.4% vs. 9.2% for the UH; $p = .08$). No difference in partial seizures was noted between the EC and the UH. The patients of the EC had a greater diversity of seizure types. Apart from the above-mentioned types, myoclonic, tonic, and atonic seizures were seen in this group, although mostly in combination with other seizure types. Patients with more than one seizure type were more numerous at the EC than at the UH (45.4% vs. 15.1%; $p < 0.001$).

Treatment

The groups were clearly treated differently. More patients were treated with monotherapy at the UH (62.5% vs. 28.0% at the EC; $p < 0.001$). At both centers, if monotherapy was used, carbamazepine was the preferred drug. The average number of antiepileptic drugs (AEDs) used per patient was 2.0 for the EC and 1.4 for the UH. There was a significant

P.2956

difference in the PDD/DDD ratio between the two centers. The median PDD/DDD ratio was 1.7 for the EC and 0.8 for the UH ($p = 0.0001$).

Composite Index of Impairment

The CII was significantly higher at the EC ($p = 0.0001$). At the UH, 37.5% of the patients had complete seizure control and no drug side effects, which resulted in a CII score of 0. This was the case for only 8.9% of patients at the EC ($p < 0.001$). For the group of patients with a CII score of >100, no significant difference was found between the two centers. At the EC, 10.7% had a CII score of >100; at the UH, this was 10.8% ($p = 1.00$) (Fig. 1).

At both centers, no clear correlation was observed between the duration of epilepsy and the outcome of any of the indexes (Spearman correlation coefficient was 0.06 or lower). Also, no significant correlation was seen between the PDD/DDD ratio and the toxicity ratings (Spearman correlation coefficient was 0.49 or lower).

Table 1 Distribution of seizure types (32 matched pairs)

Seizure type	Percentage of patients (*n*)
CPS	28.1 (9)
SGTCS	15.6 (5)
PGTCS	34.4 (11)
SPS + SGTCS	3.1 (1)
CPS + SGTCS	18.8 (6)

CPS, complex partial seizure; SGTCS, secondarily generalized tonic–clonic seizure; PGTCS, primarily generalized tonic–clonic seizure; SPS, simple partial seizure.

Table 2 Duration of epilepsy (32 matched pairs)

Duration of epilepsy	Percentage of patients (*n*)
1–5 y	25.0 (8)
6–10 y	43.8 (14)
11–15 y	18.8 (6)
16–20 y	12.5 (4)

Matched Groups of Patients from Secondary and Tertiary Care Facilities

The first study answered in the affirmative that secondary and tertiary referral centers care for different categories of patients. However, there was also clearly an overlap (Fig. 1). It was therefore decided to re-examine the data of two groups from the UH and the EC matched for seizure type and duration of epilepsy. Only 32 pairs could be collected. The seizure types and duration of epilepsy are shown in Tables 1 and 2.

Although the groups were matched for duration of epilepsy, this does not necessarily bring about a match in age groups. However, concerning age distribution, a significant difference was found only in the age group of 15 to 19 years, with six patients (18.8%) at the EC and one patient (3.1%) at the UH. No great differences were observed in the other age groups.

Composite Index of Impairments in Matched Groups

Notwithstanding matching, the two groups were significantly different with respect to the CII ($p = 0.014$). Far more patients at the UH than at the EC had a CII score of 0 (45.9% vs. 9.4%; $p = 0.001$), indicating that more patients were seizure-free and had no drug side effects. On the other hand, 18.8% of the patients at the UH had a CII score of >100; this was the case for only 9.4% of the patients at the EC. This difference, however, was not statistically significant (Fig. 2).

Seizure Activity Index and Toxicity Ratings in Matched Groups

For the SA, no significant difference was observed between the two centers ($p = 0.060$). More patients at the UH than at the EC had an SA score of 0, but twice as many patients at the UH as at the EC had an SA score of >100 (18.8% vs. 9.4%), although this by itself was not statistically significant.

The NTX rating was significantly lower for the patients at the UH than at the EC ($p = 0.003$). At the UH, 71.9% of the patients had an NTX of 0, as opposed to 21.9% at the EC.

The STX rating was likewise significantly lower for the patients at the UH than at the EC ($p = 0.016$). At the EC, 18.1% of the patients had an STX >0, as opposed to only 6.2% at the UH.

Treatment Differences of Matched Groups

Although there were some differences in mode of pharmacotherapy, none reached statistical significance. As for the individual drugs prescribed, it was noticed that the drugs ethosuximide and diazepam were prescribed only at the UH. Clobazam and vigabatrin were prescribed only at the EC (Table 3).

At the UH, more patients were treated with monotherapy (56.2%) than at the EC (40.6%), although this difference was not statistically significant. When the patients were treated with monotherapy, carbamazepine was most frequently prescribed at the EC (53.8% of the patients on monotherapy). At the UH, carbamazepine and valproate were prescribed as monotherapy for an equal number of patients (44.4%). At the EC, 56.2% of the patients were treated with polytherapy and, at the UH, this value was 37.5%. This difference was not statistically significant.

The average number of AEDs used per patient was 1.8 for the EC and 1.4 for the UH.

The difference in the PDD/DDD ratio (EC, 0.80; UH, 0.90) between the two centers was statistically insignificant, but only marginally so.

Psychogenic pseudo-epileptic (non-epileptic) seizures

Paradoxically, the diagnosis and treatment of persons with psychogenic nonepileptic seizures is a service that appears best provided by special centers for epilepsy and not in a psychiatric setting. About 30% of the patients referred to a specialized epilepsy center have nonepileptic seizures in addition to epileptic seizures, and about 10% have nonepileptic seizures

P.2957

P.2958

only. Within the centers, specialized expert teams are available for the diagnosis, treatment, and referral of these patients.

PDD/DDD, prescribed daily dose/defined daily dose.

Summary and Conclusions

Through a sometimes obscure process of growth, what began as a local appeal to take pity on people in the unenviable position of being afflicted with epilepsy has expanded into a legally constituted tertiary care system covering The Netherlands. This system cares for 14% of the patients with epilepsy in The Netherlands, presumably those with seizures resistant to therapy or those unable to cope unaided with the psychic or social aftermath of their illness. However, as the attitude of society toward people with disorders changes, and as the need to analyze the epilepsies through careful observation by trained personnel is gradually replaced by technical advances, secondary (specialist) care may eventually make tertiary care redundant. As a first step in analyzing the situation during the 1980s, the care provided by a university hospital and an epilepsy center has been studied. Overall, clear differences were observed in the patient groups. The duration of epilepsy of patients from the epilepsy center was longer, and they were more likely to have several seizure types and a higher composite index of impairment.

No distinct differences were found in the treatment policies between the secondary epilepsy care center and the tertiary epilepsy care center after patients were matched according to seizure type and duration of epilepsy. Nonetheless, distinct differences in treatment outcome were noted, as assessed by the CII. The combination of "same treatment but different outcome" agreed with the expected prevalence of more difficult-to-treat patients in a tertiary referral care center. The matching variables of "seizure type" and "duration of epilepsy" were thought to reflect the severity of epilepsy, but selecting patients by matching for seizure type and duration of epilepsy as evidence of similar severity is clearly insufficient to obtain completely comparable groups. Other factors aside from seizure type and duration of epilepsy are apparently important to the outcome of treatment of epilepsy. It will be a challenge to future researchers to find out which factors make the difference. The answer to that question will help determine whether tertiary epilepsy care will continue to be needed in the future, and suggest the appropriate equipment of such service.

During the 1980s, development started toward implementing information technology in patient care. Kempenhaeghe developed a Medical Information System (MIS) that supports patient care and administration, and this MIS system is now implemented in all epilepsy centers. This will eventually lead to a electronic patient file.

Unfortunately, although it was hoped that the electronic recording of patient's data would facilitate future comparisons between type of services and outcome using clinimetric indices, developments along those lines are still unsatisfactory.

Chapter 307

Economic Aspects of Epilepsy and Antiepileptic Treatment

Demetris K. Pillas

Caroline E. Selai

John T. Langfitt

Marc R. Nuwer

Introduction

Significance of Economic Evaluation of Epilepsy and Its Treatment Modalities

Over the last 15 years there has been a dramatic increase in the therapeutic options available for the treatment of epilepsy. Epilepsy can now be treated with 13 different U.S. Food and Drug Administration (FDA)-approved antiepileptic drugs (AEDs);[37] surgery has now been established as an effective treatment for reducing or eliminating seizures in patients with medically intractable epilepsy.[61] Furthermore, vagal nerve stimulation (VNS), which includes the first implantable device with antiseizure properties, is now considered a safe therapeutic procedure, with clinically useful and sustained benefits.[53]

Many of these developments for treating epilepsy have a higher initial cost than the older treatments they replace. On the other hand, they may offer long-term savings if an increasing number of patients undergoing the new treatments become seizure-free. Therefore, it has become necessary to evaluate the economic burden of health care alternatives as well as their therapeutic efficacy. It is no longer sufficient merely to demonstrate a satisfactory degree of efficacy for a particular treatment if the cost of such therapy would cause the health care system to deny an equivalently efficacious yet cheaper remedy to a wider group of the target population.[10]

In addition, with the growing emphasis on cost containment and managed care in health care delivery, evaluations of the cost of epilepsy and its treatment are increasingly required by government agencies, advocacy groups, and health care payers concerned with the allocation of research and treatment resources among disease conditions.

In such a context, it is of interest to review critically the recently published literature on the economic aspects of epilepsy and its treatment in order to:

- Compare the variance and distribution of costs between and within various countries
- Identify and discuss methodologic issues and limitations in calculating the cost of epilepsy
- Evaluate the cost-effectiveness of the different treatments available

In this chapter, we explore these issues by systematically reviewing all the recent epilepsy-related cost-evaluation studies, analyzing their results, comparing their findings and, discussing their implications.

Types of Economics Studies

We identified studies via Medline and hand-searching English-language, epilepsy-related, and health economics journals. To have been included, studies had to have (a) been published between January 1998 and January 2006, (b) followed one of the standard methods of health economics evaluation (cost of illness [COI], cost-minimization analysis [CMA], cost-effectiveness analysis [CEA], cost-benefit analysis [CBA], cost-utility analysis [CUA]) (Table 1), and (c) aimed to provide estimations on the cost of epilepsy alone, not including comorbidities.

We identified 31 studies: 17 COI studies,[1,3,8,9,11,17,19,21,23,24,31,34,35,41,45,63,64] four studies using a CMA,[29,30,48,58] 10 studies performing a CEA,[16,32,40,42,47,49,55,56,59,65] two studies using a CBA,[12,13] and five studies performing a CUA.[18,25,44,50,51] All studies were classified based on how the primary outcome was reported.

The general, transnational comparative, approach presented here takes into account not only the differences in the studies' methods, but the epidemiologic features (incidence and prevalence of epilepsy), stage of economic development, and organization of health care sector in the countries studied.

Table 1 Types of economic evaluation

Type of study	Description
Cost-of-illness studies (COI)	To itemize, value, and sum the costs of a particular problem with the aim of giving an idea of its economic burden
Cost-minimization analysis (CMA)	If the interventions have the same consequences, the economic analysis can concentrate on inputs only. This analysis is concerned with the identification of the intervention with the lowest possible costs
Cost-effectiveness analysis (CEA)	If the outcome of interest is the same in two programs, but they have different success in achieving the outcome
Cost-benefit analysis (CBA)	If neither the consequences nor the outcomes of two programs are the same; cost-benefit analysis aims to compare all social costs and consequences across different interventions or against a do-nothing option
Cost-utility analysis (CUA)	This analysis is preferred by analysts who have reservations about valuing benefits in dollar terms; *utility* refers to the preferences individuals or society may have for any particular set of health outcomes—this approach incorporates quality of life adjustments to treatment outcomes

Transnational Comparison of Cost-of-illness Studies

COI studies enumerate all costs attributable to a disease to arrive at a total cost of that disease. A COI study can follow a variety of perspectives.[2,5,7,14,28,33,36,38] From an epidemiologic point of view, COI studies can be conducted using either a prevalence- or incidence-based approach, depending on whether an annual or longitudinal horizon is adopted. Also, COI evaluations vary in their study design (i.e., prospective or retrospective study design) and method of data collection (e.g., questionnaire, medical database, case report). The sampling strategy is also a significant parameter when evaluating the cost of a disease. This ranges from collecting data from a general practitioner or a hospital, to estimating costs based on administrative databases or national samples. COI studies also vary as to whether the direct or indirect costs of a disease are calculated. *Direct costs* are the monetary value of resources consumed in the prevention, treatment, or rehabilitation of people with the disorder. *Indirect costs* represent the loss of productivity to society due to a disease and its treatment.[7,14]

To achieve a comprehensive transnational comparison of all recent COI studies, these study perspectives were taken into consideration when analyzing, categorizing, and tabulating the studies and their results. The results appear in Tables, 2, 3, and 4.

Comparison of COI Prevalence-based Studies

Table 2 includes only prevalence-based studies, stating the country of the study, data source, method of data collection, direct or indirect costs estimated by the study, and any additional general information in the study that is of significance.

P.2960

Comparison of COI Incidence-based Studies

Incidence-based studies are shown in Table 3, with an emphasis on the evolution of costs over time. Only the first 4 years after onset were included, because most studies estimated costs up to the fourth year.

Direct Cost Distribution

Table 4 depicts the breakdown of the direct costs of epilepsy treatment. Three categories are included:

- Hospital costs: In- and outpatient visits, admissions, emergency room visits, and emergency transportation (ambulance) costs
- Drug costs: Prescribed antiepileptic drugs (AEDs), as well as costs attributable to adverse drug reactions from the AEDs
- Other costs: Diagnostic procedures, such as laboratory tests, electroencephalography, computed tomography, and magnetic resonance imaging scans as well as medical consultations that are part of the diagnostic procedures.

Six studies that did not categorize direct costs in this way were excluded from the table.[19,23,34,35,41,63]

Cost-minimization Analysis

CMA provides the simplest economic evaluation when the alternate treatments, in this case AEDs, have equivalent clinical efficacy. To be equivalent, the comparators should be of the same efficacy in all patients, under all conditions, with similar risks of adverse events.[10]

Table 5 displays study duration, the configuration of the treatment pathways followed, and the nature of the direct costs included during the cost estimation procedure for four CMA studies, along with the mean cost per patient for each of the four AEDs that were examined.

Cost-effectiveness Analysis

CEA assesses how efficiently a specific health intervention influences health, compared with the next best alternative. Thus, CEAs specifically account for the costs to health of a disease and treatment that are typically excluded from COI studies (i.e., premature mortality, morbidity, disability, as well as pain and suffering).[36]

Tables 6 and 7 include ten CEA studies. Table 6 focuses on CEA studies on AEDs; Table 7 presents CEA studies of alternative treatments which, in this case, only incorporate surgical treatment of epilepsy. The information included relates to the AEDs/treatments compared, patient population, cost and outcome measures, as well as the general findings/results of each specific study.

Cost-benefit Analysis

CBA primarily attempts to reduce outcome measures to monetary terms. Hence, when costs and benefits are expressed in the same unit of measurement, it is possible to judge whether a specific therapeutic modality is desirable from a societal viewpoint.[26] The two published CBA studies were conducted by the same author. Therefore, a tabulation of the CBA studies is not presented.

Table 2 Main characteristics of cost-of-illness studies: prevalence-based studies

Country	Data sources	Data collection		Annual cost per patient (US$)		Comments (costs in US$)	Ref.
				Direct	Indirect		
U.S.	National sample	Retrospective	Database	1,758	—	2,053 for children	24
U.S.	Multiple MCOs	Retrospective	Database	3,007	—	Adults taking CBZ formulation (n = 1,767)	22
U.S.	MCO and medical center	Retrospective	Database	935	5,994	Total cost from 1,031–12,612 in different severity groups	8
U.S.	MCO	Retrospective	Database	1,575/3,449	—	1,575 (epilepsy-attributable cost) and 3,449 (case-control estimate)	19
U.K.	GP	Retrospective	Provider and population surveys	3,065	—	866–6,855 depending on seizure frequency	31
Italy	EC	Prospective	Questionnaire	1,098	—	547–3,530 in different prognostic categories (aged 18+)	3

Italy	EC	Prospective	Provider and population surveys	1,055	—	371–3,551 in different severity groups	63
Italy	UH, hospital and outpatient service	Prospective	Case report	1,590	—	760–2,941 in different severity groups (childhood epilepsy)	23
Italy	Referral centers	Retrospective	Case report	1,588	224	Total cost from 1,569 for adults to 2,412 for children	11
Italy	Referral centers	Retrospective	Questionnaire	1,290		411–2,941 in different severity groups	21
The Netherlands	GP, UH and EC	Prospective	Questionnaire and cost diary	2,444	—	808 cost at GP, 2,790 cost at UH, and 4,298 cost at EC	34
India	EC	Retrospective	Case report	55	128	117 cost of annual productivity loss	35
India	Medical centers	Retrospective	Questionnaire	105	283	Cost of travel included in direct cost	64
Hong Kong	EC	Retrospective	Database	433	582	Costs derived from dividing the 4-year total cost by 4	41
Burundi	National sample	Retrospective	Questionnaire	1.8	10.5	12 (epileptics), 7.7 (control group)	45
Oman	UH	Prospective	Case report	1,524	—	Only patients aged 13 and over	1

EC, epilepsy center; GP, general practitioner (physician); MCO, managed care organization; UH: University hospital.

Cost-utility Analysis

In CUA, an attempt is made to directly assess the impact of the treatments on patient well being by using a utility indicator. This approach shifts the focus from clinical indicators to the patients themselves and assesses the treatment effects, via various parameters, to determine the quality of life (QoL).[39] Although an increasing number of published studies focus on the QoL of epileptic patients, only five studies, referring to AED treatment of epilepsy, can be considered to be cost-utility studies.[18,25,44,50,51]

Table 3 Main characteristics of cost-of-illness studies: incidence-based studies

Country	Data sources	Data collection		Annual cost (US$) per patient (direct cost)				Comments (costs US$)	Ref.
				Year 1	Year 2	Year 3	Year 4		
U.S.	Medical center plus HMO	Retrospective	Database	3,813	848	569	496	3,749 to 7,671 depending on seizure frequency (in 4 years)	9
U.S.	National sample	Retrospective	Database	1,317	892	892	892	Top-down analysis	24
U.S.	Expert panel	Retrospective	Questionnaire	6,506	2,282	2,282	2,282	Bottom-up analysis	24
France	Specialists	Prospective	Cohort	2,379	626	—	—	Second year costs were more sensitive to seizure frequency	17

Conversion of the Results of Cost-of-epilepsy Studies

In transnational comparisons of health economics evaluations, several monetary issues must be considered, such as fluctuating exchange rates and the rate of inflation.

For purposes of comparison, the estimates from different countries were converted into 2003 US$. The rate of inflation was calculated using the Consumer Price Index. The exchange rate used was the mean exchange rate for the US$ for the year 2003.

Table 4 Distribution of direct costs

Country	Hospital costs (%)	Drug costs costs (%)	Others (%)	Ref.

Oman	68	23	9	1

Findings Among Economics Studies

Cost-of-illness Studies

The literature identified 17 studies performing a COI analysis. Tables 2, 3, and 4 show the results in US$ at the 2003 exchange

rate. A total of 15 of these studies were included in Table 2, as prevalence-based studies. The vast majority of the studies were conducted in the United States or Europe (three in the United States, one in the United Kingdom, five in Italy, and one in The Netherlands). Only four other countries conducted COI studies (India, Hong Kong, Burundi, and Oman). Table 3 shows that only three studies followed an incidence-based approach (one of which calculated the costs in two different ways). Two of these were based in the United States, and the other in France.

Prevalence Based-studies

Direct Costs of Epilepsy.

The estimated annual direct costs of epilepsy vary significantly from study to study and range from US$1.8 to US$3,449 (Table 2). However, a closer look reveals that a smaller disparity of costs tends to exist if they are grouped based on the degree of development of the country in which the studies were conducted. Estimated direct costs vary from US$935 to US$3,449 in the United States, US$3,065 in the United Kingdom, and US$1,055 to US$1,590 in Italy. In the less developed countries, the costs of epilepsy range from US$55 to US$105 in India, to US$1.8 in Burundi (Table 2). Nevertheless, the variation between the costs is large. Heaney et al. found that prices for medical services and AEDs vary widely even between developed countries.[27] In a comparison among eight economically developed European countries, similar medical services were found to vary by as much as 24 times, whereas the prices of similar AEDs varied up to 4.4 times. Previous reviews have speculated on the difficulty of comparing results from COI studies.[2,5,7,14,28,33,36,38] Methodologic issues give rise to such disparities in cost-of-epilepsy estimations. Perhaps future studies could normalize or reduce international disparities; for example, they might be normalized using per capita income, gross domestic product, or some other standard economic indicator.

Indirect Costs of Epilepsy.

Most cost studies in epilepsy have focused on direct medical costs because researchers have easier access to records of medical care. Records of nonmedical care are less centralized, and formal records of time costs, which are necessary for calculating indirect costs, rarely exist.[27] As a consequence, out of the 17 COI studies reviewed in this chapter, only six have estimated the indirect costs incurred by a specific society. Out of these six studies, only one found the indirect costs to be less than the direct costs.[11] This study calculated only productivity losses because of hospital visits and hospitalization to derive direct costs. The other studies reached a consensus in finding indirect costs considerably greater than direct costs. In general, four of the six studies found indirect costs to be from two to six times that of the direct costs (Table 2). Once again, the discrepancy between the findings is largely due to differences in the methodology applied.

Table 5 Cost-minimization studies

Country	Study duration (year)	Treatment pathways	Nature of direct costs	Mean cost (US$) per patient (whole follow-up) PHT	CBZ	VPA	LTG	Ref.

12 European countries	1	First-line switched to second-line mono- or polytherapy	Hospital, drugs, laboratory tests, ADR	30–86	108–328	134–880	683–1,896	29
U.K.	2	First-line switched to second-line mono- or polytherapy	Hospital, ambulatory care, drugs, laboratory tests, ADR	1,337–1,395	1,444–1,506	1,576–1,605	2,770–3,770	30
U.K.	1	If withdrawal, CBZ switched to VPA, and LTG switched to CBZ	Drugs, switching of treatment, ADR	—	337	—	980	58
India	2	First-line switched to second-line mono- or polytherapy	General drug therapy, ADR	—	60	105	—	48

ADR, adverse drug reactions; CBZ, carbamazepine; LTG, lamotrigine; PHT, phenytoin; VPA, valproate.

Distribution of Direct Costs.

Considerable variability exists in the findings among COI studies regarding the distribution of direct costs (Table 4). Four studies found hospital costs to be the highest, four others found drug costs to be the most important, and one study positions other general expenses at the top. This can be explained, once again, by the different methods used, and also by the fact that each country has a unique health care system that functions in a different way. For example, Burundi, which has a health care system that is less well developed than most Western countries, has drug costs as the main cost. The U.K.-based study by Jacoby et al. found other general costs to be most significant.[31] This was also the only study to include the cost of inpatient episodes as a separate cost component. Kotsopoulos et al. discovered that using a more comprehensive list of cost components is associated with a decrease in the contribution of drug and hospital costs to the total direct costs.[33]

Incidence-based Studies

All three studies that estimated the direct costs of epilepsy from an incidence-based approach indicate high initial health care cost at onset for most patients, followed by lower cost in subsequent years (Table 3). This reflects the high cost of initial diagnostic evaluation and the fact that some patients achieve

early remission.[7] Costs in subsequent years tend to stabilize around a fixed amount. De Zélicourt et al. found that costs during the first year were highly sensitive to the severity of seizures, whereas second-year costs had a much lower variance and were sensitive to frequency of seizures.[17]

Comparison of COI Studies: Methodological Issues

Any attempt to compare the findings of the reviewed COI studies is hampered by the methodologic variations among the studies. The methodologic differences arise from a variety of sources.

Differences in the Study Population.

Cost estimates will vary according to which population is targeted and how the sample is ascertained. Some studies included the whole spectrum of the epilepsy population, whereas others included only certain specific age groups or severity groups. Certain studies only estimated the cost of childhood epilepsy,[23] whereas others focused entirely on the cost of adult epilepsy.[3] The study by Al-Zakwani et al.

only included patients aged 13 years and above.[1] It is not surprising that no study had the same proportion of young/old people in its population, and this in itself can result in cost variation, because clear evidence suggests that childhood epilepsy is associated with greater costs than is adult epilepsy.[11,23,24] In addition to this, the various COI studies include different population groups regarding seizure frequency or seizure type/severity. Begley et al.,[9] de Zélicourt et al.,[17] and Jacoby et al.[31] found that costs differ significantly relative to seizure frequency, thereby demonstrating how populations with dissimilar seizure frequencies can affect the estimated cost. Similarly, Beghi et al.,[3] Begley et al.,[8] Garattini et al.,[21] Guerrini et al.,[23] and Tetto et al.[63] found a notable difference in costs, depending on which severity group the populations belonged.

Table 6 Cost-effectiveness of antiepileptic drugs as add-on therapy

Drugs compared	Patients	Cost measures	Outcome measures	Results (costs in US$)	Refs.
LTG and TPM	Intractable epilepsy	AED, routine treatment	50% seizure reduction	200 mg/day TPM dominates 500 mg/day LTG (0.875 probability) 400 mg/day TPM dominates 500 mg/day LTG (0.986 probability)	65
CLB, GBP, LTG, and VGB	Intractable epilepsy	AED, ADR, routine treatment	50% seizure reduction, no ADR	GBP: 14,158 per satisfied patient* LTG: 11,474 per satisfied patient* CLB: 2,363 per satisfied patient* VGB: 2,770 per satisfied patient*	56
LTG and TPM	Intractable epilepsy	AED, ADR, routine treatment	50% seizure reduction, no ADR	LTG: 11,472 per satisfied patient* 3,442 per 50% seizure reduction TPM: 6,050 per satisfied patient 2,823 per 50% seizure reduction	55
CBZ, PB, PHT, and VPA	Idiopathic epilepsy	AED, hospital costs	75% treatment response, 70% adherence	PB: $868–1639 per DALY averted $798–2386 ICER PHT: $903–1690 per DALY averted 836–2496 ICER CBZ: $1194–2106 per DALY averted $1138–3399 ICER VPA: $1708–2845 per DALY averted $1675–5003 ICER	16
LTG and standard therapy (first-line AEDs)	Intractable epilepsy	AED, ADR, routine treatment	50% seizure reduction	ICER of LTG: 715 per year	32
LTG and standard therapy (first-line AEDs)	Intractable epilepsy	AED, ADR, routine treatment	Seizure-free days	ICER of LTG: 7.6 per seizure-free day	42

LEV and standard therapy (first-line AEDs)	Intractable epilepsy	AED, ADR, routine treatment, hospitalization	Seizure-free days	ICER of LEV: 60.7 per seizure-free day	59

ADR, adverse drug reactions; CBZ, carbamazepine; CLB, clobazam; DALYs, disability adjusted life years; GBP, gabapentin; ICER, incremental cost-effectiveness ratio; LEV, levetiracetam; LTG, lamotrigine; PB, phenobarbitone; PHT, phenytoin; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid.
*A patient who achieves 50% reduction in the number of seizures and is not affected by any serious adverse drug reaction.

Table 7 Cost-effectiveness of alternative treatments

Treatments compared	Patients	Cost measures	Outcome measures	Results (costs in US$)	Ref.
Surgery, medical therapy	Refractory temporal lobe epilepsy	Direct costs, indirect costs	Seizure-free patients	Surgical therapy more effective—return of high initial surgery costs—in 7.3–35 years (depending on which costs are included in the analysis) Employment income: 29,961 seizure-free (after surgery) 27,968 improved (after surgery) 18,231 unimproved (after surgery) 21,084 (before surgery)	47
Surgery, medical therapy	Refractory temporal lobe epilepsy	AED, hospital costs, transportation	Seizure-free patients	Total direct costs over life-time: 5,646 (no surgery) Cost of surgery: 1,355 70% of patients become seizure-free after surgery 30% of patients off AED within 3 years of surgery	49
Vagal nerve stimulation, medical therapy	Children with Lennox-Gastaut syndrome	Direct costs, indirect costs	Seizure-free patients	VNS therapy more effective—return of high initial therapy costs in 2.3 years. Costs during 6 postoperative months are 3,370 less than costs during 6 months before VNS	40

VNS, vagal nerve stimulation.

Estimating the epilepsy costs of patients treated in the community requires careful case ascertainment to ensure representativeness. Retrospective ascertainment of cases contained in administrative databases has the potential to yield larger and more representative samples than does clinic-based sampling, but the validity of this approach can be highly variable. For example, AED use as a proxy for an epilepsy diagnosis has a high-false positive rate, since AEDs are prescribed for other conditions (e.g., pain, bipolar disorder).[57] Rochat et al. estimated the prevalence of epilepsy, using prescription data from the Danish National Health service.[52] Lacking diagnostic information, the authors excluded from their analysis subjects who also were prescribed high-strength analgesics, under the untested assumption that these subjects were using certain AEDs for pain instead of epilepsy. On the other hand, Frost et al. used a three-step approach that identified cases by procedure codes, followed by physician verification and record review of uncertain cases.[20]

Differences in the Methods of Data Collection.

COI studies used a variety of methods when collecting their data. Some researchers acquired their cost-estimation data from administrative databases, whereas others used a questionnaire or prepared a case report for each patient (Table 2). Langfitt notes that studies relying on questionnaires sent to patients recruited by physicians are likely to obtain unreliable data.[36] A number of studies gathered their data retrospectively, whereas others followed the patient population prospectively (Table 2). Studies that prospectively attribute episodes of care to epilepsy based on a priori criteria are more likely to provide more accurate estimates than are retrospective assessments that rely on coding algorithms or medical record data that were not designed for this purpose. It is encouraging that the number of prospective studies conducted has increased significantly in recent years. The study by Levy et al. revealed that, out of 13 prevalence-based studies reviewed (conducted between 1993 and 2000), not one was prospective.[38] Among studies from 1998 to 2004, and out of 15 prevalence-based studies, five are prospective (Table 2).

Differences in Sampling.

Some COI studies ascertained epilepsy cases from centers/clinics or general hospitals/medical centers, whereas others gathered their data from general practitioners, administrative databases, or national samples; in some studies, the data were collected from a combination of sources (see Tables 2 and 3).[34] Different sampling strategies result in different case mixes. The cost of the same type of epilepsy differed among three health care settings (clinical research hospital, general hospital, and outpatient services).[23] Clinical samples will have a higher proportion of severe cases. Samples drawn from administrative databases may be more representative of the entire spectrum of epilepsy, but also may contain nonepilepsy cases, depending on how rigorously cases are defined, as noted earlier.

Differences in What is Included in the Costs.

Although those studies that estimated the direct costs reached a general level of consensus as to which cost components they should include, this was not the case for studies that estimated indirect costs. Some studies that estimated indirect costs considered lost earnings resulting from excess unemployment and premature mortality,[8] whereas other studies included only work days lost for treatment.[11] One study used a very crude estimation model based on how many patients claimed that epilepsy was the reason they left their jobs or how it generally affected their professional lives.[35] Thomas et al.[64] and Nsengiyumva et al.[45] doubled the estimated indirect costs calculated, arguing that each patient is accompanied by one other person during his transport and admission to the hospital. These different approaches to the measurement of indirect costs illustrate the difficulties in identifying the extent to which epilepsy is to be held responsible for lost productivity. Levy states that the problem is generated by the inherent difficulty of observing the effect of a chronic disease on professional occupation.[38]

Differences in Methods of Calculation.

Two studies demonstrated the variability in costs when different methods of calculation are employed, even if the same population is used.[19,24]

Costs can be estimated using a top-down analysis or a bottom-up analysis. According to the top-down approach, COI is calculated as a percentage of the total health expenditure, whereas the bottom-up approach uses the summation of cost data from individual patients to arrive at total disease costs. The first method is a service-based analysis, whereas the latter is an individual-based analysis.[33] Halpern et al. estimated the costs of epilepsy using both methods and found very different results (US$1,317 using top-down analysis and US$6,506 using bottom-up analysis).[24] Two other approaches to determining the costs of epilepsy are the *epilepsy-attributable cost method* and the *case-control cost method*. Using the epilepsy-attributable cost method, the mean cost per patient is derived by summing all the costs classified a priori as epilepsy related. In the case-control cost method, the overall health care costs of epilepsy patients (cases) are compared with the costs for similar persons without epilepsy (controls), with the difference between cases and controls representing the marginal cost of epilepsy.[38] Frost et al. performed a study comparing the two methods and found very diverse results (US$1,575 for epilepsy-attributable cost and US$3,449 for case-control estimate).[19] Smaller differences between methods (US$1,650 vs. US$1,836) were found in a study of institutionalized mentally retarded persons.[15] This demonstrates that the choice of estimation method can significantly influence the proportion of costs attributed to epilepsy.

Most of these methodologic limitations are not confined to COI studies; they arise in all types of economic analyses.

Cost-minimization Analysis: Methodological Issues

Four studies reported a CMA (see Table 5). Three of those were conducted in Europe (two in the United Kingdom and one a collaborative effort of 12 European countries) and one in India. All four studies restricted their evaluation to include only direct medical costs. Also, all studies used a model relating to the treated patients and treatments prescribed, based on clinical trials specific to each product. Furthermore, all studies took side effects and adverse drug reactions (ADRs) associated with medical treatment into consideration, because it is now established that such ADRs are usually associated with considerable medical costs.[54]

Despite the similarities, the studies differ significantly on many other parameters:

- The studies generally followed differing combinations of treatment pathways, particularly regarding the drugs evaluated. Only the Heaney et al. studies had exactly the same configuration of treatment pathways.[29,30]
- The studies incorporated dissimilar cost components when estimating the total direct costs of the AEDs (Table 5).
- The studies differed in duration. Two of the studies had a drug follow-up period of 1 year,[29,58] whereas the other two lasted for 2

years.[30,48]

Despite the methodologic variations of these studies, there does appear to be a consensus regarding the ranking of the AEDs relevant to their cost. Lamotrigine was by far the most expensive drug, incurring more than twice as many costs as any other drug. Valproate and carbamazepine were the second and third most costly drugs respectively, incurring much more costs than phenytoin, which appears to be the cheapest drug of the four examined.

