Kindling produces a predictable pattern of evolving molecular and cellular alterations that include (i) changes in composition and biophysical properties of membrane receptors, (ii) alterations in signal transduction pathways, (iii) changes in gene transcription, (iv) neuronal cell loss in the hippocampus and other limbic structures, (v) sprouting and reorganization of neuronal circuitry, (vi) gliosis, and (vii) neurogenesis (Table 4). Previous studies have demonstrated that long-lasting increases in synaptic transmission, resembling the synaptic potentiation induced by LTP, occur early during the acquisition of kindling. Antagonism of NMDA-dependent synaptic transmission during

Table 4 Structural and functional alterations induced by kindling

30	Hippocampal sclerosis Memory loss	Epileptogenesis
90–100	Interneuron loss Reduced inhibition Spontaneous seizures	Epilepsy

application of kindling stimulation blocks the development of progressive cellular and circuit alterations, even when seizures are still evoked. Studies of kindling acquisition in transgenic mice with conditional knockout of the gene for brain-derived neurotrophic factor (BDNF) and its receptor (TrkB) have demonstrated a complete block of kindling progression despite continuing repeated seizures. Other neurotrophins (NT3, NT4) and their associated tyrosine kinase (Trk A/B) receptors may also contribute to the long-term alterations induced by kindled seizures. The NMDA and neurotrophin signaling pathways appear to be directly involved in kindling progression and in the development of chronic and long-term circuit alterations associated with seizure-induced plasticity.

As increasing numbers of seizures are evoked, the gradual progression toward epileptogenesis and spontaneous seizures is associated with continuing morphological reorganization of neurons and neural circuits accompanied by an increasing susceptibility to additional seizures and progressive behavioral changes, including memory dysfunction. The cellular structural/pathological alterations that are induced by repeated episodes of network synchronization (i.e., kindling) have been characterized in considerable detail. These changes occur with a predictable time course, as a function of the number of evoked seizures. These changes include both neuronal cell loss, and aberrant sprouting of mossy-fiber collaterals in the dentate gyrus, which form recurrent excitatory circuits.

Each evoked seizure results in a twofold increase in neuronal apoptosis. Cumulatively, there is a decrease in neuronal density associated with kindling, reflecting neuronal loss, which becomes detectable and progressively increases with increasing numbers of kindled seizures (i.e., after 3, 30, and 150 class V seizures). This neuronal loss is prominent bilaterally in the hilus of the dentate gyrus, and is also noted in CA3 and CA1, in a pattern resembling hippocampal sclerosis – the most common

lesion observed in human TLE. Neuronal loss is also observed in the medial entorhinal cortex, the lateral entorhinal cortex, and the rostral endopyriform cortex, suggesting that the neuronal loss is caused by propagation of repeated seizures and not by damage directly attributable to the stimulation delivered by an electrode. A substantial number of repeated kindled seizures (i.e., 150 class 5 seizures) eventually induce neuronal loss even in relatively 'resistant' brain structures, such as the dentate granule cell layer and CA2 (Table 5). These patterns of cell loss (including a reduction in neuronal density in the temporal pole of the rat) suggest that the progressive pathological changes associated with epilepsy in the kindled rat model parallel many features of hippocampal sclerosis in human TLE – and raise the important question of whether similar mechanisms are involved.

The kindling model enables investigators to perform experiments at different time points obtained during the progression of epileptogenesis. Investigators can carry out correlational studies – e.g., to assess functional alterations associated with seizure-induced progressive structural alterations, such as mossy-fiber sprouting after a specific number of evoked seizures. As noted earlier, kindled seizures induce aberrant granule cell mossy-fiber axon collaterals that sprout into the supragranular layer of the dentate gyrus, as revealed by the Timm staining method (which labels synapses with high concentrations of zinc). Although it is difficult to unequivocally isolate the effects of a given seizure-induced alteration on network function, these studies have revealed that synaptic reorganization and the formation of new excitatory circuits is associated with increases in recurrent excitation that become unmasked by reducing inhibition. There is also a correlation between the degree of mossy-fiber sprouting and (1) the duration of seizure activity in local circuitry, and (2) the propensity of partial seizures to propagate to more distant sites and develop into secondarily generalized seizures. Synaptic reorganization and mossy-sprouting induced by repeated seizures thus are associated with progressive permanent susceptibility to additional seizures, and potentially to development of intractable epilepsy.

The development of spontaneous seizures is associated with loss of specific GABAergic interneuron subclasses, specifically GABA transporter type 1 (GAT-1) and cholecystokinin (CCK) labeled interneurons, which provide critical somatic and axon initial segment control over spike generation. These interneuron subtype-specific alterations are accompanied by loss of GABAergic inhibition assessed by electrophysiological methods, including paired pulse and single-electrode voltage clamp techniques. Paired pulse methods demonstrate that a loss of paired pulse inhibition in the dentate gyrus occurs in association with the emergence of spontaneous seizures in kindled rats (after about 100 evoked class V seizures). Direct measurements of GABAergic inhibition using single-electrode voltage clamp techniques also confirm alterations in the kinetics and reduction in the amplitude of the evoked IPSC in granule cells consistent with reduction in inhibition in animals experiencing spontaneous

seizures. In ongoing studies of functional and structural properties of granule cells and hippocampal circuits in kindled rats experiencing spontaneous seizures, it appears that seizure-induced alterations in inhibitory circuitry involving subtype composition of GABA receptors, modifications of proportions of excitatory and inhibitory synapses, and alterations of ion cotransporters influencing Cl^- gradients all contribute to the loss of GABAergic inhibition.

Kindling as a Model for Drug Development

As a model for development of refractory TLE, kindling may potentially have predictive value as a test for new antiepileptic drugs (AEDs) to treat TLE and complex partial seizures. The benefit of the kindling model for the purpose of drug development is that it allows AED testing throughout the well-controlled epileptogenic process, and chronic efficacy studies can be conducted in fully kindled animals that have developed spontaneous seizures. Additionally, if the kindling process is completed rapidly (i.e., 1 day vs. 10 days of repeated stimulation) or if suprathreshold stimulation parameters are used, acute AED testing can be conducted to differentiate between drugs that increase seizure threshold or decrease seizure spread. Efficacy endpoints include: (1) seizure latency; (2) seizure severity based on behavioral seizure classes (see above); (3) seizure duration; and (4) AD duration. Similar endpoints can be assessed during chronic AED testing (in fully kindled animals); daily stimulation is possible at this stage without alteration of seizure parameters. Two main approaches using suprathreshold stimulation in fully kindled animal to test AEDs are possible. One method involves assessing these measures after administration of a single dose of drug (or control substance). This method does not allow differentiation between the affect of drug on partial versus generalized seizures. A second method considers this potential difference by calculating separate ED_{50} values for partial seizures, generalized seizures, and ADs. Phenytoin, carbamazepine, valproic acid, and primidone are effective against the complex partial seizures, as is phenobarbital after prolonged administration. Ethosuximide is ineffective and benzodiazepines are only moderately effective in the amygdala-kindled model. The ED_{50} values calculated for carbamazepine, phenytoin, and phenobarbital show that each of these drugs is more effective at reducing secondarily generalized seizures than at blocking focal seizures. Recent studies have demonstrated that 2-deoxy-D-glucose (2DG), an inhibitor of glycolysis, results in a twofold slowing of the kindling process, and therefore has 'disease-modifying' effects against seizure progression.

AED Responders and Nonresponders

Fully kindled rats are currently the only established model of pharmacoresistant epilepsy, and are therefore of potential use for AED development. The focal and secondarily generalized seizures observed in these animals are less sensitive to traditional AEDs than seizures evoked in the maximal electroshock (MES) test. Repeated testing of traditional AEDs (such as phenobarbital and phenytoin) on the focal seizure threshold (determined by ADs of fully kindled rats) allows separation of the animals into two distinct 'drug-responsive' and 'nonresponsive' categories. The drug-responsive animals exhibit reproducible increases in focal seizure threshold after repeated AED challenges, but nonresponsive animals fail to show any increase in focal seizure threshold. Animals categorized as pharmacoresistant or nonresponders (i.e., phenytoin or phenobarbital nonresponders) have been used for subsequent experiments, in which other established AEDs also show a reduced antiseizure effect in the nonresponsive kindled animals (relative to the drug-responsive group). Kindled rats with drug resistance are now being used to evaluate novel AEDs and to study potential mechanisms of pharmacoresistance.

Slow and Fast Kindling Strains

Racine and colleagues exploited the observation that some animals kindled more readily than others, and used breeding approaches to develop rat strains with reliable phenotypes of fast or slow kindling responses in response to stimulation of the amygdala. The selection of fast and slow strains is consistent with the view that the predisposition of an animal to undergo fast or slow kindling acquisition is under complex genetic influence. 'Slow' kindling animals require a significantly greater number of ADs to experience class V seizures; the converse is the case for 'fast' strain. The discovery that fast and slow kindling strains can be selected by breeding procedures provides an opportunity to examine genes which may be relevant to seizure susceptibility. Whether the 'fast' and 'slow' strains selected in response to stimulation of the amygdala would resemble strains selected by stimulation of other sites is currently uncertain, as is the question of whether a predisposition to one type of epilepsy enables the development of different types of seizures in other circuits.

Current Problems and Future Challenges

Kindling has provided valuable information on seizure susceptibility, the effects of repeated seizures on the brain, and the roles of different structures in initiating and maintaining seizures and regulating seizure propagation. Kindling also offers an opportunity for screening potential new AEDs for partial epilepsy. A practical disadvantage of the model is that it takes such a long time to generate animals with spontaneous seizures. Spontaneous seizures are observed only after numerous (>100) evoked class V seizures, but not in animals that that are typically labeled as 'kindled' – i.e., have exhibited only a few stage V seizures.

Although kindling is undeniably a phenomenon of seizure-induced plasticity, observed across a range of species (including primates) the relevance of the phenomena of seizure-induced plasticity (kindling) to clinical features of human TLE is still debated. One argument against the relevance of the kindling model is that the seizures are induced in *normal* brain. The consequences of seizures in normal animals may not be the same as those observed in chronically epileptic animals with established histopathology – e.g., as observed in kainate-treated rats after status epilepticus.

The practical limitations, and the uncertainty about the general relevance of seizure induced plasticity for human epilepsy must to be considered when kindling is used as a model for studying seizures, epileptogenesis, or chronic epilepsy.

Introduction

An anonymous bioscientist once commented that the best model of a cat is a cat, and preferably the same cat. According to this truism, the best way to investigate basic mechanisms of human epilepsy is with people who have the disorder. Indeed, considerable information about mechanisms of epilepsy has come from studying patients with epilepsy, even before organized approaches were designed for the animal laboratory. For instance, John

Hughlings Jackson, in the mid to late 1800s, identified the anatomic substrates of focal epileptic seizures by observing specific ictal signs and symptoms and correlating them with the location of cortical lesions at autopsy. Localization, however, required confirmation in the animal laboratory – which was obtained when David Ferrier electrically stimulated the same areas of monkey cortex and reproduced the ictal behaviors Hughlings Jackson observed in patients. This work led not only to localization of epileptogenic tissue for purposes of surgical resection (beginning in the 1880s), but to insights into localization of normal function within the human brain. Research on people with epilepsy further contributed to this effort as a result of intraoperative functional mapping with electrical stimulation in the course of surgical resection for intractable epilepsy; in this manner, Penfield and Jasper, at the Montreal Neurologic Institute, in the mid twentieth century, defined the human motor and sensory homunculi, as well as other functional properties of neocortex and mesial temporal limbic structures.

Despite these seminal human investigations, the tremendous advances in our understanding of basic physiologic mechanisms and anatomic substrates of epileptic phenomena that occurred during the latter half of the twentieth century derived almost entirely from animal research. Most of the work at this time involved electrophysiological and morphological investigations that could not readily be performed in patients. Although Crandall and the group at UCLA developed a protocol for chronic in vivo microelectrode recordings from patients undergoing presurgical evaluation for medically refractory temporal lobe epilepsy (results of which were correlated with structural disturbances obtained from en bloc resected tissue), very few centers had the facilities to carry out such research. Furthermore, invasive basic research in the epilepsy surgery setting is difficult because of the absence of control data, the need to modify research protocols to fit individual clinical circumstances, ethical constraints, the limited population that can be examined within a reasonable period of time, and cost. Such human research is essential, however, because the data obtained provide the basis for hypotheses that can then be tested more cost-effectively in the animal laboratory.

In recent years, functional neuroimaging – first with positron emission tomography (PET) and single photon emission computed tomography (SPECT), and then with functional magnetic resonance imaging (fMRI) and magnetic resonance spectroscopy (MRS) – has augmented our enhanced ability to localize the sources of electrical discharges with computerized electroencephalography (EEG) and magnetoencephalography (MEG). These techniques have also greatly increased opportunities to examine basic physiological mechanisms and anatomic substrates of human brain function noninvasively. In addition, the expanding field of genetics has stimulated tremendous research efforts with patients that should ultimately elucidate fundamental mechanisms of brain disturbances causing epilepsy. Animal research, however, will continue to play an essential role in the search for the neurobiological bases of the epilepsies, whether derived from results of human genetic studies or other human research. The development of appropriate animal models for the many forms of human epilepsy, therefore, is central to this effort.

Clinical Epilepsy, What to Model

Epileptic seizures are merely signs and symptoms of brain dysfunction and take many forms, depending upon the nature of the cerebral disturbance, its location in the brain, and preexisting conditions that influence threshold and behavioral manifestations. There are, therefore, many different types of epileptic seizures. The classification of epileptic seizures is described in the Clinical Appendix. Traditionally, ictal events are divided into focal (partial, localization-related) seizures, which begin in a part of one hemisphere, and generalized seizures, which begin on both sides of the brain simultaneously. This division is, however, an artificial dichotomy. It is unlikely that any seizures are truly generalized at onset, and also unlikely that many, if any, seizures are due to a discrete focal abnormality. Rather, most epilepsies, whether focal or generalized, require involvement of diffuse distributed cerebral networks.

Epileptic seizures can be a natural response of the normal brain to a transient insult, in which case they are called acute symptomatic, provoked, or reactive, and do not indicate an epileptic condition. Epilepsy, on the other hand, implies the existence of an enduring cerebral epileptogenic substrate capable of generating spontaneous seizures. With epilepsy, therefore, the brain is epileptogenically abnormal, whether seizures are occurring or not. Just as there are many types of seizures, there are many conditions that cause epilepsy and classification of the great variety of epileptic disorders (see Engel and Berg article on 'Classification' in Clinical Appendix). Traditionally, epilepsies are also subjected to the focal/generalized dichotomy, and in addition are divided into those that are secondary to structural or metabolic brain disturbances (symptomatic or secondary) and those that are epilepsy only, *sui generis* (idiopathic, from the Greek *idios*, or primary). The term 'idiopathic', as used here, does not mean 'cause unknown' as it does in the rest of American medicine, but infers a genetic etiology. Idiopathic epilepsies usually appear at specific periods of brain development and are thus age-related. There are conditions, however, that do not fit the criteria for recognized idiopathic epilepsy syndromes, and therefore, are presumed to be symptomatic although the causes are

unknown, and these are referred to as 'cryptogenic.' The symptomatic/idiopathic dichotomy is also artificial, and the term 'cryptogenic' is considered to be ambiguous. Accurate descriptions of epilepsy syndromes and epileptic phenomena are essential to the development of relevant experimental animal models, and animal research provides critical information for accurate clinical classification.

As there are undoubtedly many different pathophysiologic mechanisms and anatomic substrates responsible for the variety of epileptic seizures and epilepsy syndromes that are encountered clinically, an experimental animal model of one type of seizure or epilepsy may bear no relationship to other types of seizures or epilepsy. Furthermore, there are few, if any, clinical epilepsy syndromes that can be reliably reproduced in their entirety by an experimental animal model. It is helpful, therefore, to break clinical epilepsy down into a number of component parts that can be modeled or studied individually. Such components include the following:

The *interictal state* is characterized not only by a persistent epileptogenic disturbance, which may be a structural lesion or a genetically mediated disturbance, but by homeostatic mechanisms that maintain the interictal state and prevent seizures from occurring continuously.

There are mechanisms within the epileptogenic substrate, as well as normal and pathological cerebral and systemic influences, that are responsible for the *transition from the interictal to the ictal state.*

Once seizures begin, there are *mechanisms responsible for maintenance of the discharge, as well as propagation* locally and to distant structures, including engagement of brain stem systems responsible for generalized tonic–clonic seizures when secondarily generalized seizures occur.

Eventually, seizures are *terminated by multiple mechanisms*, some of which involve active inhibition or desynchronization, while others are passive effects of excessive activity. Clearly, mechanisms that act to terminate seizures are different from those that act to contain the spread of epileptic activity, because the former fail while the latter remain effective in epilepsia partialis continua.

Most (but not all) seizures are followed by *transient postictal disturbances*, which can be more disabling than the seizures themselves, and likely reflect persistent effects of the mechanisms that terminate seizures, although other seizure-induced influences can also contribute to certain postictal behaviors.

Some patients develop *interictal behavioral disturbances*, which can reflect enduring disturbances in cerebral function or, in some cases, even structure – either as a consequence of repeated ictal events or as a side-effect of the homeostatic mechanisms that act to maintain the interictal state. Brain damage results from uncontrolled status epilepticus but might also be caused by repeated, or even single, seizures. Epileptic encephalopathies are conditions where seizures themselves are the cause of progressive epileptic and nonepileptic brain disturbances.

The *development of symptomatic epilepsies (epileptogenesis)*, as a result of epileptogenic insults, occurs over long periods of time and also undoubtedly involves a number of mechanisms that differ from those associated with epilepsy itself. For instance, pharmacological agents that are effective at preventing epileptic seizures may not be effective in preventing epileptogenesis, and risk factors for developing epilepsy are not exactly the same as risk factors for experiencing an epileptic seizure. Furthermore, epileptogenesis does not necessarily stop as soon as spontaneous seizures appear, but in many instances continues, causing the epileptogenic region to increase in size and give rise to secondary epileptogenic areas – resulting in more frequent, more severe, and more intractable seizures. The onset of idiopathic epilepsies may not involve such epileptogenic processes, but rather result from an epileptogenic substrate that requires a specific stage of brain maturation for its manifestation.

Another way to appreciate the multifactorial nature of epilepsy is shown in **Figure 1**, which illustrates three factors. The first – threshold – refers to the ease with which a seizure can be induced in a given brain. Differential susceptibility to acute seizures in humans is influenced by nonspecific predisposing factors such as age, genetics, and acquired insults, which may not themselves be epileptogenic. Threshold is not a static phenomenon – it has a circadian rhythm (usually higher during wakefulness and REM sleep and lower during drowsiness and slow-wave sleep), varies with the menstrual cycle in women, and can be lowered by influences such as fever, sleep deprivation, stimulant drugs, and withdrawal from sedative drugs and alcohol. Most antiepileptic drugs act by nonspecifically modulating excitation, inhibition, and synchronization in the brain to increase threshold, which also can result in unwanted side effects.

A second factor is the specific epileptogenic disturbance, which might be an obvious structural lesion (such as a brain tumor, scar, vascular malformation, cortical dysplasia, infection, or hippocampal sclerosis), or it could be a genetically determined epileptogenic brain dysfunction. The potency of the underlying epileptogenic abnormality may also vary over time. There may be effective treatments for specific epileptogenic disturbances, or they can sometimes be surgically removed.

A third factor is precipitating influences, which determine when seizures occur. In some cases, such as the photosensitive epilepsies, the precipitating stimulus is easily identified, but in most patients these are subtle internal or external events that remain unrecognized. When precipitating factors can be identified, such as flashing lights, they can often be avoided, for instance by wearing colored glasses or patching one eye.