Equivalent Efficacy in CMA Studies

By definition, CMA studies are only conducted when it can be assumed that the alternate treatments considered are equally effective. All CMA studies of AEDs consider AEDs equally

effective when they result an equal proportion of patients achieving at least a 50% reduction in seizures. However, such an outcome measure leads to inconclusive results, because most clinical trials tend to assess efficacy of AEDs based on seizure reduction alone.[38] However, AEDs differ when judged on other criteria. For example, although carbamazepine and la-motrigine do not reportedly differ in their efficacy in controlling seizures, one study has found lamotrigine to be better tolerated and to have positive effects on subjective well-being.[10] Therefore, lamotrigine may be preferred to carbamazepine treatment. In CMA studies, only the cost-effect of AEDs is included in the evaluation, whereas the effect on patient QoL is ignored because an indicator, based on clinical efficacy rather than effectiveness, was used. Recent literature has been in agreement that it is preferable to use CEA rather than CMA when comparing the various treatments of epilepsy, because CEA avoids conclusions being based on clinical efficacy parameters alone.[10,36,38,39]

Cost-effectiveness Analysis: Methodological Issues

Ten CEA studies described in Tables 6 and 7 are indicative of the two areas in which cost-effectiveness analyses have focused recently:

- AED effectiveness: Whether novel AEDs lead to improved tolerability and seizure control, which accumulate cost savings and better health effects that offset the higher cost of the drugs (Table 6).
- Epilepsy surgery: Whether the high initial resource investment for epilepsy surgery reduces long-term costs due to improved seizure control (Table 7).

As in previous studies, a variety of methodologic limitations exist in CEA. In this type of analysis, comparisons can be made since, by definition, CEA studies include comparisons in their analysis. Therefore, a CEA study can facilitate informed decisions about which treatment pathway to follow.

Cost-effectiveness of Antiepileptic Drugs

Table 6 shows that all seven studies used patients with intractable epilepsy, five included adverse drug reactions in their calculations,[32,42,55,56,59] and five studies defined their outcome measures by calculating the proportion of patients who achieved a 50% seizure reduction[32,55,56,65] or a 75% treatment response,[16] whereas two studies focused on seizure-free days gained due to successful AED therapy.[42,59]

In their study, van Hout et al. adopted a Bayesian statistical analysis to calculate the probability that therapy A dominates or weakly dominates therapy B.[65] They found that 200 mg/day of topiramate is more effective than 500 mg/day of lamotrigine by a probability score of 0.875. If the dose of topiramate was to be increased to 400 mg/day, the probability of it being more effective than lamotrigine would rise to 0.986. It is notable that this study does not incorporate costs related to side effects of the AED. This omission may affect the results, because higher dosages of topiramate than those provided in this study have been associated with higher numbers of patients discontinuing therapy.[60]

Selai et al. attempted to estimate the cost attributable to AED use to achieve patient satisfaction.[55,56] Satisfaction was defined as the achievement of a 50% reduction in the number of seizures, as well as absence of any serious adverse drug reactions in the patient. Results, which are illustrated in Table 6, include topiramate being found to be more cost effective than lamotrigine, a finding that is consistent with those of van Hout et al.[65]

Markowitz et al. adopted a different perspective in calculating the cost-effectiveness of a certain AED therapeutic pathway.[42] The incremental cost per extra day without a seizure was calculated. Results showed that the use of lamotrigine is associated with an overall reduction of use in direct medical care resources (hospitalizations, outpatient visits, diagnostic and laboratory tests, and surgery), and that this would result in a US$ 7.6 saving per seizure-free day gained. Sheehy et al. followed a similar approach and found the incremental cost effectiveness ratio (ICER) of levetiracetam to be US$ 60.7 per seizure-free day.[59] A problem that arises from such an analysis is that there is no published evidence of seizure-free days being correlated with economic cost. Only seizure frequency has been found to be related to medical costs, as explained in the COI analysis.

The studies by Chisholm and Knoester et al. also attempted to calculate the cost-effectiveness of AED therapy based on incremental cost effectiveness ratios (ICERs).[16,32] Where as Chisholm estimated the costs required to achieve a 75% treatment response and 70% adherence, Knoester only estimated the costs required to achieve a 50% reduction in seizures. Knoester et al. measured the cost-effectiveness of lamotrigine and estimated an ICER of US$715 per year.[32] The Chisholm study found that, out of four AEDs (carbamazepine, phenobarbitone, phenytoin, and valproic acid), phenobarbitone was found to be the most cost-effective, with a US$868 to US$1,639 cost per disability-adjusted life years (DALYs) averted and an ICER of US$798 to US$2,386.[16] Costs were found to have great variation depending on which region of the developing world the countries belonged to, with African countries having the lowest costs and Eastern Mediterranean countries the highest.[16]

Cost-effectiveness of Temporal Lobectomy

Table 7 presents the three studies that have focused on the cost-effectiveness of epilepsy surgery. It shows that two of the studies examined similar patient populations using similar outcome measures, the latter being the proportion of patients becoming seizure-free after the surgery.[47,49] The third study referred only to children diagnosed with Lennox-Gastaut syndrome.[40]

Platt and Sperling found surgical therapy to be considerably effective.[47] A return of the high initial surgery costs was attained in a period ranging from 7.3 to 35 years, depending on which costs were included in the analysis. This, by itself, is illustrative of how methodologic variation can affect a study's results. It is interesting to note that the mean employment income was found to increase considerably after the surgery (from US$21,084 to US$29,961) in patients who became seizure-free, but decreased (from US$21,084 to US$18,231) in patients who did not improve after surgery.

Similarly, in their study in India, Rao and Radhakrishnan found temporal lobectomy to be very cost effective, as its initial costs were US$1,355, in comparison with total direct lifetime costs of US$5,646.[49] Because 70% of patients became seizure-free after the surgery and 30% discontinued AED use within 3 years of the surgery, the overall lifetime costs after the surgery were reduced compared to the overall lifetime costs had the surgery not taken place.

Majoie et al. focused on vagal nerve stimulation (VNS) therapy, which they found to be considerably cost-effective, as it returns the high initial therapy costs in just 2.3 years. To illustrate this, epilepsy costs during the 6 post-operative months

were found to be US$3,370 less than the costs during the 6 months before the therapy was carried out.[40]

Use of Hypothetical Modeling in CEA Studies

CEA studies showed that hypothetical modeling of certain outcomes is the most common method for such an analysis in epilepsy studies. Such outcomes could result from different treatments, services involved in treatment, treatment of ADRs, and other treatment pathways. This involves combining data from various secondary sources, thus comparing the new AEDs through situations that are not relevant to the specific CEA. Heaney offers a characteristic example of a CEA study of lamotrigine, which used data that included patients who may have failed trials of both vigabatrin and clobazam.[26] Because most of the CEA studies reviewed are retrospective and must rely on existing data, such methodologic flaws are commonly incorporated into the estimations and, consequently, the results.

Selai et al. demonstrated the importance of using an accurate model to estimate the cost effectiveness of an antiepileptic therapy.[55] Significant differences were found when presenting data as cost per patient treated, compared with the cost for reducing seizures by more than 50%, compared with cost per patient satisfied. When only the cost of a patient becoming 50% seizure-free was considered (without indices of satisfaction), the costs dropped considerably. Given that most of the CEA studies reviewed estimated cost effectiveness solely on the grounds of patients achieving a 50% seizure reduction, it is conceivable that many of the costs have been underestimated.

Table 8 Cost-utility studies

Treatment evaluated	Patients	Cost measures	Results (costs in US$)	Ref.
LTG	Refractory epilepsy	Direct costs	49,935 per QALY	44
VNS	Refractory epilepsy	Direct costs, indirect costs	52,349 per QALY (using the time trade-off method) 114,275 per QALY (using the EuroQol EQ-5D)	18
CLB, GBP, LTG, TPM, and VGB	Refractory epilepsy	Direct costs	Only TPM and VGB patients show an increase in EQ-5D scores. TPM has an ICER of 11,767 per QALY compared with VGB.	51
CBZ, LTG, TPM, and VPA	Newly diagnosed and refractory epilepsy	Direct costs	Best treatment scenarios: TPM (first-line treatment) and LTG (second-line treatment) cost 11,372 per additional QALY compared to VPA (first-line treatment) and TPM (second-line treatment).	50

The full range of pharmaceutical therapies feasibly used in the U.K. health system	Newly diagnosed and refractory epilepsy	Direct costs	Best treatment scenarios: Partial seizures: CBZ (monotherapy), VPA (monotherapy), CBZ (second- line treatment) and OXC (adjunctive therapy) if willingness to pay >27,685 per QALY. Generalized seizures: VPA (newly diagnosed epilepsy), and TPM (adjunctive therapy) if willingness to pay >53,831 per QALY.	25

CBZ, carbamazepine; CLB, clobazam; GBP, gabapentin; ICER, incremental cost effectiveness ratio; LTG, lamotrigine; OXC, oxcarbazepine; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid; VNS, vagal nerve stimulation; QALY, quality-adjusted life-year.

Cost-benefit Analysis

Only two studies performed a cost-benefit analysis.[12,13] The earlier study by Boon et al. aimed at estimating the cost-benefits of VNS.[13] A later study by this group went a step further, estimating and comparing costs of daily treatment of patients who were either treated with AED polytherapy only, underwent epilepsy surgery, or had VNS.[12]

VNS was found to be very cost-beneficial on both occasions. The study by Boon et al. estimated that, on average, the annual epilepsy-related direct medical costs dropped from US$10,665 (before the implantation) to US$5,091 (at 12 months after the implantation).[13] This group also found costs reduced from US$5,331 to US$2,757. Both studies reach a consensus, because costs seem to be reduced by half.[12] Direct costs were estimated in dissimilar ways, which might explain the variation in cost figures.

Additionally, the Boon et al. study found that the mean decrease in costs to patients who followed traditional AED polytherapy was minimal.[12] Specifically, costs were reduced from US$2789 to US$2,675 in this patient group. Interestingly, epilepsy surgery was found to be only moderately cost-beneficial, because it reduced average annual costs from US$1,618 to US$1,310. On the other hand, one could argue that a saving of US$308 per patient per year accumulates to a substantial amount over the long term.

In both studies, Boon et al. appear to define CBA idiosyncratically as costs avoided.[12,13] This is a significant shortcoming, since the term benefits should include all types of benefits (e.g., QoL improvements) and not only costs avoided.

It is not surprising that CBA studies are not very favorable to researchers conducting economic evaluations, because they require both costs and consequences to be expressed in monetary terms or ratios. Therefore, CBA studies necessitate the placing of a monetary value even on outcomes that defy economic evaluation in monetary terms. Subsequently, they exclude very important outcome measures that are impossible to equate or express as monetary values.

Cost-utility Analysis

Only five of the studies incorporated a CUA[18,25,44,50,51] (Table 8). All studies utilized the quality adjusted life years (QALY) calculation, which determines the impact of a treatment on both a patient's longevity and on the value of those additional life-years. Messori et al. focused on the use of lamo-trigine in refractory epilepsy and estimated the QoL values by prospectively interviewing a group of patients with refractory epilepsy.[44] Clinical data were obtained from a placebo-controlled clinical trial of lamotrigine,[43] and the various costs were derived from Begley's cost-of-illness study.[4] Only direct costs were taken into account.

This study concluded that the use of adjunctive lamotri-gine in refractory epilepsy costs, on average, US$49,935 per QALY (year of life in which a patient enjoys perfect health). Because this type of evaluation facilitates a comparison of treatments relating to various diseases, the cost of QALYs produced by AEDs may be compared with QALYs produced by different treatments in different areas. This study found lamotrigine to have a worse pharmacoeconomic profile in comparison to other (nonepilepsy) pharmacologic treatments.

Although this study can be considered pioneering, because it was the first CUA on antiepileptic treatment, its validity is questionable, since the data are obtained from three separate studies. As a result, the QoL data were obtained from an ad hoc study on patients not necessarily taking the drugs under evaluation.

Forbes et al. performed a CUA of VNS for adults with medically refractory epilepsy.[18] The study used a meta-analysis of randomized controlled trials of VNS and estimated that six people require the implantation of VNS devices in order for one person to experience a 50% reduction in seizure frequency. Costs saved from improved epilepsy control were taken from previously published literature. The total cost per QALY was found to be US$52,329 when using the time trade-off method and US$114,275 when EuroQol EQ-5D utility values were used.

In this study, most patients were unable to complete the time-trade off valuations, even in the presence of a research nurse; this raises questions regarding the appropriateness of using this method with epilepsy patients.

Remak et al. focused on five different AEDs (clobazam, gabapentin, lamotrigine, topiramate, and vigabatrin) and found that only topiramate and vigabatrin patients showed an increase in their EQ-5D scores. Topiramate was found to have an ICER of US$11,767 per QALY compared with vigabatrin.[51]

Another study by Remak et al. and the study by Hawkins et al. focused on evaluating the costs incurred from a variety of treatment scenarios.[25,50] Remak et al. evaluated a variety of treatment scenarios in which carbamazepine, lamotrigine, topiramate, and valproic acid were used either as first-line or second-line treatment. They concluded that the best treatment scenario would be to administer topiramate as first-line treatment and lamotrigine as second-line treatment. Such a scenario would cost an additional US$11,372 per additional QALY, compared to the second-best treatment scenario, which would involve administering valproic acid as first-line treatment and topiramate as second-line treatment.[50]

Hawkins et al. focused on the full range of pharmaceutical therapies used in the U.K. health system. They found that,

P.2968

for partial seizures, the best treatment scenarios would use carbamazepine and valproic acid (administered as monotherapy), lamotrigine (administered as second-line treatment), and oxcarbazepine (administered as adjunctive therapy) if the willingness to pay for additional health benefits exceeded US$27,685 per QALY. Similarly, for generalized seizures, valproic acid was found to be the best treatment scenario for newly diagnosed epilepsy and topiramate for adjunctive therapy, if the willingness to pay for additional health benefits exceeded US$53,831 per QALY.[25]

Caution should be used when interpreting cost-utility studies, because it has already been demonstrated that the choice of utility instrument determines the results to a considerable extent.[62] The Stavem study compared four methods of measuring utility weights (time trade-off, standard gamble, 15D, and the EuroQol EQ-5D visual analog scale) and found that these preference instruments measure different aspects of health-related QoL and, therefore yield different results.[62]

Overview of Findings

Over the last 6 years, a plethora of studies have focused on the costs of epilepsy using a number of health cost evaluation methods. In this chapter, the various studies were compared to assess the economic, conceptual, and methodologic issues in this growing literature.

Many of the authors of these studies do not fully explain their methods, which introduces uncertainties into the results and limits their value. This might be partly explained by the researchers' lack of economic expertise, since most studies were performed by medical specialists. Kotsopoulos et al.[33] and Levy[38] observed similar problems in their reviews.

Inevitably, there are many limitations and methodological complexities in epilepsy cost studies, and these limitations should be taken into consideration when interpreting the results. The main issues identified were differences in the study population, differences in the sources used to obtain the data, differences in what is included in the costs, and differences in the methods of cost estimation.

In spite of this methodologic heterogeneity, some interesting interpretations can be made regarding the results of the studies. In particular, COI studies demonstrated a marked difference among costs in various countries and health care systems. Costs tend to be higher in more developed countries in comparison to the lesser developed ones; however, this was an expected outcome (Table 2). Studies found costs in uncontrolled patients to be from 1.5[24] to 3.5[9] times higher in the first year of treatment compared to the second year, when better control is achieved through treatment. Studies examining the longitudinal aspect of epilepsy-related costs found costs to be very high in the year of onset but then decreasing until a steady figure was reached in 2 to 4 years (Table 3). COI studies focusing on the breakdown of costs came to very inconsistent results, but do show that each health care system works in a unique way and has dissimilar cost components (Table 4).

To further our understanding of the total costs of epilepsy, the authors of future COI studies must provide clear methods and analysis of their data. Such studies will continue to be of limited use unless they are conducted with a common set of methods that will allow comparisons across studies. Unfortunately, previous reviews identified the same issues of

P.2969

concern, and only a limited degree of improvement has occurred.[2,5,7,14,28,33,36,38,46]

CMA evaluations, which mainly focused on four drugs, found lamotrigine to be the most costly and carbamazepine the most economical. Nevertheless, such studies inappropriately assumed equivalent clinical efficacy of these drugs to represent equal seizure reduction rates. This resulted in these drugs being equal in all aspects and therefore being compared as such. Should a broader perspective be placed on equivalent drug efficacy, then CMA will no longer be able to be applied to the majority of AEDs, because they will be found to generate different patient outcomes.

CBA studies, which are the least popular within the literature, generally focused on VNS and epilepsy surgery, and found both these treatments to be significantly cost beneficial.[12,13] The limitations of these studies have been outlined earlier.

CEA studies found topiramate to be more cost-effective than lamotrigine, and phenobarbitone to be more cost-effective than carbamazepine, phenytoin, and valproic acid. Surgical lobectomy and VNS were found to be very cost-effective treatments in the long term. In such studies, the common use of hypothetical modeling based on secondary data is very likely to give rise to inaccurate results. Nevertheless, CEA studies, compared to CMA evaluations, avoid the efficacy of drugs being reduced to clinical efficacy parameters alone and therefore include more dimensions of the consequences of treatment.

CUA studies go a step further by assessing the treatment's effect on the patient, incorporating QoL adjustments to the treatment outcomes. This facilitates the comparison of a variety of therapeutic options across the medical spectrum in terms of patient-perceived preferences, and can ensure that resources are allocated fairly among the various diseases.

Within the span of this review (January 1998 to January 2006), only five CUA studies had been performed so far in the epilepsy field. This small number is disappointing, considering that CUA is becoming the favored tool in the economic evaluation of health care. The scarcity of CUA studies can be partially explained by the fact that there is still difficulty and controversy concerning the way the patients' point of view can be incorporated in an economic analysis and eventually expressed in monetary terms.

Summary and Conclusions

Despite the methodologic heterogeneity and the difficulties of comparing the studies, there are significant findings. If cost-of-epilepsy studies follow more uniform methodology and data collection, they can offer invaluable information about which therapeutic modalities are most effective. Only then can economic evaluations of epilepsy treatment inform decisions about the allocation of scarce health care resources.

Also, future economic studies in epilepsy must aim to evaluate the variability in costs incurred according to the various case definitions of epilepsy, severity of the disease, cost components, and various demographic influences on the disease. This will provide insights regarding the great variations in costs found by the majority of cost-evaluation studies, and will lead to a greater consensus on which specific methodology should be utilized.

The International League Against Epilepsy (ILAE) has recognized the importance of economic considerations in the development of epilepsy care and has focused on improving the methods used to conduct epilepsy cost studies so that comparisons across studies within epilepsy can be made.[51]

The expertise of economists, health service researchers, and epileptologists must be combined if we hope to overcome the methodologic problems that arise during cost evaluation of this disease. Only then will we be able to adequately document the economic burden of epilepsy and evaluate alternative strategies for its prevention and management.

Chapter 308

The Economic Impact of Epilepsy

Christoph Pachlatko

Josemir W. Sander

Introduction

Epilepsy imposes a significant clinical, epidemiologic, and economic burden on societies throughout the world. This chapter focuses on the economic dimension of this burden or impact, in particular how it can be measured and, ultimately, how it can be reduced. Three specific questions are addressed: First, what is the relevance of an economic perspective to the management of epilepsy as a public health issue? Second, what is the economic perspective on the burden of epilepsy, and how well do economic studies demonstrate this burden? Third, what is the economic perspective on evaluation, and how does economic evaluation contribute to the evidence on clinical and cost effectiveness? This chapter complements others in this volume that deal with related topics, including the issues surrounding epidemiologic burden and need, treatment effectiveness, and the costs of treatment.

Interest in the economic aspects of epilepsy has been growing in both richer and poorer countries. In the wealthier nations, an ongoing debate continues about how to curb rapidly rising health care costs. State-financed health care systems are facing the problem of an inflation of needs and, therefore, are forced to find ways to limit the expenditures for health care. On the other hand, poorer countries are facing the fact of a tremendous need for health care but inadequate economic resources. The uneven distribution of epilepsy care among countries, and sometimes within countries, does not correspond so much with real needs, but rather with underlying economic conditions. It is a well-known fact that approximately 80% of all health expenditures occur in established market economies, whereas the remaining 20% of financial resources is spent in the rest of the world, where approximately 90% of the people with epilepsy are living.[21] Therefore, it is important to consider the economic aspects of ongoing efforts to improve the situation of people with epilepsy in all regions of the world.

The growing interest in this field has led to an increasing number of publications on economic aspects of epilepsy. Since the early 1990s, attempts have been made to apply general instruments of health care economics to the field of epilepsy care. The first studies mainly concentrated on the calculation of the cost of epilepsy. In a second phase, the economic studies investigated, in particular, selected aspects of the treatment of epilepsy, such as antiepileptic drugs or epilepsy surgery, including its cost-effectiveness.[4,24] In correspondence with the World Health Organization (WHO), the perspective has been broadened once again to the global burden of disease[21] and to the assessment of the performance of different health care systems.[20,32] Furthermore, economic aspects have been included within the Global Campaign on Epilepsy, a joint initiative launched in 1997 by the International League Against Epilepsy, the International Bureau for Epilepsy, and the WHO to improve the situation of people with epilepsy worldwide.

The Rationale and Relevance of an Economic Perspective

Before considering different methods and results from economic analyses of epilepsy and its treatment, it is important to raise the question of why such studies are needed in the first place. In short, the requirement for an economic dimension in planning and evaluating treatments and services for epilepsy stems from a tension between, on the one hand, the epidemiologic or clinical need for intervention, and on the other, the resources available to meet this identified need. In the extreme case of there being no limits on resource availability, there would be little need for an economic dimension, other than to track the steady, unremitting flow of monies being channeled into epilepsy care and prevention. Equally, in the extreme case that care or prevention strategies are entirely ineffective or unavailable, economic considerations might be restricted to considering the economic consequences of the untreated natural history of disease. Of course, the reality for most diseases and most countries is that effective care and/or prevention strategies exist, but the budget is limited, which implies that choices must be made about which interventions to make available within this budget constraint. Assuming that the primary goal of a health system is to optimize potential health improvements in the population, then the choice is made mainly in terms of delivering maximum health gain for least cost. This is in fact a definition of efficiency, and is the concept underlying cost-effectiveness and other forms of economic evaluation (see later sections).

In addition, economic considerations may and certainly should enter into the debate around a number of other components of epilepsy care, including the organization or quality of primary care and neurologic services in a country, plus the financial protection of epilepsy patients and their families from potentially catastrophic payments for drugs and health care services. There is currently very little available epilepsy-specific evidence that can be drawn upon to shed light on these issues, but the experience from comparative international studies undertaken is that reliance on private, out-of-pocket payments by households for health care is a far less equitable financing mechanism than prepayment via taxation or insurance.[34] In countries where there is a high level of out-of-pocket expenditures on health, therefore, an increased likelihood exists of pushing households containing a family member with epilepsy into impoverishment.

The Epidemiologic and Economic Burden of Epilepsy

The "burden" of epilepsy can be considered at a number of levels and from a number of different viewpoints, so it is as

well to distinguish between these different perspectives when thinking about what measured burden is likely to show. Most directly, this "burden" will be felt at the individual or household level in terms of the physical pain and psychological stress associated with epileptic seizures, the (potentially catastrophic) financial implications of treatment or lost work opportunities, and, in all too many societies, the social stigma attached to this condition. By contrast, burden at the community or population level is typically expressed in terms of the epidemiologic profile of the disease (numbers of new or existing cases in the population), the financial resources devoted to prevention and treatment, and societal productivity losses resulting from premature mortality or morbidity. The focus here is on population-level estimates of both the epidemiologic and economic burden attributable to epilepsy at the national and international level, but this should not detract from the importance of establishing and sharing better information concerning the household burden of epilepsy, particularly in low-income countries where the risk of catastrophic out-of-pocket expenditures is highest.

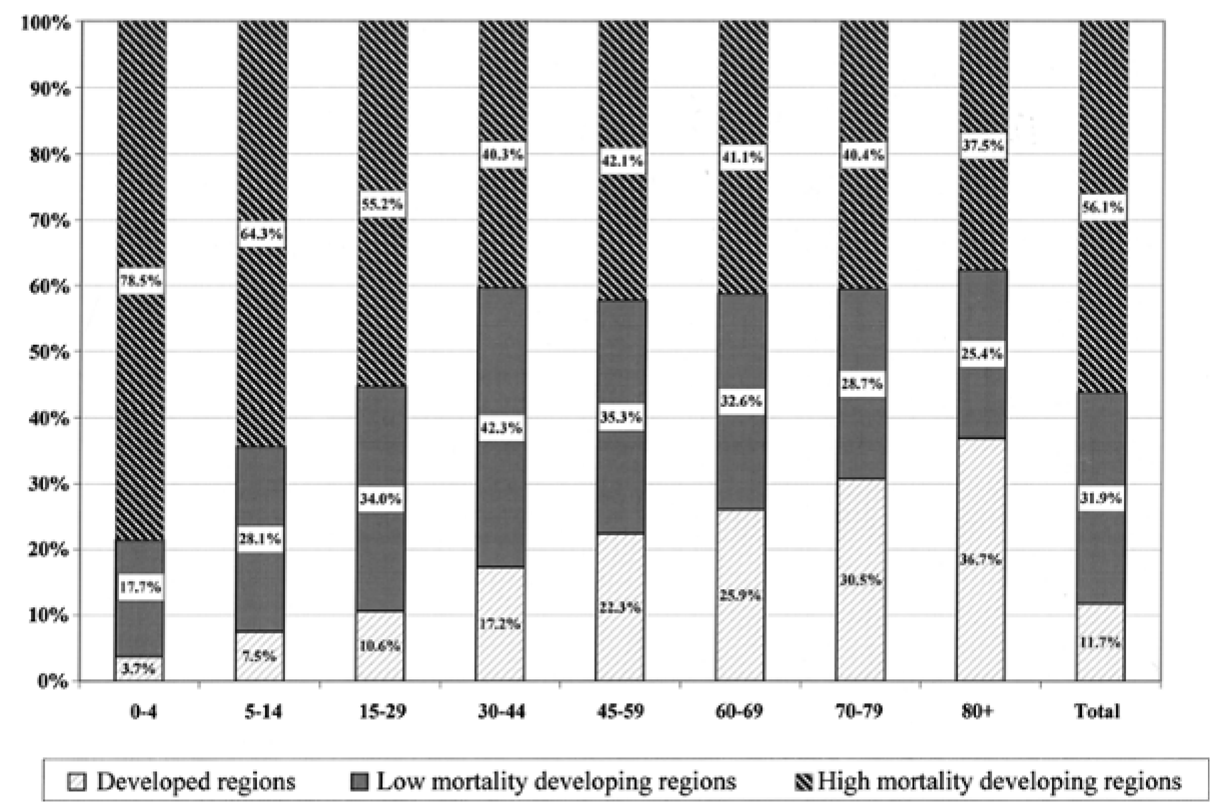

FIGURE 1. Distribution of the global burden of epilepsy by age group and level of economic development. (From World Health Organization. Statistical Annex 3, 2004. In: World Health Report 2004: Changing history (available at http://www.who.int/whr/2004/annex/topic/en/annex_3_en.pdf), with permission.)

Before illustrating the assessment of both the epidemiologic and economic burden of epilepsy, it is important to note that epilepsy is not an uniform disease, but rather a term that summarizes many conditions that have the symptom of an epileptic seizure in common. Policy-makers, such as governments or insurance agents, often do not distinguish between the different forms of epilepsy when evaluating the need for care and the services available, respectively. In economic terms, the consequences of having epilepsy may vary considerably depending on the frequency, severity, and kind of seizures. Furthermore, not all economic consequences may be attributable to epilepsy, because epilepsy is often related to an underlying disease that may continue to exist even after remission of the seizures. Various economic studies in epilepsy have therefore divided up the population with epilepsy into different prognostic groups with similar health care needs.[2]

Epidemiologic Assessment of the Global Burden of Epilepsy

From the epidemiologic perspective, epilepsy is a significant cause of disability and disease burden in the world. Using a metric called the disability-adjusted life years or DALY,[21] which can be thought of as 1 lost year of healthy life, the WHO has calculated the global burden of disease and injury attributable to different causes or risk factors. This measure of burden assesses the gap between current health status and an ideal situation in which everyone lives into old age free of disease and disability. Overall, epilepsy contributed more than 7 million disability-adjusted life years (0.5%) to the global burden of disease in 2000.[15,33] FIGURE 1 shows the distribution of DALYs or lost years of healthy life attributable to epilepsy, both by age group and by level of economic development. It is apparent that close to 90% of the worldwide burden of epilepsy is to be found in developing regions, with more than half occurring in the 39% of global population living in countries with the highest levels of premature mortality (and lowest levels of income). An age gradient is also apparent, with the vast majority of epilepsy-related deaths and disability in childhood and adolescence occurring in developing regions, whereas later on in the lifecycle, the proportion drops because of relatively greater survival rates into older age by people living in more economically developed regions. In terms of the absolute number of healthy life years lost per 1 million population, estimates range from less than 500 in early childhood and older age in developed regions to as much as 2,000 in the younger age groups of high-mortality developing regions. Owing to the consistent and comparative nature of this work, summary estimates of population health such as these provide the most appropriate measure of the relative burden of epilepsy at the international level.

That is not to say, however, that such summary measures of population health are not without limitations. For example, good-quality data on basic epidemiologic parameters (such as rates of incidence or recovery) do not exist for many developing countries, such that estimates for whole subregions of the world may be extrapolated from neighboring regions where such data do exist. Just as importantly, and in common with other disease categories, good-quality descriptive data on disability due to epilepsy were lacking at the time of this study. Recent work on the measurement of health state preferences in epilepsy[14] suggests that the disability weights applied to treated and untreated epilepsy in the Global Burden of Disease study may be underestimated. Finally, DALY estimates of the burden of epilepsy take into account neither the potential health consequences on people other than the diagnosed case (such as the burden on family members or caregivers), nor the nonhealth consequences of disease (such as lost ability to work).

Economic Assessment of the National Burden of Epilepsy

Disease burden has also been gauged from an economic perspective for many years in the form of so-called "cost of illness" studies, which have attempted to attach monetary values—as opposed to DALY estimates—to a variety of societal costs associated with a particular disorder, often expressed as an annual estimate aggregated across all involved agencies. Such studies have direct parallels with epidemiologic estimates of disease burden, in the sense that the principal aim is to influence policy-making and resource allocation by demonstrating the relative magnitude or burden associated with a particular disorder (by multiplying case prevalence by cost per case, put very crudely). The potential advantage of cost of illness studies over DALY-based estimates of burden is that they are able to measure in a single metric (money) not only the direct health-related impact of disease (in terms of health care costs, etc.) but also other economic consequences such as lost work or leisure time, and family or caregiver burden.

Economic assessments of the national burden of epilepsy have been conducted in a number of high-income countries such as Italy and the United States[1,3] and also in two developing countries, India and Burundi.[22,29] A number of comparative reviews have also been produced.[2,12,16,25] Each of these studies or reviews have set out to demonstrate the various economic implications the disorder has in terms of health care service needs and lost work productivity. For example, the Indian study calculated that the total cost per case of these disease consequences for epilepsy amounted to US$344 per year (equivalent to 88% of average income per capita), and that the total cost for the estimated 5 million cases resident in India was equivalent to 0.5% of the gross national product.[29]

An extensive array of costs is associated with epilepsy, including so-called "direct" intervention costs such as inpatient and outpatient care, medication, and diagnostic tests, and also "indirect" costs that cover lost time and productivity. The indirect cost of epilepsy, due to unemployment, underemployment, or premature death, is higher than one may assume. Studies have shown, for example, that in Europe, the unemployment rate among people with epilepsy is two or three times higher than among the general population.[9] To face unemployment or underemployment is a severe problem for these patients. At the same time, it is an (often underestimated) economic burden to society.

The wide range of potentially included cost components has resulted in significant heterogeneity in studies that attempt to capture the cost of illness (COI) of epilepsy. Key methodologic discrepancies include the range of services included in direct cost estimates (e.g., surgery, residential care, special education), the valuation of lost time (loss of productivity, loss of caregiver productivity), the inclusion of mortality costs, sampling frames (patients who are seeing specialists, adults, children), data sources (expert panel estimates, medical records, patient surveys), and the handling of comorbidity.

Table 1 provides a summary of the differing methods used in selected COI studies across a number of developed and developing countries. Most studies include inpatient and outpatient fees, drug costs, diagnostic costs, and laboratory costs. Others include the cost of surgery,[8] ambulatory transportation[5,8] and residential care, day care, and social workers costs.[13] Many of these studies use national tariff costs, which may include profits,[1,5,22] while other studies use insurance fee schedules,[8] payments, or charges. Only one study took into account mortality costs,[5] but many studies did take into account productivity losses due to loss of time from medical treatment. However, the methods with which these costs were calculated varied widely, from including only the patients' lost productivity days due to hospital visits and hospitalization, to productivity losses due to travel, to the loss of productivity time of caregivers.

Because such studies differ with respect to the exact methods used, as well as underlying cost structures within the health system, they are currently of most use at the level of individual countries, where they can serve to draw attention to the wide-ranging resource implications and needs of people suffering from epilepsy. However, like epidemiologic estimates using DALYs or some other measure of population health, COI studies are not in themselves appropriate mechanisms for allocating resources to specific treatment strategies.

The Economic Evaluation of Epilepsy Treatment

Having established the *attributable burden* of epilepsy, two subsequent questions for decision-making and priority-setting relate to *avertable burden* (the proportion of attributable burden that is averted currently or could be avoided via scaled-up use of proven efficacious treatments) and *resource efficiency* (determination of the most cost-effective ways of reducing burden). Analysis of these two issues can reveal the technically most efficient response to the attributable burden of a particular disease. FIGURE 2 provides a schematic overview of these concepts, showing how the total burden of epilepsy can be broken down into the following separate components: (a) disease burden that is already being averted via existing strategies, (b) disease burden that could be avertable via scaled-up implementation of cost-effective interventions such as antiepileptic drug treatment, and (c) disease burden that cannot currently be averted by the set of interventions under consideration.[30]

Economic analysis provides a set of principles and analytical techniques that can be usefully employed to assess the relative costs and consequences of different interventions or treatment strategies.[23] It seeks to address a number of key policy questions about the magnitude of epilepsy, the relative effect and cost of different treatment strategies, and the most appropriate use of scarce resources (Table 2). Economic evidence can be

P.2974

P.2975

generated in two distinct ways. Preferably, it would be generated on the back of additional empirical studies in a range of socioeconomic settings (particularly in developing countries, where current evidence is most scarce). Well-designed and sufficiently powered economic evaluations of epilepsy treatments are certainly needed and valuable, but they are also difficult, time-consuming, and expensive to carry out (as well as having limited application beyond the immediate confines of the study location). Alternatively, cost-effectiveness information can be generated via appropriate disease modeling of the best available existing data concerning the expected costs and effects of interventions in these different settings. The danger of this latter approach lies in the inevitable assumptions that are required to be made when basing cost-effectiveness estimates on a variety of data sources from different research settings, whereas the obvious attraction is that policy-relevant results can be generated relatively more quickly and cheaply. Over the longer-term, these two approaches can in fact be considered complimentary—empirical studies feed into initial or revised modeling exercises, while modeling studies synthesize and may even stimulate empirical research studies—but this should not detract from the shorter-term need to bring cost-effectiveness arguments into play when arguing for an increased level of resource investment to and prioritization for epilepsy care.

Table 1 Summary of methods used in selected cost-of-illness studies of epilepsy

First author year country (reference)	Inclusion/exclusion criteria	Direct medical costs	Direct nonmedical and indirect	Data sources	Comments

			costs		
Nsengiyumva 2004, Burundi (22)	Reoccurrence of at least two spontaneous seizures within 24 hours	IP, OP, DT, DG,	PC*2	Survey, retrospective	Inclusion standards are very different from other studies; assumed patients came with attendee and so doubled time costs
Thomas 1998, India (29)	Consecutive cases of epilepsy found in outpatient epilepsy service	IP, OP, DT, DG	PC (OP*2+ SE) NT*2	Retrospective questionnaire	Assumed every patient came with attendee and so doubled time and travel costs; all patients were seeing specialists
Krishnan, 2004, India (16a)	All patients at one epilepsy clinic	IP, OP, DG, EC	AT, PC (estimated)	Clinical records	Small sample, weak study
Beghi 2004, Italy (1)	18 years or older with confirmed case of epilepsy, attending epilepsy centers for over 2 years	IP, OP, DT, DG, SP		12-month prospective, questionnaire and patient-held records	Patients kept details of diagnostic tests and visits; no official records used; only adults at referral clinic included
Berto 2000, Italy (5)	Registered since 1996, diagnosed with epilepsy at last visit and had at least one follow-up, and a follow-up period of at least 12 months	IP, OP, DT, DG	PC, PCT	Clinical Records, retro	Excellent study, takes into account employment rate, working days, differentiates between children and adult costs

Jacoby 1998, UK (13)	Patients of GP and must have had active epilepsy in last 2 years or be on AEDs	IP, OP, DT, DG, EC, HV, PS, NU, RS			
Halpern 2000, USA (8)	Bottom-up approach: Expert panel of neurologists, general physicians and pediatricians	IP, OP, DT, DG, **SU,** AD	AT	Expert Panel	Panel estimates are subjective. Excluded opinion of generalists but did include cost of surgery
	Top-down approach: Subset of respondents to 1987 National Medical Expenditure Survey	IP, OP, EC		National Survey	No indirect costs
Begley 2000, USA (3)	Patients seeing specialists and generalists	IP, OP, DT, DG, **SU,** EC, PC, AT, LT	PC, MC, HP	Billing data/medical charts; survey of adult patients in treatment center	Indirect costs may be overestimated because data taken from epilepsy centers, but may be underestimates as based on adults only

Direct Costs: OP, outpatient visits; IP, inpatient visits; SE, seizure events; DT, diagnostic tests; DG, drugs; AD, drug side-effects; SU, surgery; SP, specialists; EC, emergency consultations; AT, ambulatory transportation; LT, lab tests; HV, health visitors; PS, psychiatrists/psychologists; NU, nurses; RS, remedial schooling. **Indirect costs:** PC, productivity costs; PCT, productivity costs due to travel; NT, normal transportation; MC, mortality costs.

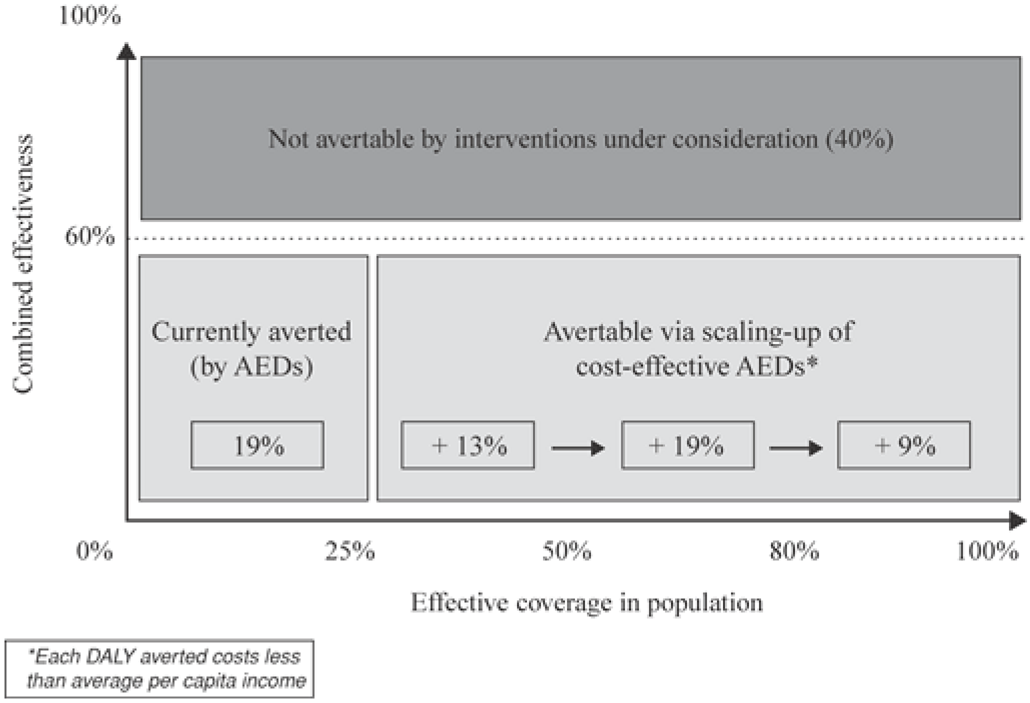

FIGURE 2. Attributable and aver-table burden of epilepsy in a WHO African subregion. (Schema is from World Health Organization. *Investing in Health Research and Development: Report of the ad hoc Committee on Health Research Relating to Future Intervention Options.* Geneva: World Health Organization, 1996; data is from Chisholm D. Cost-effectiveness of first-line anti-epileptic drug treatments in the developing world: a population-level analysis. *Epilepsia.* 2005;46:751–759, with permission.)

Table 2 Policy questions addressed by economic analysis of epilepsy

Policy question	Research task	Evidence generated
1. How significant is the burden of epilepsy?	Estimate burden of disease (DALYs) Identify other social and economic consequences of disorders	% of total disease burden caused by epilepsy Estimates of monetary impact on economy
2. How effective is epilepsy treatment?	Estimate current effective coverage Assess impact of new interventions	Comparative efficacy of interventions % of burden averted with current treatment or avertable with better treatment strategies
3. What will it cost to provide effective care?	Calculate full cost of interventions Estimate cost of scaling-up coverage	Comparative cost of interventions at different levels of treatment coverage

4. What are the most efficient strategies?	Integration of costs and effectiveness Inclusion in essential packages	Evidence-based priorities for the efficient allocation of health care resources

Despite the identified need for cost-effectiveness evidence by, among others, the International League Against Epilepsy[23] and the WHO,[31] there remains a relative paucity of empirically based economic evaluations from developed countries, and a total absence in developing countries. This, despite the likelihood that, due to their low price and established

efficacy, use of older AEDs in primary health care settings can be expected to represent a very cost-effective use of health care resources. Most completed economic evaluations have been concerned with specific treatment modalities, in particular the cost-effectiveness of different AEDs—either comparing first-line treatment or considering newer AEDs as add-on pharmacotherapy—and epilepsy surgery.[12,25]

Economic analysis of different first-line AEDs in the context of higher-income countries has been carried out using a form of economic evaluation called *cost-minimization analysis*, which assumes that treatment effectiveness is the same for each comparator, thereby coming down to a simple comparison of which drug produces this effect for the lowest cost. Assuming equal efficacy, and basing estimates of resource use on a consensus panel, an economic appraisal of carbamazepine, lamotrigine, phenytoin, and valproate as initial treatment in adults with newly diagnosed epilepsy was carried out, first in the United Kingdom and subsequently across 12 European countries.[10,11] This study found that lamo-trigine was two or three times more expensive in terms of direct health service costs incurred. Assuming equal efficacy remains a contested area, however, with manufacturers of newer AEDs dedicated—and in some cases mandated by regulatory authorities—to showing reduced sedative effects.

A number of economic evaluations have also been carried out in high-income countries for adjuvant pharmacotherapy using newer AEDs, arguably because that is where new market opportunities (and also regulatory standards) are greatest. For example, one study showed that the use of lamotrigine resulted in an overall reduction in the use of health resources,[17] a phenomenon referred to as a *cost-offset* (i.e., additional drug costs are offset by lower service use). The cost-effectiveness measure in this study was the additional cost associated with the newer drug per extra seizure-free day gained over the study period. An alternative measure that has also been used in this context is the Quality Adjusted Life Year (QALY), which combines both the quantity and quality of life into a composite index of health outcome. Economic evaluations of this kind are called *cost-utility analysis*. One such study using this method calculated that the cost of gaining one QALY as a result of using adjunctive lamotrigine amounted to US$50,000.[19]

For the subset of patients with refractory temporal lobe epilepsy, incremental costs per QALY gained have also been computed for surgery (in comparison to medical therapy), with results in the range US$16,000 to US$27,000.[12] Using a lifetime approach, these studies indicate the potential economic advantages of investing in the shorter-term in order to produce long-term improvements in both seizure control and quality of life.[25]

Economic evaluations of different epilepsy treatments from lower-income countries are few and far between. Two of these come from a tertiary referral center in the Indian state of Kerala, where both a study of the cost and effects of surgery plus a pharmacoeconomic study comparing phenobarbitone, phenytoin, carbamazepine, and valproate (plus combinations) were carried out.[26,27] The annual drug cost of phenobarbitone and phenytoin was estimated at US$15 to US$20, significantly lower than the cost of carbamazepine or valproate (US$50 and US$90, respectively). No estimation was made for the cost of health care visits or program management, however. For patients with refractory temporal lobe epilepsy, the cost of anterior temporal lobectomy was estimated at US$1,200 (compared to US$150 for similar patients not undergoing surgery), and the outcome was that 70% were seizure-free 2 years postoperatively (compared to about 10% for medically treated cases).

Another study stems from Colombia, which, based on an epilepsy surgery program established over the last decades in Cartagena.[7] has shown the feasibility of epilepsy surgery in a developing country. Although the cost of the surgical treatment in Colombia is relatively low (<US$2,000 for an operated patient), the program meets

international standards. Compared with the high cost of lifelong medication, it is evident that epilepsy surgery may be effective also in economic terms.

More recently, information has been generated as part of a wider WHO cost-effectiveness work program[28] on the amount of burden averted by the current or scaled-up use of AED treatments in low- and middle-income regions of the world, together with estimates of cost and cost-effectiveness.[6] Effectiveness was expressed in terms of DALYs averted, and costs were expressed in international dollars (I$, which take into account differences in purchasing power between countries or world regions). Compared to a do-nothing scenario (i.e., the untreated natural history of epilepsy), results from nine developing WHO subregions suggest that extending AED treatment coverage to 50% of primary epilepsy cases would avert between 150 to 650 DALYs per 1 million population (equivalent to 13%–40% of the current burden). This burden can be averted at an annual cost per capita of I$0.20 to I$0.80 for phenobarbitone and phenytoin (I$70–I$120 per treated case), and I$0.25 to I$1.33 for carbamazepine and valproate (I$105–I$207 per treated case). These cost estimates includes the AED drug itself, health care use, and also program implementation costs such as training and administration.

Older first-line AEDs (phenobarbitone, phenytoin) were most cost-effective because of their similar efficacy but lower acquisition cost (I$800–I$2,000 for each DALY averted). In all nine developing regions, the cost of securing 1 extra healthy year of life was less than average per capita income. Extending coverage further to 80% or even 95% of the target population would evidently avert more of the burden still, and would remain an efficient strategy despite the large-scale investment in manpower, training, and drug supply and distribution that would be required to implement such a program.

The results for one WHO developing subregion in Africa—consisting of 20 countries with a high rate of child mortality and a very high level of adult mortality—are depicted in FIGURE 2, which divides the total attributable burden of epilepsy as follows: (a) burden that is averted by AEDs at current levels of effective treatment coverage (19% of total burden), (b) burden that could be averted via the scaling-up of AEDs (up to a further 41% of total burden is averted if complete coverage could be reached), and (c) burden that is not avertable via AEDs (estimated to be 40%, although this assumes that the current level of drug compliance would prevail).

It may be argued that the purchase of the low-cost AEDs (like phenobarbitone) does not resolve the whole problem, because it is known that, in various regions of the developing world, epilepsy is not considered to be a medical problem but rather a trouble with social or spiritual implications. In such regions, medical treatment is not asked for unless there is a basic knowledge among the people offering primary health care. In addition there is a need for securing permanent access to AEDs, since an interruption of the treatment may cause a dangerous deterioration of the disease (indeed, if phenobarbitone is not gradually withdrawn but suddenly stopped, life-threatening status epilepticus may ensue). However, these arguments enhance the high impact of economic factors on the development of epilepsy care, especially in remote rural areas. An improvement of the condition will depend on the sustained access to low-cost treatment and improved knowledge of how to use it. From an economic viewpoint, it still is the most cost-effective approach to use low-cost AEDs for a large number of untreated people.

Summary and Conclusions

The burden of epilepsy manifests itself at a number of different levels. Taking a population-level approach, both epidemiologic

P.2977

and economic studies have revealed the extent of the negative impact of epilepsy on existing levels of health and health care. It is an unfortunate truth that the current burden, often couched in terms of the "treatment gap in epilepsy,"[18] is most concentrated in regions with the greatest health challenges and the least resources with which to respond to these challenges. More positively, however, one can conclude that, in these very regions, there exists the greatest opportunity to reduce current levels of epilepsy-related deaths and disability, employing efficacious treatments that have been shown to be a highly cost-effective use of scarce resources.

Although the volume of completed studies remains modest, particularly in middle- and low-income countries, increasing economic evidence supports the argument that interventions for epilepsy are not only available and effective but also affordable and cost-effective. This constitutes an important argument both for increased parity with other (noncommunicable) diseases and for increased investment into service development for this condition. This message has been supported and disseminated in all continents by the works and projects of the aforementioned Global Campaign on Epilepsy.

Critical factors in the successful implementation of such a scaled-up level of service delivery, apart from renewed political support and investment, can be expected to relate to appropriate training, continuity of drug supply, and enhanced consumer or community involvement.

Acknowledgment

The authors would like to acknowledge the contribution of Gaurav Banka, who undertook a COI literature review for epilepsy as part of an internship with the WHO in 2005.

Title: *Epilepsy: A Comprehensive Textbook, 2nd Edition*

Chapter 309

Information Transfer and Education

Patricia K. Crumrine

Simon D. Shorvon

Introduction

The purpose of an international textbook on epilepsy is to educate as many people as possible about the field of epilepsy, thus enhancing the care of those with this condition. The ability of those working in the field to provide information to each other, their patients, and their patients' families and to the community at large is an important role. This means not only giving information, but also interpreting, comparing, and objectively evaluating the information and its sources. How this is accomplished is constantly changing. The ability to obtain and evaluate new information is critical to the clinician working with epilepsy. Today's clinicians have limited time to read journals and attend out-of-town meetings, yet they have increasing demands to document ongoing educational credits (CMEs). The sources for new information have changed from the time when the physician depended on scientific journals for the main source to the present, when there are many resources available. Industry is now playing a larger role in the information transfer process, and the ability to evaluate the objectivity of this for the health care provider becomes necessary.

The role of information transfer or dissemination affects all persons in the health field. This service is necessary for the ongoing education of physicians, scientists, physicians- and scientists-in-training, medical students, nurses, other health care providers, patients, their families and the community at large. The means for providing this service vary depending on the group that is involved and the specific goal of the information transfer. Technology advances have improved the way that information may be disseminated. Today, larger portions of the population are computer literate and have access to computers. Information provided via this means may be able to reach larger numbers of people.

The physician as an educator has a role in the information transfer process. In the past, most information was provided through written materials (books, journals) and lectures and seminars. Thus, information was often limited to only those within the medical field and was not readily available to lay people and the community at large. Currently, the means of information transfer include not only books, journals, and seminars, but also peer-developed guidelines for evaluation and treatment of specific diseases, Web-based audio/video seminars, online information with detailed discussions of disease processes, video presentations of surgical procedures, and active support groups for many chronic diseases.[3]

It is important for the treating physician and other health care providers to be knowledgeable about the current social and cultural issues pertinent to the populations that they treat. This means being able to apply these issues to the process of information transfer. Information and means of delivery that are acceptable and appropriate for one population may be totally unacceptable for another.

The dissemination of new research in the epilepsy field is critical to the quality of care for patients with epilepsy. This transfer requires the ability to provide health care providers access to information on new diagnostic tools, technology, and treatment options for patients once they have been evaluated as safe and available. This transfer also requires providing the interpretation of this research to the health care provider and the public.

The role of this chapter is to provide the reader with information about information transfer concerning epilepsy, ways of dissemination, self-education, the role that Health Insurance Portability and Accountability Act (HIPAA) regulations play in this information transfer, and ways of evaluating the effectiveness of this transfer.

Dissemination of Information Pertinent to Epilepsy

Epilepsy is a chronic condition affecting 2.7 million people in the United States and 50 million people worldwide.[55] It affects individuals of all ages, from the newborn to the elderly; 4% of individuals who reach the age of 85 years will have developed epilepsy. Many of these people will be cared for by health care providers who are not epileptologists and whose primary training in epilepsy consists of what they learned during their educational years in medical school and residency. A report by the National Institute for Clinical Excellence (NICE) in the United Kingdom noted epilepsy misdiagnosis rates of 20% to 31%.[37] This report cited the financial impact of these misdiagnoses as £160,125,000 ≠ British pounds, total cost. Krauss et al.[36] reviewed stories published in the media concerning epilepsy. They found that 31% of the stories contained errors; many of these were inaccurate reports on the science of epilepsy. Even physicians and pharmaceutical spokespeople provided incorrect information concerning drug treatments. These facts emphasize the need for education and dissemination of information to treating physicians and the public.

The National Center for Chronic Disease, Prevention and Health Promotion in the United States gathered experts in the field of epilepsy to develop a public agenda. This meeting led in 1997 to the first major public health conference on epilepsy, Living Well with Epilepsy, and the collaboration of multiple organizations in the United States with defined goals that included the following:

- Assessment of evidence linking elements of care to clinical outcomes in special populations of patients with epilepsy.
- Development of health service purchasing specifications for services related to epilepsy.
- Enhancement of awareness and understanding of epilepsy through targeted education and awareness campaigns and increased support of research.

- Development of a bibliography/database of work related to epilepsy self-management.
- Implementation and evaluation of the self-management interventions in epilepsy.
- Support of population-based epidemiologic studies of epilepsy prevalence, incidence, and health care needs in selected communities.
- Assessment of the utility of existing health care data sets for studying trends in access to care, levels of care, and other demographic variables related to epilepsy.
- Continuing development of a tool to assess public perceptions of epilepsy.
- Support of epidemiologic studies of preventable causes of epilepsy, including traumatic brain injury and infections such as cysticercosis.
- Evaluation of the incidence, prevalence, and patterns of care for epilepsy in a managed care setting.[9]

A second conference, Living Well with Epilepsy II, was held in 2003 to revisit the goals set by the first conference and develop new strategies for improved awareness. The organizers noted that there was still a lack of awareness concerning the seriousness of epilepsy and available treatment options. This lack of information involved all segments of society, including health care providers, patients with epilepsy, and the general public.[10] One of the charges from this conference was to address self-management and assure that those with epilepsy have the information and support needed to manage the condition and its treatment.

Learning Methods

Adult learners have different styles and needs for learning. As students, many of us quickly realized which manner of learning works best for us. Most of us experienced the lecture format as we passed through our educational programs. This method involves listening and comprehending and then processing the information for future retrieval. For some this is easy, whereas for others it is not. For some, the process of note taking enhances learning skills with this method. Others find that what they read and visualize leads to better learning and information retrieval. In the field of health care, learning has often been by demonstration and discussion. Technology has added another dimension to learning tools with the development of audio/video formats. Many lectures today are enhanced with digital slides, audio, and/or video. Another new tool that lends itself to the learning process is the ability to access information over the Internet. All of these methods are applicable to all those who need to learn about epilepsy: medical students, physicians-in -training, physician/specialists, nurses, other health care providers, researchers, patients, family members/caregivers, teachers, employers, and the public. For each of these groups, one or more of the methods may be applicable to the learning process.

Information Transfer to Health Care Providers

Traditional and Current Means of Information Transfer

Historically, physicians and other health care providers obtained information from textbooks, formal lectures offered as part of the educational process, peer-reviewed journal articles, annual meetings of their medical specialty, weekly or monthly "grand rounds" in hospital settings, and, more important, discussion with their peers. Other than the lectures in medical school, for which testing procedures existed, there generally were no means for evaluating the effectiveness of the learning process. Textbooks provide good general scientific and treatment information but may not always have the most up-to-date information on current therapeutic options because the publishing of textbook material may be several years behind current accepted therapy practices. Even journals may be somewhat out of date by the time their new information is published.

Technology advances have increased information resources available to health care providers. Information is available electronically. Journals and textbooks also are available via this format. Thus, physicians spend less time in libraries than in the past. There has also been a tremendous increase in the number of scientific journals being published. Educators have had to learn new ways of presenting information for lectures. The use of 35-mm slides has become a technology of the past. Most presentations now use a Power Point format with digitized video images. The problem sometimes is that of information overload. Lowe and Barnett noted that as of 1994 there were 17,000 new biomedical books and 30,000 biomedical journals published annually.[40] They estimated that a physician would have to read 19 original articles per day to maintain knowledge in a field. They also noted that most physicians in this time period obtained their information, not from books or journals, but from other health professionals. However, there is not always a filtering system in place to provide information that is relevant and up to date for a particular physician and clinical setting.

Traditionally, the exposure of medical students to information has been via lecture and bedside teaching methods. The amount of time devoted to teaching about epilepsy has always been small. Many students may complete their training in medicine without having seen a seizure or treated someone with epilepsy. Many training programs in the Western Hemisphere and Europe have implemented problem-based learning that provides exposure to a wide variety of disease states at all levels of medical school training. However, the amount of time spent on epilepsy remains small.

Information on epilepsy in nursing education and other health care education was a small part of the nursing educational process in the past. With the development of specialties in nursing, nurses with interests and talents in working with patients with epilepsy have become valued members of epilepsy teams. These nurses have become active members of the epilepsy community, working in hospital settings and as educators, researchers, and public health advisors. One example of their activities is the guideline for competencies for epilepsy nurse specialists published by the Royal College of Nursing.[12] Nurses have worked to increase knowledge of epilepsy in the school setting and have developed educational tools for of nurses in this field.[46]

Documentation of continuing medical/nursing education (CME/CNE) and maintenance of certification (MOC) are mandated by many states in the United States and many other countries. The numbers and types of CME credits vary from state to state and country to country. This documentation is often imposed by state licensing renewal processes and hospital accreditation. As with other types of learning, CME can be obtained in various formats, including attending accredited seminars, reviewing journal articles answering questions, and engaging in online activity through a hospital-, university-, CME-accredited organization. Continuing education is now required by many health care professions (e.g., physicians, nurses, pharmacists, dentists.)

The Accreditation Council for Continuing Medical Education (ACCME) in the United States reported in 2004 that they sponsored (directly and jointly) 71,564 activities, with 6.5 million participating physicians and 3.2 million participating nonphysicians. The range of activities included courses, regularly scheduled conferences, Internet enduring materials, other enduring materials, and journal-based CME.[2] Enduring materials

are printed, recorded, or computer-assisted instructional materials which may be used over time at various locations. Is continuing education effective in changing the practice of health care providers? Davis et al. reviewed the literature for articles relating to the effectiveness of various educational strategies from 1975 to 1994.[14] They specifically looked for studies that were randomized trials of education strategies that assessed physician performance and/or health care outcomes. Of 99 trials with 160 interventions, they found that 70% demonstrated a change in physician performance and 48% produced a positive change in health care outcomes.

Information Transfer to Students and Physicians-in-Training

Traditionally, information transfer and education have been via didactic lectures and bedside demonstration. The younger generation of students and physicians is very technology savvy and uses computers and other technologies easily. They have grown up using computers for most of their educational years and find that information accessible via this mode is to their liking. They incorporate this into other modes of information storage such as handheld devices (personal digital assistants, PDAs). Their learning modes are often different from those of their senior physicians. They are more comfortable in obtaining information electronically than from textbooks, and read this information off computers. They may be less likely to subscribe to printed journals in the future than this generation of physicians.

Time constraints of resident hours in the United States have changed the ways of educating residents and even medical students. There is often less bedside teaching than in the past. Within medical schools there is a renewed interest in providing quality education. Some schools have established academies of medical educators to advance the mission of education.[33] Although initial evaluations of these academies show that schools recognize teaching efforts by their faculty members and promote them for these efforts, it is unclear what the outcome is relative to student learning.

Epilepsy Information/Education

Epilepsy education constitutes a small portion of the curriculum for the typical medical student and resident. A study performed by Mason et al. evaluated three seminars on epilepsy given to third-year medical students.[41] They found that the seminars improved general knowledge of the subject but did not change attitudes about it.

Education about epilepsy for physicians in training is quite variable. Those in surgical specialties probably never receive any education during their training years. Those in primary care specialties such as medicine, pediatrics, and family practice may receive some, but this varies. Unique programs have been developed to teach neurology and child neurology residents about epilepsy. The J. Kiffin Penry Epilepsy Education Program runs two of these. They consist of a several-day minifellowship, with the curriculum consisting of daily lectures, workshops, and case presentations about epilepsy. Participants take pre- and post-tests to assess the knowledge gained.

Information Transfer to Patients and Caregivers

Patients, families, and other caregivers traditionally depended on their primary physician for information concerning medical status and treatment. A family might have had a general health care book on the bookshelf at home. Much of their information often came from friends or other family members. The patient accepted what was said to him or her and did not question the treating physician. Medicine has changed and now encourages the patient and family to participate in the care as an active member of the team. The availability of information through various media contributes to this participation. The use of the Internet to access information has increased patient knowledge but has also contributed to patient confusion about which treatment option may be the best. Kind et al. studied the availability of computer and Internet access in a low-income urban population in the United States.[35] In a survey of 260 people they found that 58% had access to a computer and 41% had home Internet access. Ninety-two percent of those surveyed indicated that they would like to discuss information on the Internet with a health professional. A Harris Poll from 2003 surveying Internet use reported that 67% of all adults have been online and that 57% use the Internet at home.[30] The estimate for European usage is 35.5%, and for worldwide usage it is about 15.2%.[42] Harrisinteractive surveyed patients in four countries (United States, France, Germany, and Japan) in January 2002.[28] This report noted that those surveyed in United States and Japan were most concerned about using Web sites not based in their own countries. Americans and Japanese were the most likely to purchase drugs online if they were available from pharmaceutical companies.

Patients and their families desire information about their health problems and treatment. This information contributes to improved compliance with medication, better relationships with health care providers, and a more positive outlook about the patients' medical problem.[27,38,48,49,51,52] The Healthy People 2010 Information Access Project is a collaboration of U.S. government agencies, public health organizations, and health science libraries to assist the public health workforce find and use information effectively.[54,55] A study by Deber asked whether patients wanted their physicians to do the problem solving and whether they wanted to be involved in the decision making.[15] Most of the patients wanted the physician to do the problem solving, but a significant percentage wanted to be involved in the decision making part of the process. Deber discussed the problems that occur with patient education, which included the following issues: (a) the importance of the manner in which information is presented; (b) the potential for overwhelming the patient with large amounts of information; (c) the possible confusion for the patient of conflicting treatment options; and (d) the variability in quality of information, its completeness, and its accuracy.

Besides the Internet, other sources of information and education that have been used in the clinical setting are pamphlets, video tapes, drug information sheets, physician/nurse phone calls, and, more recently, e-mail communications. Many patients express interest in the ability to communicate with their health care provider via email because they can do this on their own time, do not have to wait for a phone call from their provider, and feel freer in asking questions. People's learning styles differ, and what may work for one patient may not be as effective for another. Eaden et al. carried out a randomized trial comparing the efficacy of a video plus an informational leaflet to an informational leaflet alone for patients about surveillance and cancer risk in ulcerative colitis.[18] They noted that there was no clear advantage of the video plus the leaflet over the pamphlet. They suggested that staff time and costs should be weighed in the consideration of which medium to use.

Email has become increasingly popular for patients and their health care providers. A Harrisinteractive telephone survey conducted in March 2002 noted that 110 million adults use the Internet for health information.[52] Many of those surveyed indicated a willingness to pay for these services. What

they hoped to obtain from this service was the ability to ask questions of the health care provider without having to make a visit, fix appointments, receive results of medical tests, and obtain prescriptions.[29] The results of a University Pediatric Faculty Practice survey of 1,018 adults accompanying a child reported that 47% used the Internet for medical information.[5] Of these, only 47% considered that the information was good.

Epilepsy Information and Education

How does this information translate into the care of patients with epilepsy? Patients and their families have consistently indicated that they wanted information from their physicians about the disorder and its causes and treatments.[8,43] A U.K. study by Buck et al. in 1996 solicited information via questionnaire from patients with epilepsy concerning their satisfaction with their care.[8] Patients were asked whether they thought that their physician had adequate knowledge about epilepsy and whether he or she provided enough information concerning this. Sixty-seven percent of those responding to the survey stated that their physician, usually a general practitioner, gave them enough information about their epilepsy. On the question of whether they felt that the physician had considered their personal views, 71% felt that the general practitioner was more likely to do so compared to the hospital specialist.

Information Transfer to the Community and Public

The public has become more knowledgeable about diseases, treatments, and outcomes. There are many resources for this knowledge; these include television documentaries, news reports, magazine articles, and the Internet. National organizations and parent support groups play significant roles in the dissemination of this information. With some diseases, there is a stigma attached to the disorder, and education of the public is more difficult. Bagley in 1972 studied the attitudes of the public toward epilepsy, cerebral palsy, and mental illness and found that those with epilepsy were rejected more often than those with the other two illnesses.[4] Even 23 years later Baumann found similar results concerning attitudes toward children with epilepsy compared to those with asthma.[6] The Epilepsy Foundation of America and many other chapters of the International League Against Epilepsy (ILAE) have launched public awareness programs aimed at educating employers, teachers, public servants such as police, and the public at large. The ILAE together with the World Health Organization (WHO) and the International Bureau for Epilepsy (IBE) undertook a joint campaign in 1997 called “Out of the Shadows.”[32] The primary goal of this campaign is to increase public and professional awareness of epilepsy and raise epilepsy to a plane of acceptability in the public domain. The Epilepsy Foundation of America has a “Speak Up, Speak Out” campaign encouraging those with epilepsy and their families to advocate for important issues related to epilepsy and health care.[22] They also sponsor a Public Policy Institute each year; children from around the United States travel to Washington, D.C., meet with their representatives, and tell their stories about the impact that epilepsy has had on their lives. The Living Well with Epilepsy II conference in 2003 addressed ways of improving public awareness and acceptance of those with epilepsy.[21] Similar activities are carried out by other affiliates of the ILAE around the world. In third world countries, efforts have been undertaken to improve health access for those with epilepsy and diminish the stigma associated with the disorder.