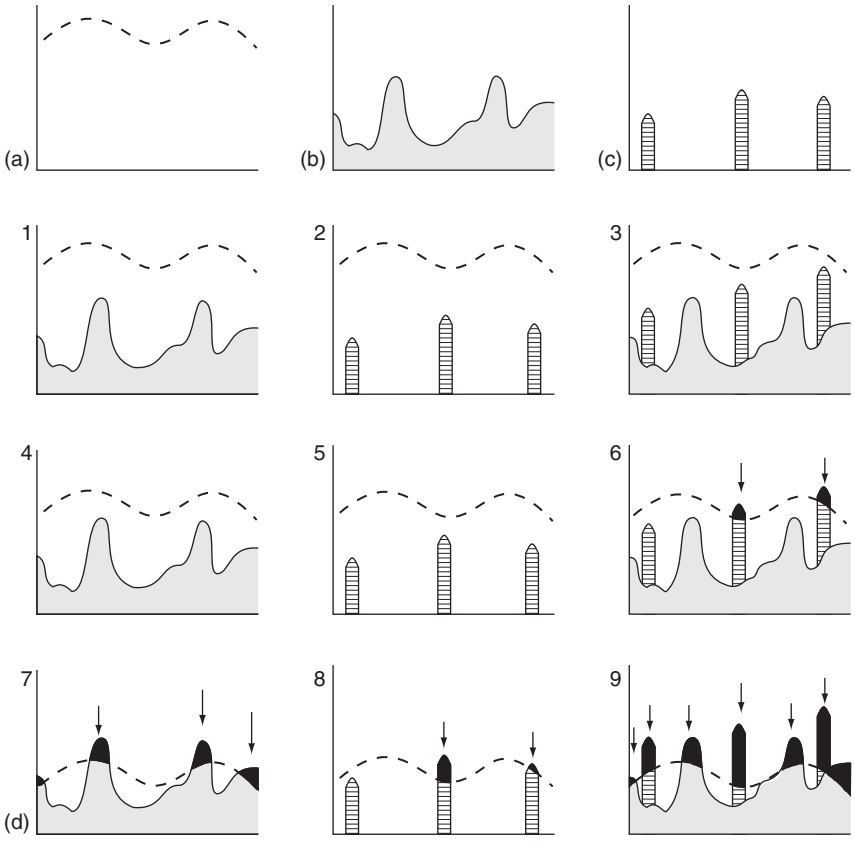

Figure 1 A schematic illustrating the interactions of the fluctuating threshold for seizures determined by *nonspecific predisposing factors* (a); independent fluctuations of a *specific epileptogenic disturbance* (b); and intermittent *precipitating factors* (c). With a high threshold, epileptogenic disturbances and precipitating factors alone (d1, d2) and combined (d3) fail to generate seizures. With an intermediate threshold, epileptogenic disturbances and precipitating factors alone (d4, d5) fail to generate seizures, but seizures (*arrows*) occur when these factors are combined (d6). With a low threshold, epileptogenic disturbances and precipitating factors alone (d7, d8) are each capable of generating seizures, and when combined (d9) generate even more seizures, perhaps constituting status epilepticus. Types of Animal Models

Each of the many aspects of epilepsy discussed in the previous section could be studied individually in the animal laboratory by utilizing phenomenological paradigms that mimic a particular component part of the clinical disorder. In their most fundamental form, these may not be models of epilepsy, but rather, epilepsy 'equivalents'. A common component part that was studied effectively for many years is the ictal event itself. Acute experimentally-induced seizure models have been extremely useful for investigating mechanisms of seizure maintenance, propagation, and termination, but they provide no information concerning epileptogenesis, the epileptogenic abnormality that exists in chronic epilepsy, the transition from the interictal to the ictal state, or the consequences of epilepsy. In recent years, research has been more focused on chronic animal models of epilepsy, which come closer to reproducing some of the more common human epilepsy conditions; however, there are currently no experimental animal models for the majority of human epilepsy syndromes.

Whether studying models that represent epileptic equivalents, acute epileptic seizures, or chronic epilepsy, two conditions are important in order to extrapolate results to patients – or to other animal models: age and species. Epileptic mechanisms are different in the neonatal brain than they are in the immature brain; mechanisms during various stages of brain development are different from those of the adult brain and, as we are now learning, from the aged brain. Epileptic phenomena have been studied in a large variety of animal species ranging from single-cell organisms to subhuman primates. Flies, worms, fish, and frogs have been used to create relatively inexpensive experimental preparations. Guinea pigs, cats, and dogs have been popular laboratory animals for epilepsy studies in the past, but most animal research on epilepsy today is carried out on rats, and more recently mice as a result of the availability of mutant and transgenic mice. Even when studying a single species, results obtained from one strain may be different from those of another because of genetic predisposing factors. For instance, rat strains have been developed that kindle rapidly, and

others that are relatively resistant to kindling. Similarly, preexisting genetic epilepsy alters epileptogenic mechanisms; for instance, the photosensitive baboon *Papio papio* kindles much more rapidly than do nonepileptic baboons or monkeys. Most animal research is carried out on males in order to avoid variability introduced by hormonal cycles of females; however, animal models are needed to understand the mechanisms of gender differences that exist in some human epilepsies.

Presumed Epileptic Equivalents

Examples of laboratory phenomena that are believed to reflect mechanisms that contribute to epileptogenesis or ictogenesis are listed in Table 1. Based on responses to specific categories of antiepileptic drugs, posttetanic potentiation is believed to be a model of generalized tonic–clonic seizures, and repetitive stimulation of cat spinal cord to be a model of absence seizures. Long-term potentiation, bursting neurons in vitro, and fast ripples are considered to be components of focal seizures, although they could also contribute to some generalized seizures. Reductionist models have been created in simple organisms that are believed to reflect epileptic equivalents.

Table 2 lists mechanisms believed to underlie epileptogenesis, and that may be targets for the development of surrogate markers. Although epilepsy equivalents are useful for investigating mechanisms of epilepsy, research on target mechanisms could help to develop biomarkers in order to: (1) identify patients at risk for epilepsy following potential epileptogenic insults, who may then be treated with preventive interventions; (2) diagnose epilepsy after a single seizure, in order to institute therapy as early as possible; (3) determine whether an antiepileptic drug, or other therapeutic intervention, will be effective without the need to wait for a second seizure to occur; (4) identify patients whose epilepsy is pharmacoresistant, who should then be considered for early surgical treatment; and (5) localize the epileptogenic region reliably, and cost-effectively, for surgical resection.

Altered glial function and gliosis
Inflammatory changes
Angiogenesis
Altered excitability and synchrony

Acute Experimentally-Induced Seizure Models

Examples of acute experimentally-induced seizure models are shown in Table 3. Localized application of electrical stimulation, convulsant drugs (such as penicillin, bicuculline, picrotoxin, and pentylenetetrazol) that block inhibition, and convulsant drugs (such as carbachol and kainic acid) that enhance excitation are commonly used to model focal seizures. Maximal electroshock and systemic convulsant drugs (such as pentylenetetrazol, allylglycene, bicuculline, kainic acid, convulsant barbiturates, ouabain, anticholinesteraces, and thiosemicarbazid) have been used to model generalized tonic–clonic seizures. Certain subcortical electrical stimulations, subcutaneous pentylenetetrazol, intramuscular penicillin in the cat, intracerebroventricular opioids, γ-hydroxybuterate injection, CO_2 withdrawal, and hyperthermia in immature animals are believed to produce seizures that mimic human absences. These different acute seizure models involve a variety of underlying mechanisms, and the relevance of each to acute symptomatic epileptic seizures – or epilepsy – in patients remains to be demonstrated. For instance, the seizures of childhood absence epilepsy appear to have a relatively consistent, well-defined, clinical manifestation, yet the ictal phenomenology appears to be reproduced by a large number of experimental perturbations. Further research is necessary to determine what these different purported models have in common with each other, and ultimately with the human condition.

Experimental models of status epilepticus can be induced by a variety of chemoconvulsants such as bicuculline,

Status epilepticus (bicuculline, fluorothyl, cobalt-homocystein, kainic acid, pilocarpine, soman, electrogenic)

fluorophyl, cobalt-homocystein, kainic acid, pilocarpine, and soman, as well as by electrical stimulation. These models are important for understanding the breakdown of mechanisms that naturally terminate ictal events, as well as for understanding the evolution of pathophysiological events that appear to change over time, resulting in pharmacoresistant status epilepticus, brain damage, and death.

Chronic Experimentally-Induced Epilepsy Models

Examples of chronic experimentally-induced models are shown in **Table 4**. Freeze lesions, partially isolated cortical slabs, and metals such as alumina, cobalt, tungstic acid, and ferric chloride have been used for decades, particularly to mimic neocortical epileptogenic lesions. Tetanus toxin and immunologic challenges are more recent approaches. Beginning in the 1970s, kindling became the most popular chronic model for the study of epileptogenesis, but technically it is not a model of epilepsy because, as usually performed, seizures do not occur spontaneously, but require electrical stimulation. This approach was most commonly applied to the limbic system and brought the process of epileptogenesis under laboratory control. If kindling is continued long enough, spontaneous seizures do occur; however, this is a difficult experimental model to create and maintain.

Most research on chronic epilepsy today utilizes models of mesial temporal lobe epilepsy with hippocampal sclerosis, which develop after status epilepticus. Systemic pilocarpine, kainic acid, and electrical stimulation-induced self-sustained status epilepticus result in bilateral hippocampal damage and other diffuse lesions that eventually give rise to spontaneous seizures arising from the limbic system. Intrahippocampal kainic acid produces unilateral hippocampal sclerosis with less-diffuse cerebral toxicity and less-frequent seizures, perhaps better modeling the human condition.

With the advent of high-resolution MRI, it has become apparent that malformations of cortical development, particularly focal cortical dysplasia, are common causes of medically intractable focal epilepsy in patients. Several animal models have been developed to study these important pathological conditions in the laboratory.

Spontaneous epileptic seizures, or paroxysmal activity presumed to bear some relationship to epileptic seizures, exist naturally in animals from flies to subhuman primates. **Table 5** lists examples of genetic animal epilepsy models that have been used for investigations into pathophysiologic mechanisms of idiopathic epilepsies. In addition, human gene discovery efforts are yielding candidate genes for epilepsy that can be inserted into mice in order to characterize the aberrant gene products and determine how these proteins eventually lead to the manifestation of epileptic signs and symptoms. Because of species and strain differences, the resultant in vivo models may bear no resemblance to the human condition from which the gene mutation was derived; however, critical information about underlying mechanisms may still be obtained. Aberrant genes, for instance, may not directly influence excitation, inhibition, and synchronization, which predispose the animal to ictal events; rather, they may alter brain development in ways that, in some species but not others, lead to an epileptic condition long after the effects of the mutant gene have disappeared.

The recognition that experimentally-induced ictal events are not epilepsy, and that research into basic mechanisms must involve chronic models with spontaneous seizure generation, was a major paradigm shift. We now know, however, that experimentally inducing an epileptogenic abnormality in a normal animal brain is also unsatisfactory as a model of the human condition, because people who develop epilepsy often, or perhaps always, have underlying predispositions (such as susceptibility genes) that alter their threshold not only to spontaneous seizures but also to epileptogenesis. Clinical research, therefore, must identify these predisposing factors so that they can be incorporated into appropriate experimental animal models of chronic epilepsy.

to improve diagnoses, treatments, prognoses, preventions, and ultimately cures for the many different types of human epilepsy – models of acute epileptic seizures, and occasionally models of chronic epilepsy, are also used for research into normal brain function, and for screening antiepileptic drugs and other therapeutic and diagnostic approaches. Physiological psychologists, in particular, have investigated the fundamental neuronal substrates of normal cerebral functions such as memory, by perturbing the system with experimentally-induced epileptic seizures (usually electroconvulsive shock) to produce a generalized tonic–clonic seizure. Neuroanatomists have taken advantage of the propagation of focal seizures to trace normal functional pathways in the brain using topical convulsants such as strychnine (strychnine neuronography) and penicillin. These important applications of experimental models of epilepsy, however, are beyond the scope of this article.

Testing Therapeutic and Diagnostic Approaches

New therapies, as well as novel concepts for diagnosis, are tested first in animal models before they can be studied in patients. The most common use of experimental animal models for this purpose is screening potential antiepileptic compounds. There are tens, if not hundreds of thousands, of compounds identified as potential antiseizure medications, and rapid-throughput, cost-effective approaches for screening them are therefore necessary. Maximal electroshock and subcutaneous pentylenetetrazol-induced acute seizures in mice are the screening methods of choice; however, maximal electroshock is a model for generalized tonic–clonic seizures, and subcutaneous pentylenetetrazol is a model for typical absence seizures, both of which are already effectively treated by available antiepileptic drugs. Many seizure types, however, such as atonic seizures and most focal neocortical and limbic seizures, are notoriously pharmacoresistant. This 'pharmacoresistance' may be no coincidence, given that potential antiepileptic compounds are not screened for efficacy against these seizure types in animal models, and many thousands of excellent drugs for these conditions have undoubtedly been discarded because they do not have anticonvulsant or antiabsence properties in the established models for drug evaluation (mentioned earlier).

Although there are many useful animal models of chronic focal epilepsy, these are generally considered to be too expensive and time-consuming for routine screening purposes. Only one antiepileptic drug (leviteracetam) has ever reached the marketplace after failing maximal electroshock and subcutaneous pentylenetetrazol screening, because it was found to be effective against a chronic model of temporal lobe seizures (amygdala-kindled seizures). Although it would be ideal if potential antiepileptic compounds were routinely screened against amygdala-kindled seizures, or seizures of other chronic models of mesial temporal lobe epilepsy, such screening is not likely to happen in the current research climate, for financial reasons; these models tend to be time-consuming and labor-intensive. Consequently, rapid-throughput, cost-effective animal models for pharmacoresistant epilepsies are badly needed.

Animal models have also been important for developing nonpharmacologic therapies, such as the ketogenic diet, vagus nerve stimulation, and deep brain stimulation. Many of these therapies have been devised serendipitously, or by trial and error, and their mechanisms of action are still unknown. Animal research is central to efforts to understand why certain interventions are effective against some seizure types and not others, and to use this information to develop better, more focused interventions with fewer side effects.

There are currently no effective interventions to prevent epilepsy (i.e., antiepileptogenesis), but there has been considerable research in this area. This work requires testing in animal models, such as kindling, where the time course of epileptogenesis is reliably reproducible.

Advances in the diagnosis of epilepsy have also depended, in part, on animal research; for instance, fluorodeoxyglucose positron emission tomography (FDG-PET) was based, to a certain extent, on 2-deoxyglucose (2DG) autoradiography performed on animals with epilepsy. Efforts to identify reliable surrogate markers of epileptogenicity and epileptogenesis, such as α-methyl-typtophan (AMT) and fast ripples, also require extensive animal research.

Understanding Fundamental Neuronal Mechanisms

Most of the seminal research on basic mechanisms carried out in the last century used the neocortical penicillin focus to characterize acute ictal discharges, their patterns of propagation, and (to a lesser extent) mechanisms of seizure termination. Amygdala kindling made it possible to investigate epileptogenesis, secondary epileptogenesis (which previously was studied with the mirror focus phenomenon), and distant pro- and antiepileptic consequences of the epileptogenic process. The current predominance of the use of models of mesial temporal lobe epilepsy with hippocampal sclerosis is not inappropriate given that mesial temporal lobe epilepsy is the most common form of human epilepsy, that hippocampal sclerosis is the most common epileptogenic lesion, and that this condition is among the most medically refractory of all epilepsies – contributing significantly to the total health burden of epilepsy. Now that high-resolution MRI has recognized malformations of cortical development to be a much more important cause of epilepsy than that previously believed (accounting for a large portion of patients previously diagnosed as cryptogenic), there is increasing interest in the development of animal models of these conditions. Treatments for many other human epilepsies, however,

have suffered from the fact that no appropriate animal models yet exist. There are, for instance, no valid models for atonic seizures, or for epileptic encephalopathies such as West, Landau-Kleffner, and Dravet syndromes.

In vitro approaches are primarily used for biochemical, molecular biological, and anatomical research protocols. In vitro slice preparations are also commonly used for electrophysiological studies. Slices can be prepared from chronic animal models, and acute ictal discharges can be induced in slice preparations from normal animals by manipulating the ionic composition of the bath fluid as well as by adding chemoconvulsants and/or applying electrical stimulation. It is important to recognize, however, that although these epileptiform discharges are useful for elucidating neuronal substrates of epileptic abnormalities, they are epileptic equivalents (not epileptic seizures) that lack a behavioral/clinical correlate.

In vivo biochemical studies can be carried out using microdialysis, permitting samples of extracellular fluid to be analyzed for released neurotransmitter and other chemical constituents. Such in vivo experiments are obviously essential for research paradigms that require data related to the behavioral characteristics of the epileptic seizures and/or their consequences (e.g., interictal behavioral disorders). In vivo electrophysiological studies are also important for studying the role of neuronal systems beyond local circuits, when longitudinal studies in the same animal are necessary to evaluate the development of epileptogenesis, and for studying the progression of an epileptic condition over time. Small animal PET and MRI technology now also makes it possible to study structural and functional anatomy, and local biochemical processes such as glucose metabolism, in a longitudinal fashion.

Considerable epilepsy research today involves gene discovery, including studies that employ microarray approaches to identify alterations in gene expression. Identification of epilepsy genes, and of differentially regulated gene expression profiles from epileptic humans and animals (not only from brain but also blood), will lead to hypotheses that must then be tested in experimental animal models. The mechanisms by which epilepsy gene products alter brain development and excitability must be investigated in animal models. The role of specific protein products of regulated genes in the mediation of epileptogenesis and epileptogenicity will need to be studied by inducing epilepsy in genetically manipulated animals.

With increasing ability to carry out invasive basic research on patients with epilepsy in the epilepsy surgery setting, as well as the tremendous advances in structural and functional neuroimaging that also permit mechanistic hypotheses to be pursued with human subjects, there remains an overriding need for parallel reiterative human animal research – i.e., studies using human data to validate the relevance of animal models, and then using these validated models to follow up on aspects of human research that cannot be pursued further (for logistical, ethical, or economic reasons) in patients. The cycle then requires that we return to patients, to confirm the relevance of results obtained in the animal laboratory.

Finally, results of research on animals with seizures and epilepsy are being used to devise and test computer models where variables can be easily altered to carry out investigations of fundamental neuronal mechanisms in the 'dry' lab. This work, however, is not likely to eliminate the need for animal research. Results from computer simulations need to be confirmed by further observations in living organisms; if such confirmation cannot be done in patients, it will need to be done in animal models.

Summary

There are many types of epileptic seizures and epilepsy syndromes. Within each specific epilepsy syndrome or ictal event, there are many component parts involving different pathophysiologic mechanisms and anatomic substrates. Individual component parts can be modeled, and epilepsy equivalents – which may not be epileptic in themselves – can be effective targets for certain types of epilepsy research. In vitro and in vivo models of acute ictal phenomena are valuable, but do not represent epilepsy; models of epilepsy must include an enduring epileptogenic abnormality capable of eliciting spontaneous seizures. Models of chronic epilepsy are essential for research on the epileptogenic process, as well as on mechanisms responsible for the transition from the interictal to the ictal state, and consequences of epilepsy. Epilepsy models can be used for research into normal brain function and for screening antiepileptic drugs and other potential antiepileptic interventions, as well as for testing new diagnostic technologies. They are obviously essential for research into fundamental mechanisms of epilepsy. There remains an overriding need to develop valid animal models for many severe epilepsy syndromes for which no models currently exist. Despite increasing basic research in the clinical setting as well as developments in computer modeling, there will continue to be a need for animal models, and for reiterative parallel human/animal paradigms that use observations from patients to develop hypotheses that can only be pursued in the animal laboratory, and then validated by further studies in patients.