Self-Education and Self-Management for Those With Epilepsy

Self-management implies that a person has a certain amount of knowledge about his or her medical condition. Data from reports of management of chronic diseases in both the United States and the United Kingdom indicate significant benefits of providing patients with information.[25] This resulted in reductions in outpatient visits by 37% and in accidents by 34%.[25] This type of patient–physician role has been studied in various age groups, including adolescents with chronic illness.[47] Self-management begins with the diagnosis of epilepsy and involves establishing a relationship with the treating physician. Self-management was one of the goals of the Living Well with Epilepsy II Conference that took place in 2003.[10] This is a goal that both the treating physician and the patient/caregiver should work toward from the onset of the diagnosis of epilepsy. Although there has not been much research related to the self-management of epilepsy, the few studies that exist demonstrate positive effects of self-management, control, and social support.[26] Part of self-management is understanding and coping with the diagnosis. This may require an understanding of one's feelings of anger, frustration, depression, or guilt.[49] The physician and epilepsy nurse can play an important role in assisting the patient and family through this initial process. Early referral to community support services is also important in assisting the patient and the family in the role of self-management.

The Centers for Disease Control and Prevention in collaboration with the American Epilepsy Society, the Epilepsy Foundation, and the Agency for Healthcare Research and Quality are developing a bibliographic database for the self-management of epilepsy. The sponsored research project includes the development of a computerized epilepsy self-management project.[17] The goals of these researchers are to use such a program to assist patients with treatment issues, improve knowledge, provide information to help with dealing with stress and sleep issues, and improve compliance with taking of their medication.

Many epilepsy associations in the United States and throughout the world have Web sites with self-help information.[19,20,23] The guidelines from *Epilepsy Action* cite four keys to self-management: (a) working knowledge, (b) personal awareness, (c) confidence, and (d) taking responsibility. The last is especially important and involves knowledge of the roles of the environment, stress, sleep, food and alcohol, illness, and hormones in seizure control.[19] This guideline also gives patients some specific instructions on questions that they can pose to their physician during visits.

As with information transfer to others, learning skills and preferences vary relative to the person. These issues should also be discussed with the health care worker. This opens up the opportunity to provide information in formats that enhance the greatest learning, including pamphlets, lectures, support groups, audiotapes, videos, CDs, books, and Internet resources. The ultimate goal for the patient is to accept the diagnosis, work toward the best control possible without side effects of medication, and be able to continue with his or her activities and employment and enjoy a good quality of life.

The ability to self-manage depends on the ability to establish a good working relationship with the health care worker (physician, nurse practitioner, nurse). Physicians have not always been recognized to be the best listeners. Patients and families of patients with chronic illness frequently complain that physicians in acute care settings do not listen to their explanation of the illness or treatment. This lack of understanding occurs in spite of the fact that these people deal with the chronic

illness on a daily basis. A study by Braddock et al using audiotapes of primary care office visits to evaluate six criteria for informed decision making reported that discussions leading to informed decision making included fewer than two of six described elements.[7] These elements were as follows: (a) discussion of the clinical issue and nature of the decision, (b) discussion of the alternatives, (c) discussion of the pros (or benefits) and cons (or risks) of the alternatives, (d) discussion of uncertainties associated with the decision, (e) assessment of the patient's understanding, and (e) asking the patient to express a preference.[7] There are still patients who prefer to defer to their physicians for final decisions. A study by Levinson et al. noted that this preference was more likely to occur in populations of older and poorer patients.[39] The physician must be able to read patients, understand their desires, and assist them in the process of understanding and working with their illness.

Research Information and Dissemination

Information concerning new treatments and devices needs to be available to the treating physician and to the public in a timely fashion. In the past, the transfer of this information has been through peer-reviewed journals to physicians and then from physicians to patients and their families. The timeline for this transfer can be months after the availability of a new therapy. The explosion of information now available to physicians limits the time that they can spend reviewing new ideas critically. Information comes from peer-reviewed journals, the Internet, and often from pharmaceutical industry representatives. Physicians still feel that the information that they receive from peer-reviewed journals about new therapies represents the best information. Although many physicians use electronic sources of information, they do not consider these as reliable as the peer-reviewed journals.[3] Other forms of information transfer related to research and new technologies occur at national or international society meetings. In these settings, health care providers have the opportunity to experience new ideas and then share them with their peers at home and their patients. Pollock advocated a system in academic institutions that requires health care providers attending a society meeting to return to their home institution and give a presentation of what they heard and learned.[44] Patients today often search for the newest treatments for complex disorders. They come to their physician visits armed with information that they obtained from the Internet or a magazine or newspaper. It is not uncommon that the information that they bring is something that the physician has not read.

Patients and families see the physician as the primary resource for new information about therapies or diagnostic studies. It is important to find ways in which health care providers can find the time to seek out this information from reliable sources.

Role of Epilepsy Organizations and Support Groups

The health care provider, researcher, patient, and patient caregiver have an increasing array of information resources and support groups about epilepsy available to them. Many patients are very resourceful and access these resources without any prompting or difficulties. For others, the health care provider can be very helpful in directing the patient to these services. Among these resources are the following:

1. Epilepsy Foundation of America (EFA)
2. International League Against Epilepsy (ILAE) and it various national chapters
3. World Health Organization
4. International Bureau for Epilepsy (IBE)
5. Centers for Disease Control and Prevention (CDC)

The national chapters of the International League Against Epilepsy provide services to local populations in the form of printed materials, workshops, lectures, support groups, advocacy for employment, information on educational and legal issues, and camps for children with epilepsy. As noted earlier, the ILAE, IBE, and WHO began a joint initiative in 1997 called “Out of the Shadows.” This is a global campaign designed to improve the diagnosis, treatment, prevention, and social acceptance of people with epilepsy. The second phase began in 2001 with the goals of promoting public and professional education, identifying the needs of people with epilepsy, and encouraging governments and departments of health to address the needs of people with epilepsy.[16]

In addition to these global activities, the local chapters of these organizations strive to provide services to people with epilepsy on a daily basis. One difficulty for the person with epilepsy and the family is that often they are unaware of these organizations and the opportunities for services. If the medical care of the person with epilepsy is in the hands of a general physician who does not have much contact with epilepsy services, the patient may not be provided with the information about them. The availability of information on the Internet is changing this somewhat, but there are still many people who do not receive services.

These organizations educate the public about epilepsy and advocate for services for persons with epilepsy. In spite of the increased publicity concerning epilepsy, people with epilepsy still perceive a stigma.[34,50]

Role of the Pharmaceutical Industry in Information Transfer and Education

The role of the pharmaceutical industry in medical education and information dissemination is very significant in the current market. Figueras and Laporte noted that the marketing budgets for pharmaceutical companies exceeds those for research and development.[24] They also noted that these companies play very important roles in medical societies and continuing medical education, and that because health care systems provide limited access to independent information, the pharmaceutical industry therefore becomes the bigger player in the dissemination of health information both to professionals and the public.[24] Many companies now have an "applied therapeutics" team whose primary goal is the development and dissemination of scientific information both internally and externally.

A report by the Accreditation Council for Continuing Medical Education in 2001 noted that more than half of the funding for CME came from commercial resources.[1] This report also noted that about one third of medical schools in the United States receive about half of their CME funding from the industry. Because of the increasing need for physicians to have mandated CME credits, there will be a need for educational resources. Most responders to a survey taken at a CME conference stated that they were there because of the need for CME and to learn about latest treatments.[13]

The other dilemma related to information from pharmaceutical industries is that many health care providers have been investigators in the clinical trials for the drugs or devices in question. One study recommended that patients be informed

P.2984

of financial and publication agreements between the industry and persons conducting the trials.[11]

There is a need to develop specific relationships with industry that benefit the patient and the health care provider without compromising standards of medical practice.

The Future of Information Transfer

Health Insurance Portability and Accountability Act

The passage of the Health Insurance Portability and Accountability Act (HIPAA) in 1996 and its implementation in 2003 has had a profound impact on information transfer in the medical community. It has affected direct patient care and clinical research. Those with chronic illnesses who seek services from multiple health care providers frequently feel the effect of this regulation. Sharing of medical information from one provider to another is more cumbersome than before. Enrolling patients in clinical studies requires several extra steps to ensure that patient confidentiality is maintained. Sharing of information with school officials, employers, and others involved in the day-to care of the patient may be limited unless permission is obtained from the patient or family member. This limitation of information may affect the care that patients receive if an acute medical problem arises. The epilepsy population is particularly impacted by HIPAA. For children with epilepsy, providing school nurses and teachers with information may be difficult. The same applies to employers of patients with epilepsy.

As we move forward with the development of medical record systems, these regulations will play a role in their design and management.

Electronic Records

Medical information is increasingly collected and stored electronically. Inpatient information is placed in electronic systems. Medical records are available on a number of archival systems throughout the United States and Europe. As technology has permitted the conversion of data to digital forms, the ability to store this information electronically has increased. Many hospitals store all patient orders, laboratory studies and results, and inpatient and outpatient records electronically. The thrust is to eliminate the paper medical record. The hypothesis is that use of electronic medical records will save the health industry billions of dollars, with improved health care efficiency and safety.[31] Another potential advantage of electronic records could be to provide patients with their personal electronic record, giving them more opportunity to participate with the health care provider in their care.[53] There are large-scale projects currently looking at ways to transfer computer-based information over the World Wide Web and maintain patient confidentiality.[45] The hope is that this can prevent repetition of tests, aid in identification of patient allergies and medications, and provide good patient care at a savings.

Many physicians use PDAs when they see patients in the hospital or office. Many of the PDAs now have Internet and phone capabilities, permitting access to many sources of information such as drug databases, Current Procedural Terminology codes, and other resources. Information obtained and stored in this manner is commonplace in the Western medical world.

As we move into the next decades, more and more of the information that we obtain and share will probably occur via electronic sources. Less of this will occur via paper sources such as journals, books, and newspapers. Even today, many medical journals offer an online version of the journal as a subscription option. At this stage, it is difficult to evaluate the efficacy of these various forms as they relate to physician learning, patient learning, and patient care. These are projects for the future.

Summary and Conclusions

The availability of information relative to epilepsy and other medical conditions is available in many formats. The physician as both a learner and an educator needs to be aware of these resources both for his or her education and for the education of his or her patients. With increasing demands on the heath care provider's time, it becomes important for the provider to be able to find information in places that he or she can access off-hours, such as the Internet, online seminars, and journal articles. The public also is increasingly interested in having more medical information available to them. The patient and caregivers are more facile with using the Internet and seeking out information. It is the responsibility of the health care provider to make appropriate resources available to their patients and guide them through the understanding of the information. In addition to standard methods of information resources, nonprofit organizations and support groups are playing greater roles in providing information to patients and their families. As physicians move forward in their training and practices, it is important to remember that learning is a lifelong process. Methods and tools for learning and the information itself will change, and physicians must be aware of these changes.

Color Plates

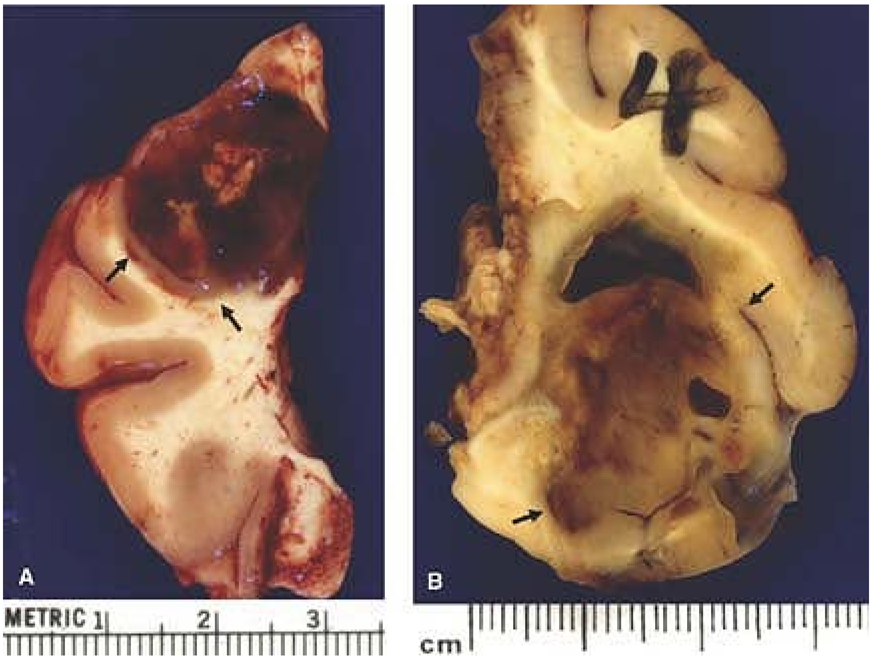

FIGURE 12.1 Tumors associated with intractable epilepsy, resected from two different patients. Note clear demarcation of the tumors from surrounding brain (indicated by *arrows*). Tumor shown in panel **A** is significantly hemorrhagic, whereas neoplasm in panel **B** is relatively homogeneous with focal cavitation. Both tumors clearly involve the cortex. (See black and white image.)

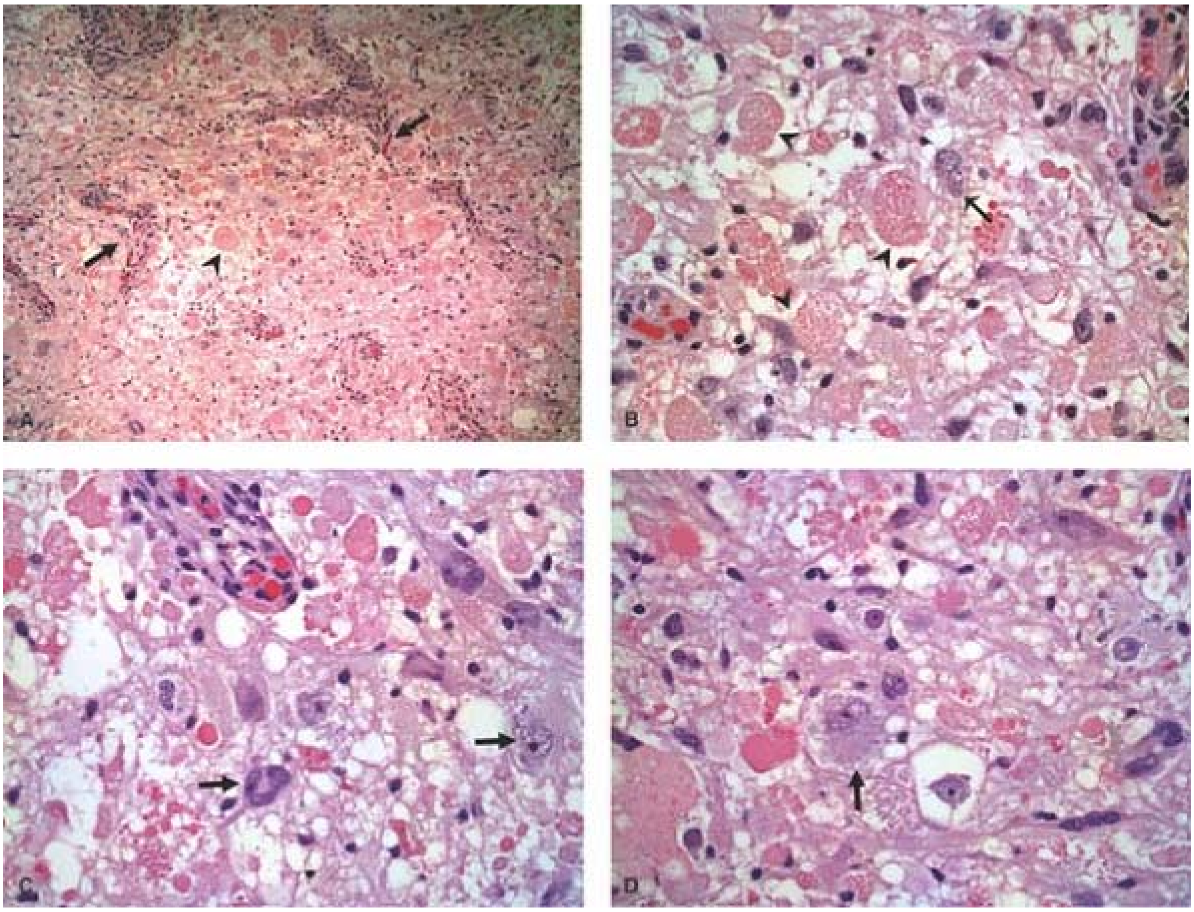

FIGURE 12.2 Ganglioglioma. **A.** Prominent vascularity in the tumor, with scattered perivascular lymphocytes (*arrows*). *Arrowhead* indicates a granular eosinophilic (cytoid) body; several of these are shown at higher magnification in panel **B.** *Arrow* in panel B shows a lobulated, dysmorphic nucleus. **C.** Several lobulated and bizarre nuclei are seen, though at least one cell (at right) retains neuronal features, including nucleolated nucleus and basophilic cytoplasm. **D.** Several dysmorphic neurons (e.g., highlighted by *arrow*). (All sections stained with hematoxylin & eosin.) (See black and white image.)

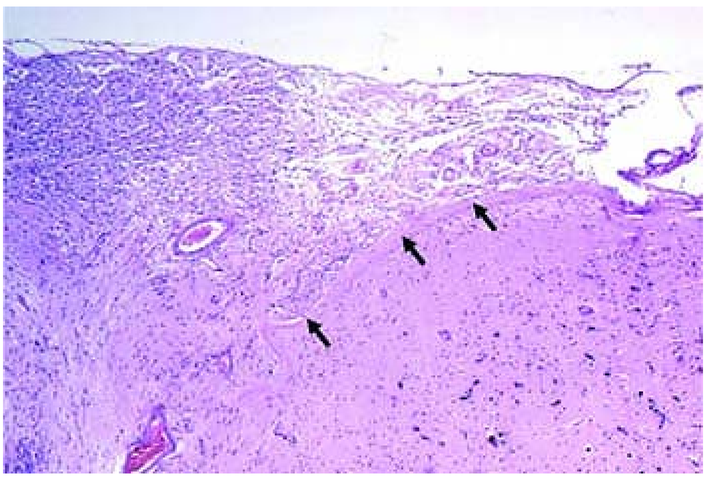

FIGURE 12.3 Gangliogliomas often extend into the subarachnoid space, even when they otherwise lack malignant (high-grade) features. *Arrows* indicate pial margin; large excrescence of tumor is seen at upper left. (Hematoxylin & eosin stain.) (See black and white image.)

P.CP-2

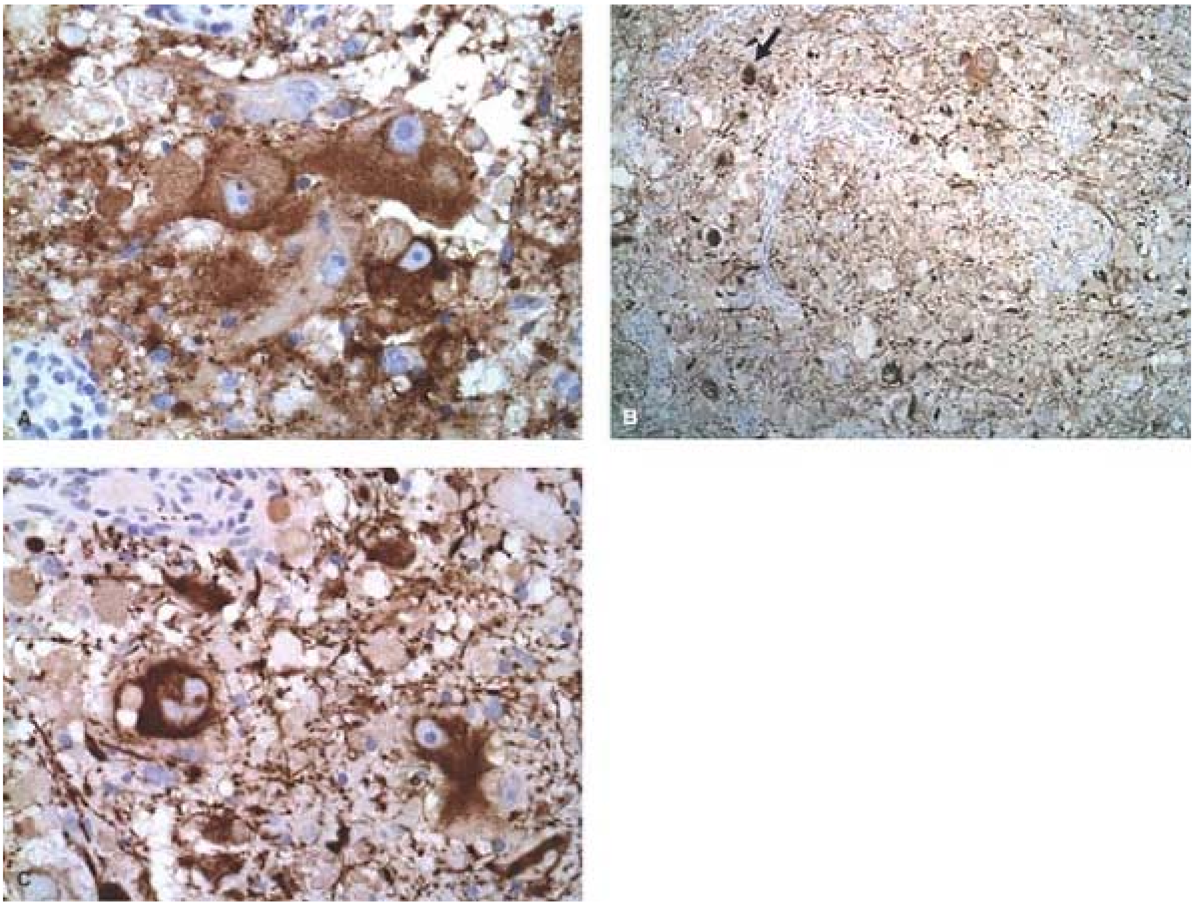

FIGURE 12.4 Immunohistochemical features of ganglioglioma. Panel **A** shows a section immunostained with antisynaptophysin, whereas panels **B** and **C** show sections immunostained with primary antibodies to neurofilament. All antibodies 'decorate' atypical and dysmorphic neurons; antineurofilament also highlights neuronal processes throughout the field. (See black and white image.)

P.CP-3

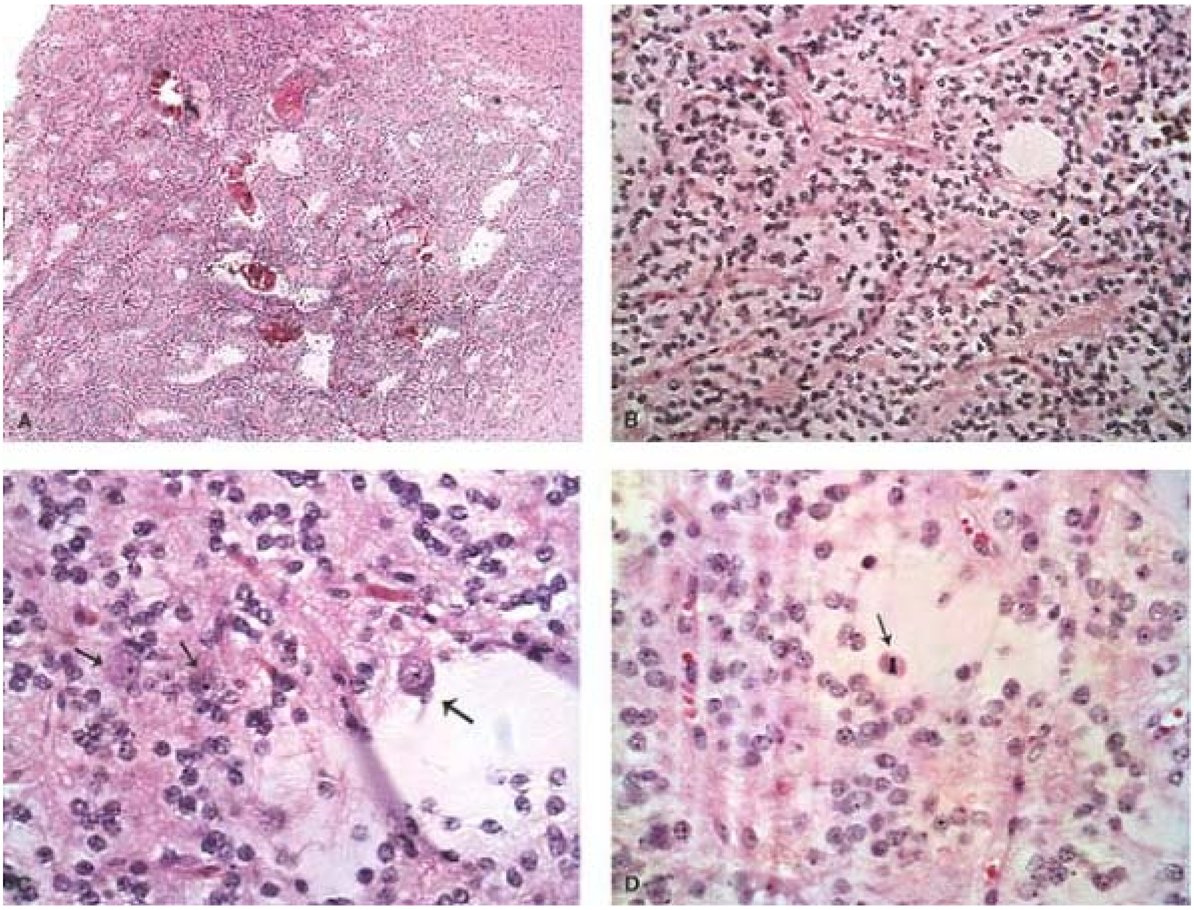

FIGURE 12.5 Dysembryoplastic neuroepithelial tumor. **A, B.** Representative fields in the tumor show sheets of relatively uniform round, oligodendroglia-like cells with compact nuclei and microcystic spaces. Panel **C** shows cells with distinctly neuronal phenotype (*arrows*). Neuron at right of this panel appears to be "suspended" in a vaguely mucoid matrix. Panel **D** shows a mitotic figure (*arrow*), an unusual feature in this neoplasm. (All sections stained with hematoxylin & eosin.) (See black and white image.)

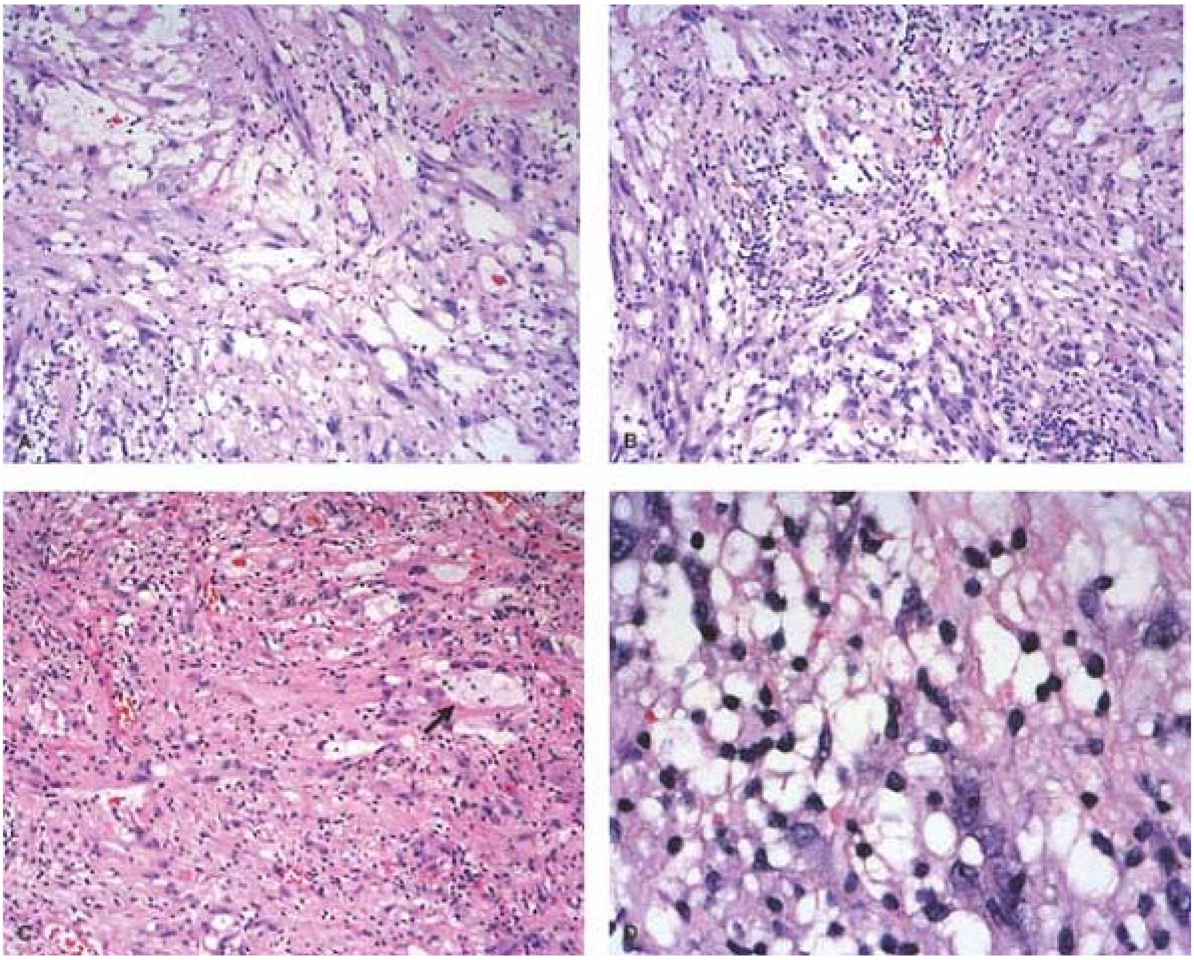

FIGURE 12.6 Pleomorphic xanthoastrocytoma. All panels (from hematoxylin & eosin-stained sections) show a pleomorphic neoplasm composed of spindled or compact cytoplasmic elements. Panel **B** shows a sparse lymphoid infiltrate, a common finding in this tumor. Xanthomatous or foamy cells sometimes aggregate into small groups (*arrow* in panel **C**). Cells with foamy, clear, and multiloculated cytoplasm and pleomorphic nuclei are highlighted in panel **D**. Despite this, mitoses are relatively rare in this tumor. (See black and white image.)

P.CP-4

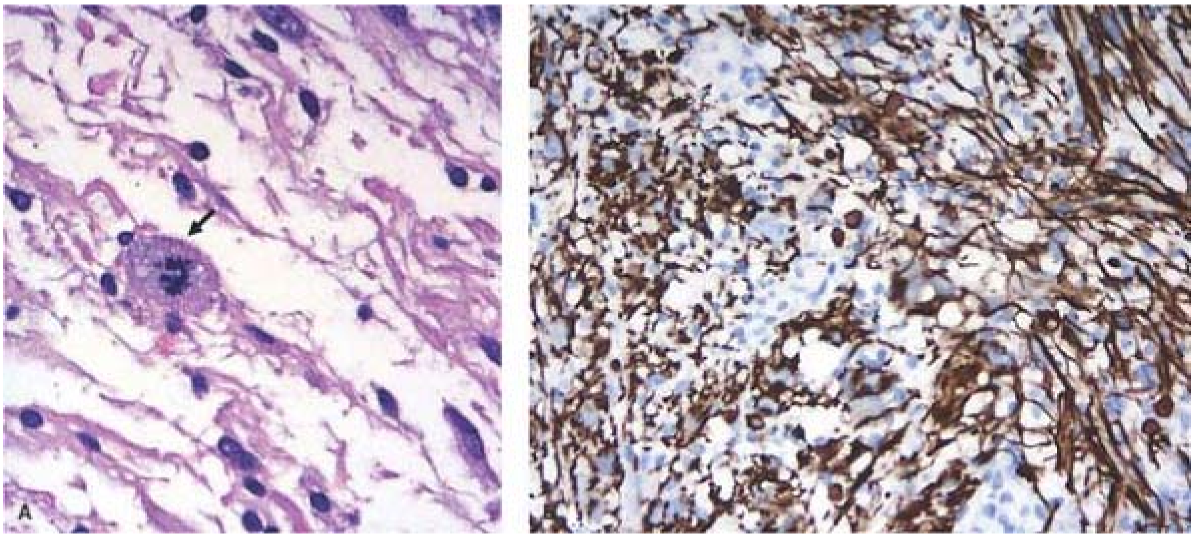

FIGURE 12.7 Pleomorphic xanthoastrocytoma (PXA). **A.** Atypical mitosis, a relatively rare finding in most PXAs (Hematoxylin & eosin-stained section.) **B.** Glial fibrillary acidic protein-immunostained section shows prominent cytoplasmic immunoreactivity. (See black and white image.)