Models of Generalized Seizures in Freely Moving Animals

L Velíšek, Albert Einstein College of Medicine, Bronx, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Models of generalized seizures are frequently used in the pharmaceutical industry for initial testing of novel compounds for anticonvulsant activity. These models historically include maximal electroshock seizures and minimal pentylenetetrazol seizures. The drugs active against tonic hindlimb extension seen in maximal electroshock seizures were thought to prevent seizure spread; drugs active against minimal pentylenetetrazol seizures (also referred to below as clonic seizures) were thought to increase seizure threshold. These two models still carry some value for routine drug testing, for their simplicity and high throughput.

The current choice of models of generalized seizures is much wider, and more complex models of generalized seizures in freely moving animals have an important use in research. These models may yield interesting information about responsiveness of the nervous system to convulsant drugs – i.e., about propensity of the brain to respond with seizure activity to external stimuli. This seizure susceptibility may be modified by many factors, including genetic conditions, hormonal milieu, previous seizure experience, and environmental conditions (e.g., stress). Models of generalized seizures can be used to determine efficacy of antiepileptic drugs under various conditions. Since different models utilize alterations in different neurotransmitter systems, these studies may help to elucidate mechanisms of antiepileptic drug action. Finally, if action of convulsant drugs is studied during early postnatal development, information can be gathered about nonlinear evolution of seizure propensity of the developing brain.

Many convulsant drugs administered systemically stimulate either the entire brain (bilateral effects) or they activate those brainstem structures projecting bilaterally to upper brain regions. This view is based on current EEG and imaging techniques. The resulting seizures will be perceived as stemming from the entire brain (or at least from the EEG-accessible parts), and considered as primarily generalized. In contrast, some convulsant drugs may create a strong unilateral source (focus) of epileptic activity as identified by current technology, and epileptic activity will spread from this focus bilaterally. These seizures will then be considered secondarily generalized.

Background

Primary generalized seizures – seizures that appear to arise simultaneously over broad regions of the brain – are very common in the human population. Examples of human primarily generalized seizures are absence seizures,

Models of Generalized Seizures in Freely Moving Animals

L Velíšek, Albert Einstein College of Medicine, Bronx, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Models of generalized seizures are frequently used in the pharmaceutical industry for initial testing of novel compounds for anticonvulsant activity. These models historically include maximal electroshock seizures and minimal pentylenetetrazol seizures. The drugs active against tonic hindlimb extension seen in maximal electroshock seizures were thought to prevent seizure spread; drugs active against minimal pentylenetetrazol seizures (also referred to below as clonic seizures) were thought to increase seizure threshold. These two models still carry some value for routine drug testing, for their simplicity and high throughput.

The current choice of models of generalized seizures is much wider, and more complex models of generalized seizures in freely moving animals have an important use in research. These models may yield interesting information about responsiveness of the nervous system to convulsant drugs – i.e., about propensity of the brain to respond with seizure activity to external stimuli. This seizure susceptibility may be modified by many factors, including genetic conditions, hormonal milieu, previous seizure experience, and environmental conditions (e.g., stress). Models of generalized seizures can be used to determine efficacy of antiepileptic drugs under various conditions. Since different models utilize alterations in different neurotransmitter systems, these studies may help to elucidate mechanisms of antiepileptic drug action. Finally, if action of convulsant drugs is studied during early postnatal development, information can be gathered about nonlinear evolution of seizure propensity of the developing brain.

Many convulsant drugs administered systemically stimulate either the entire brain (bilateral effects) or they activate those brainstem structures projecting bilaterally to upper brain regions. This view is based on current EEG and imaging techniques. The resulting seizures will be perceived as stemming from the entire brain (or at least from the EEG-accessible parts), and considered as primarily generalized. In contrast, some convulsant drugs may create a strong unilateral source (focus) of epileptic activity as identified by current technology, and epileptic activity will spread from this focus bilaterally. These seizures will then be considered secondarily generalized.

Background

Primary generalized seizures – seizures that appear to arise simultaneously over broad regions of the brain – are very common in the human population. Examples of human primarily generalized seizures are absence seizures,

generalized clonic seizures, and generalized tonic-clonic seizures. Animal research and improved diagnostic techniques (especially imaging) have recently led to the view that at least some of the seizures previously categorized as 'primary generalized' are actually of focal origin (e.g., in the somatosensory cortex), but spread rapidly (i.e., are actually secondarily generalized). Without question, however, primary generalized seizures constitute a significant proportion of the seizure types seen clinically. Models of generalized seizures in experimental animals contribute a great deal to understanding the mechanisms of seizure spread and control, and also to the search for better antiepileptic therapy; indeed, two generalized seizure models are used for routine testing of newly synthesized compounds (see earlier text). In addition, many epileptic syndromes of childhood involve primarily generalized seizures. Examples of these syndromes are early myoclonic encephalopathies (newborns), infantile spasms (age: 3–12 months), and Lennox-Gastaut syndrome (age: 1–8 years). While current animal models of generalized seizures correspond very well to human generalized clonic, tonic-clonic, and absence seizures, the satisfactory models for many childhood epileptic syndromes involving generalized seizures still do not exist. Recently, better models for infantile spasms have been developed (see Stafstrom and Velíšek), giving the field an opportunity to study underlying mechanisms and more effective therapeutic agents for this catastrophic seizure syndrome of childhood. However, there is a pressing need to develop models for other catastrophic seizure syndromes (associated with progressive mental retardation and, frequently, death) in order to improve current therapy. Appropriate and accurate animal models can provide insights into pathogenesis of these syndromes, and lay the foundation for future mechanistic treatments.

Methodology

Generalized (either primarily or secondarily) seizures can be induced in freely moving animals by systemic injection of chemical substances (convulsant drugs), by direct electrical stimulation of the brain, or they can develop from genetic defects. Models based on systemic injection of convulsant drugs require very simple equipment: a syringe with an appropriate size needle, a convulsant drug in a solution, an observation cage, and a stop-watch. Needle size depends on the density of the injected solution and, of course, on the route of administration. Subcutaneous injection (usually in the skin fold on the back of the neck) requires a fine needle (26 gauge), while administration of a dense solution intraperitoneally will require larger needle, 22–24 gauge. Intravenous administration may be more complicated. The tail vein is commonly used in rats. However, to access this vein, the rat must be well restrained during the entire injection procedure. While very simple, the administration of convulsant drugs by injection produces also significant stress (restraint, pain), which may be hard to standardize for the experimental groups. Alternatively, inhalation of the convulsant ether (flurothyl) can be used to elicit generalized seizures. Flurothyl evaporates easily at room temperature. Since it has convulsant features in both experimental animals and human experimenters, an air-tight cage must be used and the entire system should be placed in the fume hood for additional protection. This arrangement also requires use of a precision microinfusion pump, which delivers flurothyl into the air-tight chamber at a constant rate (although other approaches – e.g., bolus delivery to the air-tight chamber – are also possible).

General electrical stimulation of the entire brain (maximal electroshock) is theoretically possible in freely moving animals, but impractical because the stimulating current is delivered via ear-clip electrodes that easily displace. Therefore, maximal electroshock is generally given with animals restrained. In freely moving animals, electrical stimulation of specific brain sites via implanted electrodes can be used to generate an epileptic focus and secondarily generalized seizures. Additionally, this procedure may be used to model the process of epileptogenesis (i.e., kindling from the focus). Furthermore, some convulsant drugs although injected systemically preferentially affect a restricted part of the brain (because of very high receptor density). These drugs even with systemic administration can be used to create a seizure focus with secondarily generalization.

Pentylenetetrazol

Pentylenetetrazol-induced seizures are elicited most commonly by a bolus dose of subcutaneous or intraperitoneal aqueous solution of pentylenetetrazol, between 40–120 mg kg^{-1} in both rats and mice. Pentylenetetrazol administration results in blockade of GABA(A) receptor (via the TBPS site in the chloride channel). Delivery of graded pentylenetetrazol doses intravenously is also possible; such an approach can be used to determine seizure threshold or threshold of individual components of pentylenetetrazol-induced seizures.

Bicuculline and Picrotoxin

Both drugs are GABA(A) receptor antagonists. Bicuculline competes with GABA on its binding site, while picrotoxin occupies its own binding site in the associated chloride channel. Bicuculline cannot be easily dissolved in water or saline. Those bicuculline salts, which can be dissolved in water, do not cross blood-brain barrier, and therefore cannot be used for systemic administration in adult animals. Therefore, bicuculline is usually dissolved in 0.1 N HCl and pH is titrated back with 0.1 N NaOH. The final pH will be acidic, and thus painful if injected in the area with abundant nerve endings. Hence, bicuculline solution should be

preferentially administered intravenously (around 2 mg kg^{-1}), as a second choice intraperitoneally (6–8 mg kg^{-1}), and only exceptionally subcutaneously. In adult animals, intraperitoneal administration is limited by the 'first-pass' effect, during which the mature liver enzymatic system metabolizes a large portion of the injected drug, resulting in substantially higher dosage required for the same convulsant effects than during intravenous administration. Picrotoxin, on the other hand, can be dissolved in saline. Doses between 3–6 mg kg^{-1} are usually injected intraperitoneally.

Flurothyl

Flurothyl is a liquid ether, usually delivered by a precision microinfusion pump into an air-tight chamber. The rate of delivery depends on the chamber size. We use chambers between 9 and 14 l (volume), with a CO_2 scavenger. For these chambers, flurothyl delivery at 20–40 µl min^{-1} leads to seizure occurrence in mice or rats within 8–12 min. With continuous flurothyl delivery, the latency to onset of seizure marks the seizure threshold. The seizures are the result of flurothyl blockade of GABA(A) receptors, with the addition of opening of sodium channels and activation of the cholinergic system.

Strychnine

Strychnine sulfate can be dissolved in normal saline (at 1 mg ml^{-1}) and doses for adult rats are between 2–3 mg kg^{-1} subcutaneously. Seizures are elicited by blockade of glycine-operated chloride channels, which are abundant in the spinal cord and brain stem.

Kainic Acid (KA)

KA-induced seizures are usually induced by a systemic injection of aqueous solution of KA (with pH adjustment, although the final pH is still acidic), a neurotoxic analog of glutamate with preferential effects in the limbic system. Frequently, a bolus dose of KA is administered intraperitoneally. In rats this bolus dose is between 10–20 mg kg^{-1}, while mice usually require a higher dose, between 20–40 mg kg^{-1}. An alternative approach is to infuse graded doses of KA in the tail vein (in rats, 2.5–5 mg kg^{-1} every 5–20 min) until seizures occur.

N-Methyl-D-Aspartate (NMDA)

NMDA can be dissolved in saline up to 50 mg ml^{-1}. Systemic doses that induce seizures in adult rats range between 150–300 mg kg^{-1}. NMDA activates NMDA subtype of glutamate receptors. NMDA doses for eliciting seizures in developing rats are an order of magnitude lower than for the adult rats, at least in part because of better blood-brain barrier permeability in immature brain. Another reason for this higher sensitivity to NMDA may be the transiently increased NMDA receptor density in the immature brain, and the different subunit composition of NMDA receptors in infancy (high content of the NR2B subunit).

Maximal Electroshock Seizures

For maximal electroshock seizures, a device capable of delivering currents up to 300 mA is required (high voltage!). Current is delivered via ear-clip electrodes and the normal range is between 150–200 mA for seizure induction in rats. The rat is usually restrained during the stimulation protocol.

Kindling

Delivery of short (1–2 s) trains of alternating current (either sinusoid or rectangular pulses), at frequencies 50–60 c s^{-1} (Hz), at regular intervals, which is initially subthreshold for generalized seizure discharge and eventually leads to evoked seizures, is called kindling. The principle of kindling consists in delivery of subthreshold stimulus for motor seizures. With repetitions of this stimulus at appropriate intervals (4–48 h in adult rats) the seizures develop, become more and more severe, and also permanent. While initial stimulations produce focal electrical discharges (focal afterdischarges must be induced by the kindling stimulus), repeated stimulations lead to more severe stages of motor seizures, which represent secondary generalization.

Genetic Models

There are two well developed genetic models of primarily generalized absence seizures. One model was discovered in Strasbourg (Genetic Absence Epilepsy Rat from Strasbourg, GAERS) and the other in The Netherlands (WAG/Rij rat). Both strains are viable and reproduce well. There is also a genetically-based model of generalized seizures precipitated by loud sound (Genetically Epilepsy-Prone Rat; GEPR). In addition, several models of spontaneously occurring seizures in mutant mice are available.

Results

Drugs Affecting $GABA_A$ Receptors

Pentylenetetrazol, bicuculline, picrotoxin and flurothyl significantly block $GABA_A$ receptor function. Therefore, seizures induced by these drugs have many common features: Low doses of these convulsants (or early during the induction phase) elicit behavioral arrest and staring. In the EEG, spindle-shaped trains of spike-and-wave are recorded (Figure 1). Later during induction (or with moderate doses), myoclonic whole body twitches occur, accompanied by individual spikes on the EEG (often

Drug	*P7*	*P12*	*P18*	*P25*	*Adult (P60–90)*
Pentylenetetrazol			- -	—	—
Bicuculline		- -	—	—	—
Picrotoxin	—	—	—	—	—
Flurothyl		- -	—	—	—

Ages indicate postnatal days in rats. Full line marks regular occurrence of clonic seizures, if sufficient dose of the convulsant drug is used. Dotted line indicates infrequent or even rare occurrences.

overlapping with movement artifacts). After myoclonic twitches, clonic seizures of forelimbs and face develop. These seizures last for several seconds to tens of seconds. If the clonic seizure is severe enough to disturb upright posture, the animal immediately and actively regains balance. In the EEG, the seizure presents as a series of spike-and-wave discharges. Finally, with larger doses of convulsant, or after longer time intervals, tonic-clonic seizures occur. These seizures begin with wild running, followed by the loss of righting ability. While lying on the cage floor, the animal displays tonic extension of limbs, concomitant with clonus of all four limbs. On the EEG, seizures usually start with fast polyspikes followed by spike-and-wave complexes. All features occur throughout development except for clonic seizures, which are developmentally specific and also dependent on the convulsant drug (Table 1).

Strychnine

This drug produces myoclonic twitches and tonic-clonic seizures with loss of righting. During the seizures, extensions of the trunk, limbs, and tail are prominent. The EEG correlate of these strychnine-induced seizures are predominantly spikes and sharp waves.

Kainic Acid

KA induces developmentally specific seizure syndromes. In adult rats, after automatisms consisting of rapid and alternating head rotations ('wet dog shakes') or rarely of scratching, clonic seizures of face and forelimbs occur with preserved righting. These convulsions are sometimes termed 'limbic seizures,' a term that emphasizes the focal initiation of epileptic activity. At the time of clonic seizure development, epileptic activity is already secondarily generalized and the seizure pattern is similar to the pattern described above (i.e., the clonic seizures seen in flurothyl, pentylenetetrazol, bicuculline or picrotoxin seizure models). In adult animals, tonic-clonic seizures after KA are rare; however, clonic seizures may last for many minutes to hours, developing into status epilepticus (continuous seizure activity lasting 30 min and more). Severity of the status epilepticus episodes correlates with the degree of resulting neuronal damage in the hippocampus. Epileptic EEG activity precedes motor seizures, and can be recorded earlier in limbic structures than in the neocortex.

NMDA

In adult animals, NMDA induces periods of wild running followed by generalized clonic seizures with complete loss of righting ability. This seizure pattern is similar to the tonic-clonic seizure pattern described above after pentylenetetrazol, flurothyl, bicuculline or picrotoxin. However, tonic seizure phase follows, rather than precedes, the clonic phase. Usually the occurrence of the tonic phase indicates a lethal ending for the seizure. Cortical EEG associated with NMDA injection is very nonspecific, consisting of periods of EEG suppression and polyspike-and-wave discharges.

Maximal Electroshock Seizures (MES)

Maximal electroshock delivered via ear-clip electrodes immediately produces tonic-clonic convulsions with the loss of righting. If the current is strong enough, the following sequence occurs: tonic flexion of forelimbs, tonic flexion of hindlimbs, tonic extension of forelimbs and tonic extension of hindlimbs. Prolonged tonic hindlimb extension frequently marks the end-point of the experiment.

Kindling

Stimulation of a sensitive brain structure, such as hippocampus, amygdala, entorhinal cortex, etc., delivered at low intensity, produces an EEG afterdischarge (Figure 2). With repeated stimulations, the duration of afterdischarges increases and behavioral seizures develop. These seizures have a character of clonic seizures of face and forelimbs, with preserved righting ability, as described above for

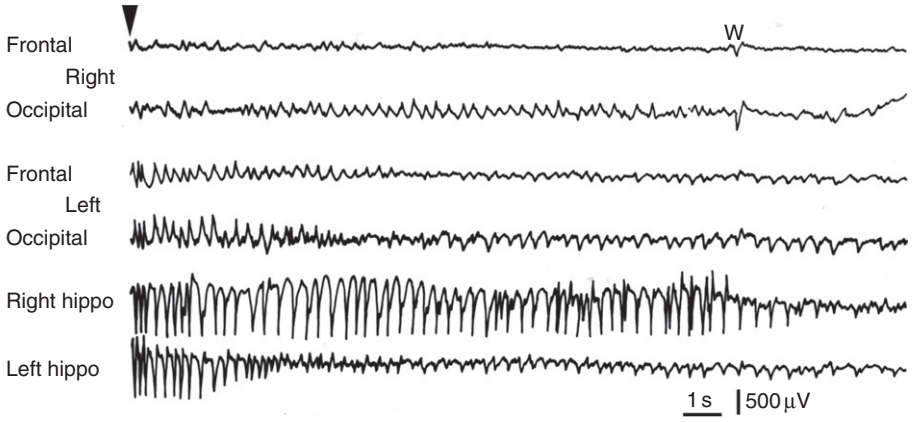

Figure 2 Afterdischarge following hippocampal stimulation in the adult rat. Trace legend indicates areas of neocortex, in which recordings have been performed. Left and right hippo indicate recordings from the left and right hippocampus. Arrowhead points to the end of stimulation (electrode in the left hippocampus). The afterdischarge consisting of spike-and-wave complexes follows (well seen in the trace recorded in the right hippocampus) with cessation about 2 s after a 'wet dog shake' (W) occurred. Calibration 500 μV, time mark 1 s.

convulsant drugs acting at $GABA_A$ receptors. Behavioral seizures also evolve, and can be classified according to the widely accepted Racine scale (Table 2). Once the stage 4 seizures occur, the seizures are considered secondarily generalized.

Genetic Models

Both GAERS and WAG/Rij rat strains develop EEG activity consisting of periods of spike and wave rhythms, with crescendo-decrescendo amplitude (spindle shaped) resembling the 3 Hz spike-and-wave discharges in human absence epilepsy. Behaviorally, these EEG episodes are accompanied by motionless stare. Another rat model, the GEPR, comes in two variants: GEPR-3s show moderate clonic seizures, and GEPR-9s exhibit severe tonic-clonic seizures with the behavioral seizure patterns very similar to those described above for $GABA_A$ receptor acting drugs.

Future Goals

Our discussions in this article should convince the reader that in the current era of molecular and cellular neurobiology, there is still significant room for models of generalized seizures in freely moving animals. Sometimes it is difficult to determine what these models model, what the underlying mechanisms might be, and what the consequences of these seizures are for the brain. However, there are precise fits for some models – e.g., the genetic absence models in rats provide important insights into the mechanisms of absence seizures in humans, most recently suggesting focal cortical origins of spike-and-wave absence epilepsy.