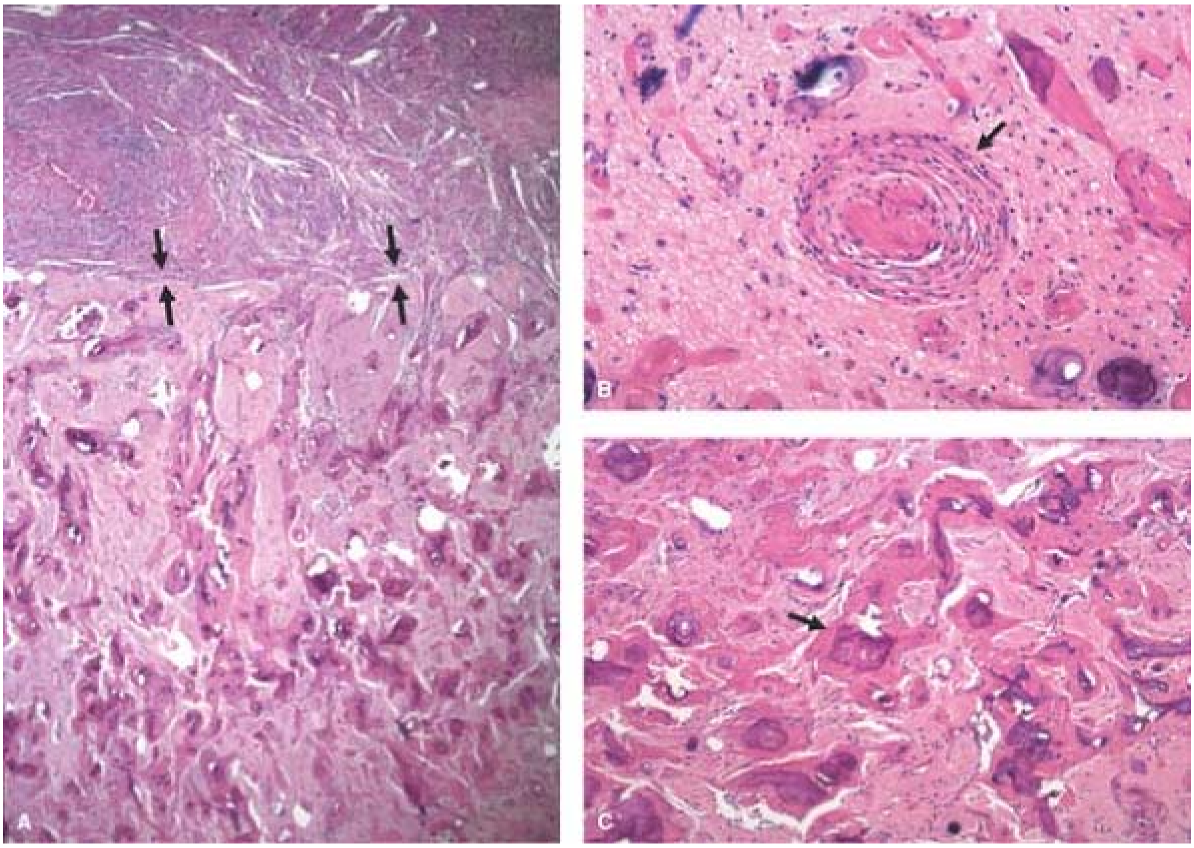

FIGURE 12.8 Meningioangiomatosis, with overlying meningioma. **A.** *Arrows* indicate the interface between brain parenchyma (lower portion of the image) and meningioma (above). The brain parenchyma shows

thickened, focally calcified blood vessels surrounding islands of disorganized neuroglial tissue. Details of the parenchymal abnormality are seen in panel **C**; *arrow* (in C) highlights a region of dystrophic calcification. Panel **B** shows a thrombosed thickened artery (*arrow*) with prominent smooth muscle cell hyperplasia in its wall. (All sections stained with hematoxylin & eosin.) (See black and white image.)

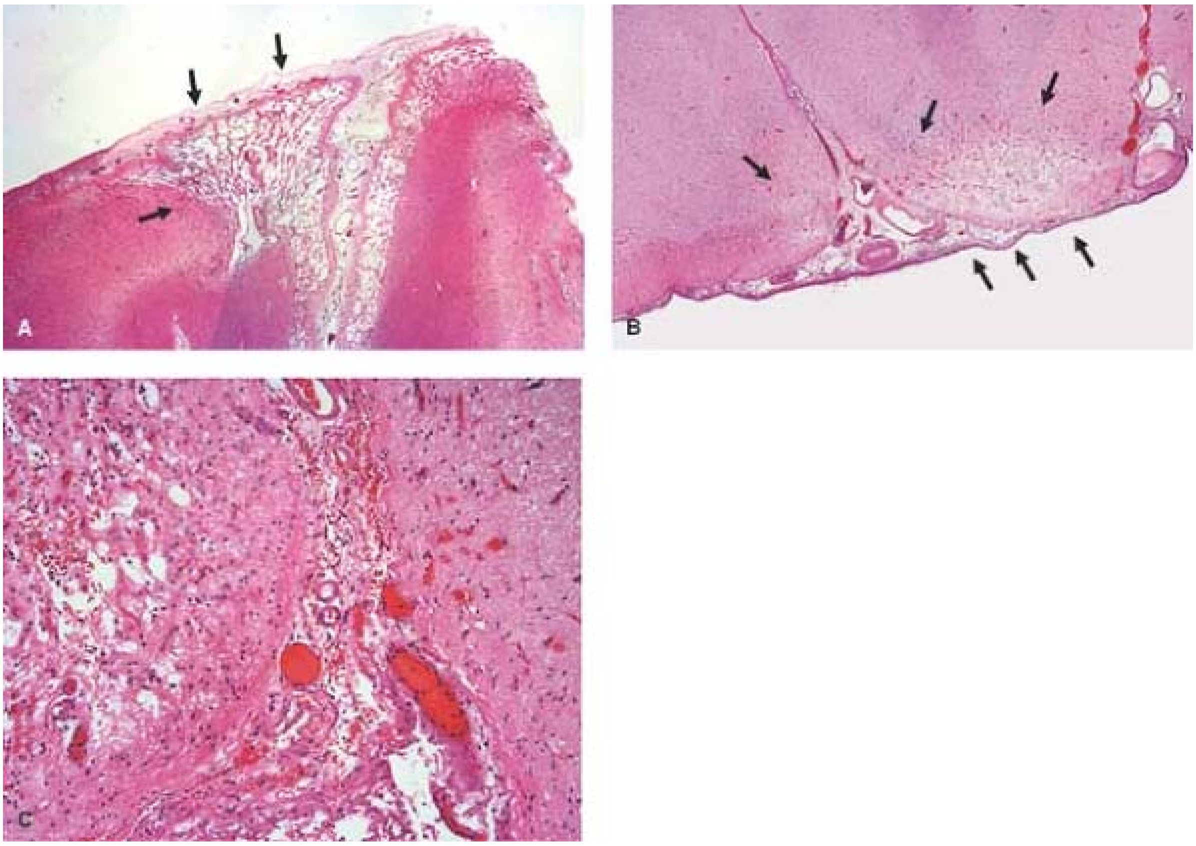

FIGURE 12.9 Rasmussen encephalitis (RE). Panel **A** shows extensive cortical cavitation, in one region affecting an entire gyrus (*arrows*). Panel **B** shows a more circumscribed region of cortical injury showing faint cystic cavitation, delineated by the *arrows*. Panel **C** shows detail of the region of microvacuolization, with intense astrocytic gliosis. (All panels are from sections stained with hematoxylin & eosin.) (See black and white image.)

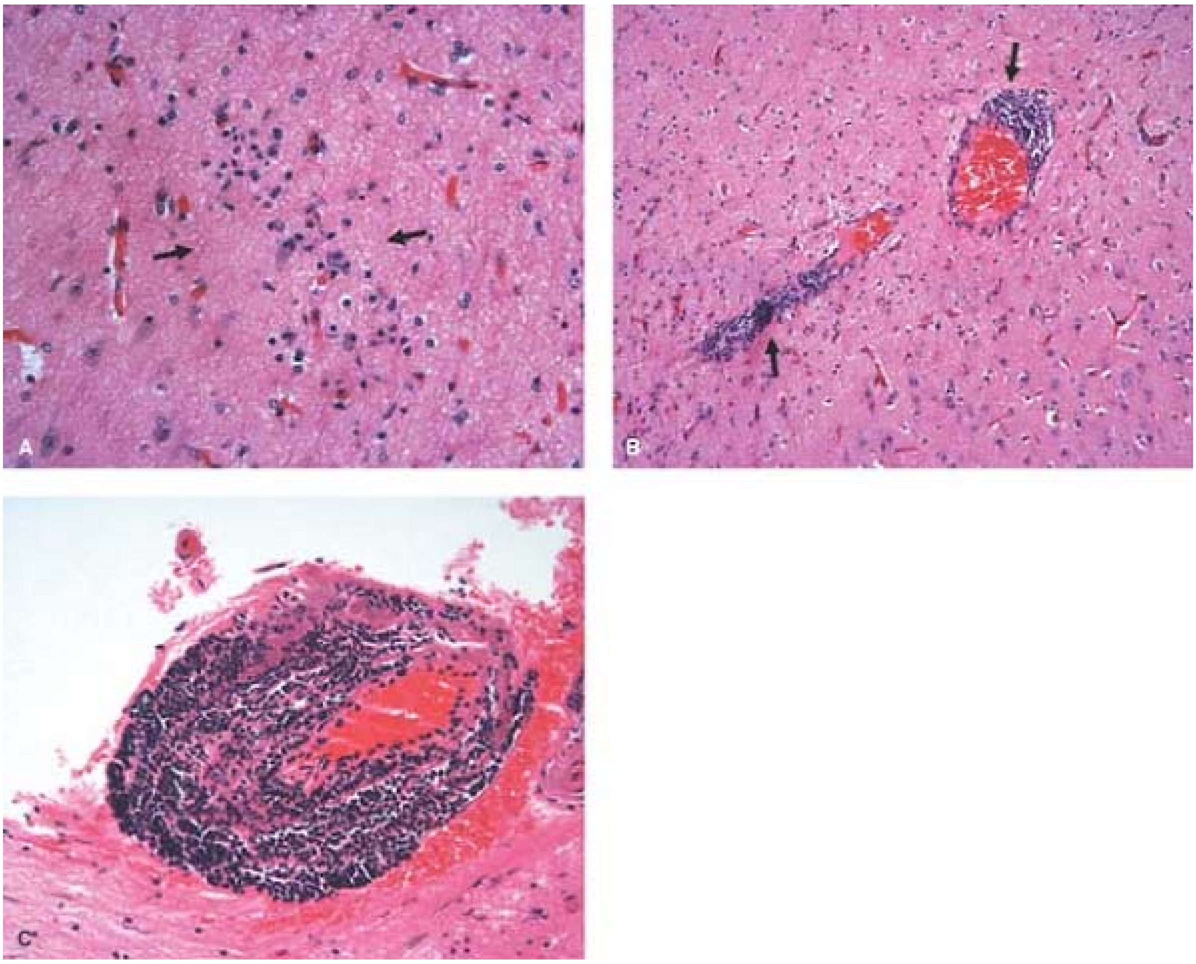

FIGURE 12.10 Rasmussen encephalitis/Rasmussen syndrome. **A.** *Arrows* indicate a poorly defined inflammatory/microglial nodule. **B.** Prominent angiocentric chronic inflammation in a region of brain with slight rarefaction and gliosis. Notice patchy nature of the inflammatory infiltrate. **C.** A meningeal vein showing dense transmural lymphocytic infiltrate *without* evidence of injury of the vessel wall or thrombus. (All panels are from sections stained with hematoxylin & eosin.) (See black and white image.)

P.CP-6

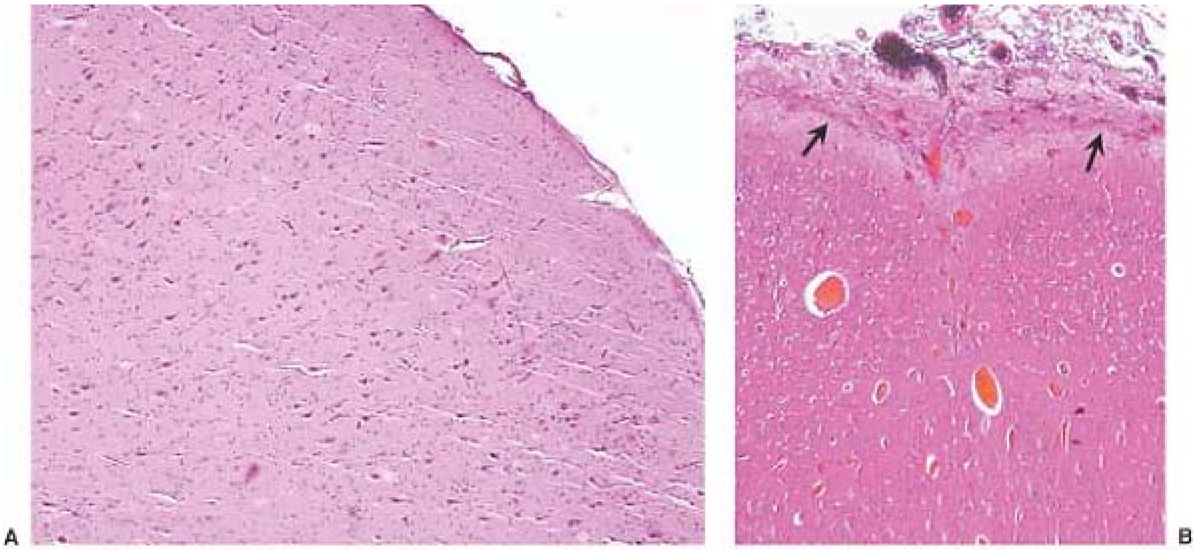

FIGURE 14.2 Representative micrographs of the resection specimen obtained from the child with magnetic resonance imaging (MRI) and intraoperative appearances illustrated in Fig. 1. **A:** Low-magnification view of a representative region of cortex shows a modest degree of neuronal disorganization. **B:** A focus of polymicrogyria, one of many seen in the resection specimen. Also note a "rind" of disorganized glial tissue covering the pia, with apparent extension into the subarachnoid space (*arrows*). (Hematoxylin and eosin stain.) (See black and white image.)

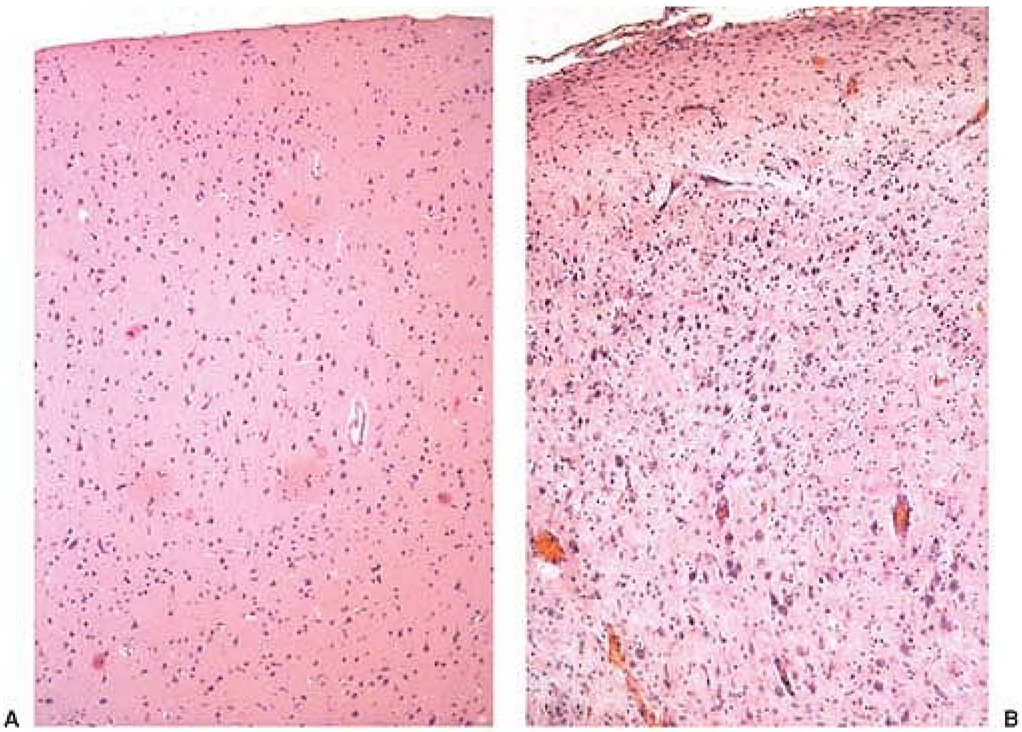

FIGURE 14.5 A: Relatively normally organized cerebral cortex from a surgical resection specimen. **B:** Region with severe cortical dysplasia shows pronounced cortical disorganization, with abnormal

crowding of neurons and abnormal orientation of many cells. Both panels are from micrographs photographed at the same magnification from sections stained with routine hematoxylin and eosin stains. (See black and white image.)

P.CP-7

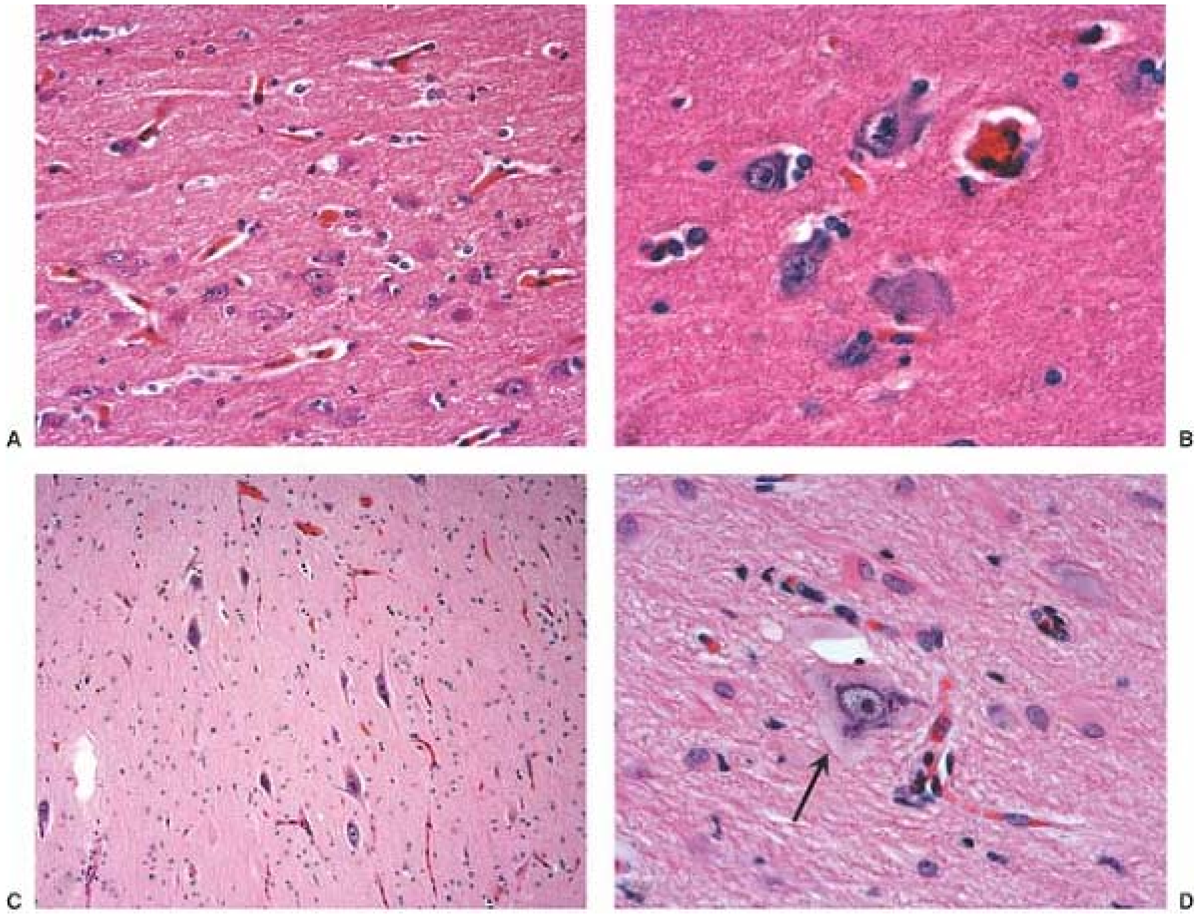

FIGURE 14.6 Neuronal disorganization and dysmorphism in cortical dysplasia/malformations of cortical development. **A:** Intermediate-magnification micrograph shows crowded and abnormally oriented neuronal cell bodies. **B:** Same features shown at a higher magnification. **C:** Variably enlarged and abnormally distributed neurons near the cortex-white matter junction. **D:** Magnified view of a dysmorphic neuron (*arrow*) with clumping of Nissl substance around the nucleus and clearing of the peripheral cytoplasm. Gemistocytic astrocytes are seen distributed around this neuron. (All panels are from hematoxylin and eosin-stained sections.) (See black and white image.)

P.CP-8

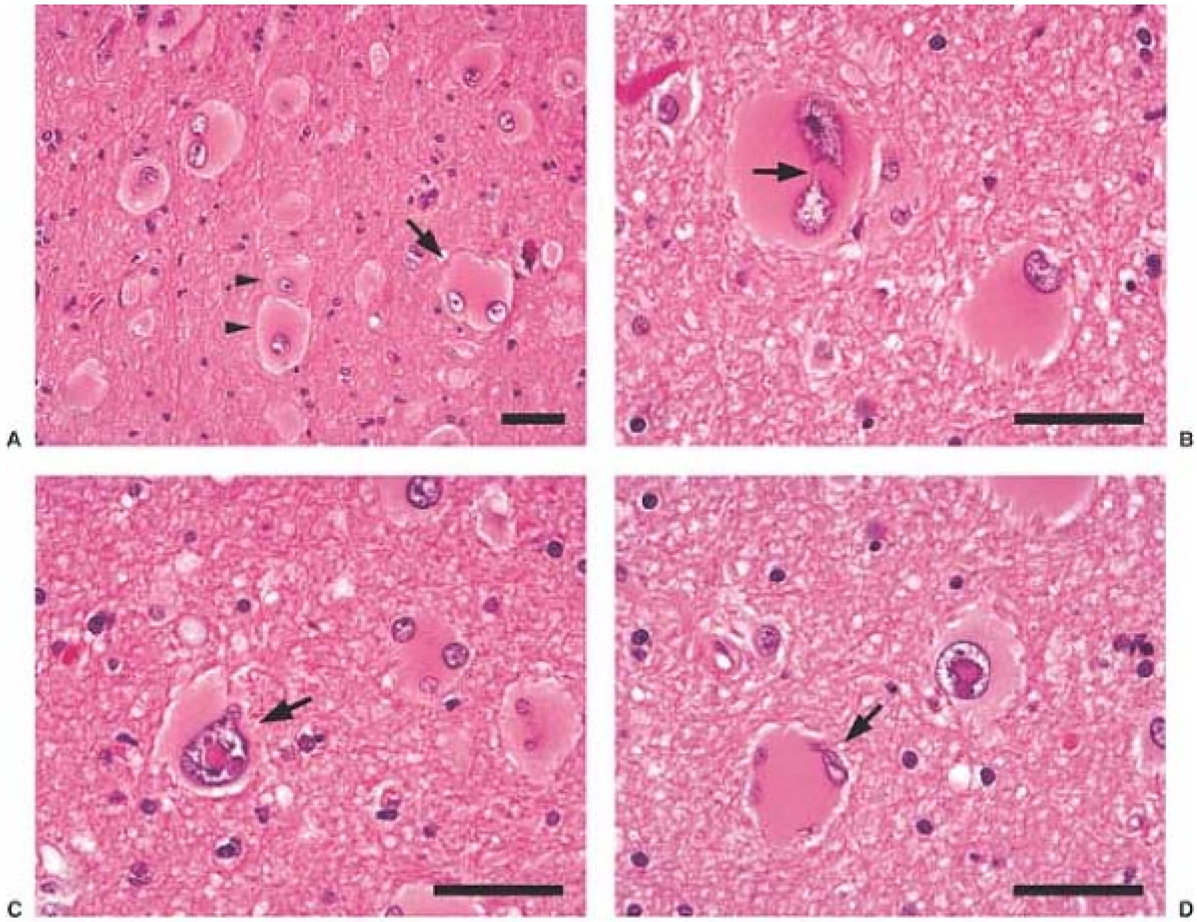

FIGURE 14.7 Typical balloon cells, with variably pronounced nuclear atypia. Hematoxylin and eosin stains. **A:** Balloon cells often show binucleation (*arrow*). Paired balloon cells are also seen (*arrowheads*). **B:** A balloon cell with a nuclear bridge connecting two nuclei (*arrow*). **C:** Balloon cell with marked nuclear atypia and/or nuclear invagination with nuclear budding (*arrow*). Also note the Marinesco body-like intranuclear inclusion. **D:** Balloon cell with multinucleation and/or micronucleation (*arrow*). Bars = 50 μm. (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol* 2002;12:212–233; with permission.) (See black and white image.)

P.CP-9

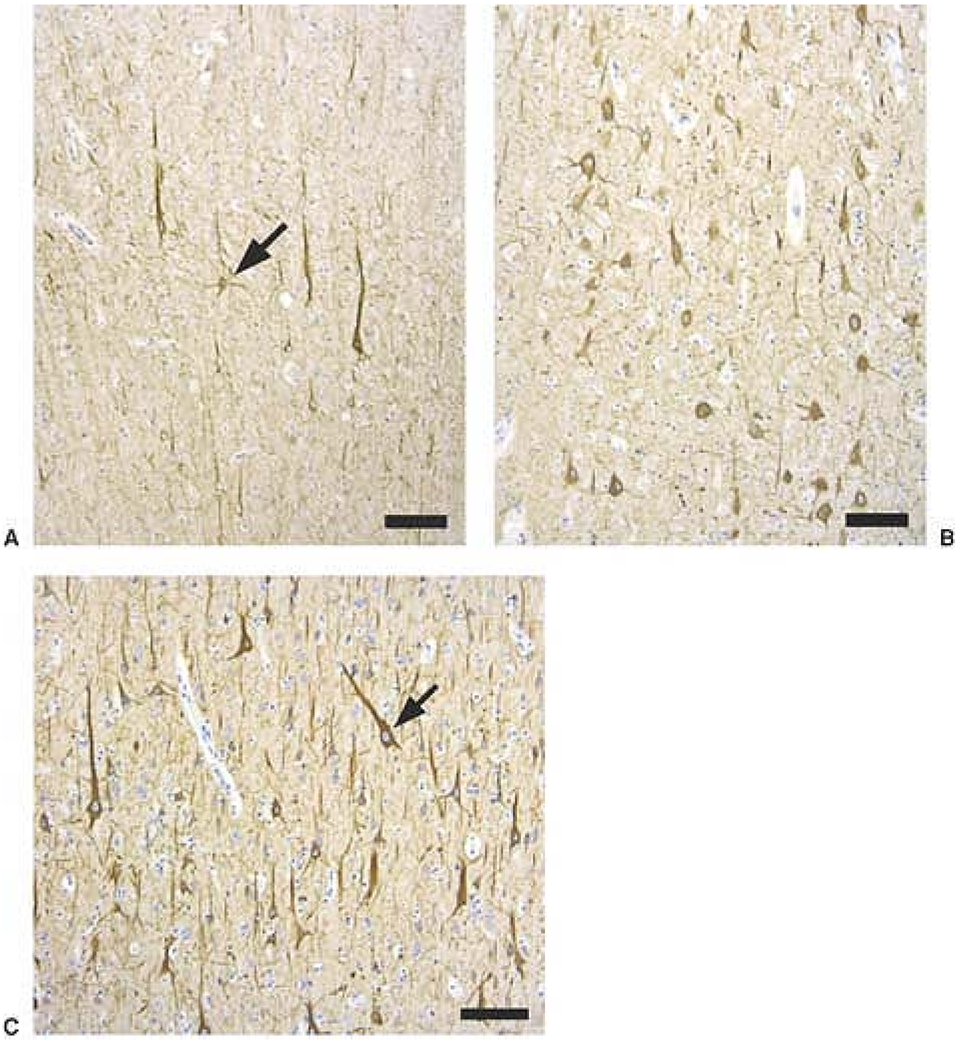

FIGURE 14.8 Neurofilament (N52, high-molecular-weight neurofilament antibody) immunohistochemistry of surgically resected corticectomies. **A:** Relatively normal cortex from a patient with temporal lobe epilepsy. Some, although not all, of the pyramidal neurons in layers III and V as well as multipolar interneurons (*arrow*) are positive for N52. **B:** Focal cortical dysplasia. Neuronal dyslamination and dysmorphic, multipolar, cytomegalic neurons are evident. **C:** Relatively normal cortex adjacent to a region of cortical dysplasia. More pyramidal neurons (in layers III and V) are more strongly immunoreactive for N52 than in control cortex (A), and an abnormally oriented pyramidal neuron (*arrow*) is also easily identified. The pial surface is at the top in each panel. Bars = 100 μm. (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol*. 2002;12:212–233; with permission.) (See black and white image.)

P.CP-10

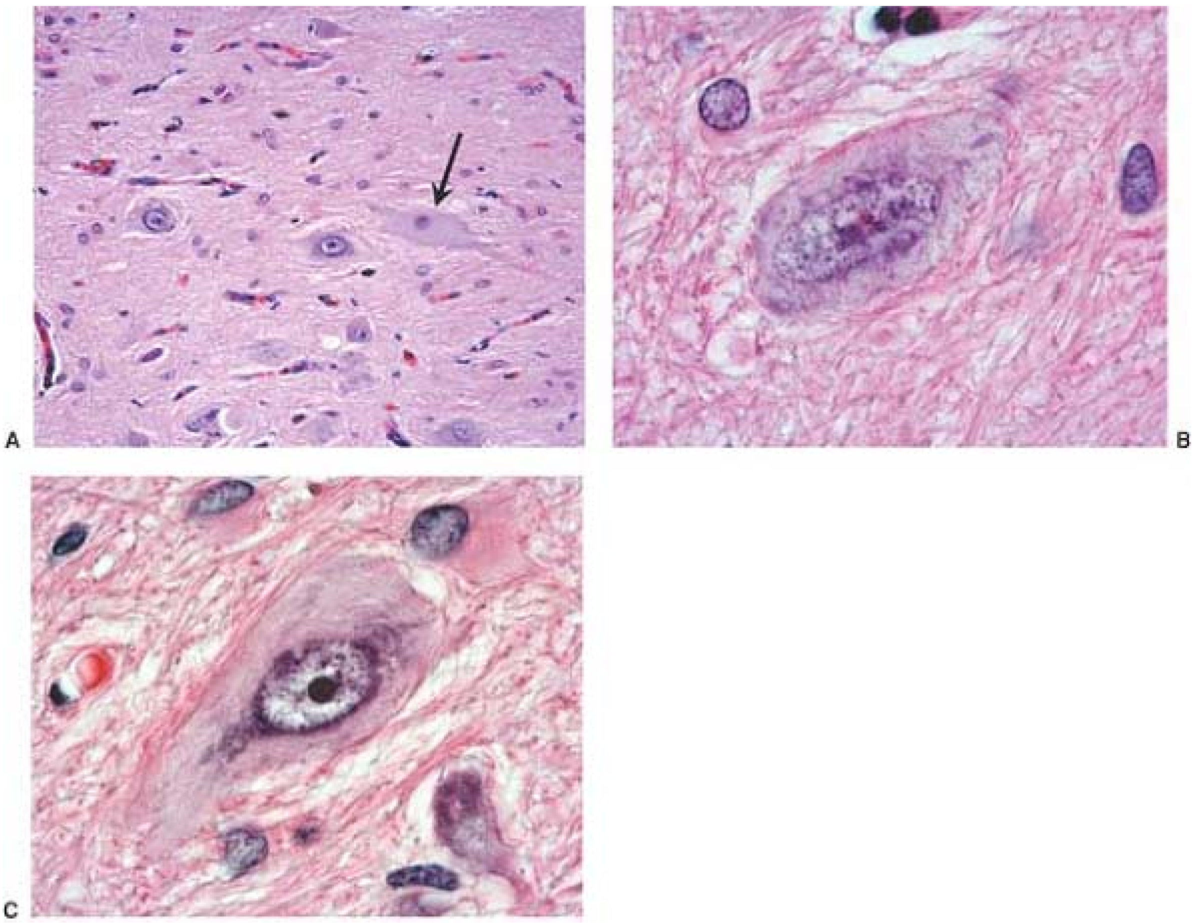

FIGURE 14.9 Histologic features of severe cortical dysplasia. **A:** Dysmorphic and enlarged neuronal cell bodies. Arrow indicates a cell that shows a "neuronal" nucleus but pale, glassy amphophilic cytoplasm (lacking Nissl substance) of the type more commonly seen in gemistocytic astrocytes. **B, C:** Dysmorphic, enlarged neurons with coarseness of the cytoplasm, suggestive of neurofibrillary change. (All panels are micrographs from hematoxylin and eosin-stained sections.). (See black and white image.)