Table 2 Racine scale for kindling-induced generalized seizures in adult rats

Stage	*Behavioral expression*
1	Mouth and facial movements
2	Head nodding
3	Clonus contralateral to the stimulus site
4	Symmetrical forelimb clonus with rearing
5	Rearing and falling (yet regaining upright position)

There is a need to investigate old models of generalized seizures, and to create new ones. There are several reasons why new models are necessary: (1) New models may better reflect the human condition, and thus help to improve studies of the disease mechanisms. (2) For some human seizure syndromes, there are no corresponding animal models. For example, our understanding and treatment of Lennox-Gastaut syndrome would be immeasurably helped by research on a relevant animal model. Similarly, early infantile epileptic encephalopathies have no available models though there is an urgent need to improve their therapy and find underlying mechanisms. Thus, further exploitation of existing models of generalized seizures and development of new models will play a major role in future epilepsy research.

Introduction and Background

Epilepsy is clinically manifested in recurring, self-sustaining bursts of abnormal electrical activity (epileptic seizures) in the brain. In contrast to reactive seizures, which occur in response to 'environmental stimuli' (e.g., fever, hypoglycemia, presence of seizure-inducing agents), epileptic seizures occur at unpredictable intervals. With only few exceptions (e.g., reflex epilepsies), seizures appear in the absence of any clear identifiable triggers. In contrast, isolated seizures can be induced in many different ways, even in intact and healthy brain without any previous experience of epileptic activity or behavior. Under experimental conditions, seizures can be induced chemically, using seizure-inducing or convulsive drugs (chemoconvulsants). These drugs do not fall into any specific pharmacological category, and they act through many different mechanisms. Chemoconvulsants can be used to induce seizures in various animal species, including mammals, invertebrates, fishes, or birds. For many experimentally used drugs, seizure induction has also been described in humans, for example, after overdose or accidental intoxication. Chemoconvulsants involve drugs of different origin, including plant toxins (strychnine), weapon-grade organophosphorus substances (soman, sarin), or bacterial toxins (tetanus toxin). Many drugs that are used clinically for various indications can induce convulsions/seizures when overdosed or administered in a way that leads to nonphysiological concentrations in the brain. Some of these drugs are used experimentally, such as aminophylline (theophylline and elhylenediamine; drug used to treat asthma), isoniazid (antimicrobial agent used in chemotherapy of tuberculosis), lidocaine and cocaine (local anesthetics), and penicillins (antibiotics).

In experimental epileptology or pharmacology, seizures induced by chemoconvulsants represent frequently used models, induced to study generation or generalization of epileptic activity and to search for new anticonvulsant drugs. Such models also represent powerful tools to study effects of sex, age, genetic background, or additional pathologies on seizure susceptibility or development. In addition, chemoconvulsants with known mechanisms of action can be used to study postnatal development and functional maturation of neurotransmitter systems and ion channels, and to investigate the role of specific systems (e.g., neurotransmitter receptors or metabolic pathways) in brain excitability or seizure development.

Chemoconvulsant models are inexpensive and widely used. Their major advantage is that the procedure is simple and convenient, and models are usually well described. For many of these models, there are standard methods of evaluations, with relatively standard scoring systems developed to quantify seizure severity and pattern. Thus, the results obtained from these models are usually highly reproducible and comparable across different laboratories. There are, however, some disadvantages that should be

Introduction and Background

Epilepsy is clinically manifested in recurring, self-sustaining bursts of abnormal electrical activity (epileptic seizures) in the brain. In contrast to reactive seizures, which occur in response to 'environmental stimuli' (e.g., fever, hypoglycemia, presence of seizure-inducing agents), epileptic seizures occur at unpredictable intervals. With only few exceptions (e.g., reflex epilepsies), seizures appear in the absence of any clear identifiable triggers. In contrast, isolated seizures can be induced in many different ways, even in intact and healthy brain without any previous experience of epileptic activity or behavior. Under experimental conditions, seizures can be induced chemically, using seizure-inducing or convulsive drugs (chemoconvulsants). These drugs do not fall into any specific pharmacological category, and they act through many different mechanisms. Chemoconvulsants can be used to induce seizures in various animal species, including mammals, invertebrates, fishes, or birds. For many experimentally used drugs, seizure induction has also been described in humans, for example, after overdose or accidental intoxication. Chemoconvulsants involve drugs of different origin, including plant toxins (strychnine), weapon-grade organophosphorus substances (soman, sarin), or bacterial toxins (tetanus toxin). Many drugs that are used clinically for various indications can induce convulsions/seizures when overdosed or administered in a way that leads to nonphysiological concentrations in the brain. Some of these drugs are used experimentally, such as aminophylline (theophylline and elhylenediamine; drug used to treat asthma), isoniazid (antimicrobial agent used in chemotherapy of tuberculosis), lidocaine and cocaine (local anesthetics), and penicillins (antibiotics).

In experimental epileptology or pharmacology, seizures induced by chemoconvulsants represent frequently used models, induced to study generation or generalization of epileptic activity and to search for new anticonvulsant drugs. Such models also represent powerful tools to study effects of sex, age, genetic background, or additional pathologies on seizure susceptibility or development. In addition, chemoconvulsants with known mechanisms of action can be used to study postnatal development and functional maturation of neurotransmitter systems and ion channels, and to investigate the role of specific systems (e.g., neurotransmitter receptors or metabolic pathways) in brain excitability or seizure development.

Chemoconvulsant models are inexpensive and widely used. Their major advantage is that the procedure is simple and convenient, and models are usually well described. For many of these models, there are standard methods of evaluations, with relatively standard scoring systems developed to quantify seizure severity and pattern. Thus, the results obtained from these models are usually highly reproducible and comparable across different laboratories. There are, however, some disadvantages that should be

emphasized. First, chemoconvulsants are xenobiotics, and as any other systemically administered drug, they must penetrate through barriers, be appropriately distributed, metabolized, and eliminated. Pharamacokinetics of chemoconvulsants can be affected by other drugs that are present in the organism at the same time (including tested anticonvulsant drugs), and also by sex, age, or genetic predisposition. Thus, a different efficacy of chemoconvulsive drugs in individual strains of rats or mice can reflect genetically related differences in seizure susceptibility, as well as differences in pharmacokinetic parameters. Also, these models usually mimic isolated (reactive) seizures, not epilepsy as a chronic disease. There are however some exceptions. For example, some chemoconvulsants (e.g., GABAergic antagonists, local anesthetics) can be used for chemically induced kindling, a model of progressive enhancement of seizure susceptibility or epileptogenesis. In addition, there are drugs with various mechanisms of actions (e.g., the cholinomimetic drug pilocarpine, agonists of excitatory amino acid (EAA) receptors such as kainate), which induce convulsive status epilepticus (SE), a highly destructive and epileptogenic brain insult. In great majority of surviving (adult) animals experiencing drug-induced SE, spontaneous recurrent seizures develop within days or weeks. Thus some chemoconvulsants induce reactive seizures (i.e., they have ictogenic potential) and also epilepsy as consequence of seizure-induced brain damage (i.e., they also have epileptogenic potential).

Methods

Chemoconvulsants can be administered systemically or focally onto/into various brain structures. Systemic administration (subcutaneous (s.c.), intraperitoneal (i.p.) or intravenous (i.v.)) is most widely used, because administration is simple and does not request any special equipment or procedure. Focal administration/injection is technically more difficult, but intraparenchymal injection of convulsive drugs can create specific models of seizure activity, including acute or chronic seizures with known site of seizure onset. Infusion of chemoconvulsants into the brain ventricular system is also used. With this procedure, however, there is no control of the focus of seizure onset, because all structures surrounding ventricular system can be affected. Focal or intracerebroventricular administration generally involve the use of much lower doses of chemoconvulsants than those used with systemic injections, by-passing problems with hematoencephalic barriers (some convulsive drugs do not cross the blood–brain barrier (BBB)) or with systemic metabolism of the drug. In general, water insoluble chemoconvulsants, or drug solutions with pH different from physiological values, are not optimal for focal delivery, because organic solvents or local changes of pH may affect tissue excitability independently of the convulsant drug.

Results – Mechanisms of Actions and Seizure Types Induced by Chemoconvulsants

To provoke reactive seizures, drugs suppressing inhibition (GABAergic or glycinergic) or potentiating EAA transmission are used most frequently. There are, however, many other drugs with different mechanisms which can induce reactive seizures, including agents that interact with the opioid system (morphine), with acetylcholine neurotransmission (pilocarpine), or have direct interaction with ion channels (4-aminopyridine). Depending on their mechanisms of action, chemoconvulsants induce various types of seizure activity, with different EEG and behavioral correlates. Seizure pattern is also affected by dose, route of administration, or additional pharmacological manipulation. In addition, seizure features can change with age of experimental animals, with some chemoconvulsants (e.g., NMDA, homocysteine, homocysteic acid) inducing age-specific seizures types. Because of limited space, I will focus only on effects of some drugs studied in our laboratory. Because we have studied primarily developmental epileptology for many years, specific age-related features of chemically induced seizures will be stressed in the following paragraphs.

Suppression of GABAergic Inhibition

Drugs interacting with the GABAergic system are probably the most frequently used type of chemoconvulsant. This group of drugs involves $GABA_A$ receptor antagonists and also drugs that block GABA synthesis (**Figure 1**). The antagonists bind to different binding sites of $GABA_A$ receptors, but despite these differences, they tend to induce similar seizures – with quantitative rather than qualitative differences in their effects. GABA-related chemoconvulsants induce several types of epileptic activity, dependent on dose, means of administration, and latency after administration. After systemic administration, myoclonic twitches appear with short latency, accompanied by isolated spikes in the EEG. Most GABAergic chemoconvulsants induce 'absence-like' seizures, reflected in freezing behavior and spike and wave spindles (frequency around 5 Hz; **Figure 2**) in the EEG. These seizures can often only be detected in EEG recordings, since the behavioral manifestation is rather subtle. Clonic seizures occur after higher dose of these chemoconvulsnts or with longer latency after the administration. Behaviorally, these clonic seizures are expressed as clonus of forelimb and head muscles, with hindlimbs usually widely abducted, and tail erect; rearing and/or falling frequently occurs during convulsions. Righting reflexes are preserved. In the EEG, clonic seizures are typically seen as spike-and-wave activity (**Figure 2**). Generalized tonic–clonic

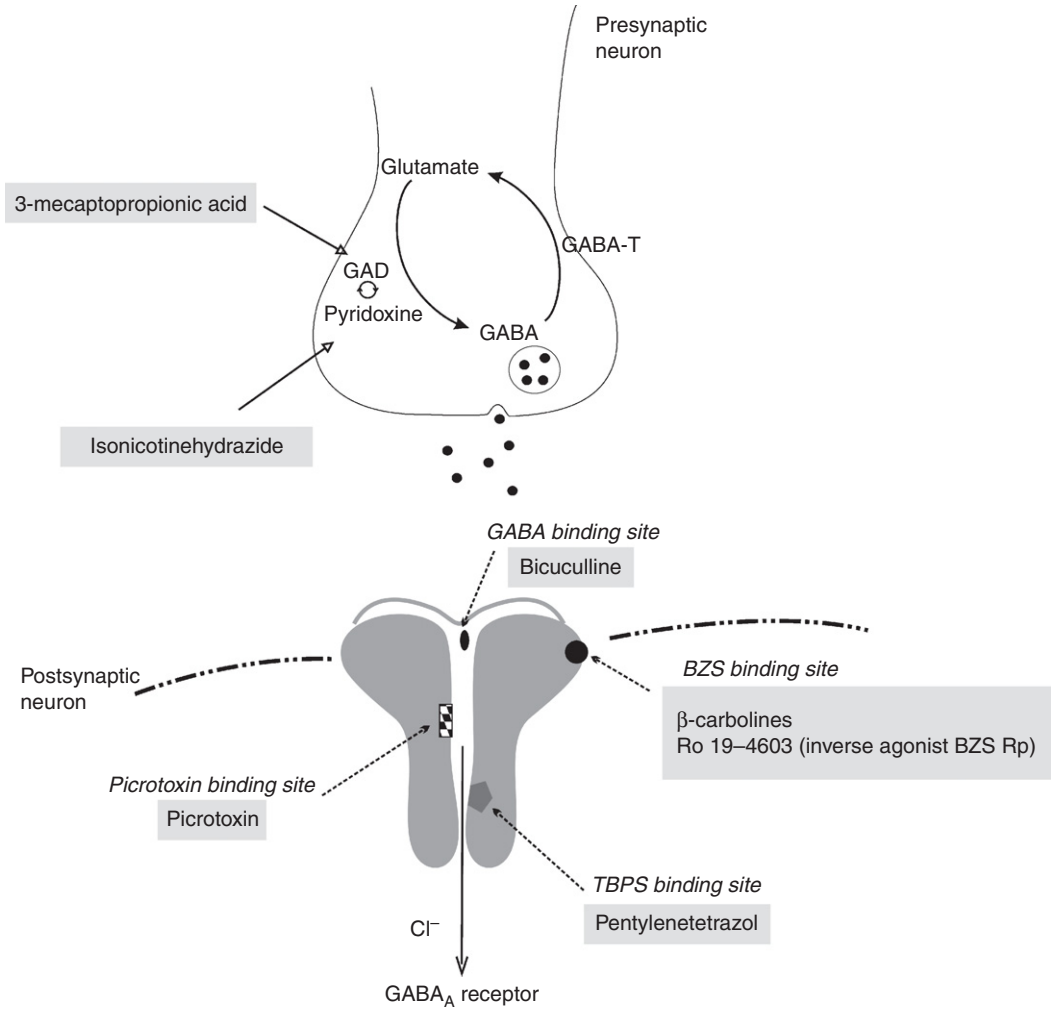

Figure 1 Schematic drawing illustrates different sites of action (pointed by arrows) of GABAergic seizure drugs mentioned in the text. GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD). Inhibition of this enzyme (direct (3-MPA) or through blockade of the GAD coenzyme pyridoxine (isonicotinehydrazide)) results in decrease of GABA synthesis, failure of inhibition and development of seizures. Inhibitory effects of GABA can be antagonized also by blockade of different binding sites at postsynaptic $GABA_A$ receptors. For details, see text.

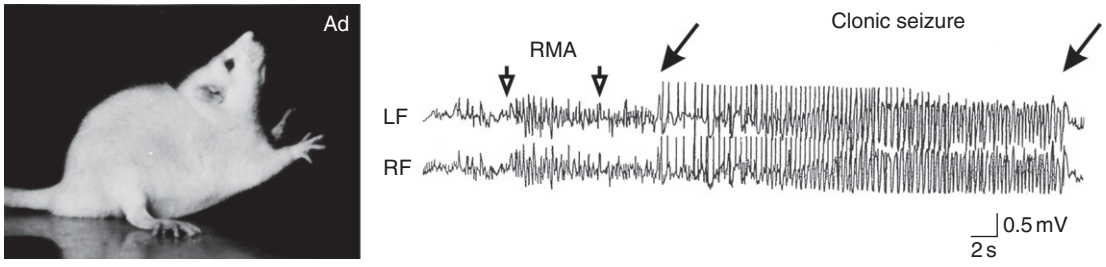

Figure 2 Photograph on the left demonstrates clonic seizure induced by systemic administration of PTZ in adult rats. The elecrocorticogram on the right site illustrates the typical pattern of clonic seizure (the onset and the end are marked by black arrows). In ECoG, clonic seizure is preceded by spike + wave discharge (RMA – rhythmic metrazol activity; empty arrows) which represents absence-like seizures. In behavior, discharge is accompanied by behavioral arrest.

seizures (GTCS; 'grand-mal' type) are the most severe type of epileptic seizures induced by chemoconvulsants. In rodents, they are expressed as a short initial phase of wild running, followed by loss of righting reflexes, then by a tonic phase (usually lasting for 5–15 s), and finally a clonic phase (lasting for tens of minutes). Incomplete, generalized clonic seizures, without a tonic phase, can also be induced. Such seizures are most frequently seen in pharmacological studies,

since some antiepileptic drugs specifically block only tonic phase of generalized tonic–clonic seizures. In EEG recordings, generalized tonic–clonic seizures are represented by polyspikes or polyspikes and waves activity.

After focal injections, GABAergic drugs can induce focally generated seizure. Both EEG and behavioral pattern of focal seizures depend on the exact site of injection, and as well as dose and age of animals.

Pentylenetetrazol (pentamethylenetetrazol, metrazol, PTZ) was formally used as a nonspecific stimulant of the nervous system. It is easily water soluble and it crosses BBB. PTZ noncompetitively antagonizes the $GABA_A$ receptor, likely through a benzodiazepine binding site and an allosteric interaction in the chloride channel. PTZ injected subcutaneously, together with maximal electroshock, are the most frequently used models employed to search for new antiepileptic drugs. As mentioned earlier, PTZ induces various seizure patterns. The clonic seizures induced by PTZ were historically used as a model against which antiabsence drugs were tested. These seizures can, however, be suppressed by some antiepileptic drugs, which aggravate absence seizures in human patients (e.g., barbiturates or gabapentin). Thus, it has been suggested that PTZ-induced clonic seizures model myoclonic (rather than absence-like) seizures. Low doses of PTZ induce absence-like nonconvulsive seizures, which may represent a better model of human absences than seen with higher dose PTZ, but this low-dose model is not frequently used. To test antiabsence efficacy of new drugs, genetic models with spontaneously occurring absence seizures are now preferred over chemically induced models. Generalized tonic–clonic seizures induced by PTZ represent a model of primary or secondary generalized seizures in humans. Repeated intraperitoneal administration of low doses of PTZ may be used to induce SE. In subthreshold doses, repeated PTZ administration leads to the progressive development of kindled seizures.

The behavioral and electrical patterns of PTZ-induced seizures are highly age-related. In rats, both absence-like nonconvulsive seizures and clonic seizures cannot be reliably induced during the first 2 weeks of life. In contrast, generalized tonic–clonic seizures are observed starting in the first postnatal days. The behavioral pattern of these seizures, however, reflects the level of maturation of the motor system; for example, **Figure 3** demonstrates differences in the tonic phase in P7 vs. adult rats.

The $GABA_A$ receptor antagonist bicuculline, and the Cl-channel blocker picrotoxin, induce similar seizure phenomena as seen with PTZ. In contrast to PTZ, however, bicuculline induces clonic seizures as early as P12. Both bicuculline and picrotoxin cross the BBB; however, in contrast to picrotoxin, bicuculline is not easily water soluble. For focal (intracerebral) administration, the use of a water soluble derivative of bicuculline, bicuculline methiodide, is recommended. Notably, the ability of bicuculline methiodide to cross the BBB decreases with age. Systemically administered bicuculline methiodide induces clonic or generalized tonic–clonic seizures in rats up to

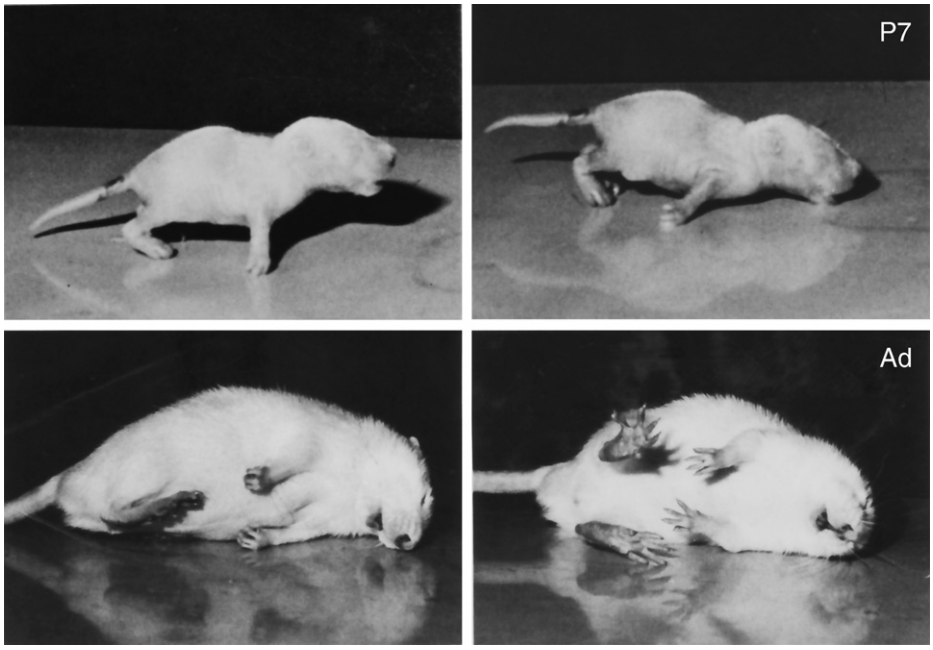

Figure 3 Generalized tonic–clonic seizure in P7 and adult rats. Tonic phase is demonstrated on the left site, beginning of the clonic phase on the right site. The difference in tonic phase on both forelimbs and hindlimbs (left site) between both age groups reflect level of maturation of the motor system.