P.CP-11

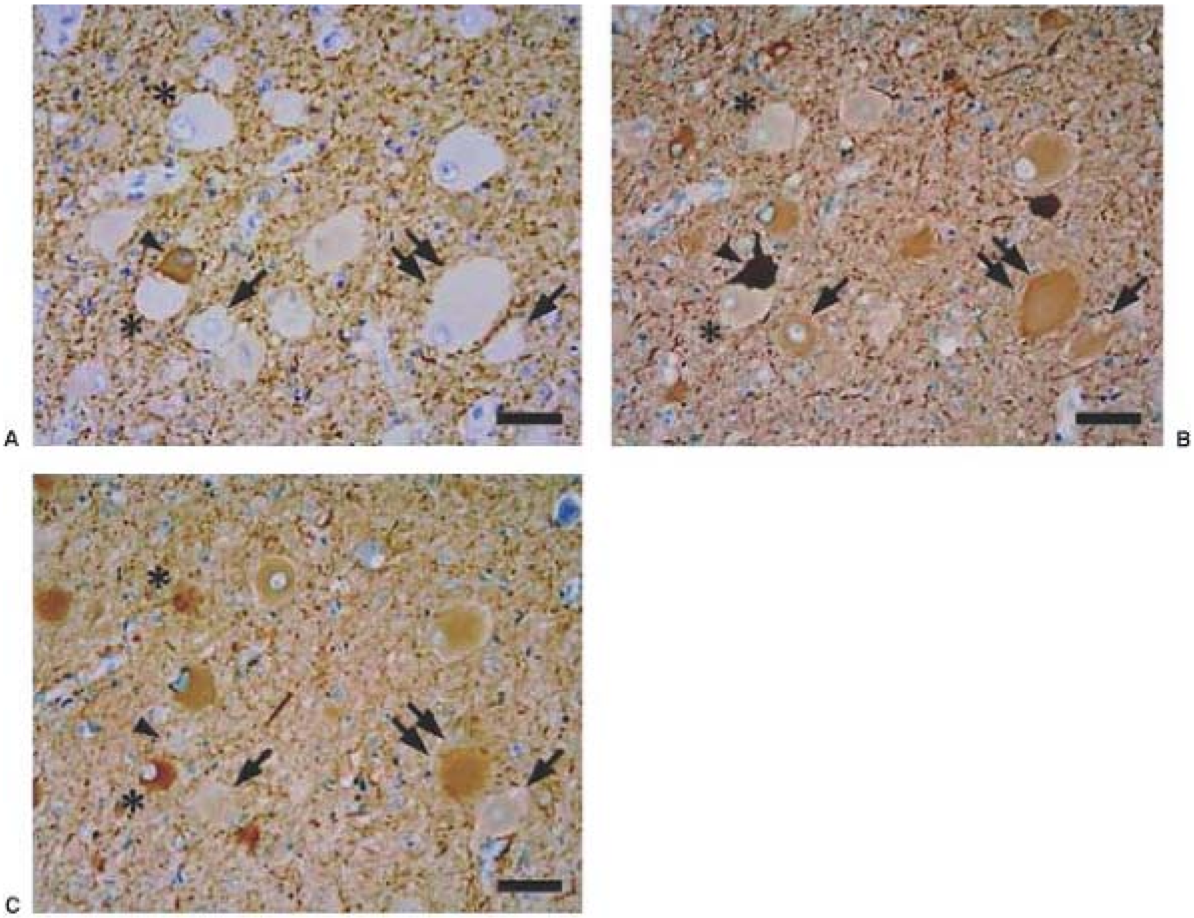

FIGURE 14.10 Balloon cells show various patterns of neuroectodermal differentiation. Some show only glial (glial fibrillary acidic protein [GFAP]) or neuronal (neurofilament) differentiation, whereas others show both GFAP and neurofilament immunoreactivity. Only rare balloon cells are immunoreactive for phosphorylated neurofilament (*arrowhead*, panel A). However, most are immunoreactive with nonphosphorylated neurofilament (panel B) with varying intensities. Some are immunoreactive for both GFAP and nonphosphorylated neurofilament (*double arrows*, panels B and C). Symbols and arrows in all panels indicate the same cell identified in serial sections. Arrowhead indicates a balloon cell that is phosphorylated neurofilament (p-NF)-positive, NF-positive, and GFAP-negative. Arrows indicate balloon cells that are p-NF-negative, NF-positive, and GFAP-negative. Asterisks indicate balloon cells that are p-NF and NF-negative but GFAP-positive. Double arrow indicates a balloon cell that is p-NF-negative, NF-positive, and GFAP-positive. Bars = 50 μm. (Panel A, section stained with primary antibody to phospho-NF, panel B with primary antibody to NF, panel C with primary antibody to GFAP). (From Crino PB, Miyata H, Vinters HV. Neurodevelopmental disorders as a cause of seizures: neuropathologic, genetic, and mechanistic considerations. *Brain Pathol*. 2002;12:212–233; with permission.) (See black and white image.)

P.CP-12

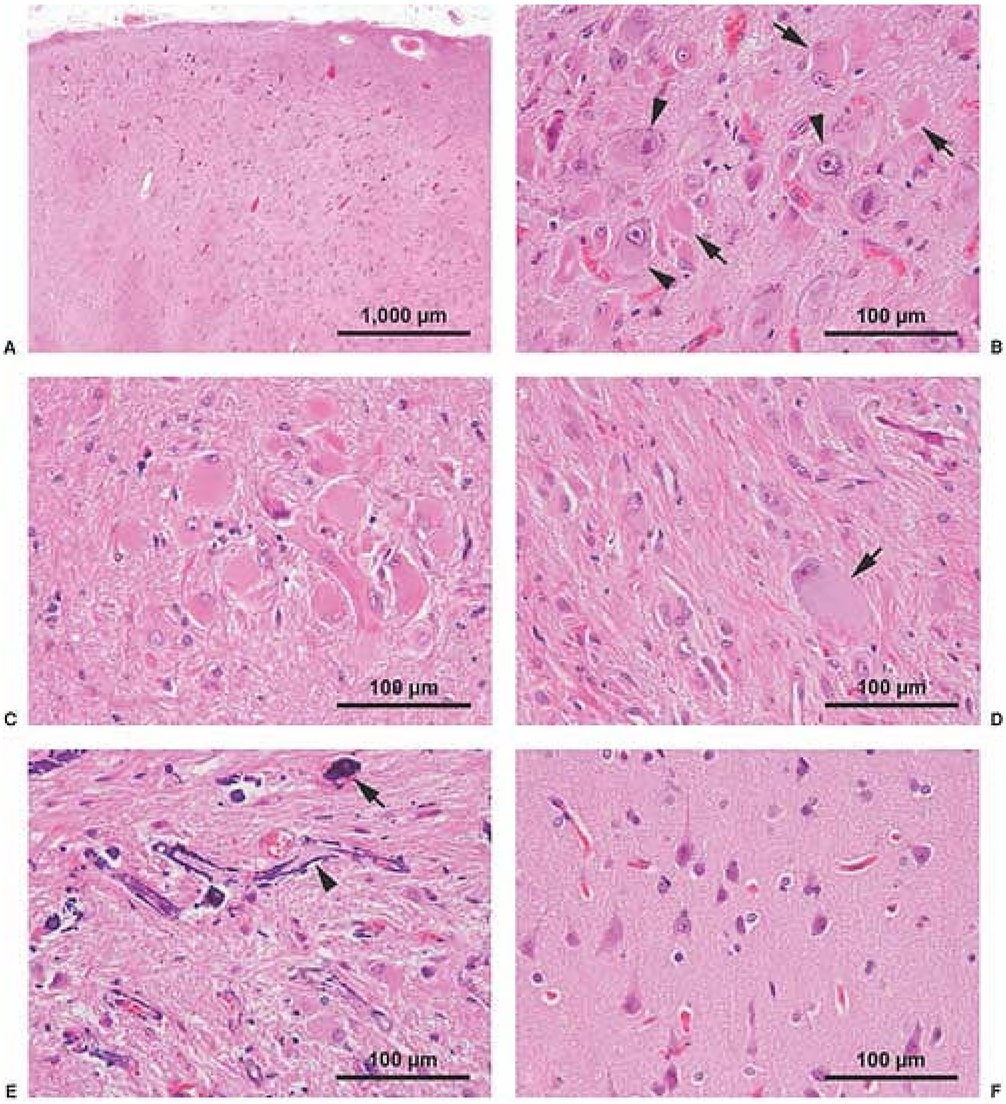

FIGURE 14.13 Cortical tuber in a child with tuberous sclerosis complex (TSC). **A:** Low-magnification view shows a disorganized collection of neuroglial cells, some enlarged. **B:** Magnified view of the lesion showing "balloon cells" with eccentric nuclei and glassy eosinophilic cytoplasm (*arrows*), admixed with dysmorphic, markedly enlarged neurons containing Nissl substance in their cytoplasm (*arrowheads*). **C:** A cluster of balloon cells within the tuber. **D:** An abnormal neuroglial cell showing morphologic features of both dysplastic neuron and balloon cell (*arrow*). Note the eccentric nucleolated nucleus and the enlarged pale but slightly basophilic cytoplasm, raising the possibility that the cell represents a transitional form of neuroglial cell. **E:** Various degrees of punctate calcification (*arrows*) and calcifications along vessel walls (*arrowheads*) are often seen in TSC tubers. **F:** Morphologically normal cerebral cortex (for comparison with features of the tuber). (All panels are micrographs from sections stained with hematoxylin and eosin.) (See black and white image.)

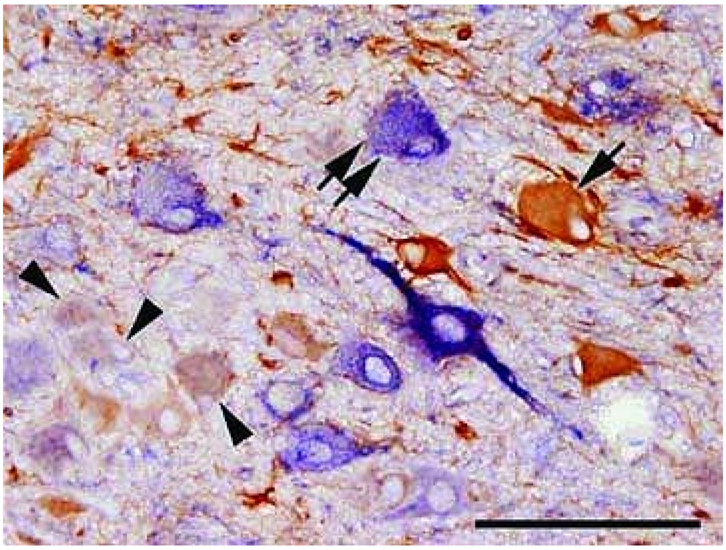

FIGURE 14.14 Immunohistochemical findings in a tuberous sclerosis complex (TSC) tuber. Double-label immunohistochemistry confirms colocalization of glial fibrillary acidic protein (GFAP) (*brown color*) and nonphosphorylated neurofilament (*purplish-blue*) in a subpopulation of balloon cells (*arrowheads*) in a TSC tuber, suggesting a failure of commitment in neuroglial differentiation. Note that some abnormal neuroglial cells are immunoreactive for GFAP (*arrow*) or nonphosphorylated neurofilament (*double arrows*). Scale bar = 100 μm. (See black and white image.)

P.CP-14

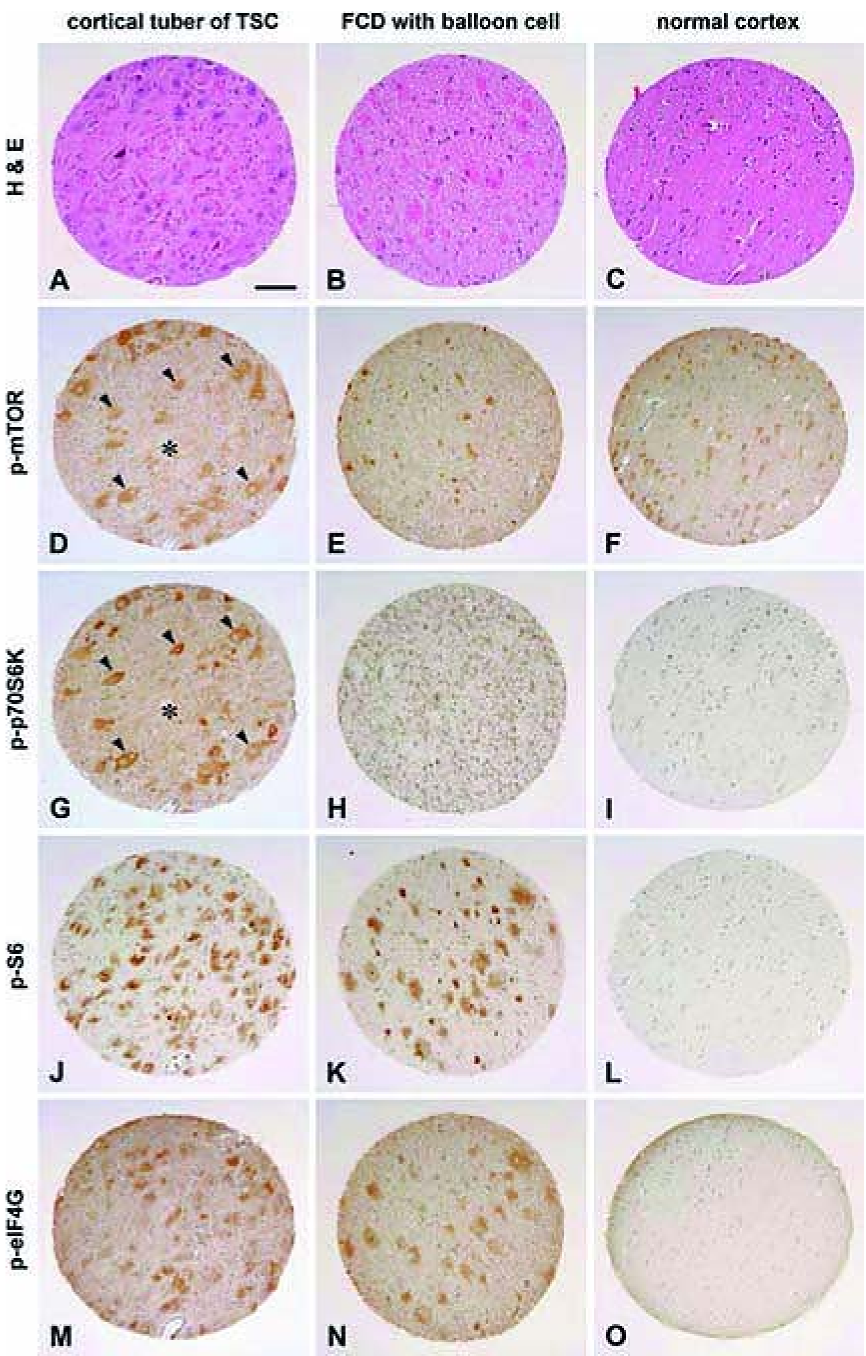

FIGURE 14.16 Tissue microarray (TMA) analysis of insulin signaling pathways in tuberous sclerosis complex (TSC) tubers, focal cortical dysplasia, and control tissues. The left column represents sample cores from a TSC tuber **(A, D, G, J, M)**; the middle column represents focal cortical dysplasia (FCD) with balloon cells (Palmini type IIB) **(B, E, H, K, N)**; and the right column represents histologically normal cerebral cortex **(C, F, I, L, O)**. Stained with hematoxylin and eosin (H&E) (A–C), p-mTOR (D–F), p-p70S6K (G–I), p-S6 (J–L), and p-eIF4G (M–O). Immunostains were performed on consecutive serial sections, and the same cells can be easily identified in different stains (e.g., *arrowheads* in D and G). Expression of p-p70S6K appears to be specific to the TSC tuber (panel G). Note the population of abnormal neuroglial cells in the TSC tuber expressing p-S6 and/or p-eIF4G (e.g., central area of each core shown in panels J and M), despite negative expression of p-mTOR and p-p70S6K (the same areas indicated by asterisks in panels D and G). Each core has a 0.6-mm diameter. Bar = 100 μm. eIF4G, eukaryotic translation initiation factor 4G; mTOR, mammalian target of rapamycin; p-, phospho-; p70S6K, 70-kDa ribosomal

protein S6 kinase; S6, 40S ribosomal protein S6. For details of methodology, see Miyata et al. (2004). (From Miyata H, Chiang ACY, Vinters HV. Insulin signaling pathways in cortical dysplasia and TSC-tubers: tissue microarray analysis. *Ann Neurol*. 2004;56:510–519; with permission.) (See black and white image.)

P.CP-15

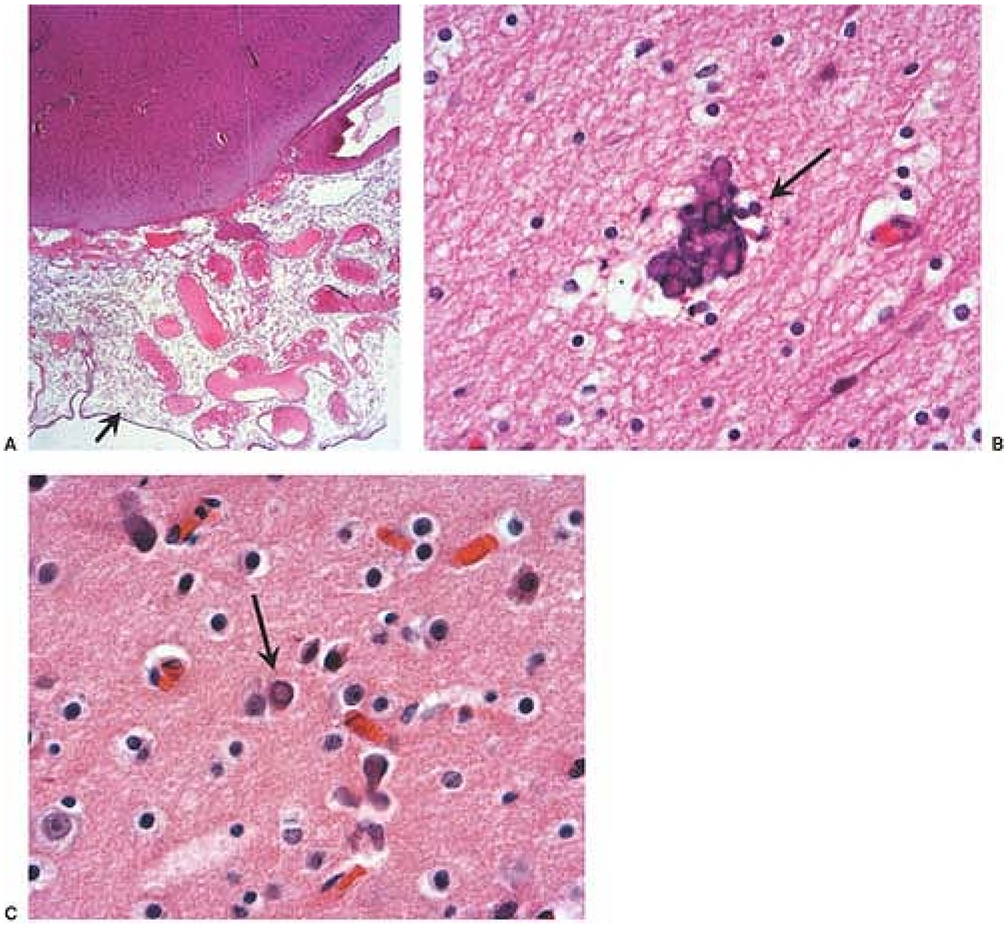

FIGURE 14.18 Sturge-Weber-Dimitri syndrome, microscopic features. **A:** Dense angiomatosis of meningeal vessels in the occipital region (*arrow*). **B, C:** Punctate calcifications (*arrows*) in the underlying brain parenchyma. (See black and white image.)

P.CP-16

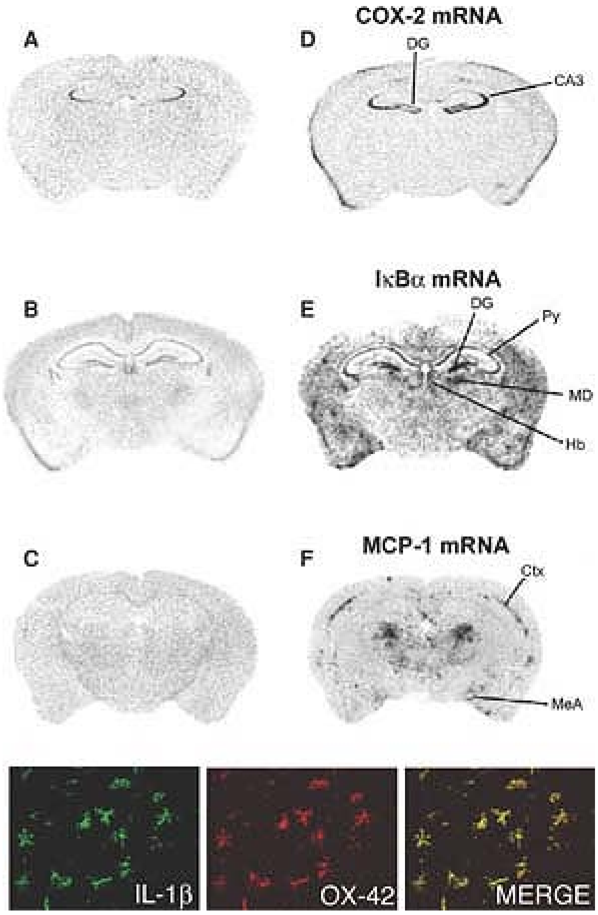

FIGURE 25.2 Seizure-induced expression of genes encoding proinflammatory molecules in rodent forebrain areas after seizures. Panels **D** through **F** show the increased hybridization signal of COX-2, IkBα, (an index of NFκB activation), and the chemokine monocyte-chemoattractant protein (MIP)-1, 24 hours after seizures induced by pilocarpine in mouse forebrain sections (adapted from Turrin NP, Rivest S. Innate immune reaction in response to seizures: Implications for the neuropathology associated with epilepsy. *Neurobiol Dis.* 2004;16:321–334, with permission). Very low or nondetectable expression was found in basal conditions (saline-injected mice), as depicted in corresponding panels **A** through **C**. The phenotype of the expressing cells was identified using selective markers: The majority of cells expressing these inflammatory mediators were infiltrating monocytes and parenchymal microglia; in some instances also endothelial cells were positive. Neurons also overexpressed COX-2 and IkB mRNA. Micrographs in bottom row depict IL-1ß and OX-42$^+$ microglia and their merged image, respectively. Ctx, cortex; CA3, pyramidal layer regions; DG, dentate gyrus; Hb, habenular nucleus; MD, mediodorsal thalamic nucleus; MeA, medial amygdala; Py, pyramidal cell layer. (See black and white image.)

P.CP-17

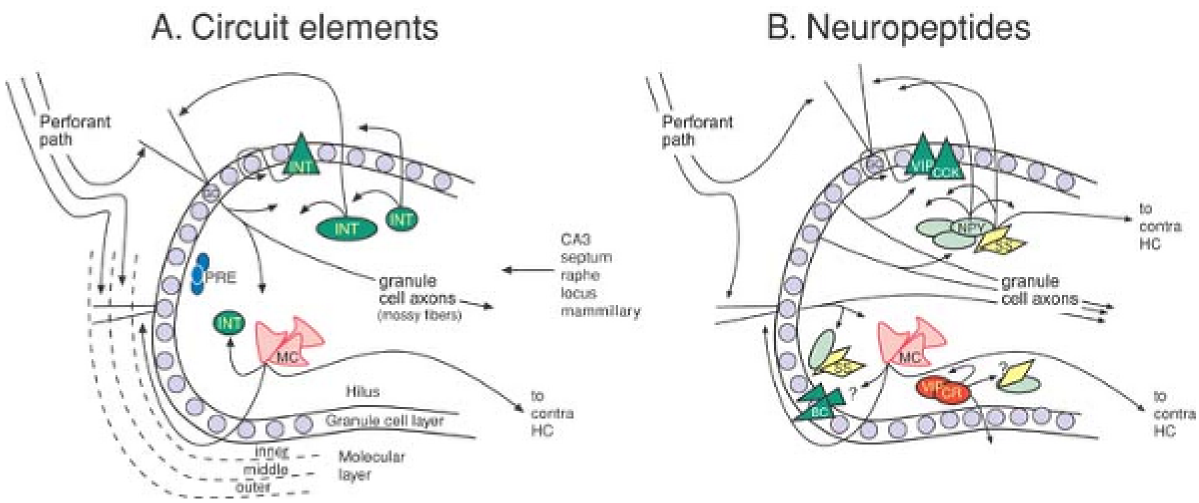

FIGURE 27.1 Circuit elements and neuropeptides in the rat dentate gyrus under normal conditions. **A:** Major components of dentate gyrus circuitry. These include the dense layer of granule cells (*GC*); diverse GABAergic "interneurons" (*INT*), hilar mossy cells (*MC*), as well as precursors to granule cells (*PRE*) that are located in the subgranular zone. The major afferent input to the dentate gyrus is the perforant pathway, which contains the axons of neurons in the entorhinal cortex. Lateral entorhinal neurons innervate the outer molecular layer (*outer*) and medial entorhinal neurons innervate the medial molecular layer (*medial*). Mossy cells and other fibers innervate the inner molecular layer (*inner*). In addition, inputs to the dentate gyrus also arise from area CA3 pyramidal cells, the septum, dorsal raphe, locus coeruleus, mammillary bodies, and other areas. The main projections from the dentate gyrus are from the granule cell axons (the mossy fibers), which terminate locally on hilar processes and the layer containing the proximal dendrites of CA3 pyramidal cells (stratum lucidum; not shown). In addition, mossy cells project both ipsilaterally and contralaterally to the dentate gyrus. Some GABAergic neurons also project contralaterally. Reproduced with permission from Freund TF, Buzsaki G. Interneurons of the hippocampus. *Hippocampus*. 1996;6:347–470; and Scharfman HE. The role of nonprincipal cells in dentate gyrus excitability and its relevance to animal models of epilepsy and TLE. In: Delgado-Esqueta AV, Wilson W, Olsen RW, Porter RJ, editors. *Basic mechanisms of the epilepsies: molecular and cellular approaches*, 3rd ed. New York: Lippincott-Raven; 1999:805–820.[77,179] **B:** Many neuropeptides are expressed in the normal dentate gyrus, and some of the most well-studied examples are shown.[77] Opiates are mainly expressed in granule cells. In contrast, other neuropeptides are primarily present in interneurons. Basket cells contain both vasoactive intestinal polypeptide and cholecystokinin; hilar neurons that innervate the outer molecular layer (as well as other targets) express neuropeptide Y and/or somatostatin; vasoactive intestinal polypeptide and calretinin that define a population that innervates the inner molecular layer, as well as other interneurons; in addition, other vasoactive intestinal polypeptide-containing cells exist and may be coupled by gap junctions.[90] Recent studies have indicated that substance P has widespread expression in interneurons.[197] (See black and white image.)

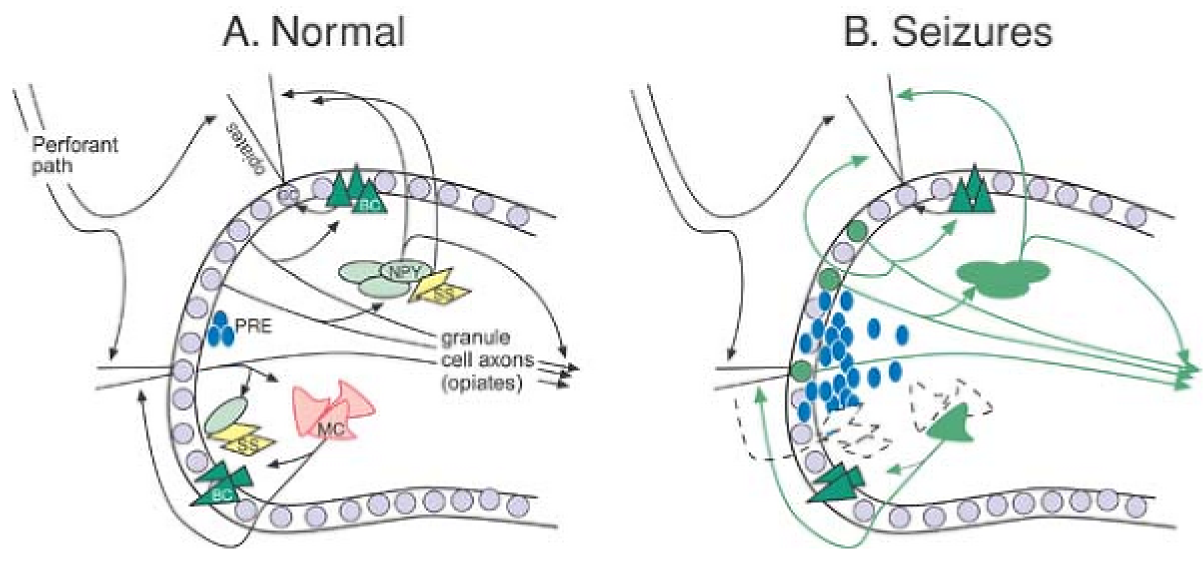

FIGURE 27.2 Changes in neuropeptide Y and somatostatin in the dentate gyrus after seizures. **A:** Normal circuitry and expression of neuropeptide Y and somatostatin in the rodent dentate gyrus. **B:** Alterations in neuropeptide Y and somatostatin in animal models of epilepsy are illustrated schematically. For the neuropeptide Y system, these changes include: (a) new expression in granule cells and their axons, the mossy fibers; (b) increased expression in interneurons that normally express neuropeptide Y—this effect appears to develop mostly after acute rather than chronic seizures; (c) novel expression of neuropeptide Y in some mossy cells;[88] and (d) expression in newly formed granule cells, although the extent that this occurs is unclear. In addition, changes in receptors occur (not shown). For the somatostatin system, the best documented alteration is seizure-induced cell death of those interneurons that normally express this peptide. (See black and white image.)

P.CP-18

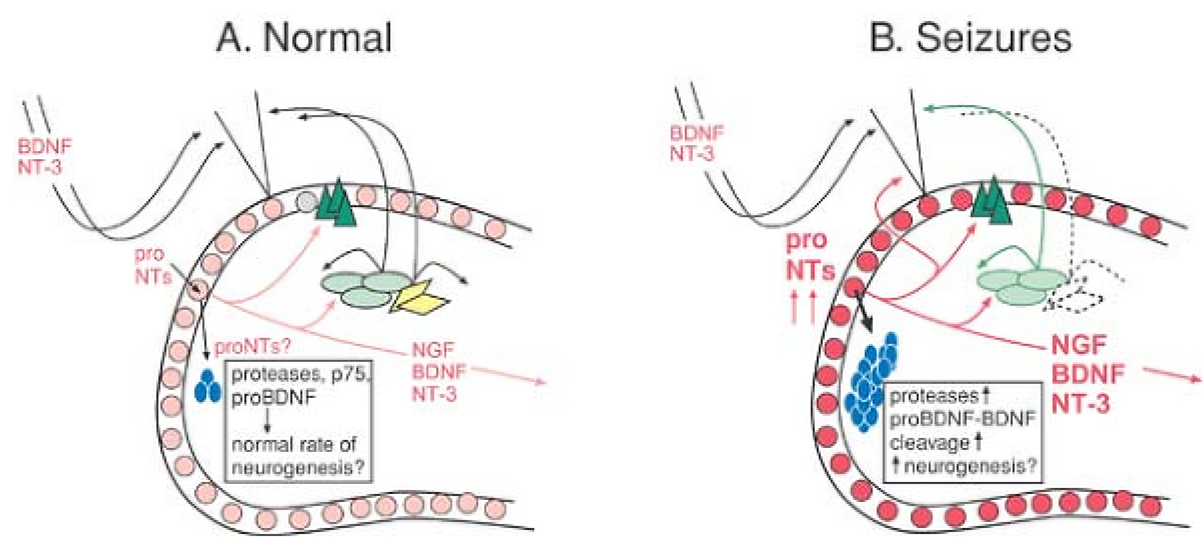

FIGURE 27.3 Changes in neurotrophins in the dentate gyrus after seizures. **A:** Normal pattern of expression of the neurotrophins NGF, BDNF, and NT-3. The predominant cell type expressing neurotrophins normally is the

granule cell. In addition, lower levels of BDNF and NT-3 are present in perforant path axons. Proneurotrophins are present in the soma and are thought to be released in the vicinity of the soma. Proneurotrophins are typically cleaved by extracellular proteases, but can also act directly on p75 receptors to modulate survival. **B:** Changes in neurotrophins associated with chronic seizures are schematically illustrated. NGF and BDNF expression is increased in granule cells, and NT-3 levels decline; BDNF and NT-3 decline in the perforant path when seizure-induced entorhinal cell loss occurs. The altered levels of neurotrophins are likely to have diverse effects on granule cell structure and function. In addition, indirect effects may occur, such as induction of neuropeptide Y by BDNF, either in granule cells or adjacent interneurons (cf. Figure 2). Upregulation of proneurotrophins are also likely and, in the case of proBDNF, increased synthesis may influence seizure-induced cell death by increased activation of the p75 neurotrophin receptor, or seizure-induced neurogenesis by the increase in BDNF that would result from proBDNF cleavage. These changes, as well as alterations in receptors for neurotrophins, are likely to have a complex net effect on the excitability of the dentate gyrus. (See black and white image.)

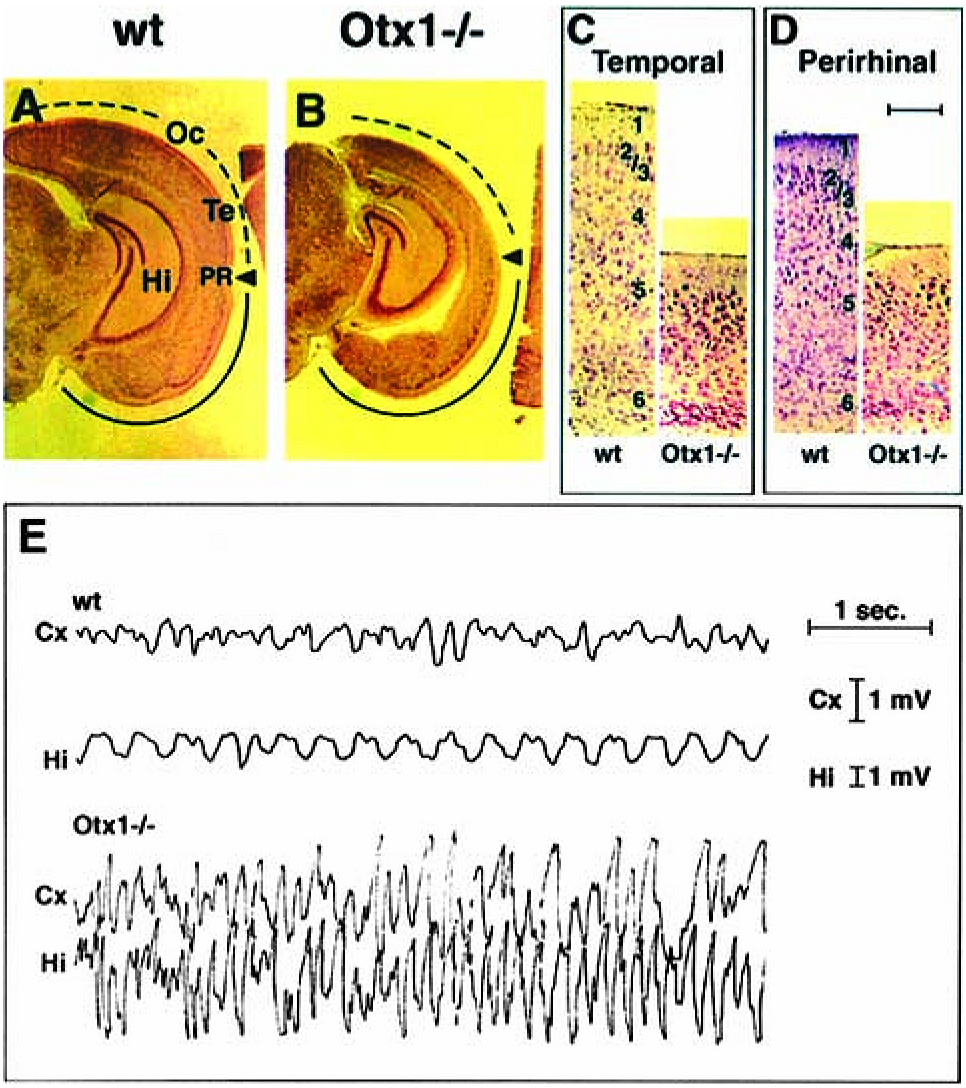

FIGURE 36.13 Morphologic **(A, B)**, histologic **(C, D)**, and electroencephalographic (EEG) **(E)** comparison

of wild-type (wt) and Otx$^{-/-}$ mice. Note the reduction of temporal (Te) perirhinal (PR) cortices and hippocampus (Hi) in Otx$^{-/-}$ mice. Representative EEG recordings from neocortex (Cx) and Hi during a convulsive seizure of Otx$^{-/-}$ mice is shown in panel E, where the EEG recording from a wild-type (wt) animal is shown for comparison. (From Acampora D, Barone P, Simeone A. Otx genes in corticogenesis and brain development. *Cereb Cortex.* 1999;9:533–542; with permission.) (See black and white image.)

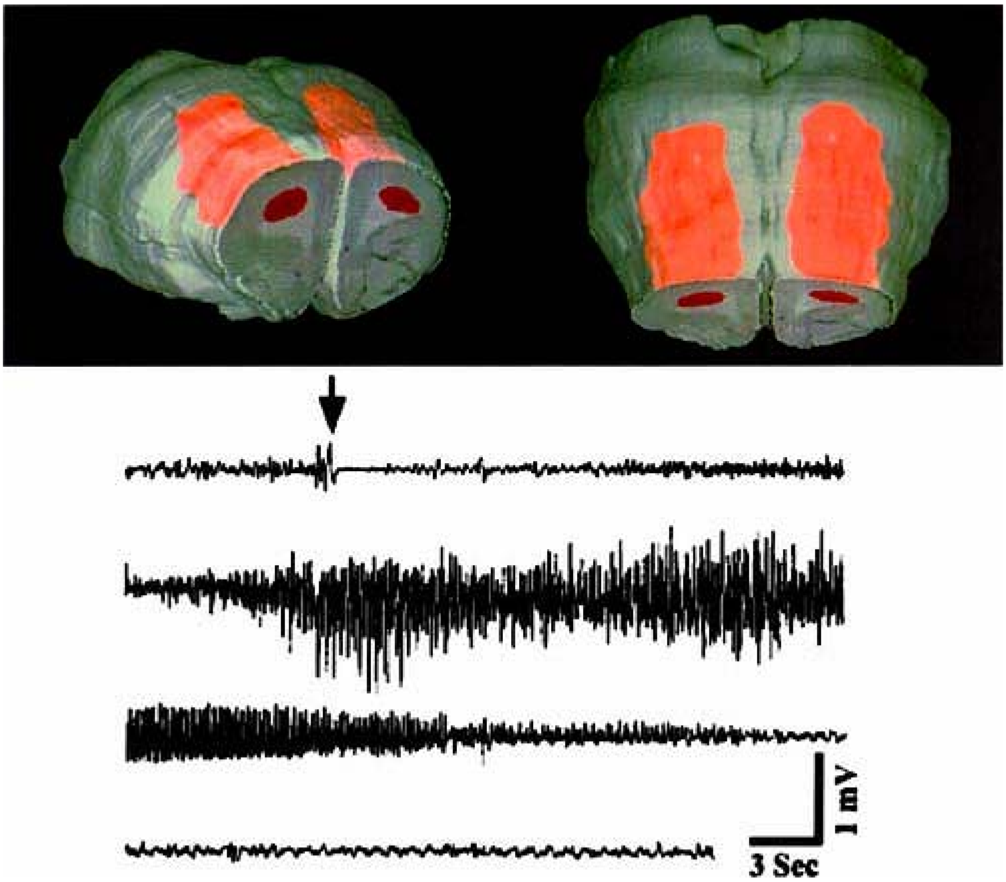

FIGURE 36.15 Top: Three-dimensional reconstruction of the telencephalic internal structural heterotopia (TISH) shown in red at the cut surface of the brain and in pink where it is viewed through the overlying cortex. **Bottom:** Electroencephalographic (EEG) recordings of a convulsive seizure in a TISH rat. The four lines show continuous EEG recording from a single electrode positioned in the normotopic neocortex (*arrow* indicates seizure onset). Seizure activity can be observed as changes in the frequency and amplitude of the EEG. (Modified from Lee KS, Schottler F, Collins JL, et al. A genetic animal model of human neocortical heterotopia associated with seizures. *J Neurosci*. 1997;17:6236–6242). (See black and white image.)

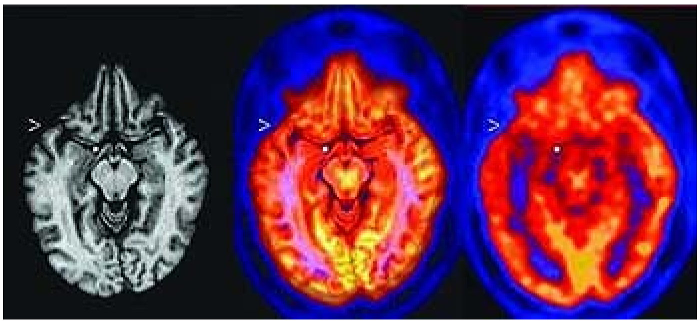

FIGURE 80.1 Coregistered axial image plane of magnetic resonance imaging (MRI) and interictal 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a limbic temporal lobe epilepsy (TLE) patient. The gray-scale MR image **(left)** and the color PET image **(right)** are coregistered in the center image. The MRI and PET data were reoriented parallel to a line through the anterior and posterior commissures. A widespread area of reduced [^{18}F]FDG activity is evident on the left side of the PET image; inspection of the PET image alone does not clarify whether the reduction extends from mesial structures (at the dot internal to the brain FDG image) of the temporal lobe into the basal frontal lobe, nor whether the lateral temporal hypometabolism (at the arrowhead) extends above the sylvian fissure. The dot and arrowhead appear at the same coordinates in the MRI and the coregistered MRI-PET images as in the PET image, clarifying that all sites with severe hypometabolism are confined to the temporal lobe. (See black and white image.)

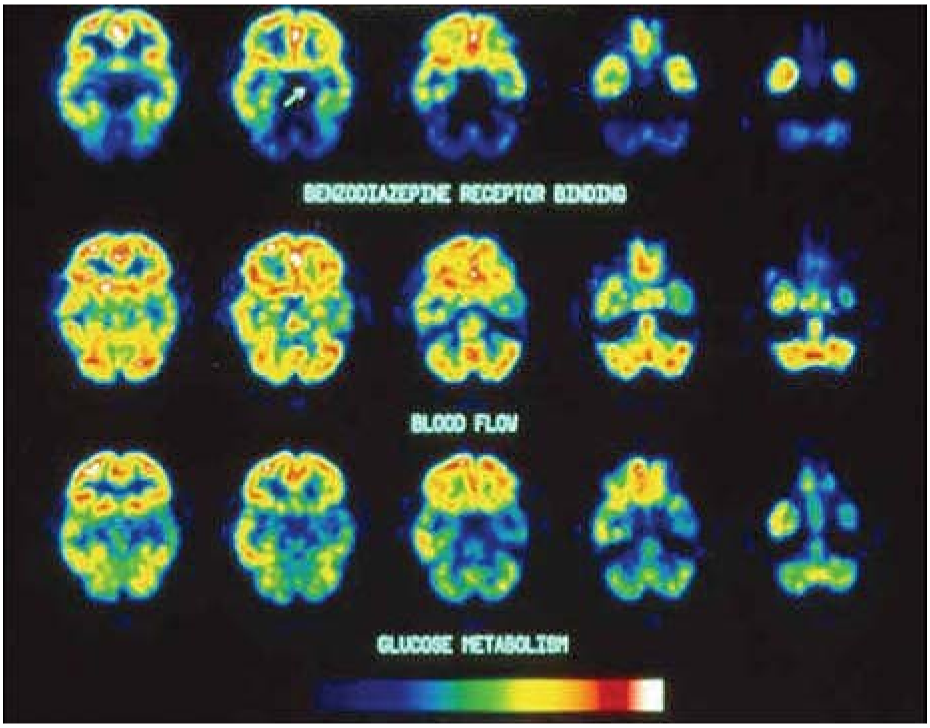

FIGURE 80.7 Coregistered interictal [^{11}C] flumazenil and 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) positron emission tomography (PET) images of a mesial temporal lobe epilepsy (TLE) patient. Flumazenil transport rate is determined predominantly by regional cerebral blood flow. Flumazenil distribution volume is determined by the regional density of central benzodiazepine receptors. Five adjacent image planes are displayed for each modality. The more superior image plane is to the left of each row. The subject's left is on the right of each image. Images of glucose metabolism and flumazenil transport rate show a widespread left mesial and lateral temporal decrease. Images of flumazenil distribution volume show a highly localized left anterior mesial temporal decrease (*arrow*). The specimen at efficacious temporal lobectomy demonstrated sclerosis of the left anterior hippocampus. (From Henry et al. with permission.) (See black and white image.)

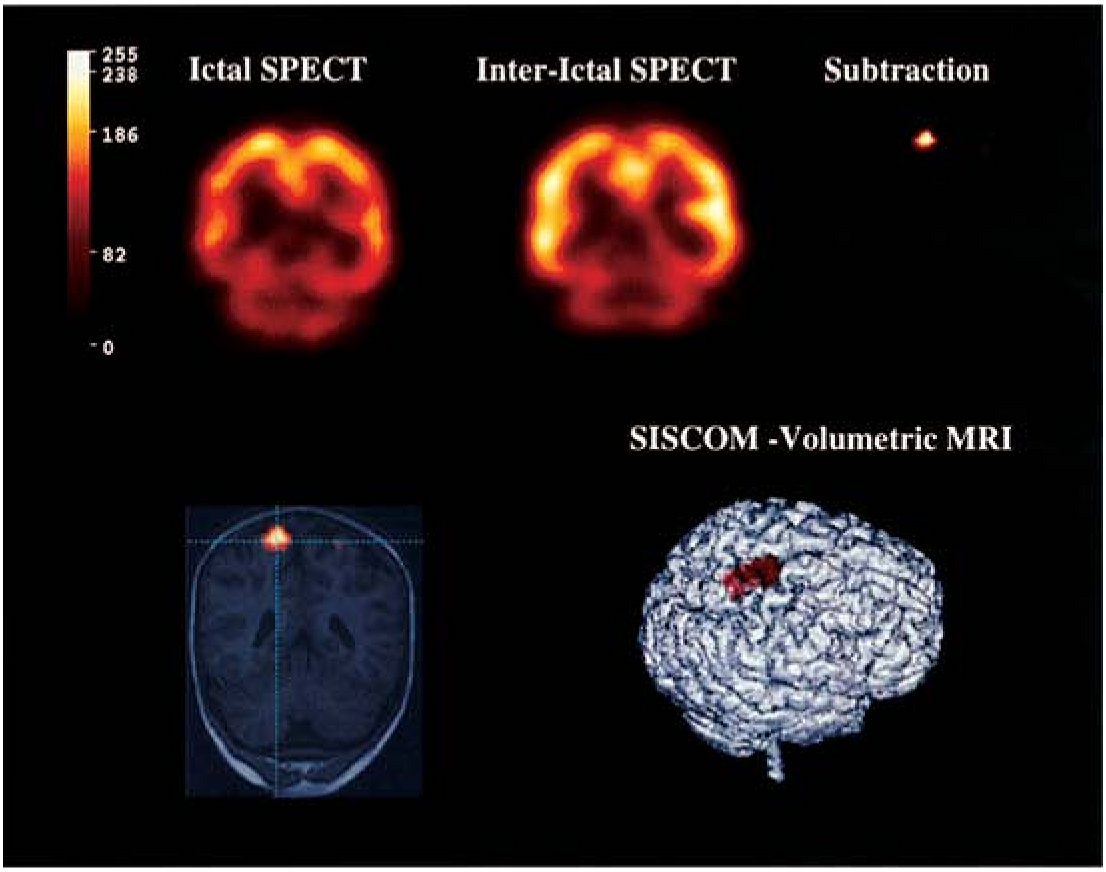

FIGURE 81.2 Steps to obtaining subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) image. Ictal (*upper left*) and interictal (*upper middle*) SPECT images are obtained. After normalization of their mean intensities and coregistration with each other, subtraction is performed to obtain a “difference” image (*upper right*). The difference image is then coregistered with MRI at specific planes (*lower left*) or on the surface of a three-dimensional MRI (*lower right*). (From So E. Role of neuroimaging in the management of seizure disorders. *Mayo Clin Proc*. 2002;77:1251–1264, with permission.) (See black and white image.)

P.CP-22

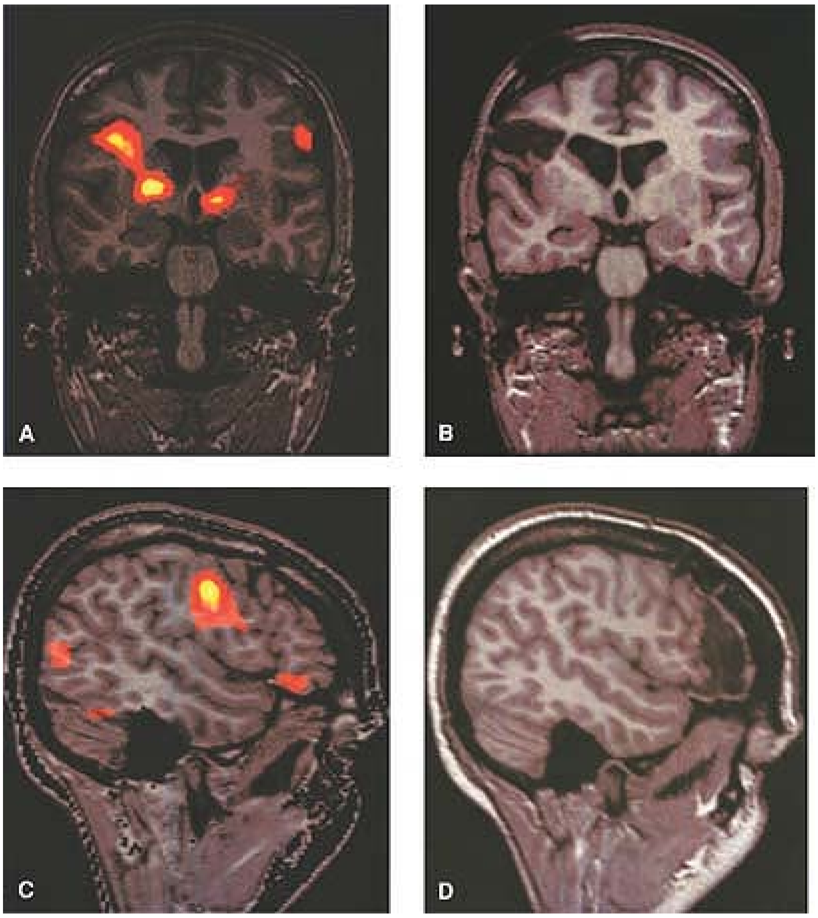

FIGURE 81.3 Preoperative subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) images (A and C) and postoperative MRI (B and D). **A, B:** Complete resection of neocortical region underlying SISCOM focus. **C, D:** Nonresection of neocortical region underlying SISCOM focus. (From O'Brien T, So E, Mullan B, et al. Subtraction peri-ictal SPECT is predictive of extratemporal epilepsy surgery outcome. *Neurology*. 2000;55:1668–1677, with permission.) (See black and white image.)

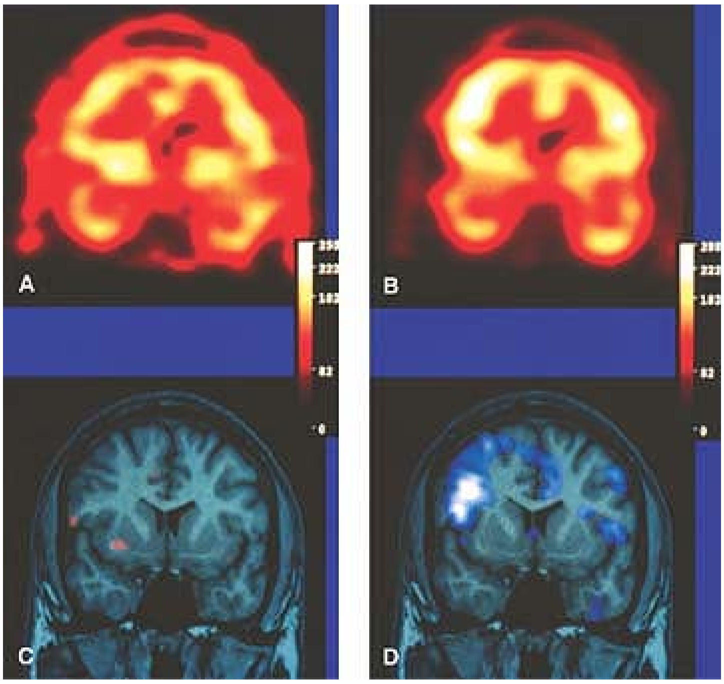

FIGURE 81.4 Subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (magnetic resonance imaging) (SISCOM) with "positive" subtraction for detecting hyperperfusion focus and "negative" subtraction for detecting hypoperfusion focus. **A:** Postictal SPECT image obtained from radiotracer injection at 88 seconds after seizure termination. **B:** Interictal SPECT image. **C:** "Positive" subtraction shows no hyperperfusion focus. **D:** "Negative" subtraction shows a hypoperfusion focus at the right frontal region. (See black and white image.)

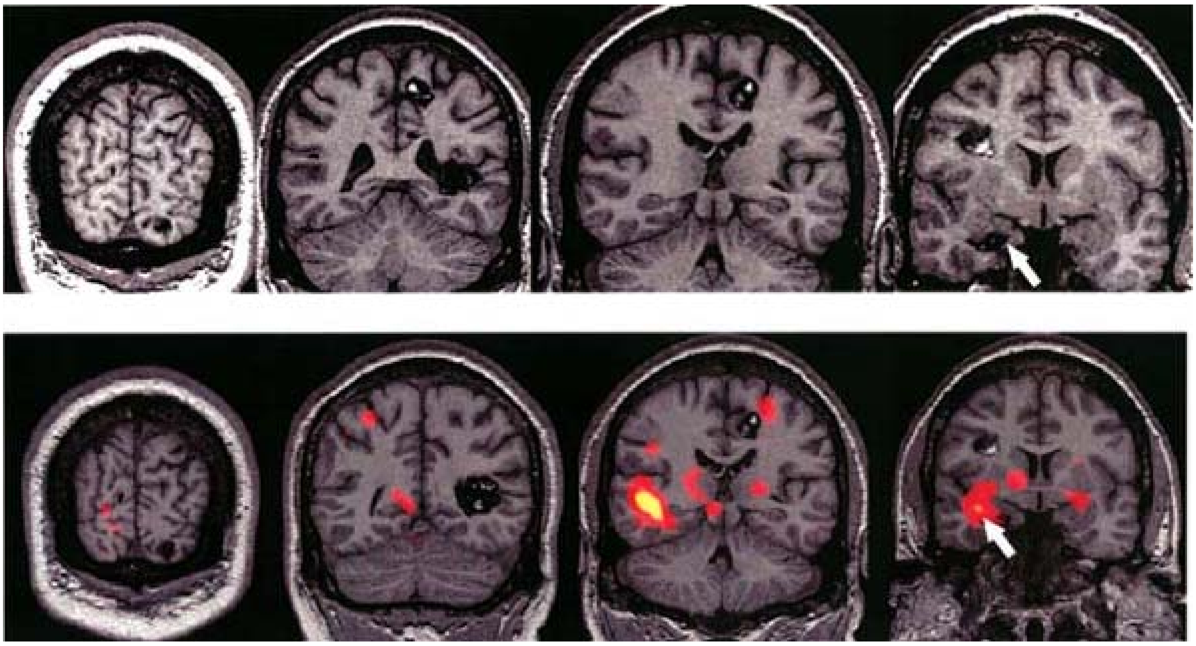

FIGURE 81.5 Coronal MRI (magnetic resonance imaging) (*top row*) and subtraction ictal SPECT (single photon emission computed tomography) coregistered to MRI (SISCOM) (*bottom row*) images of a patient who had medically refractory partial epilepsy associated with multiple cavernous angiomas. Electroencephalography did not localize seizure onset. SISCOM shows ictal hyperperfusion focus at the right mesial temporal angioma, and seizure semiology was compatible with right temporal onset seizures. Resection of the right temporal angioma and its immediate surrounding tissues resulted in seizure freedom. (See black and white image.)

P.CP-24

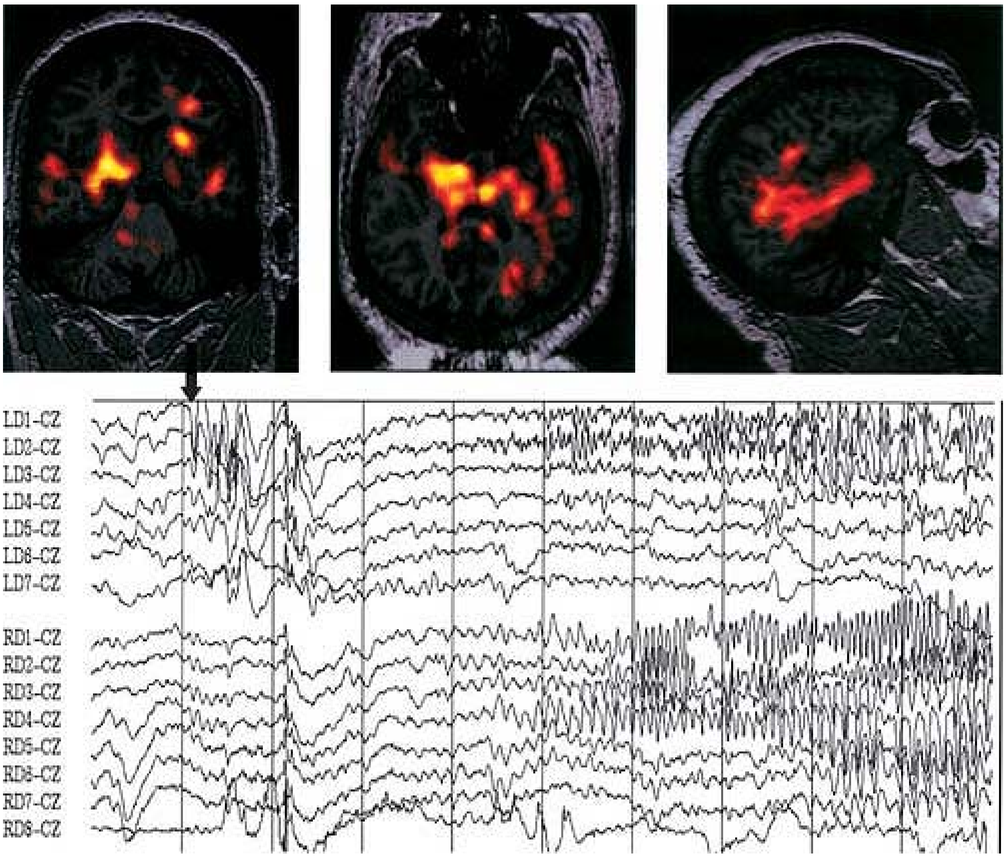

FIGURE 81.6 Subtraction ictal SPECT (single photon emission computed tomography) coregistered on MRI (magnetic resonance imaging) (SISCOM) images (*top*) and bilateral mesial temporal depth electrode recordings (*bottom*) in a patient with left mesial temporal sclerosis and seizure onset. SISCOM shows dominant hyperperfusion focus involving the right mesial temporal and thalamic regions (*upper left* and *middle*). There is also a streak of less intense hyperperfusion at the left temporal region (*upper right*). Left mesial temporal depth electroencephalogram (LD1-7 referred to Cz) shows seizure onset (*arrow*) with subsequent rapid spread to involve the right mesial temporal depth electrodes (RD1-8 referred to Cz). (See black and white image.)

P.CP-25

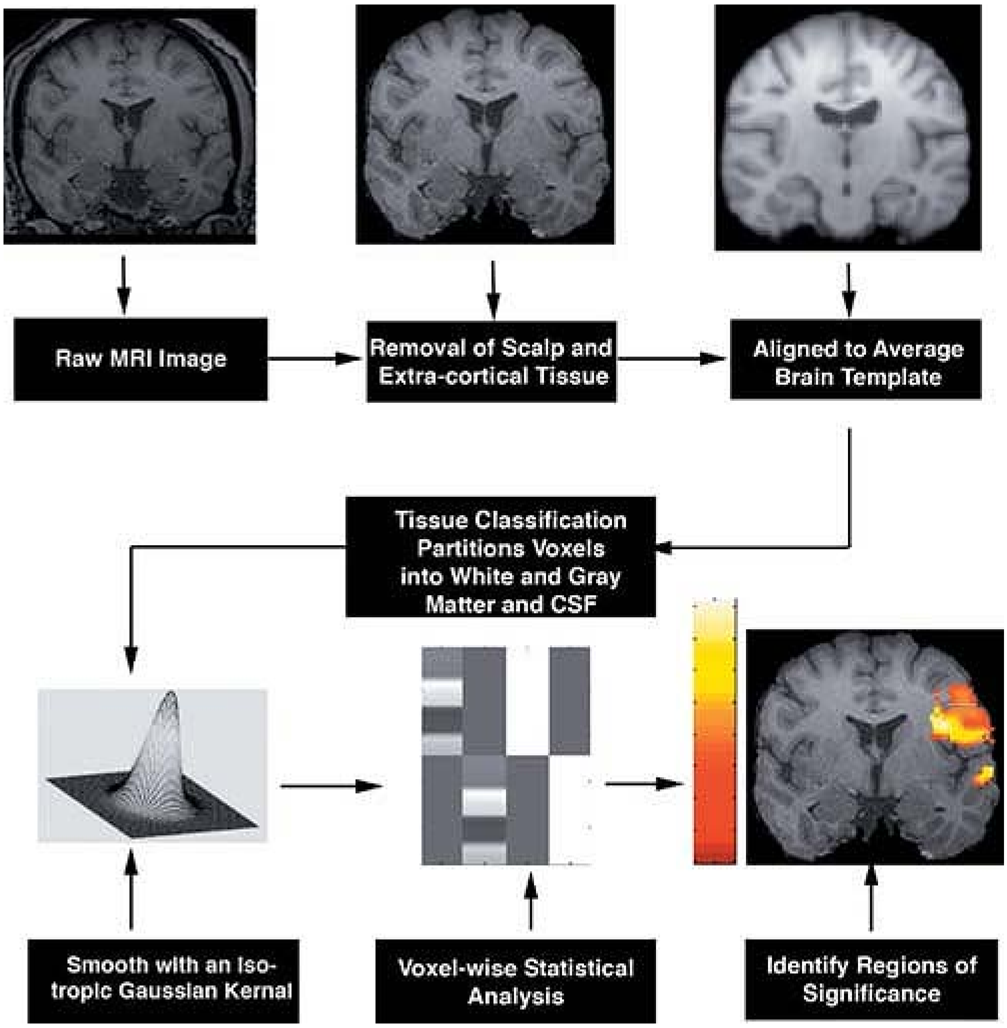

FIGURE 84.1 Steps in voxel-based morphometry. Scalp and extracortical tissues are removed from raw images, and the resulting brain images are normalized to a standard template. Gray and white matter and cerebrospinal fluid (CSF) are automatically classified based on voxel intensity values. Normalized images are smoothed with an isotropic Gaussian kernel. Voxelwise statistical analysis based on generalized linear model is applied to the images to identify regions of significance. MRI, magnetic resonance imaging. (See black and white image.)

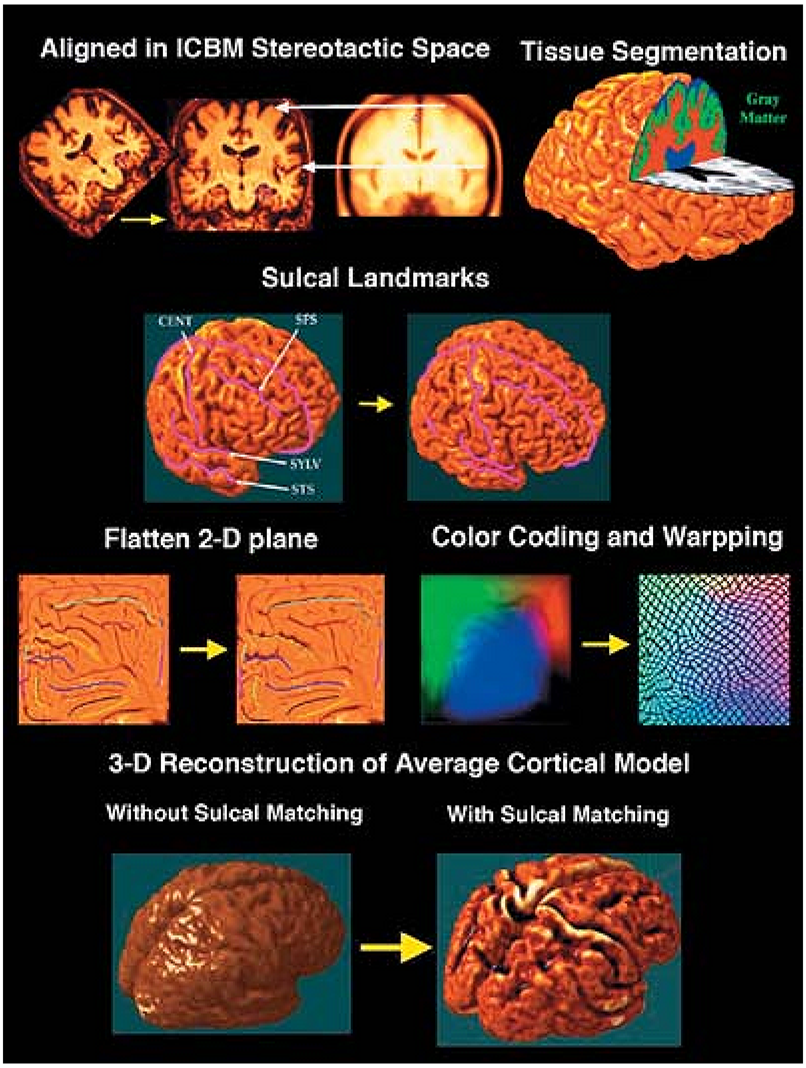

FIGURE 84.2 Steps in cortical pattern-matching algorithm. Raw images are first globally aligned to a standard template. Tissue classification partitions the image into gray and white matter and cerebrospinal fluid based on voxel intensity. A three-dimensional (3D) cortical model is extracted from each scan, and sulci are traced and labeled directly on the surface model. A geometric flattening process transforms the cortical model into two-dimensional (2D) space with retained sulcal landmarks. A color-coding system with intensities of the red, blue, and green corresponding proportionally to the x, y, z location of the three-dimensional cortical model plot the original coordinates onto the flat map. A warping technique uses the sulcal landmarks to constrain one cortical region onto another. The result produces an averaged cortical model for each group across subjects. ICBM, International Consortium for Brain Mapping; CENT, Central Sulcus; SFS, Superior Frontal Sulcus; STS, Superior Temporal Sulcus; SYLV-Sylvian Fissure. (See black and white image.)