P18, but not in older animals, probably due to gradual maturation of the BBB.

Drugs acting as inverse agonists on the benzodiazepine binding site of $GABA_A$ receptors (β-carbolines and Ro 19–4603) have been shown to induce seizures. β-Carbolines (methyl-6,7-dimethoxyl-4-ethyl-β-carboline (DMCM) and methyl-β-3-carboxylate (β-CCM)) induce both clonic and generalized tonic–clonic seizures, but they are less frequently used than the previously mentioned chemoconvulsants. The spectrum of seizures induced by Ro 19-4603 (imidazothieno-diazepinone (*tert*-butyl5,6-dihydro-5-methyl-6-oxo-4H-imidazol [1,5-*a*] thieno [2,3*f*] [1,4] diazepine-3-carboxylate) is the same as seen with PTZ, except that clonic seizures can be successfully induced as early as P7 in rats.

In addition to drugs affecting directly $GABA_A$ receptors, glutamic acid decarboxylase (GAD) inhibitors, which inhibit GABA synthesis, are potent chemoconvulsants. The inhibition of GABA synthesis decreases GABA concentration, thus both $GABA_A$ and $GABA_B$ receptors are less likely to be activated. The relatively specific inhibitor of GAD, 3-mercaptopropionic acid (3-MPA), elicits clonic as well as generalized tonic–clonic seizures as early as the first week of life. In this model, clonic seizures last for several minutes (in the PTZ model, the duration of clonic seizures is tens of seconds). Sensitivity to 3-MPA changes with age; the CD_{50} for different age groups of rats is shown in Figure 4. Also, the initial phase of GTCS – wild running – is longer and more intense with 3-MPA as compared with PTZ. GABA synthesis can also be inhibited by other drugs (allylglycine or isonicotinehydrazide); none of these drugs, however, are routinely used in experimental epileptology or in pharmacological screening.

Penicillin in low doses acts as $GABA_A$ antagonist. The penetration of penicillin through the BBB is, however, very limited. When administered topically, penicillin induces focal seizures, with seizure pattern depending on exact location of application. Behaviorally, ictal activity may be associated with clonic seizures. In the past, models of epileptic seizures induced by focal administration of penicillin were frequently used to study various cellular epileptic phenomena; however, it is currently used much less frequently.

Taken together, seizures induced by drugs suppressing GABAergic inhibition represent well-described models of several types of epileptic activity. Both seizure pattern and severity are highly age and dose dependent. Some of these models are routinely used for drug screening.

Drugs Suppressing Glycinergic Inhibition

The suppression of glycinergic inhibition, by the alkaloid strychnine, induces generalized clonic or tonic–clonic convulsions as early as P3 in rats. Rats that are 3-weeks old (P18–P25) are the most sensitive age group in this model. Typically, the tonic seizure phase is accompanied by apnotic pause and high mortality. Strychine-induced seizures are highly pharmacoresistant, and are therefore considered as a possible model of therapy-resistant seizures by some authors. Currently, the use of strychnine-induced seizures in drug screening is limited.

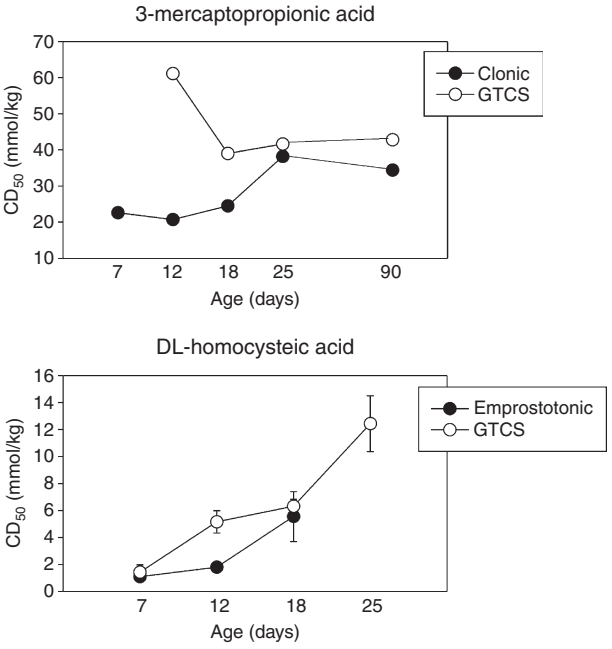

Figure 4 Age-related changes of CD_{50} (50% convulsive dose i.e., estimated dose which induces seizures in 50% of animals in experimental group) for two types of seizures induced by two seizure drugs with different mechanisms of actions. Note differences in age-related susceptibility to clonic and generalized tonic–clonic seizures after administration of 3-mercaptopropionic acid (on the top). Such differences cannot be simply explained by maturation of BBB or pharmacokinetics of used drugs. They rather reflect development of target structures or seizure generators. CD50 for both seizure types induced by D,L-HCA acid increases with age of animals. Flexion seizures however cannot be induced in animals older than P18.

Enhancement of EAA Excitation

Agonists of EAA receptors can induce both clonic and generalized tonic–clonic seizures. In the EEG, spike, spike and wave, or polyspike activity is usually recorded after administration of these chemoconvulsants. Shortly after administration, or after low-dose administration, various behavioral automatisms (scratching, wet dog shakes, washing, chewing, etc.) occur. Typically, behavioral features are drug specific and their pattern is age and dose dependent. Importantly, some EAA agonists (i.e., agonists of NMDA receptors) can induce age-specific seizure types.

Kainic acid (kainate or KA; agonist of KA EAA receptors) represents the most frequently used agonist of EAA

receptors. Usually, kainate is used to produce convulsive SE, which subsequently results in chronic seizure discharge. To induce SE, KA can be administered systemically (due to limited penetration through the BBB, the necessary dose increases with age) or intracerebrally. The development of KA-induced SE and its consequences are highly specific to the strain of rat or mouse used for the experiment. Seizure features are also affected by age of animals. In 2-week-old rats, generalized clonic–tonic seizures represent the most frequent seizure type; their incidence, however, decreases with age of animals. Also, intense scratching is a typical automatism seen within the first 2 weeks of age; starting with the third week of life, scratching is gradually replaced by wet dog shakes.

After systemic administration of *N*-methyl-D-aspartate (NMDA; agonist of NMDA type of EAA receptors) to rats of all age groups, there is development of clonic–tonic seizures, preceded by marked hyperlocomotion and tail flicking. Generalized clonic–tonic seizures are accompanied by very high mortality. In rats younger than 3 weeks, systemic administration of NMDA induces a very characteristic seizure pattern, so-called flexion (emprostotonic) seizures (**Figure 5**). Because of their highly age-specific occurrence, flexion seizures may represent a valuable model of infantile spasms. The relevance of this model must be further validated. After NMDA administration, flattening of the electrocorticogram (ECoG) is typically seen; however, in spite of an almost isoelectric EEG, various seizure behavioral phenomena are observed. Permeability of the BBB, as well as sensitivity of NMDA receptors, decreases with age; thus, much higher doses of drug are necessary to induce generalized seizures in adult rats.

Intracerebrally administered NMDA induces severe excitotoxic brain damage and development of generalized clonic or tonic–clonic seizures in freely moving animals. Mortality of experimental animals is much lower compared with systemic administration. This lower mortality makes it possible to follow animals for long periods. Thus, intracerebral injection of NMDA has been suggested as a model of traumatic or ischemic brain injury by some authors.

Effects of homocysteic acid as well as homocysteine are at least partially mediated by NMDA receptors, even though other mechanisms must also be considered. D,L-Homocysteic acid (HCA) and its stereoisomers induce seizures similar to NMDA (**Figure 5**). There are certain differences between effects of D- and L-HCA. Both stereoisomers induce flexion as well as generalized tonic–clonic seizures, but there are marked differences in the initial signs of actions. The behavior after L-HCA resembles behavioral changes induced by NMDA (tail flicking, hyperlocomotion), whereas D-HCA administration induces behavioral features that can be classified as epileptic automatisms (sniffing, chewing). Also, EEG suppression is induced by L-but not D-HCA. This difference may reflect different mechanisms of action of the two stereoisomers. Sensitivity to D,L-HCA acid changes with age; the CD_{50} for different age groups of rats is shown in **Figure 4**. When administered intracerebrally, HCA results in the development of severe and long-lasting SE, and massive excitotoxic brain damage.

Homocysteine (HC) acts through multiple mechanisms, including the interaction with ionotropic and metabotropic glutamate receptors. In addition to flexion and generalized tonic–clonic seizures, HC also induces clonic seizures similar to those induced by PTZ or other GABAergic drugs; such seizures do not develop after administration of NMDA or HCA. Automatisms (sniffing, washing, and chewing) precede seizure development. Both clonic and generalized tonic–clonic seizures occur in all age groups of rats. Flexion seizures are frequently seen in up to the second week of life, but they are uncommon in older animals.

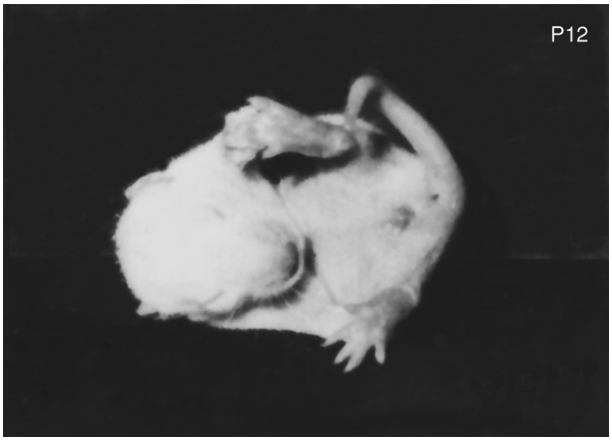

Figure 5 NMDA-induced flexion (emprostotonic) seizure in P12 rat.

Future Goals

Chemoconvulsants have been used for many years to study the general properties of neuronal tissue as well as specific features of seizures, or to screen for new antiepileptic drugs. There is, however, still great potential for future development. Despite recent progress, there are no relevant and widely accepted models of specific seizure types – e.g., age-specific or pharmacoresistant seizures – that can be used for drug screening. Recently described flexion seizures represent a promising possibility, but verification and pharmacological analysis are still needed. Further, in parallel with development of such seizure models, there is also a need for relevant models of chronic diseases, such as age-related epileptic syndromes and pharmacoresistant or progressive epilepsies. Such models should mimic morphological and functional features of the disorder of interest, including development of spontaneous seizures, seizure pattern, and pharmacological

sensitivity. Chemoconvulsants are likely to play an important role in development of such models, as seen in the recently described model of epilepsy induced by the intrahippocampal infusion of tetrodotoxin in developing rats.

Introduction

In vitro preparations permit investigators to undertake studies of the principles of generation, spread, and the termination of seizures – using methods which are difficult to employ under in vivo conditions. In vitro approaches provide precise control of temperature and ionic environment, stable recording conditions for electrophysiology (e.g., for recordings from subcellular compartments such as dendrites, axons and presynaptic terminals), and pharmacological and visual access that are not available in in vivo studies of mammalian brain. Recent development of fluorescent dyes now enables studies on various aspects of metabolism and changes in ion concentrations, in different intracellular compartments (including mitochondria). Occurrence and spread of seizure-like events (SLEs) can be monitored with extracellular recording techniques (e.g., multiple electrodes), voltage sensitive dyes, or even intrinsic optical signals. In vitro models of seizure activity must, of course, be validated – and such validation can be accomplished by assessing these models with respect to their sensitivity to antiepileptic drugs (which should be similar to that of the human condition being modeled). Since about 30% of epileptic patients do not become seizure free with classical anticonvulsant drugs, there is a need to develop in vitro models that mimic drug-resistant epilepsy.

Background

Features of Seizure-like Events

Although the behavioral aspects of seizures are lacking in in vitro preparations, many treatments which induce seizures in vivo induce similar electrical events in vitro. These activities can be termed seizure-like events (SLEs) if they last more than 10 s; are associated with a sustained depolarization of neurons and glia; and are accompanied by a negative extracellular DC field potential shift superimposed by clonic- or tonic-like events. Tonic-like

sensitivity. Chemoconvulsants are likely to play an important role in development of such models, as seen in the recently described model of epilepsy induced by the intrahippocampal infusion of tetrodotoxin in developing rats.

Introduction

In vitro preparations permit investigators to undertake studies of the principles of generation, spread, and the termination of seizures – using methods which are difficult to employ under in vivo conditions. In vitro approaches provide precise control of temperature and ionic environment, stable recording conditions for electrophysiology (e.g., for recordings from subcellular compartments such as dendrites, axons and presynaptic terminals), and pharmacological and visual access that are not available in in vivo studies of mammalian brain. Recent development of fluorescent dyes now enables studies on various aspects of metabolism and changes in ion concentrations, in different intracellular compartments (including mitochondria). Occurrence and spread of seizure-like events (SLEs) can be monitored with extracellular recording techniques (e.g., multiple electrodes), voltage sensitive dyes, or even intrinsic optical signals. In vitro models of seizure activity must, of course, be validated – and such validation can be accomplished by assessing these models with respect to their sensitivity to antiepileptic drugs (which should be similar to that of the human condition being modeled). Since about 30% of epileptic patients do not become seizure free with classical anticonvulsant drugs, there is a need to develop in vitro models that mimic drug-resistant epilepsy.

Background

Features of Seizure-like Events

Although the behavioral aspects of seizures are lacking in in vitro preparations, many treatments which induce seizures in vivo induce similar electrical events in vitro. These activities can be termed seizure-like events (SLEs) if they last more than 10 s; are associated with a sustained depolarization of neurons and glia; and are accompanied by a negative extracellular DC field potential shift superimposed by clonic- or tonic-like events. Tonic-like

discharges are characterized by relatively fast small transients with a frequency above 8 Hz. Clonic-like discharges consist of relatively large, 50–200 ms duration field potential transients. Following a seizure-like event, there is usually a postictal depression period. Interictal discharges then reappear, eventually leading to the next seizure-like event. Interictal discharges can be 'pro-ictogenic,' but there are also examples where the frequent occurrence of interictal discharges appears to prevent seizure generation. Criteria to discriminate between pro- and antiepileptic interictal discharges in the clinical environment have not yet been worked out, and can only be determined experimentally.

Intracellular recordings from neurons reveal transient depolarizations superimposed by bursts of action potentials during the initial phase of a seizure-like event, a sustained depolarization (about 30 mV) during the tonic phase, and depolarization shifts which again evoke bursts of action potentials superimposed on a slowly declining membrane potential during the clonic phase. During the tonic phase, intrasomatic recordings show frequently aborted spikes or no action potentials at all, due to depolarizing inactivation of sodium currents. However, as the depolarization propagates electrotonically into the axon, axonal action potentials will occur where the depolarization is weak enough to prevent inactivation of sodium currents; hence, high frequency axonal firing can be observed during the tonic phase of seizure-like events. Following a SLE, a long-lasting (~30 s) after-hyperpolarization is often observed, with reduced synaptic noise and initial suppression of interictal discharges.

Seizure-like events are typically accompanied by rises in extracellular potassium concentration ($[K^+]_0$) to levels near 12 mM (with an undershoot to below baseline following the seizure-like event), decreases in extracellular calcium concentration ($[Ca^{2+}]_0$) by up to 0.6 mM, decreases in sodium and chloride concentrations ($[Na^+]_0$ and $[Cl^-]_0$), and changes in the size of the extracellular space. Changes in pH are also characteristic, with an initial alkalotic shift followed by acidosis.

Special Features of In Vitro Models

It must be noted that treatments which induce seizures in animals and humans often induce only relatively short recurrent discharges in slice preparations. This 'discrepancy' is most notably the case with agents which interfere with GABAergic or glycinergic synaptic transmission, such as strychnine, bicuculline, penicillin, and picrotoxin. By contrast, agents which block potassium currents, such as 4-aminopyridine, barium, or cesium, are more likely to induce seizure-like events. Conditions in which changes in Mg and Ca bathing medium concentrations are used to induce seizure-like events bear some relationship to the eclamptic seizures in humans. In such cases, opening of the blood–brain barrier as a consequence of sudden surges in blood pressure leads to a hypomagnesaemia and a hypocalcaemia in the interstitial space of the CNS – which in turn may contribute to ictogenesis. Delayed inactivation of sodium currents, as observed with veratridine, can induce ictal events both in vivo and in vitro. Based on these observations, it appears that interference with intrinsic neuronal excitability is more likely to result in seizure-like activity in vitro than is interference with inhibitory synaptic transmission.

It should also be noted that most seizure models are used in otherwise healthy tissue. Less information is available about seizure characteristics in tissue from chronically epileptic animals or humans. For example, it remains unclear why we were unable to reliably induce seizure-like events in slices from human epileptic tissue with low Mg bathing medium, bicuculline, 4AP, and other agents – but elevating potassium successfully evokes seizure-like events in these tissues. Since 4AP has also been reported to fail to induce seizure-like events in the entorhinal cortex of kainate treated rats with spontaneous frequent limbic seizures, it is possible that adaptive homeostatic plastic changes develop in chronically epileptic tissue which prevent frequent occurrence of seizures. Understanding such mechanisms might open new strategies for the cure of epilepsies.

Methods

Two types of in vitro preparations are easy to use for studies of seizure generation: acute slices and organotypic slice cultures. Slice cultures can be made from rat or mouse tissue slices if prepared under sterile conditions early after birth. The most useful method seems to be the procedure described by Stoppini *et al.* More intact preparations of early postnatal neocortex or hippocampus, which correspond to perinatal human tissue, offer advantages for studying epilepsy features in immature systems. An isolated brain preparation offers additional research options. Increasingly, preparations are used which preserve interarea connectivity – for example, between the entorhinal cortex and the hippocampus, between the amygdala and the entorhinal cortex–hippocampal formation, or between the neocortex and the thalamus. Acute slice preparations exploiting brain stem tissue, involving regions often involved in generation of myoclonic seizures and in secondary generalization of seizures, have been much less studied.

Use of acute slice preparation requires attention to a number of problems. Such preparations have undergone a period of ischemia. Further, many fiber projections entering and leaving the brain slice are severed. While recording from slices, synaptic reorganization is likely to occur. Moreover, the thickness of the preparation requires

supply of nutrients which is dependent on exchange by diffusion from an artificial cerebrospinal fluid (ACSF) (and thus indirectly dependent on perfusion rate). In the intact brain, the average distance between capillaries is only 50 μm, providing efficient exchange of oxygen and nutrients to the neural tissue. In acute slices, diffusion processes are much less efficient. Exchange of the extracellular solution in acute brain slices takes about 60 min when investigations are performed under interface conditions, and about 20 min when investigations are performed under submerged conditions. The induction of seizure-like events in submerged slices requires perfusion rates of more than 3 ml min^{-1} in order to provide for sufficient supply of oxygen. Due to the limitations of diffusion, and in order to provide a sufficient oxygen and glucose supply, solutions saturated with 95% of oxygen and high glucose content are typically used for maintaining acute slices.

The ionic contents of the artificial cerebrospinal fluid should be close to physiological levels. Presently, few investigators add amino acids (determined to be 0.6–2 mM glutamine and about 20 μM GABA and taurine in normal CSF) to the ACSF; the addition of e.g., glutamine to ACSF for perfusion of slices from chronic epileptic animals may uncover spontaneous epileptiform discharges. Our laboratory uses ACSF containing (in mM): NaCl 124, KCl 3, $MgSO_2$ 1.8 or 1.2 (the latter being close to physiological Mg concentration in CSF), $CaCl_2$ 1.6, NaH_2PO_4 1.25, $NaHCO_3$ 21 (26 at room temperature) and glucose 10. The solution is equilibrated with carbogen gas (95% O_2/5% CO_2) to maintain a pH of 7.4 and the osmolarity of the solution should be about 290 mOsm. Ca^{2+}, Mg^{2+}, and K^+ concentrations must be carefully adjusted, as small variations in concentrations of these ions have marked effects on neuronal activity. The extracellular Ca^{2+} concentration ($[Ca^{2+}]_0$) in vivo is about 1.2 mM which is mimicked in slices by 1.6 mM. The reason for this difference is the chelating effect of HCO_3 on Ca^{2+} (HCO_3 precipitates about 25% of the free $[Ca^{2+}]_0$). An issue in preparation of slices is the choice of anesthetic (and depth of anesthesia) used in initial sacrifice/decapitation. Pups are frequently anesthetized by putting them on dry ice, a procedure that exploits the anesthetic effect of high carbon dioxide levels combined with hypothermia. Many labs use gas anesthetics such as ether or halothane. This choice gives reliable anesthesia with a reasonable therapeutic gap between deep and irreversible anesthesia. It should be noted that very deep anesthesia leads to circulation arrest and hypoxia, and causes cessation of protein synthesis (slices prepared in this way often do not exhibit long-term plasticity). Gas anesthesia works well in both sexes. Barbiturate anesthesia has the drawback that females often require more anesthetic to obtain an adequately deep state – but frequently are put down so deeply that they die before decapitation. Ketamine anesthesia interferes with NMDA receptors, an effect not always desirable in studies on seizures; in addition, long term effects on synaptic plasticity have been reported.

Our procedures for preparing hippocampal slice cultures follow published protocols. In brief, hippocampal slices (400 μm) are cut using a tissue chopper from 7–9 day-old Wistar rats, under sterile conditions. Slices are immediately transferred to ice-cold, oxygenated (95%) minimal essential medium (MEM) at pH 7.3. Slices with intact anatomical structure are maintained on a biomembrane surface (0.4 μm, Millicell-CM, Millipore) at an interface between culture medium (1 ml, containing: 50% MEM, 25% Hank's balanced salt solution, 25% horse serum (Gibco), and 2 mM L-glutamine (pH 7.4)) and humidified atmosphere (5% CO_2, 36.5 °C) in an incubator. Half of the culture medium is replaced every second day. Slices cultures are used after 7 days in vitro.

Results

Generally, before studying seizure induction, the viability of the tissue should be tested; experiments should be carried out only on preparations which present with 'normal' physiological responses – i.e., which show no signs of epileptiform alterations such as multiple population spikes. A good test of viability (in addition to that described earlier) is whether LTP or LTD can be maintained beyond 20 min. Slices exposed to prolonged ischemia lose the capability for protein synthesis and therefore cannot maintain long-lasting changes in synaptic plasticity. The induction of seizure-like events in such preparations yields atypical discharge patterns, disturbances in ionic homeostasis, and rapid decline of the preparation, once SLEs are induced. Often it is impossible to record spontaneous activity.

Low Ca Induced Epileptiform Activity

Recordings in vivo have shown that extracellular Ca concentration can drop to levels as low as 0.2 mM during seizure activity. Studies initiated in vitro showed that lowering extracellular Ca^{2+} (i.e., in the bathing medium) could induce regular seizure-like events which lasted for about 30 s and recurred in a clock-like fashion. Similar events can also be induced when the hippocampus is treated with Ca chelating agents in vivo. This pattern of activity depends on low (0 mM) Ca treatment and simultaneous elevation of $[K^+]_0$ to 5.5 mM. The induction of seizure-like events coincides with blockade of evoked synaptic transmission. It is a result of reduced surface charge screening (which increases neuronal excitability) and reduced Ca-dependent K currents. In addition lowering of Ca activates a cationic current which may contribute to the generation of the epileptiform discharges. Electrographically, the events appear to mimic tonic-like discharges, with slow negative shifts upon which a series of population spikes are

superimposed. The appearance of population spike activity is somewhat delayed with respect to the onset of the negative field potential shift. Clonic-like after-discharges are not apparent. Intracellular measurements reveal a membrane depolarization of about 30 mV (corresponding to the negative shift in the field), with superimposed action potentials. When normal Ca levels are restored in the bathing medium, the tissue behaves normally, with little signs of neuronal deterioration.

Interestingly, the low Ca activity spreads with a low speed similar to that observed for seizure-like events in the entorhinal cortex induced by low Mg and 4-AP – a preparation in which synaptic transmission is maintained. These results suggest that nonsynaptic mechanisms – likely potassium diffusion – are involved in seizure spread. As evoked transmitter and peptide release is blocked under conditions of low Ca, this model is particularly well-suited for studies on mechanisms of nonsynaptic seizure spread, and also for studies of whether/how anticonvulsants directly modify neuronal excitability. The low Ca model works well in rat hippocampal area CA1 where neurons are densely packed. Tissue from juvenile animals appears to be more sensitive to the low Ca condition (i.e., SLEs are more readily generated). The low Ca model does not work in human tissue (even when potassium concentration is elevated) or in other brain areas with low cell packing density – unless the size of the extracellular space (ES) is reduced by treatment with hypoosmolar solutions (which, however, also affects transmembrane Cl concentration gradients). For example, in the dentate gyrus, low Ca-induced seizure-like events may require simultaneous application of augmented potassium concentration (~10 mM) and/or modification of extracellular osmolarity. Under submerged conditions, the induction of low Ca seizure-like events appears to be facilitated by lowering recording temperature (for still little-understood reasons), but in interface chambers lowering of temperature blocks this activity. Pharmacologically, low Ca seizure-like activity responds to carbamazepine (CBZ), phenytoin (PHT), and valproate (VPA) in clinically relevant concentrations. The activity can also be blocked by the application of DC fields. Application of veratridine, which removes fast inactivation of sodium channels, causes SLEs similar to those seen with low Ca, and these events persist when synaptic transmission is blocked.

Low Mg Induces Seizure-like Events

Epileptiform activity can be induced in virtually all epilepsy-sensitive regions of the brain by omitting Mg from the ACSF. The induction of this activity depends on increased neuronal excitability due to reduced surface charge screening, facilitated transmitter release, and the activation of NMDA receptors due to the removal of the Mg block of NMDA receptor-operated ion channels. Initially these events are sensitive to the application of NMDA receptor antagonists – which is consistent with the idea that the activation of NMDA receptors is critical for the induction of such events. However, NMDA receptor antagonists may lose their efficacy with increasing time after application of low Mg. In such cases, a form of long-lasting synaptic potentiation is observed. In slices of isolated rat hippocampus, lowering Mg induces recurrent, short duration discharges which share properties of interictal discharges. Shorter events are reminiscent of sharp wave ripple complexes. They are initiated in area CA3 and propagate to area CA1. The dentate gyrus does not normally participate in this activity, although these recurrent epileptiform discharges do involve the hilus. These interictal-like discharges last for 60–150 ms, are characterized by positive-going field potential transients in stratum pyramidale of area CA1 and CA3, and are superimposed by bursts of population spikes. Low Mg seizure-like events can be induced in rat hippocampus by simultaneously applying baclofen or elevating potassium. In mice, omitting Mg from the ACSF can cause seizure-like events which are similar to those observed with low Mg in rat limbic structures such as temporal neocortex, entorhinal cortex, and subiculum. Each of these regions can produce seizure-like events when isolated from the remaining structures of the hippocampal formation. The seizure-like events in subiculum, EC, and temporal neocortex are characterized by negative potential shifts superimposed by high frequency small amplitude oscillations followed by clonic-like afterdischarges. Intracellular recordings reveal depolarization shifts of up to 30 mV, upon which are superimposed prolonged bursts of action potentials. During clonic-like after discharges, depolarization shifts are observed which trigger a series of action potential discharges. In combined hippocampal – entorhinal cortex slices, the seizure-like events most frequently start in medial entorhinal cortex but can also begin in temporal neocortex, lateral entorhinal cortex, or the subiculum. The seizures spread from the site of origin with a low speed to neighboring areas. The speed of spread is slightly lower than that for low Ca-induced seizure-like events. The spread of activity can be monitored by multiple DC recording electrodes or by use of intrinsic optical signals. Low Mg seizure-like events possess the same pharmacological properties as seizures induced in vivo – that is, they are sensitive to CBZ, PHT, and VPA, and also to benzodiazepines and barbiturates in clinically relevant concentrations. However, when seizure-like events are induced by low Mg in organotypic hippocampal slice cultures, they do not respond to standard antiepileptic drugs and hence may represent a valuable model of pharmacoresistant epilepsy.

Interestingly, seizure-like events induced by low Mg may show different properties in frontal cortex slices. In this brain region, the epileptiform pattern does not include afterdischarges. Further, the activity spreads more

rapidly than in temporal/limbic structures and the episodes are much shorter than in the entorhinal cortex, amygdala, and hippocampus. This feature of low Mg activity suggests that the relatively short, frequent, seizure episodes often observed in clinical frontal lobe epilepsies are dependent on the intrinsic properties of frontal cortical tissue.

Low Mg-induced seizure-like events show different characteristics of the spread when induced in chronic epileptic tissue. In both pilocarpine-treated animals and kindled animals, the seizure spread is facilitated. Interestingly, there are two routes of low Mg seizure spread in pilocarpine treated animals – one through the subiculum and one through the dentate gyrus. In contrast, the seizure spread in kindled animals is preferentially through the dentate gyrus, suggesting that the DG has lost some of its filtering properties. A low Mg seizure spread is also facilitated in preparations from rat pups, where the hippocampus is variably involved.

Importantly, seizure-like events disappear some time after inducing low Mg, and are replaced by shorter events which most frequently represent tonic–like discharges. These events can be mistaken for interictal discharges. However, since the ionic change and the intracellularly recorded signals accompanying these activities differ from the properties of interictal discharges in duration and amplitude, we believe that these events correspond to activity patterns observed during prolonged status epilepticus. As the application of GABA and GABA-uptake inhibitors reverse these events to seizure-like patterns, a loss of GABAergic functions seems to be involved in this activity. Since muscimol blocks this activity at low concentrations, the change is likely not due to alterations in GABA receptor affinity but more likely due to the consumption of GABA in the GABA shunt of the tricarboxic acid cycle. These late recurrent discharges are of particular interest, as they are not blocked by standard anticonvulsants even when high concentrations of these agents are applied. The induction of low Mg activity involves omission of Mg sulfate from the perfusate. The first epileptiform discharges appear after 40 min under interface recording conditions, and after 20 min under submerged conditions. Transition to the late recurrent, pharmacoresistant discharges occurs between 30 and 90 min after the onset of epileptiform activity. The low Mg model works also in human neocortex but not in hippocampal slices from most patients with temporal lobe epilepsy.

4-Aminopyridine Induced Seizure-like Events

4-Aminopyridne (4-AP) is a blocker of transient potassium currents. At low concentrations, it affects potassium currents containing specific Kv1 or Kv3 subunits, while at higher concentrations (millimolar range) it also affects other potassium currents of the Kv 4 family. In rat hippocampus, 4-AP usually induces recurrent discharges. In parahippocampal structures such as the entorhinal cortex, subiculum and temporal neocortex, and also in the amygdala, 4-AP elicits seizure-like events. Similar discharge is produced organotypic hippocampal slice cultures. The seizure-like events start with an initial bursting period, and give rise to a tonic-like episode and clonic afterdischarges superimposed on slow negative potential shifts; these electrographic events are associated with ionic changes characteristic of seizure-like events. In interface recordings, the activity commences about 40 min after the application of 50 or 100 μM 4-AP. Transition to late recurrent discharges – after more than 1.5 h of ongoing seizure-like activity – may or may not occur. These seizure-like events respond to all standard anticonvulsants. Late pharmacoresistant activity can be evoked by combining bicuculline with 4-AP. In slice cultures, 4-AP induced seizure-like events are usually resistant to standard antiepileptic drugs. Human tissue and entorhinal cortex from kainate treated rats with limbic epilepsy appear to be less sensitive to 4-AP. In pilocarpine treated epileptic rats, 4-AP fails to induce seizure-like events in about 50% of slices; the efficacy of 4-AP in these slices correlates with seizure frequency prior to preparation of slices.

Seizure-Like Events Induced by Elevating Potassium Concentration

Early in vivo studies in different species suggested that elevating potassium concentration can induce seizure-like events in hippocampus. This effect is readily mimicked in vitro by raising extracellular potassium in ACSF from 3 mM (standard in most laboratories) to 7.5 mM. This activity also responds to standard anticonvulsant drugs. When $[K^+]_0$ is elevated to 11 mM, and Ca lowered at the same time, seizure-like events can be induced in the dentate gyrus of Sprague–Dawley rats. Interestingly, in Wistar rats, the induction of seizure-like events with high K and moderately lowered Ca and Mg is difficult to reproduce. The high K model is very reliable in human tissue. Different forms of seizure-like activity can be induced by high K in all studied regions, including temporal neocortex. If the slices in which seizure-like events are induced come from patients who are resistant to carbamazepine or valproate, the seizure-like events induced by high K are also generally resistant to VPA and CBZ; however, occasionally one slice (or one region) may respond to CBZ or VPA, suggesting that the area of brain which determines pharmacoresistance may be smaller than the epileptogenic area.

Stimulation Induced Seizures

Short trains of repeated high frequency electrical stimuli have also been used to induce ictaform activity, in the form

of afterdischarges. In combined hippocampal–entorhinal cortex slices from young Sprague–Dawley rats (P21–P30), repeated trains (100 Hz, 0.1 ms pulses, 1 or 2 s train duration) in the presence of 0.5 mM Mg eventually resulted in self-sustained status epilepticus. In slices from older Sprague–Dawley rats, ictaform afterdischarges have been induced by stimulus trains when slices were bathed in low Mg and low Ca concentrations and elevated K, or with 1.3 mM Mg and 5 μM 4-AP bathing media. Trains of repetitive stimulation in organotypic slice cultures are also, in some cases, able to induce afterdischarges and spreading depressions.

Focal Induction of Seizure-like Events

Although the majority of in vitro models for seizures are thought to mimic the aspects of focal or partial epilepsies, few attempts have been made to induce seizure-like events by focal manipulations. Seizure-like events in the models described in this article usually have focal onset – most frequently in the entorhinal cortex, but sometimes in area CA3 and more rarely in area CA1. An interesting alternative approach involves the focal application of bicuculline (50 μM) and high K (10 mM) to the EC. In such investigations, experimenters can study the spread patterns of epileptiform activity, for example, from the EC to the hippocampus in normal and kindled rats, and in pilocarpine-treated rats. Another method of focal induction involves discrete application of carbachol (10 mM) from a pipette, with short pressure pulses (10–200 ms).

Directions for Future Research

At present many in vitro studies are limited to preparations from healthy animals. In these preparations, one major question is not yet fully resolved. Preictal discharges are often noted, which are generated by the release of GABA, preceding seizure-like events. This observation has led to the hypothesis that GABAergic synaptic transmission is required for the induction of seizures. However, an avalanche of inhibitory activity precedes seizure-like events when they are spreading from the site of ignition into neighboring areas; this preictal inhibition was recently shown to slow seizure spread. Thus, the preictal GABAergic signals may represent an anticonvulsant mechanism. To resolve this debate, studies are required which focus on the role of inhibition at the sites of seizure onset.

A second general problem is that most in vitro studies are done in normal tissue (treated as described in this article) and not on tissue derived from patients during surgery or from epileptic animals. In fact, in such epileptic tissue, mechanisms might be discovered which counteract ictogenesis. In any case, adaptive changes in cellular and synaptic properties, as well as in neural circuits, are rarely taken into account and certainly are not reproduced in manipulations of normal tissue slices.

Finally, in vitro preparations are restrained to minimal circuits. Depending on the orientation of the preparation, these circuits are differently disturbed. Systematic studies on effects of circuit maintenance are still lacking. Importantly, the onset of seizures is often controlled by a rather distributed network which cannot be maintained under in vitro conditions. Therefore, many findings from in vitro preparations await confirmation from in vivo studies.

Seizure Predisposition and Expression in the Genetic Epilepsies as Exemplified by the Genetically Epilepsy-Prone Rats

Introduction

Investigations undertaken in genetically epilepsy-prone rats (GEPRs) have contributed appreciably to an understanding of the epilepsies and of their comorbidity with the affective disorders. Although genetic determinants of rare forms of monogenic epilepsies have been identified in some cases, most genetic epilepsies, including those in the GEPR, are complex polygenic disorders with or without known experiential contributions. Whether sustained before, during, or after birth, brain injury is believed to be etiologically important in some epilepsy cases. Many people or other mammals with epilepsy are not known to have sustained injury or to have ontogenetically dependent structural defects. These and other factors suggest that epilepsy is a diverse group of neurological disorders with few, if any, unifying causal features. Nevertheless, evidence supports the concept that genetically determined seizure predisposition may link multiple epilepsies and some depressive disorders into a partially common diagnostic category. Overall, comparatively little investigative scrutiny has been focused on the etiologic role of genetically determined seizure predisposition in the polygenic epilepsies. Until the latest iterations of the definition of epilepsy, prominent roles for seizure predisposition have been often ignored. We propose future steps that may produce a positive shift in experimental epileptology and in clinical medicine.

Background

Predisposition

The subject of seizure predisposition has received considerably less emphasis in the medical sciences literature than the subject of seizure initiation. The disparity between these subject areas is evident in data that we collected on December 5, 2007 in a search of the Ovid Medline database. During the 30-year interval of 1978–2007, our Ovid search identified 599 publications on the subject of seizure predisposition versus 2261 on the topic of seizure initiation. This disparity is striking, particularly given the fact that during the last three decades, investigations – of the GEPR, other polygenic models, and neurologically normal mammals – have provided increasing evidence that seizure predisposition is the fundamental neurological dysfunction that distinguishes many, if not most, brains with epilepsy from those of healthy subjects. In GEPRs, seizure predisposition is present in the seizure naïve condition (i.e., in animals that have never had a seizure).

Seizure predisposition is a condition of the brain wherein the paroxysmal episodes can be triggered by endogenous neuronal events and/or exogenous stimuli that fail to ignite seizures in the 'normal' animal. Such neuronal liability is exhibited by the moderately epileptic GEPR-3, the more severely epileptic GEPR-9, humans with epilepsy, and other epileptic mammals. Moreover, predisposition typically includes exaggerated seizure responsiveness to stimuli that also cause seizures in nonepileptic subjects. For example, GEPR-3s and GEPR-9s kindle more rapidly than nonepileptic controls, with the highest rate being a strikingly evident trait of the GEPR-9. Such acceleration is also evident in the 'fast kindling rat.' With seizure predisposition, the brain may exhibit abnormally low thresholds to systemically administered convulsant chemicals. However, the pharmacokinetics of chemoconvulsants may be abnormal in some genetically epileptic mammals, and little research has been carried out to explore this possibility.