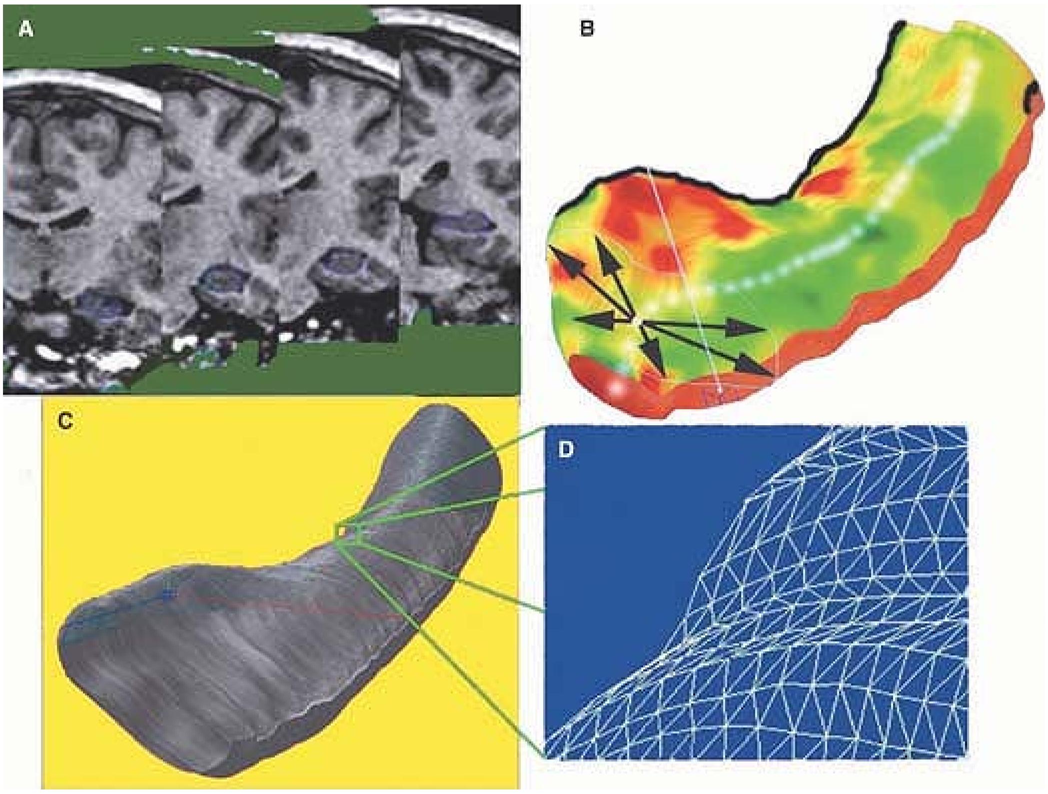

FIGURE 84.3 Steps involved in three-dimensional (3D) hippocampal modeling. Each individual's hippocampus is traced in consecutive coronal magnetic resonance imaging sections **(A)** and converted to a 3D parametric surface **(B)** in which the radial size of the hippocampus is measured from a centerline and plotted in color on the surface to index radial atrophy. These meshes are averaged across subjects **(C)**, and atrophy relative to control means is computed at each surface grid point **(D)**. (See black and white image.)

P.CP-27

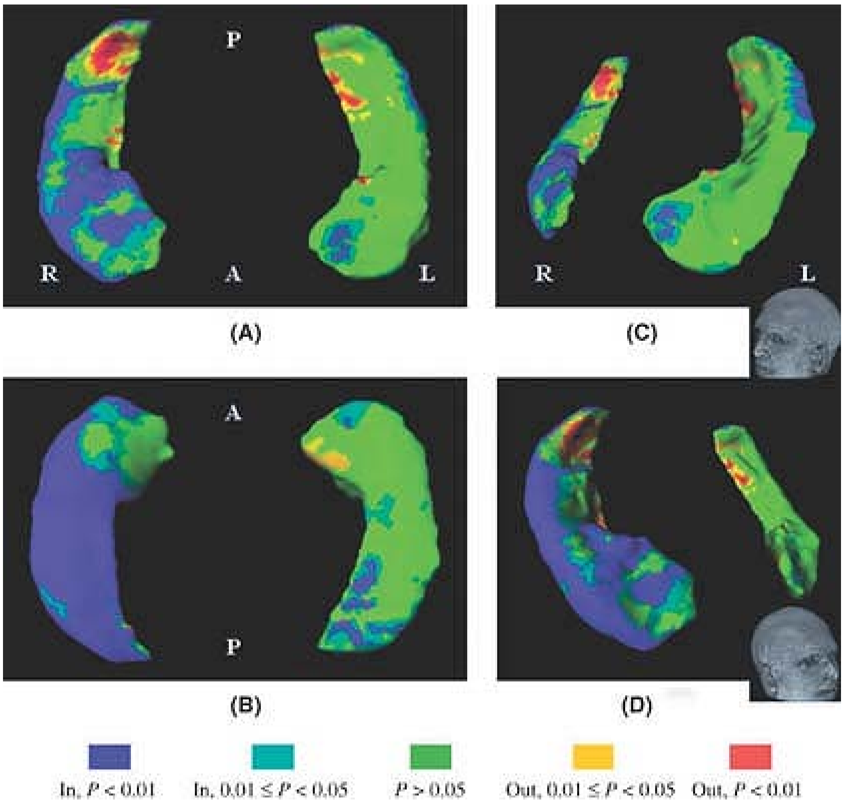

FIGURE 84.4 Large-deformation, high-dimensional brain mapping reveals bilateral hippocampal deformity in right mesial temporal lobe epilepsy patients. Similar bilateral changes were found in left temporal lobe epilepsy patients. Inward deviation is shown in purple (p < .01) and turquoise (.01 = p < .05). Outward deviation is shown in red (p < .01) and yellow (.01 = p < .05). **A:** View from above. **B:** View from below. **C:** View from a perspective slightly above and to the left of a midline plane, showing the top side. **D:** View from a perspective slightly above and to the right of a midline plane, showing the top side. A, anterior; L, left; P, posterior; R, right. (From Hogan RE, Wang L, Bertrand ME, et al. MRI-based high-dimensional hippocampal mapping in mesial temporal lobe epilepsy. *Brain*. 2004;127:1731–1740, with permission.) (See black and white image.)

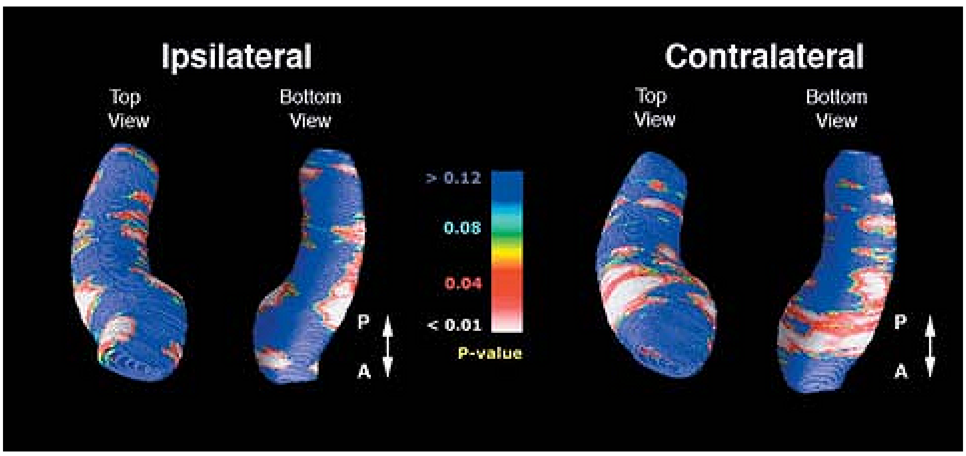

FIGURE 84.5 Maps identifying regions where seizure-free (SF) and not-seizure-free (NSF) surgical outcome groups differ in their degree of atrophy. Group difference maps show mean hippocampal volume differences ipsilateral **(left)** and contralateral **(right)** to the side of seizure onset. Areas of significant atrophy between the two surgical outcome groups are plotted as a map of *p* values. The NSF groups show significantly greater diffuse atrophy in the ipsilateral hippocampus, whereas the contralateral side shows a more region-specific atrophy pattern. The maximal atrophy is seen in the anterior and lateral aspects of the contralateral hippocampus. A, anterior; P, posterior. (Adapted from Lin JJ, Salamon N, Dutton RA, et al. Three-dimensional preoperative maps of hippocampal atrophy predict surgical outcomes in temporal lobe epilepsy. *Neurology*. 2005;65:1094–1097, with permission.) (See black and white image.)

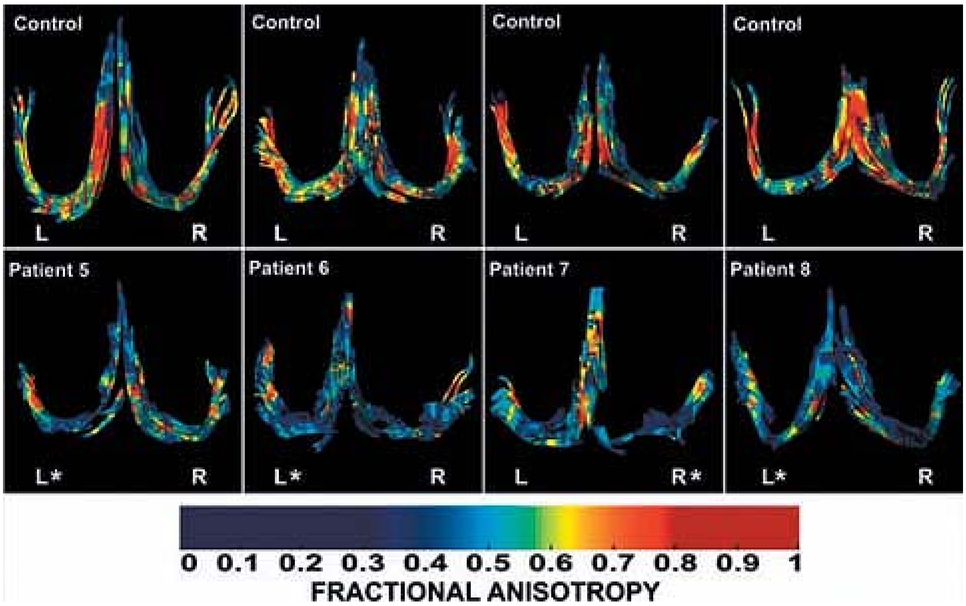

FIGURE 84.6 Diffusion tensor imaging tractography mapped the integrity of the fornix in four healthy controls and four patients with unilateral mesial temporal lobe sclerosis (MTS). Fractional isotropy for each voxel is color coded, with higher values denoting greater structural organization. Fornix of patients with MTS has lower anisotropy and less continuous tracts. Asterisk indicates the side of MTS. L, left; R, right. (From Concha L, Beaulieu C, Gross DW. Bilateral limbic diffusion abnormalities in unilateral temporal lobe epilepsy. *Ann Neurol*. 2005;57:188–196; with permission.) (See black and white image.)

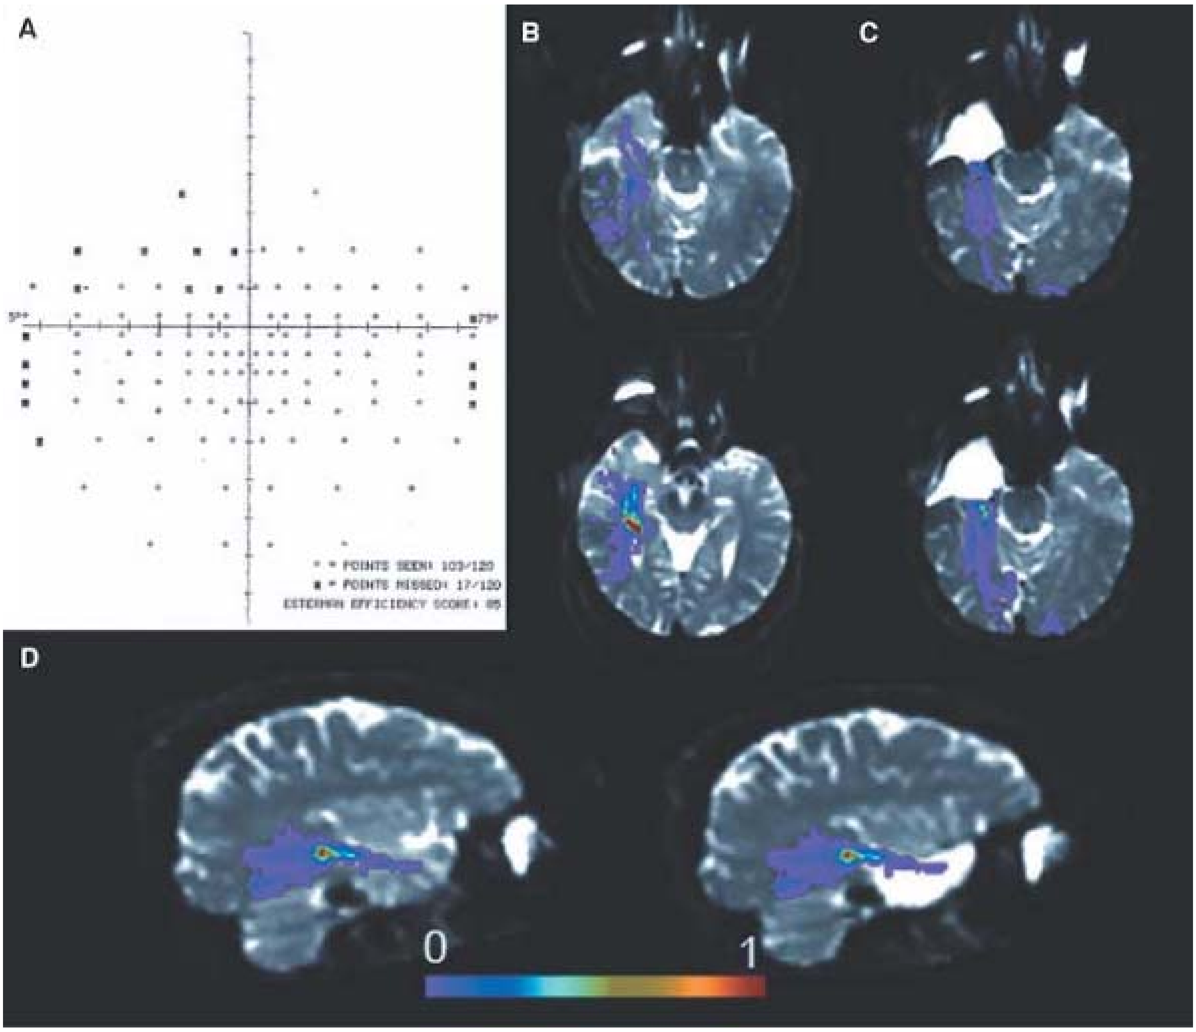

FIGURE 84.7 Postoperative visual field demonstrates a superior homonymous quadrantanopia **(A)**. Preoperative right optic radiation overlaid on preoperative axial **(B)** images; postoperative right optic radiation overlaid on postoperative axial image **(C)**; preoperative optic radiation overlaid on preoperative sagittal **(D, left)** image and postoperative optic radiation overlaid on postoperative sagittal **(D, right)** image. These images show that the preoperative tract overlies the resected anterior temporal lobe, resulting in postoperative visual field deficit. (From Powell HW, Parker GJ, Alexander DC, et al. MR tractography predicts visual field defects following temporal lobe resection. *Neurology*. 2005;65:596–599; with permission.) (See black and white image.)

P.CP-29

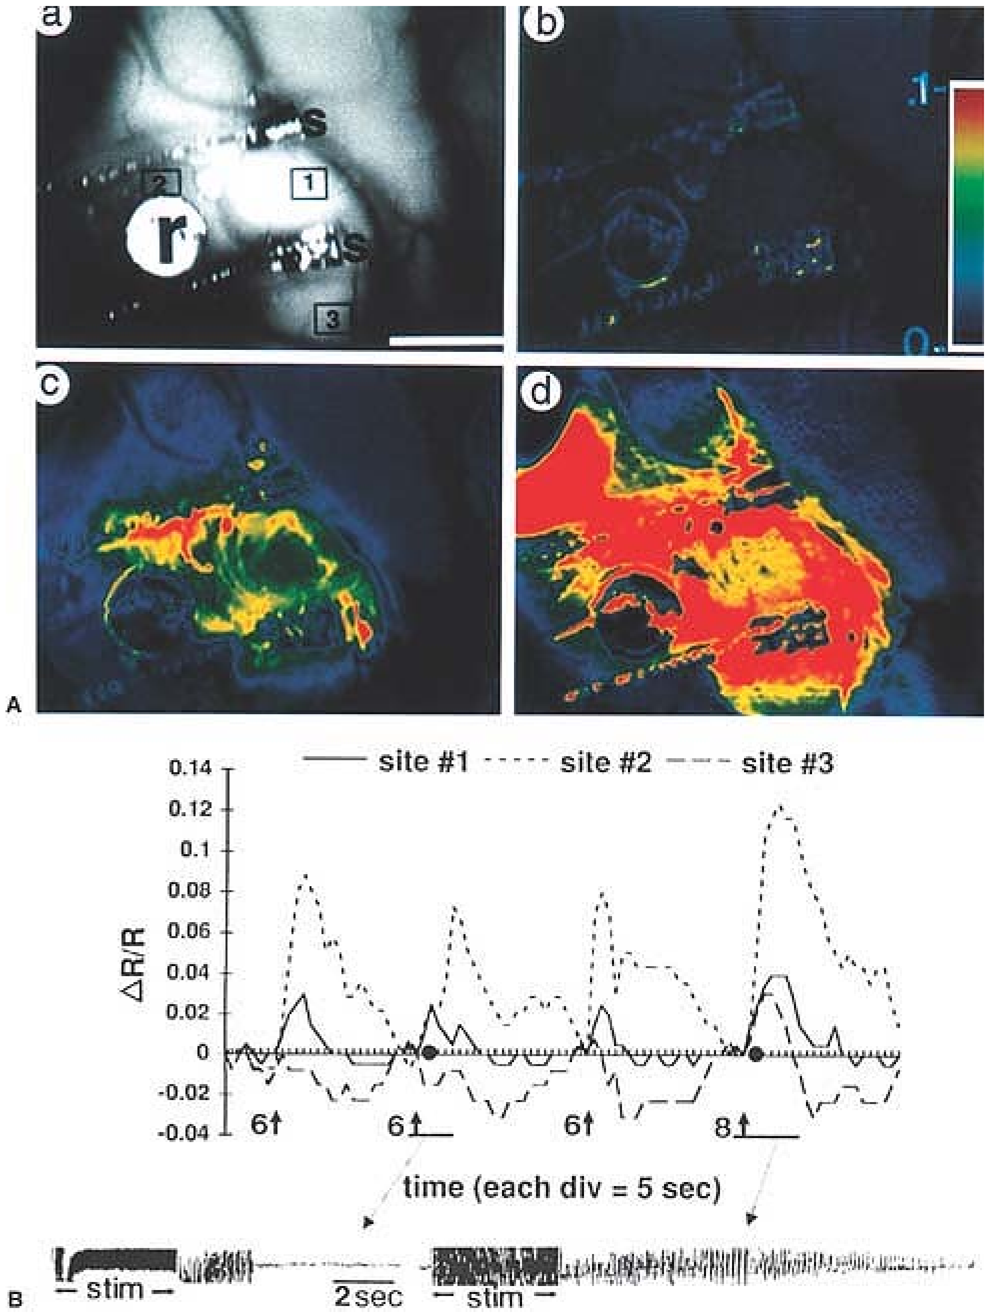

FIGURE 86.3 A: Human frontal cortex exposed at the time of a neurosurgical procedure for treatment of medically intractable epilepsy. Recording surface electroencephalographic (EEG) electrode is represented by *r*, the two stimulating electrodes by *s*. *Boxes 1, 2, and 3* are regions of interest where the optical changes in the intrinsic signal were measured for Figure 3B. Scale bar = 1 cm. **Ab:** Control image subtracted from another control image showing the baseline noise. The pseudocolor scale bar (*right*) shows the intensity of the optical changes, with black being below baseline, blue near baseline, and red maximal. **Ac:** Optical changes at the end of the second stimulation at 6 mÅ, which evoked a short seizure "afterdischarge" episode. The peak changes are near the recording electrode with a surrounding region that is black, suggesting that the optical changes in that region are below baseline. **Ad:** Optical changes after the fourth stimulation are at 8 mÅ, which evoked a more prolonged and intense seizure episode compared with the other intense optical change. **B:** The optical changes from the three boxes shown in Figure 3Aa are shown, as well as the surface EEG recording from the second stimulation (optical changes in Fig. 3Ac; *lower left*) and the surface EEG recording from the second

stimulation (optical changes in Fig. 3Ad; *lower right*). From Haglund MM, Ojemann GA, Hochman DW, Optical imaging of epileptiform and functional activity from human cortex. *Nature*. 1992;358:668–671; with permission. (See black and white image.)

P.CP-30

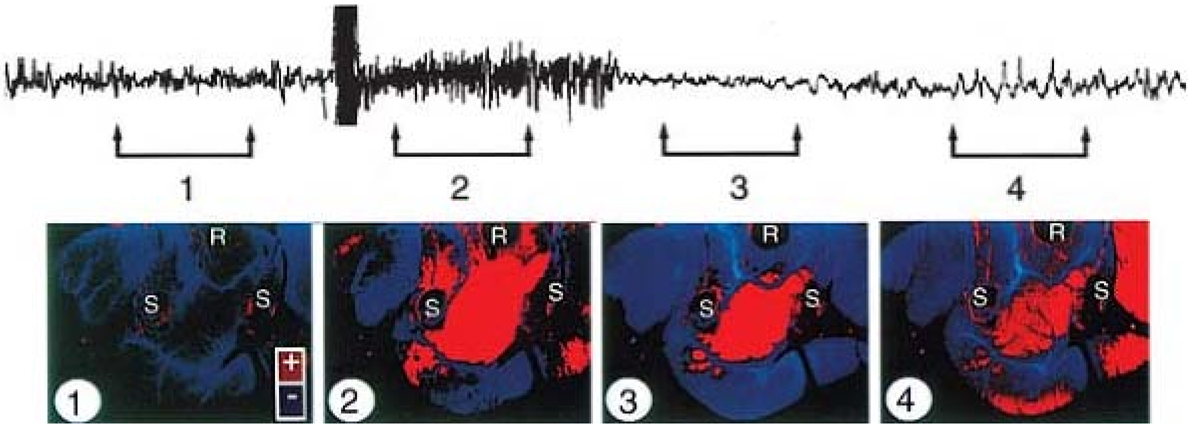

FIGURE 86.4 Upper trace: Surface electroencephalographic (EEG) trace from the recording electrode (*r* in the *lower images*). The brackets represent the period during which the optical images in the *lower panel* were collected and a baseline image was subtracted from each of the images. The four brackets show the baseline, seizure, postictal, and recovery electrical recordings, respectively. **Lower panel:** Optical changes before and after electrical stimulation at the afterdischarge threshold (stimulating electrodes represented by *s*). The optical changes are shown in a two-color scheme, so positive changes correlated with increases in neuronal activation are shown in red, whereas optical changes in the intrinsic signal below baseline are shown in blue. The optical changes in the positive direction correlate with the increases in electrical activity, especially the seizure activity in bracket No. 2. The optical changes also correlate with the quiescent postictal surface EEG recording in bracket No. 3, where the optical changes are below baseline. (See black and white image.)

FIGURE 106.1 Cutaneous manifestations of antiep-break ileptic drug hypersensitivity. **A:** Patient with phenytoin-induced maculopapular eruption. (Figure kindly provided by Dr. Gavin Wong, Liverpool, U.K.). **B.** Patient with carbamazepine-induced urticaria. (Figure kindly provided by Dr. Clodagh King, Liverpool, U.K.). **C.** Patient with carbamazepine-induced toxic epidermal necrolysis. (See black and white image.)

P.CP-31

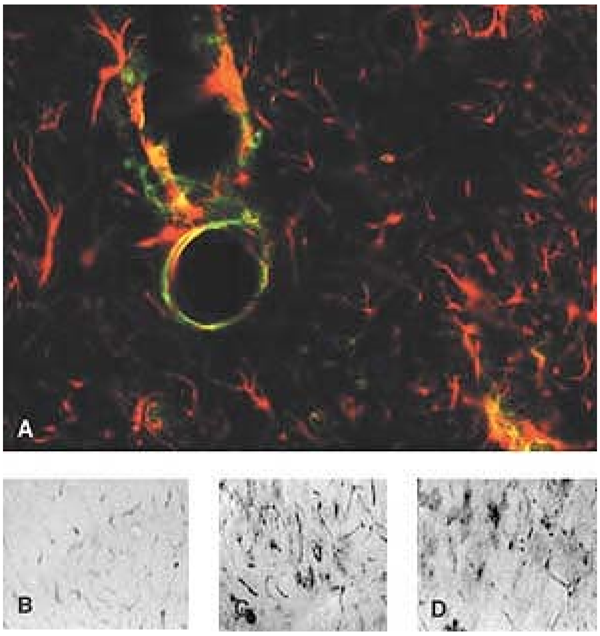

FIGURE 115.3 Overexpression of P-glycoprotein (P-gp) in an animal model. **A:** Merged image (20×) showing P-gp immunolabeling (*green*) and glial fibrillar acidic protein (GFAP)-positive astrocytes (*red*) in the rat cortex 18 hours after pilocarpine-induced status epilepticus. Colocalization signal (*yellow*) depicts P-gp expression in astrocytic endfeet adjacent to brain microvessels. **B, C, D:** Representative immunohistochemical micrographs (10×) depicting P-gp immunolabeling in control rat hippocampus **(B)** and 18 hours after pilocarpine-induced status epilepticus. Note that in the control panel only, vessels are lightly labeled, whereas seizures induced P-gp overexpression both in vessels and in astrocytes **(C, D)**. (See black and white image.)

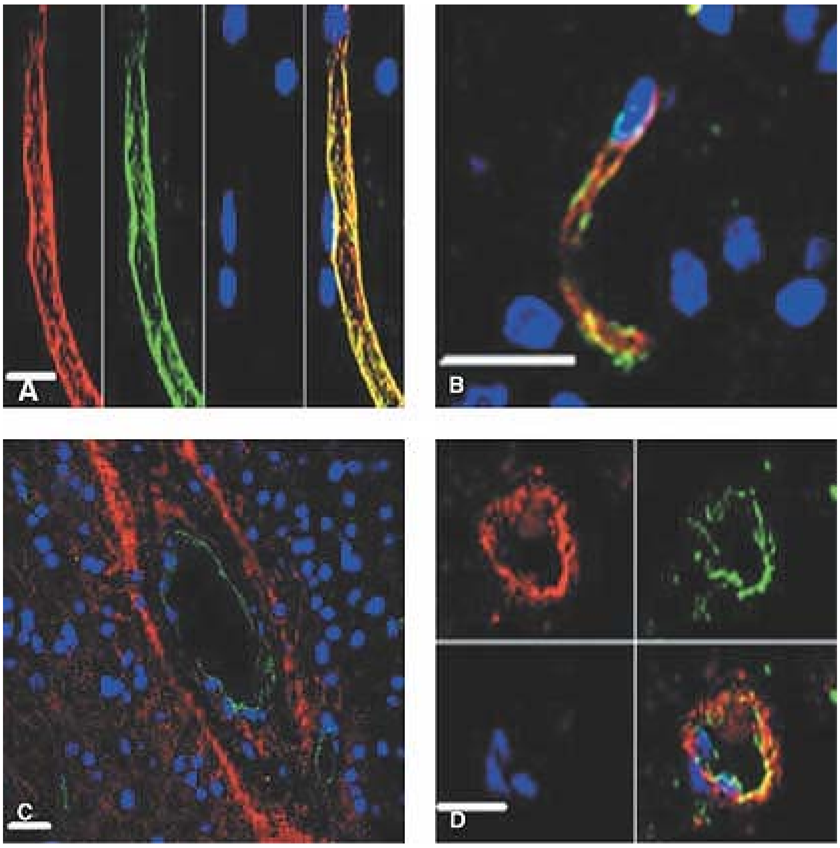

FIGURE 115.4 Overexpression of multidrug transporters in human epileptogenic brain tissue. Immunohistochemistry using fluorescently labeled antibodies shows co-localisation of fluorescence, and thus labeling, for a combination of tranporters and presumptively transporter-related proteins in microvasculature in a section of hippocampus resected from a patient with refractory epilepsy due to hippocampal sclerosis. In **(A)** to **(D)**, blue labels cell nuclei. In **(A)**, red labels P-glycoprotein (-gp), green labels Breast Cancer Resistance Protein (BCRP), and in the extreme right panel, the two are shown to co-localise by the merged yellow colour. In **(B)**, there is co-localisation, though to a lesser extent, of P-gp (red) and major vault protein (labeled green). **(C)** P-gp (green) does not co-localise in these sections with multidrug-resistance associated protein 1 (MRP1, red). In **(D)**, BCRP (green) co-localises with P-gp (red). In all sections, the scale bar represents 30μm. (See black and white image.)

(See black and white image.)

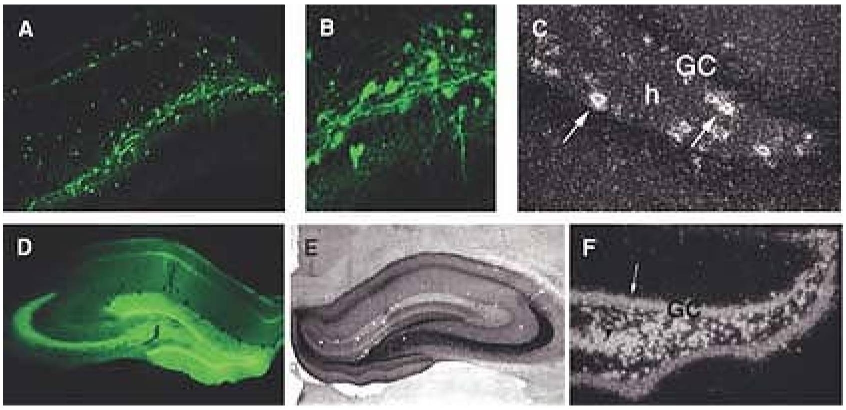

FIGURE 134.6 Influence of viral serotype on green fluorescent protein (GFP) and neuropeptide Y (NPY) expression in the rat hippocampus. Serotype 2 adeno-associated virus (AAV) induces transgene expression specifically in hilar interneurons with a spread of about 1.5 mm around the injection site. Panels **A** and **B** depict GFP in hilar interneurons and their fibers. Panel **C** depicts NPY mRNA in hilar interneurons (*arrows*). Note that granule cells do not express the transgene. Chimeric serotype 1/2 induces a larger transgene expression including hilar interneurons, mossy fibers, and granule cells with an extension of approximately 2.5 mm around the injection site. Panel **D** illustrates GFP distribution throughout the hippocampus. Panels **E** and **F** show NPY immunoreactivity and its mRNA, respectively.

Note that an intense hybridization signal is observed in granule cells (*arrow* in F) and CA3 (*arrowhead* in F). Transgenes were selectively expressed in neurons since they were under control of neuronal enolase promoter. GC, granule cells; h, hilus. (See black and white image.)

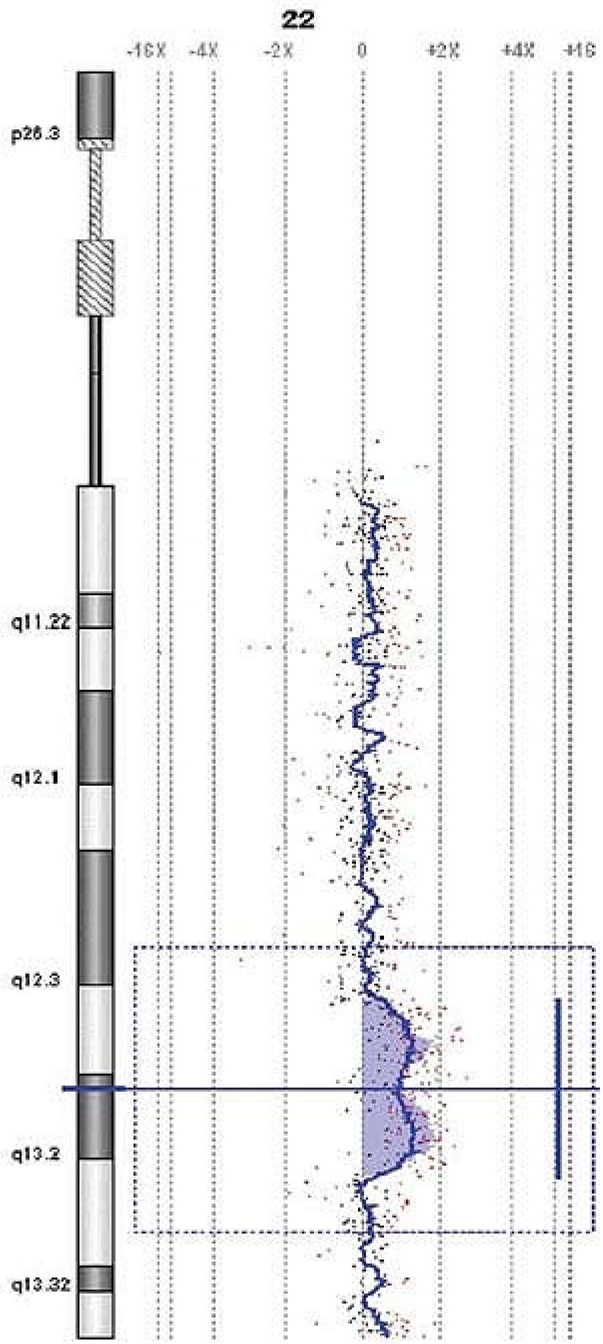

FIGURE 260.1 Eight-year-old girl with early-onset focal epilepsy and dysmorphic features. 6.9 Mb duplication at 22q13.1q13.2 detected through oligo-array-CGH at 75 kb resolution; log2 ratio of signals intensity is increased in the duplication region where red signals are located more proximal to the +2x line than are the remaining ones. This interstitial duplication had not been detected at conventional karyotyping nor, obviously, after FISH with subtelomeric probes. (See black and white image.)