Introduction

Investigations undertaken in genetically epilepsy-prone rats (GEPRs) have contributed appreciably to an understanding of the epilepsies and of their comorbidity with the affective disorders. Although genetic determinants of rare forms of monogenic epilepsies have been identified in some cases, most genetic epilepsies, including those in the GEPR, are complex polygenic disorders with or without known experiential contributions. Whether sustained before, during, or after birth, brain injury is believed to be etiologically important in some epilepsy cases. Many people or other mammals with epilepsy are not known to have sustained injury or to have ontogenetically dependent structural defects. These and other factors suggest that epilepsy is a diverse group of neurological disorders with few, if any, unifying causal features. Nevertheless, evidence supports the concept that genetically determined seizure predisposition may link multiple epilepsies and some depressive disorders into a partially common diagnostic category. Overall, comparatively little investigative scrutiny has been focused on the etiologic role of genetically determined seizure predisposition in the polygenic epilepsies. Until the latest iterations of the definition of epilepsy, prominent roles for seizure predisposition have been often ignored. We propose future steps that may produce a positive shift in experimental epileptology and in clinical medicine.

Background

Predisposition

The subject of seizure predisposition has received considerably less emphasis in the medical sciences literature than the subject of seizure initiation. The disparity between these subject areas is evident in data that we collected on December 5, 2007 in a search of the Ovid Medline database. During the 30-year interval of 1978–2007, our Ovid search identified 599 publications on the subject of seizure predisposition versus 2261 on the topic of seizure initiation. This disparity is striking, particularly given the fact that during the last three decades, investigations – of the GEPR, other polygenic models, and neurologically normal mammals – have provided increasing evidence that seizure predisposition is the fundamental neurological dysfunction that distinguishes many, if not most, brains with epilepsy from those of healthy subjects. In GEPRs, seizure predisposition is present in the seizure naïve condition (i.e., in animals that have never had a seizure).

Seizure predisposition is a condition of the brain wherein the paroxysmal episodes can be triggered by endogenous neuronal events and/or exogenous stimuli that fail to ignite seizures in the 'normal' animal. Such neuronal liability is exhibited by the moderately epileptic GEPR-3, the more severely epileptic GEPR-9, humans with epilepsy, and other epileptic mammals. Moreover, predisposition typically includes exaggerated seizure responsiveness to stimuli that also cause seizures in nonepileptic subjects. For example, GEPR-3s and GEPR-9s kindle more rapidly than nonepileptic controls, with the highest rate being a strikingly evident trait of the GEPR-9. Such acceleration is also evident in the 'fast kindling rat.' With seizure predisposition, the brain may exhibit abnormally low thresholds to systemically administered convulsant chemicals. However, the pharmacokinetics of chemoconvulsants may be abnormal in some genetically epileptic mammals, and little research has been carried out to explore this possibility.

The concept of seizure predisposition does not demand the coexistence, or the experientially induced development, of seizure circuitry that is specific to epilepsy. Two convulsive seizure circuitries have been demonstrated in mammals, whether seizure naïve or experienced, or whether genetically normal or epileptic. One network is denoted as the forebrain seizure circuitry. This rostral substrate generates episodes that are known clinically as cortical/limbic seizures. The other network is caudal to the forebrain circuitry, and is designated as the brainstem seizure circuitry. This second brain substrate drives episodes known clinically as generalized tonic/clonic seizures (GTCSs). Even though both the rostral and caudal seizure substrates are subject to modification by locally directed electrical currents or other types of kindling (including overt seizures per se), neither set of circuitry is created de novo by kindling processes.

The forebrain and brainstem seizure circuitries share evolutionary outcomes of mammalian genetics in neurologically normal brains. Both seizure substrates also participate in normal neurological functions. Additional and anomalous seizure circuitries may be genetically determined. For example, a unique seizure circuitry may underlie infantile spasms in some cases of West syndrome. Also, the GEPR appears to exhibit a genetically determined anomalous and localized seizure circuitry within the inferior colliculus. The brainstem seizure circuitry can be triggered by a localized seizure within the inferior colliculus in response to the acoustical activation of cochlear hair cells. The inferior colliculus rapidly becomes a component of the circuitry of the generalized brainstem seizure in GEPR-9s and 10s, and probably other GEPRs, with field potential electrographic characteristics that match those of the other caudal structures. Brainstem seizures in GEPRs can also be elicited by electrical stimuli despite surgical removal of the inferior colliculus. Moreover, the highly exaggerated brainstem seizure responsiveness characteristic of the GEPR is retained in the absence of the inferior colliculus, although a seizure can no longer be activated by sound stimulation.

In the foregoing discussion, we have emphasized the concept that seizure predisposition is a condition wherein some animals exhibit a greater level of seizure predilection than is typical of their neurologically normal counterparts. We now turn to the idea of relative seizure responsiveness of different subdivisions within the mammalian brain. More specifically, we refocus on the relative propensity of the forebrain versus brainstem seizure circuitry, whether in nonepileptic or epileptic mammals. Although in GEPRs, and probably humans with epilepsy, the neuroanatomical extent of genetically determined seizure predisposition encompasses both the forebrain and brainstem seizure networks, the degree of predilection differs between the two parts of the brain. Also, in neurologically normal mammals, the seizure propensity of these two seizure networks differs appreciably.

In nonepileptic mammals, the greatest degree of seizure predilection appears to exist in the rostral seizure circuitry. Accordingly, the threshold for seizure ignition in the forebrain is below that of the brainstem (the forebrain–brainstem threshold ratio being less than 1). The accentuated seizure propensity of the rostral brain has also been demonstrated in the moderately epileptic GEPR-3 strain. However, despite the similarity of the propensity ratio between GEPR-3s and their nonepileptic counterparts, both sets of circuitry in GEPR-3s exhibit exaggerated seizure responsiveness when compared with the anatomically corresponding circuitry of nonepileptic subjects. In the more severely epileptic GEPR-9 strain, both the rostral and caudal thresholds are below the neuroanatomically corresponding threshold of the GEPR-3. In contrast to the GEPR-3, the threshold ratio in the GEPR-9 is greater than unity. Consequently, GEPR-9s are likely to exhibit brainstem seizures (generalized tonic/clonic seizures) in lieu of, or as a consequence of, forebrain seizures (cortical/limbic seizures).

Relation of Forebrain and Brainstem Seizures to Human Seizures

Based on a substantial body of electrophysiological and behavioral evidence – from studies in GEPRs and primates (including humans) with epilepsy – we have previously advanced the hypothesis that forebrain seizures in multiple mammalian species are equivalent to seizures subsumed under the terms 'cortical/limbic' and 'partial seizures' in human medicine. Seizures that are commonly evaluated in limbic kindling paradigms are produced by a part of or all of the forebrain seizure circuitry. Forebrain seizures, including every category of kindled seizure in the Racine classification system, occur in nonkindled and nonepileptic mammals (including humans) in response to an appropriate electrical stimulus, whether delivered by intracerebral or transcorneal electrodes.

In kindled or seizure-naïve mammals, the magnitude of a single electrical stimulus determines the behavioral seizure class exhibited. Prior kindling stimuli are not needed to produce any of these seizure classes. A relatively weak stimulus causes class 1 or 2 forebrain seizures (Racine classification system); a stimulus of intermediate magnitude causes forebrain seizures of moderate severity (class 3); and a relatively strong stimulus triggers class 4 or 5 seizures. The neuroanatomical extent of seizure activity throughout the forebrain seizure circuitry is an important determinant of the severity of the seizure as indicated by seizure class. Although the Racine class 4 and 5 seizures occur in response to activation of most or all of the forebrain seizure circuitry, these episodes are not equivalent to a generalized tonic/clonic seizure in humans or other mammals as some investigators have argued. Rather, these 'Racine' episodes are appropriately viewed as manifestations of maximally

severe, pervasive, or generalized seizures driven by forebrain circuitry in mammals. Use of the term 'maximal seizure' (without qualification) contributes to confusion because it does not distinguish these forebrain episodes from maximal brainstem-driven seizures.

In experimental epileptology, electrically induced brainstem seizures of maximal severity are commonly designated as maximal electroshock seizures (MES). A maximally severe brainstem seizure is a GTCS, whether in a rodent, nonhuman primate or human. Such seizures are essentially alike behaviorally and electrographically in humans, GEPR-10s, and other mammals. In GEPR-9s and GEPR-10s, such GTCSs have been observed to occur spontaneously and in response to multiple sensory stimuli. However, prodromal running episodes occur in the sound-induced submaximal forms of GTCSs in rodents, but not in humans.

Importantly, the term 'brainstem-driven seizure' does not imply absence of a simultaneously occurring seizure in the forebrain circuitry. Indeed, most brainstem seizures also drive an electrographically prominent seizure within the forebrain, although examples of brainstem seizures that are not paralleled within the forebrain have been fully documented in GEPR-9s and GEPR-10s. When driven by a brainstem seizure, the forebrain circuitry does not exhibit electrographic morphology similar to a cortical/limbic seizure. Rather, the forebrain appears to mimic in essentially every detail the electrographic morphology and temporal qualities of the overpowering brainstem seizure.

Forebrain or cortical/limbic seizures are well known as triggers for GTCSs in many humans with epilepsy and in GEPR-9s and GEPR-10s. This phenomenon appears to be extremely rare or absent in nonepileptic rats and (perhaps) in humans without epilepsy or seizure predisposition. In GEPRs, the pervasiveness of the forebrain seizure is unrelated to the probability that a GTCS will be triggered by a seizure within the rostral circuitry. Accordingly, a unilateral forebrain seizure and a bilateral forebrain seizure generalized throughout the forebrain circuitry are equally likely to ignite GTCSs in GEPR-9s and 10s. Clinically, people who experience what is now believed to be a brainstem seizure triggered by a forebrain seizure have commonly been designated as exhibiting a partial seizure secondarily generalized to a tonic/clonic seizure.

Scope of Seizure Predisposition

The scope of seizure predisposition may be extensive but not unlimited. In some people with epilepsy, seizures are triggered by visual stimuli, thinking, music, speaking, writing, and/or eating. Many individuals with epilepsy experience spontaneous seizures. People with idiopathic or generalized or focal epilepsies reportedly exhibit abnormally low pentylenetetrazol seizure thresholds. Predisposition in GEPRs also includes spontaneous seizures, exaggerated responses to the seizure inducing properties of pentylenetetrazol, flurothyl, aminophylline, barbiturate withdrawal, morphine via intracerebroventricular administration, hyperbaric conditions, transcorneal or transauricular electrical current, intracerebral limbic kindling, and forebrain seizure-induced brainstem seizures. Stimuli that produce seizures in GEPRs but not in their nonepileptic counterparts include acoustic stimuli, hyperthermia (only adults have been evaluated), and less dependably handling and postural alterations.

Seizure predisposition is sometimes assumed to include a predilection to all seizure inducing modalities. However, broad the scope of seizure predisposition may be, data demonstrate limitations. For example, although supratherapeutic doses of many antidepressant drugs induce seizures in humans, GEPRs and other mammals, the GEPR (and probably humans with epilepsy) do not exhibit predisposition to such seizures. Nevertheless, the medical literature contains many warnings that physicians should be especially cautious about using these medications in patients with epilepsy.

While medical science literature may be devoid of direct claims that predisposition to one convulsant is tantamount to predisposition to all other seizure-inducing modalities, this view seems to be a common one. However, for the antidepressive treatments, this notion is erroneous. Almost all antidepressive agents appear to exert anticonvulsant effects in doses that are approved by the FDA for treatment of affective disorders. This beneficial property of the antidepressive treatments was first demonstrated decades ago in multiple seizure and epilepsy models, including GEPRs and epileptic baboons. Confirmation studies in humans with epilepsy include a double blind crossover investigation, other methodologically less rigorous studies, and a recent analysis of seizure incidence data from FDA Phase II and III clinical trials of antidepressants approved between 1985 and 2004. The absence of seizure liability for therapeutic-range doses of most of the antidepressive medications probably stems from multiple factors. For example, these treatments augment noradrenergic and serotonergic neurotransmission. Activation of these two transmitter systems produces marked anticonvulsant effects in the GEPR and other species including primates.

Methodological Considerations and Results

Generalized Convulsive Seizures

We have previously proposed three types of generalized convulsive seizures. One occurs throughout the forebrain seizure circuitry. The second is generalized through the brainstem seizure circuitry. The third is a brainstem-driven seizure that is mimicked electrophysiologically

in the forebrain. Our concept of generalized convulsive seizure departs sharply from the term 'generalized epileptic seizure' as defined in 1973 by Gastaut and his collaborators (*Dictionary of Epilepsy*). This 1973 definition emphasized the difference between unilateral versus bilateral seizures, did not distinguish between the rostral and caudal seizures, and did not distinguish between a seizure that is generalized throughout the forebrain and the one that is bilateral, but within only a part of the forebrain circuitry in both hemispheres. Also, the classification did not provide a framework to distinguish between a focal and a generalized brainstem seizure. Finally, the earlier concept did not set forth a classification for brainstem seizures that drive a seizure in the forebrain.

In our approach to classification, both forebrain and brainstem seizures have the potential to involve the entire musculature of the body. However, generalized forebrain seizures are characterized by behaviors that are clearly distinct from those of generalized brainstem seizures. Behaviors of brainstem seizures that are concomitantly mimicked in the forebrain may be indistinguishable (or perhaps only slightly different) from brainstem seizures restricted to the caudal circuitry. Our system of classification also runs completely counter to modern concepts that define seizures as disordered, high amplitude rhythmic discharges of populations of neurons that arise only from the cerebral cortex. The corticocentric concept essentially rules out the possibility of seizures being driven from the brainstem circuitry. While electroencephalographic field potential determinations in multiple species show that seizures occur in the cerebral cortex, measurements are rarely made in the brainstem structures (especially in humans) and so one cannot conclude that seizures do not arise within (and are not driven by) caudal structures.

Detailed electroencephalographic and behavioral measurements in multiple mammalian species, including GEPRs and primates, provide strong evidence that GTCSs are brainstem phenomena. Nevertheless, any shift away from cerebral cortex dogma is thwarted by the several impediments. First, electroencephalographic measurements in humans are primarily made via scalp electrodes. Information regarding brainstem field potentials is therefore unattainable. Only if the scalp electrodes reveal the absence of a cortical seizure during GTCS behaviors might an investigator infer seizure activity in another deeper part of the brain. But, even this inverse approach to the question is unlikely, since in the vast majority of GTCSs, the brainstem seizure circuitry drives seizures within the forebrain that mimic those in the brainstem.

Second, electroencephalographic measurements in humans are almost always made under conditions that are known (from studies of nonhuman species) to disallow any detection of seizures that occur in the brainstem, rather than the cerebral cortex. For example, electroencephalographic measurements during seizures in humans are almost always made after, rather than during, the first seizure in previously seizure naïve individuals. Ethical considerations, rather than scientific imperatives, may dictate the exclusion of first seizure measurements. From studies of seizure naïve GEPRs, it is clear that the initial GTCS may occur in the absence of electroencephalographic seizure in the cerebral cortex. Whether the first GTCS in humans with epilepsy occurs in the absence of a cortical seizure will probably remain unknown.

Third, other evidence demonstrates that the window of opportunity for observing only brainstem electrographic seizures is vanishing in the intact GEPR. With continued selective brother/sister inbreeding for specific traits of epilepsy, GTCS in the brainstem and the forebrain began to occur almost simultaneously, with the initial high amplitude spiking first appearing in the brainstem reticular formation and subsequently in the cerebral cortex. Later in strain development, rostral and caudal spiking began to occur seemingly at the same time throughout the brain, even upon first seizure. These observations suggest that with a sufficient level of genetic seizure predisposition, the onset of initial high amplitude spikes in the caudal brain may become indistinguishable from those in the rostral subdivisions of the brain. The mechanisms of coordinated seizure onset throughout the brain warrant intensive investigation.

Seizure Expression

Both the electrophysiological and behavioral characteristics of forebrain-driven seizures differ from those of brainstem-driven seizures. Forebrain seizures are characterized by one or more of several behaviors: immobility with maintenance of muscle tone and posture; facial, neck, and forelimb clonus; head and neck turning, and gradual extension of the hip joints. If in a sitting posture at the onset of the seizure, a biped may partially rise. A quadruped may rise from a four legged posture so that it sits on its haunches with its vertebral column oriented in a position largely vertical to the floor. Bilateral forelimb clonus is typical during these rearing episodes. In both bipeds and quadrupeds, 'rising' may be interrupted by slumping to the floor. A forebrain seizure characterized by the full range of these behaviors is commonly known as a class 5 episode according to the Racine system that was developed through studies in rodents for grading the magnitude of cortical/limbic seizures.

Maximally severe brainstem seizures in GEPRs and humans are characterized by behaviors that differ sharply from those of maximally severe forebrain seizures. These caudally determined behaviors include initial massive limb thrusts, followed immediately by loss of righting posture, and then tonic rigidity throughout the body with the superimposition of clonus, a behavior that increases in amplitude and decreases in frequency as tonic rigidity

subsides. Postictal flaccidity is common following the termination of tonic and clonic features of maximally severe brainstem seizures.

Both rostral and caudal seizure types include some behavioral components that might be mistaken as volitional because they are typical behaviors known to occur in the absence of a seizure. 'Scratching' is part of the cortical/limbic seizure repertory, but also commonly occurs in normal mammals in the absence of a seizure. Similarly, running behavior is produced in quadrupeds by a sound-induced brainstem seizure, but is nevertheless common in the absence of a seizure. In contrast, the sequential and repetitive elements of a seizure generalized throughout the rostral circuitry (class 5 in the Racine categorization) are probably seizure- and circuitry-specific, as are the tonic/clonic behaviors driven by a brainstem seizure that is generalized throughout the caudal circuitry (Class 10 in the Jobe and colleagues scale).

A brainstem seizure commonly drives an electrographic seizure in the forebrain. Nevertheless, such a rostral seizure is correctly designated as a brainstem seizure because the seizure determinants are within the brainstem. Accordingly, during a brainstem seizure, forebrain neuronal activity is entrained by the seizure within the brainstem so that the rostral electrographic morphology and rhythm mimic those of the brainstem. At the close of a brainstem seizure expressed throughout the brain, a condition of seizure refractoriness ensues. This transitory postictal anticonvulsant condition of the brain probably prevents the expression of forebrain-determined seizures in direct response to a brainstem-driven seizure of maximal severity. During a generalized tonic/clonic seizure, a forebrain-determined seizure is excluded by the aggressive pervasiveness and overwhelming dominance of the brainstem seizure.

Submaximal brainstem seizures have the capacity to trigger forebrain-driven seizures. However, the maximal class 9 and class 10 brainstem seizures do not appear to have this feature. Rather, they drive brainstem electrographic seizures in the forebrain. Adult GEPR-9s or -10s that experience a sufficient postictal anticonvulsant effect against forebrain seizures will not exhibit a forebrain seizure at the close of the brainstem seizure. At a specific stage of development, GEPR-3s also exhibit brainstem seizure-induced forebrain seizures.

Noradrenergic and Serotonergic Pathophysiology as a Determinant of Predisposition

Genetically generated noradrenergic and serotonergic deficits are major determinants of seizure predisposition in GEPRs. The moderate magnitude of predisposition in GEPR-3s arises at least partly from moderate deficits in both types of monoaminergic transmission. The more marked level of seizure predisposition in GEPR-9s is caused by a more pronounced noradrenergic deficiency.

Data from cell culture experiments support the concept that the noradrenergic deficiencies of GEPR-9s are characterized by deficits in the density of noradrenergic neurites in terminal fields innervated by the locus ceruleus, in the concentration of norepinephrine per noradrenergic neuron, and in challenge-evoked norepinephrine release within noradrenergic terminal fields. The deficits in noradrenergic morphology of the GEPR-9 appear to arise from causative factors located within both the region of the locus coeruleus and its terminal fields. Similar investigations show that the noradrenergic deficiencies of the brains of GEPR-3s are less pronounced than those of GEPR-9s. Serotonergic deficits are characteristic of both GEPR-3s and GEPR-9s.

As previously described, noradrenergic and serotonergic neurons are located outside the forebrain and brainstem seizure circuitry. Neither type of monoaminergic neuron initiates or maintains a seizure within either set of circuitry. However, both noradrenergic and serotonergic neurons innervate these units of seizure initiation and continuation, and control the concentrations of norepinephrine and serotonin in the extracellular fluid surrounding (and within) the circuitry. A deficiency of these two transmitters in the extracellular fluid increases the likelihood that fluctuations in neuronal activity within the circuitry will initiate a seizure. Conversely, elevation of norepinephrine and/or serotonin concentrations produces anticonvulsant effects, thereby providing a 'shield' to protect or defend the circuitry against the onset of dysfunctional neuronal initiatives. Within the circuitry, sufficient decrements in GABAergic and increments in glutamate transmission initiate and continue convulsive seizures. In the intact mammal, such dysfunctional episodes of neuronal activity can be prevented by sufficient increments in noradrenergic and serotonergic transmission. In contrast, complete discontinuation of monoaminergic transmission does not initiate a seizure. The excitatory and inhibitory components located within the circuitry per se continue to function, but the anticonvulsant properties of monoaminergic transmission have been lost. Freedom from these external constraints allows excessive responses to excitatory influences initiated internally within the circuitry and/or delivered to the circuitry by other parts of the brain.

Future Directions and Recommendations

Predisposition Model for Preclinical Development of Treatments and Preventions

We recommend that a seizure and epileptogenesis predisposition paradigm be created for the preclinical development of epilepsy treatments and preventions. Such a paradigm was first proposed by Jobe and Laird more

than 20 years ago, and has the potential to foster the discovery of novel treatments that are exceptionally effective in the common polygenic epilepsies. We anticipate that the models of polygenic pathophysiology of seizure predisposition will, in some instances, enable the detection of antiepileptic effectiveness in exquisitely small nontoxic doses or magnitudes. We believe that in some cases, the use of nonepileptic animals in the traditional seizure screening protocols of the past, has resulted in the detection of potentially useful treatments, but only in toxic dose in these animals. If we are correct, the past 60 years of antiepileptic drug screening has included multiple cases wherein potentially major advances have been systematically and mistakenly eliminated from the discovery process. The cumulative 'failures of the past' may be one of several rich sources for future achievement. An important goal should be to shift from anticonvulsant screening to an antipredisposition (antiepileptic) programmatic emphasis.

Clinical Model for Detection of Surrogate Indices of Predisposition

We recommend the development of an imaging-based neurochemical and -receptor analysis program (e.g., PET) designed to detect surrogate indices of predisposition to seizures and epileptogenesis in humans. Surrogate indices are essential to obviate the need for convulsive seizure-inducing drugs or electrical stimuli to establish seizure predisposition in humans without clinically relevant symptoms. Because ethical practice of medical science prohibits the induction of seizures in healthy people, predisposition cannot be directly evaluated. Initially, our proposed program for the identification of surrogate markers would be structured to detect presynaptic and postsynaptic indices of noradrenergic and serotonergic deficiencies at an early stage, before genetically determined predisposition becomes exacerbated by the superimposition of experientially dependent epileptogenesis.

Because of the comorbidity between epilepsy and depressive disorder, this program could initially target seizure and depression naïve siblings (and parents) of patients with these disorders. This approach would capitalize on the concept that noradrenergic and serotonergic deficiencies are common causes of genetic predisposition in both disorders. These and other discoveries provide a plausible basis for using noradrenergic and/or serotonergic deficits in humans as surrogate indices of seizure predisposition. Several investigations already provide support for noradrenergic and/or serotonergic deficits in humans with epilepsy. These studies have led to the discovery of α-receptor noradrenergic deficits in epilepsy patients undergoing brain surgery; however, these patients have a history of seizures, so that the pristine condition of seizure naivety remains unknown in humans.

We propose that seizure naïve siblings, parents, and progeny of documented epilepsy patients be evaluated with PET to determine the status of both the noradrenergic and serotonergic systems of the brain. Investigations of seizure naive patients with major depressive disorder might be an especially fruitful group for such investigations. Multiple factors support the use of these categories of people. Pertinent elements of the rationale underlying our proposed studies have been described in other parts of this manuscript. Individuals identified with monoaminergic deficiencies would become eligible for prophylaxis against epileptogenesis. This potential preventative would be designed to restore their transmitter function towards that of appropriately matched people without epilepsy or depressive disorder.

A Model for Spontaneous Seizures in the GEPR

We recommend further investigations with the GEPR as a predisposition model. These investigations should include the development of three major types of spontaneous seizure GEPRs: GTCSs, cortical/limbic seizures, and cortical/limbic seizures with secondary ignition of GTCSs. Infrequent spontaneous seizures have been observed in GEPRs as in epileptic baboons and in people with epilepsy. Although weeks and months of continuous monitoring of field potential EEG in GEPRs has not been undertaken, interictal spikes or spike/wave complexes may occur as they do in epileptic baboons and humans. Moreover, since spontaneous seizures in GEPRs are not known to be caused by identifiable exogenous stimuli or by focal lesions, they are likely to be initiated by interictal events or by other endogenous vicissitudes in neuronal activity that have not been defined (and would not be capable of producing seizures in normal animals). The initial goal of these proposed studies would be to identify these electrographic events.

As a corollary to the above proposal, we recommend that the National Institutes of Health develop a funding mechanism for maintenance and further development of the GEPR models of epilepsy, depressive disorder, and of comorbidity between epilepsy and affective illnesses. A major impediment to scientific investigations with the GEPR pertains to the absence of a vender/advocate. Neither GEPR-3s nor GEPR-9s are commercially available and they cannot be obtained from the NIH. Presently, both the GEPR-3 and GEPR-9 strains are facing imminent extinction.

Introduction: Rationale for the Model

The importance of cholinergic mechanisms for epilepsy was already suspected by neurologists at the turn of the nineteenth century. The convulsant potential of acetylcholine and physostigmine was experimentally demonstrated, using electrocorticographic monitoring, as early as the late 1930s. In the following years, the use of acetylcholine, mainly in in vitro models, contributed to the understanding of electrophysiological phenomena involved in epileptic spike discharges, neuronal depolarization, and burst generation. In the 1980s, investigators demonstrated that periodic administration of carbachol effectively induced kindling, and that administration of high doses of pilocarpine – a cholinergic agonist – may lead to the acute induction of status epilepticus (SE) and to the subsequent onset of spontaneous seizures.

The pilocarpine model of epilepsy, as it is now called, thus emerged shortly after the kainate model. The kindling model, pilocarpine model, and kainate model constitute the three most widely used animal models of epilepsy. Over the years, the particular features of the pilocarpine model, such as a high frequency of spontaneous recurrent seizures and robust supragranular mossy-fiber sprouting, have contributed to its wider acceptance and use.

The pilocarpine model of epilepsy relates both to a model of acutely induced seizures culminating with a prolonged episode of SE, as well as to a model of chronic spontaneous seizures that follows – at some delay – the initial acute seizure period. The acute induction of seizure activity is characterized by long-lasting limbic SE associated with sustained electrographic discharges in limbic structures. Introduction: Rationale for the Model

The importance of cholinergic mechanisms for epilepsy was already suspected by neurologists at the turn of the nineteenth century. The convulsant potential of acetylcholine and physostigmine was experimentally demonstrated, using electrocorticographic monitoring, as early as the late 1930s. In the following years, the use of acetylcholine, mainly in in vitro models, contributed to the understanding of electrophysiological phenomena involved in epileptic spike discharges, neuronal depolarization, and burst generation. In the 1980s, investigators demonstrated that periodic administration of carbachol effectively induced kindling, and that administration of high doses of pilocarpine – a cholinergic agonist – may lead to the acute induction of status epilepticus (SE) and to the subsequent onset of spontaneous seizures.

The pilocarpine model of epilepsy, as it is now called, thus emerged shortly after the kainate model. The kindling model, pilocarpine model, and kainate model constitute the three most widely used animal models of epilepsy. Over the years, the particular features of the pilocarpine model, such as a high frequency of spontaneous recurrent seizures and robust supragranular mossy-fiber sprouting, have contributed to its wider acceptance and use.

The pilocarpine model of epilepsy relates both to a model of acutely induced seizures culminating with a prolonged episode of SE, as well as to a model of chronic spontaneous seizures that follows – at some delay – the initial acute seizure period. The acute induction of seizure activity is characterized by long-lasting limbic SE associated with sustained electrographic discharges in limbic structures. Several parameters have been used to assess subsequent chronic epileptogenicity, which appears

after the acute induction stage. These parameters include thresholds for fluorothyl-induced seizures, kindling facilitation, and response to paired electrical pulses. However, the best criterion for the epileptic condition is the occurrence of actual spontaneous seizures. As in temporal lobe epilepsy (TLE) patients with prolonged febrile convulsions, spontaneous recurrent seizures occur after a seizure-free interval that consists of apparently normal behavior and electrographic activity. Accordingly, the phenomenological descriptions and pathological changes after SE-induced damage are critical for understanding the process of epileptogenesis.

Background: Natural History

The administration of pilocarpine to rodents induces ictal and interictal epileptic activity in hippocampal and cortical electrographic recordings. These electrical phenomena are correlated with a sequence of behavioral alterations that includes akinesia, ataxic lurching, facial automatisms, progressing to motor seizures, and SE. After a single application of these drugs, SE can last from 6 to 12 h. After spontaneous remission of SE, animals are comatose and both hippocampal and cortical recordings show a depressed EEG with occasional high-voltage spiking activity. These events have been called the 'acute period' of this model, and metabolic studies performed during this period have revealed increased glucose utilization – mainly in the hippocampus and other limbic structures, thalamus, and substantia nigra. The pattern of neuronal loss observed in these animals closely corresponds to the areas that are metabolically activated during SE. The cytopathology following SE does not mean that the cholinergic system has excitotoxic potential. It is rather believed that the cholinergic system may play a role in triggering and maintaining seizure activity. It is, indeed, the excessive synaptic release of glutamate that leads rapidly to neuronal depolarization and breakdown of membranes. The synaptic release of acethylcholine is thought to provide a sustained drive that keeps neurons firing (as seen in SE), but without causing any neuropathological damage per se. According to this hypothesis, the function of the cholinergic system is in the maintenance of sustained seizure activity that drives excitatory glutamatergic mechanisms responsible for neuronal damage. Accordingly, experiments have shown that anticholinergic drugs could prevent sustained seizures but are not useful for seizure arrest.

Animals surviving the acute period of SE proceed to a latent 'seizure-free' period with apparently normal behavior – except for some aggressiveness if manipulated and toward other rats if they are maintained in groups. This latent period lasts 1–8 weeks, depending on the animal strain and the method used to induce SE, and ends with the occurrence of the first spontaneous seizure. The recurrence of spontaneous seizures during the 'chronic period' may vary according to the details of the model, ranging from 1 seizure per month to several seizures per day.

The evolution of spontaneous seizures follows the behavioral and electrographic stages of kindling. This aspect of epileptogenesis has been better characterized for the pilocarpine model. In the majority of Wistar rats subjected to the pilocarpine, the first seizure is normally characterized by paroxysmal discharges localized in the hippocampus or amygdala, without changes at cortical recording sites. Behavioral correlates of this limbic seizure consist of motor arrest followed by eye-blinking, chewing, and head nodding – resembling kindling stages 1 or 2. The following seizures show gradual synchronization of neocortical and hippocampal regions, and longer duration of ictal events. Forelimb clonus, and rearing with falling (as in kindling stages 4 or 5) are the hallmarks of these later generalized seizures. The progression of spontaneous seizures tends to be quite variable, in terms of duration of paroxysmal discharges and sequence of behavioral stages, from animal to animal. Several seizure stages of similar or lesser intensity can be observed before a generalized motor convulsion is reached. Once the generalized convulsion (i.e., like a stage 5 kindled seizure) occurs, then the vast majority of the following seizures are also generalized. These observations made in the pilocarpine model of epilepsy suggest that the development of epilepsy, as a consequence of SE, follows the stages of kindling.

Methods: Generation of the Model

The acute model was originally described in rats and subsequently in mice. Pretreatment of the animals with scopolamine was shown to prevent the development of convulsive activity caused by pilocarpine. The original descriptions of the model included the subcutaneous administration of methyl-scopolamine, at the dose of 1 mg kg^{-1}, to reduce the peripheral effects associated to the autonomic activation caused by pilocarpine. Studies have clearly demonstrated that activation of M1 muscarinic receptors is critical for the induction of SE by systemic administration of pilocarpine. Pilocarpine has been shown to effectively produce acute seizures in Wistar and Sprague-Dawley rats. The initial characterization of the model in Swiss mice was later followed by its description in C57BL/6, CD1; CF1, kinin B1 and B2 receptor knockout mice; and 129SV background strains. Administration of pilocarpine to a different rodent species, *Proechimys* sp., has also been shown to be effective at triggering acute seizures. Finally, systemic administration of pilocarpine to the common marmoset (*Callithrix jachus*) promotes acute seizures and SE.

Pilocarpine has been shown to trigger acute seizures after intracerebroventricular, and intrahippocampal administration. In addition, while the intrahippocampal administration of pilocarpine in rats triggers spontaneous recurrent seizures in just some of the injected animals, supragranular mossy-fiber sprouting ipsilateral to the injection is found in all animals.

Regarding age sensitivity, the pilocarpine model can be induced in rats starting from postnatal day 11 to animals of ~12 months of age. Administration of pilocarpine to postnatal day 3–6 rats leads only to minor electroencephalographic changes characterized mostly by flattening of the background activity and occasional low-amplitude, low-frequency spikes with no clear seizure behavior. In 7–10-day-old rats, more frequent spikes, with grater amplitude, are seen in both cortex and hippocampus, together with infrequent spike and wave complexes – but still without clear motor seizures. Intense behavioral signs, evolving (in some animals) to limbic seizures and SE, occurs when pilocarpine is administered to animals older than 11 days. Animals ranging from 15 to 21 days of age appear to have the greatest sensitivity to pilocarpine-induced SE; at this age, SE develops with a shorter latency, and more often results in death as compared with adult animals. It is important to note that young animals usually have a greater susceptibility to the acute induction of seizures by pilocarpine, often requiring doses that are 30% lower than that used for adult animals. From the morphological point of view, the pattern of neuronal loss and ensuing plastic changes, however, is markedly less in these young animals than that seen in adult animals. In contrast, induction of multiple episodes of SE in 7–9-day-old rats pups results in important plastic changes, leading to long-lasting epileptogenesis, as manifested by electrographic epileptiform discharges, behavioral deficits, and in vitro hyperexcitability of hippocampal networks.

For the adult animal, susceptibility to the convulsant effects of pilocarpine increases with age; the threshold dose for generalized seizures is essentially constant from 30 to 70 days, but decreases thereafter, particularly beyond 100 days. Older (and thus heavier) rats not only require a smaller dose of pilocarpine to develop SE but also have a greater mortality rate. Indeed, pilocarpine-triggered seizures in adult animals often have an intense tonic phase followed by respiratory arrest and death, even when produced by small doses of pilocarpine. In this sense, for experiments aimed at studying the functional and morphological consequences of pilocarpine-induced SE the ideal age range for rats is between 2 and 3 months of age at the time of status induction.

Although most studies have been conducted with male animals, it has been shown that female rats – both young (starting at postnatal day 7) and adults (usually 2–3 months of age) – can have acute seizures induced by pilocarpine. The induction of SE with pilocarpine in female rats leads to an increased diestrous, suggesting an anovulatory estrous cycle and an inadequate luteal phase. In addition, pregnant and lactating rats show a clear effect of the hormonal changes that characterize such conditions, with animals having less-frequent spontaneous seizures.

As described earlier, the susceptibility of different animals to pilocarpine-induced seizures is influenced by a number of different factors. Indeed, even for the same animal species, strain, gender, and age (in this case 2–3–month-old, male, Wistar rats), the dose required to induce SE across a significant number of animals has been shown to range from 400 to 320 mg kg^{-1}. Therefore, for anyone using the model, it is useful to assess the sensitivity of the particular animal batch to be used for experimentation.

The remaining issues associated with the induction of SE depend on the intended use of the model. The use of 400 mg kg^{-1} of pilocarpine will most likely result in a 100% chance of induction of severe SE associated with a high mortality rate in the few hours after status onset. In addition, depending on the animal species and strain, this high dose may result in a number of animals having severe tonic seizures followed by respiratory arrest as a very early seizure manifestation. With the reduction of the injected dose, seizures are likely to be less severe and associated with a greater survival rate. This reduction, however, also results in a smaller number of the animals developing SE – and thus with a less-efficient use of the animals (often requiring a greater initial number of animals to achieve a given set of animals with SE per group). This 'negative' effect of lower dose pilocarpine can be used to advantage to generate a control group that, despite being injected with pilocarpine, did not develop SE. Such controls may more effectively allow investigators to assess the effects of SE induction, as opposed to effects associated with administration of pilocarpine per se.

For studies aimed at inducing SE in a great percentage of the animals, and with a high and long-term survival rate, the best strategy is to titrate the administered dose of pilocarpine. With this protocol, the administration of a pilocarpine dose yielding SE in ~40% of the animals is followed; for those animals not developing clear seizures, by the subsequent administration pilocarpine at 30% of the initial dose within 1 h after the initial administration. This procedure can be continued for one or two additional doses. Animals not responding to these subsequent doses probably comprise a category of resistant animals.

In the pilocarpine model, induction of SE is critical for the later development of spontaneous seizures. Pilocarpine-induced SE, however, is usually associated with a large mortality rate in the initial 3-day period. Mortality rate is effectively reduced by controlling the severity of the status episode. It has been shown that achieving complete control of SE in the first hour after its onset results

in a large number of animals not developing spontaneous seizures. Good survival rate associated with the development of epilepsy (i.e., spontaneous seizures) in all of the animals can be accomplished by titrating the severity of the SE; after 90 min of free-running SE, the various drugs can be used to diminish SE without actually abolishing it. Thus, diazepam at a dose of 5 mg kg^{-1} or thionembutal at a dose of 25 mg kg^{-1} are good alternatives for this purpose. Both the dose used for the induction of SE and the duration of this episode should be carefully monitored to yield the greatest frequency of animals developing intense SE episodes and surviving to exhibit spontaneous epileptic seizures.

In the following hours after SE induction, animals often become comatose and unable to care for themselves. Animals to survive 12 or more hours after SE induction should remain in the laboratory overnight (not returned to the vivarium). Administration of saline, glucose, and electrolytes, by subcutaneous or intraperitoneal route, can help to minimize loss of animals in this period. By the following day, some animals are already alert and able to care for themselves, while others are still in a poor condition. For the latter group, hand feeding is an alternative and can have good results (fruit juices mixed with sweetened milk and mashed rat food pellets). In addition, leaving fruit slices in the floor cage also helps in a faster recovery.

For rats subjected to free-running SE, with no use of anti-SE medication, the chance of eventually developing spontaneous seizures is 100%. Controlling status 90 min after its onset, as described above, results in a similar yield of animals with spontaneous seizures. Earlier control of status, initiated before 90 min, or its more complete control, achieved with higher doses of anti-SE medication, are likely to reduce the percentage of animals developing spontaneous seizures. Once developed, spontaneous seizures do not remit for the animal's lifetime.

Recent Results: Characteristics and Defining Features

Behavioral and Clinical Features

The sequential pattern of electrographic changes during the acute phase, immediately following the injection of pilocarpine, is characterized by a significant theta rhythm that replaces the background activity in the hippocampus and low-voltage fast activity in the cortex. This activity progresses to high-voltage fast activity with spikes in the hippocampus. The spiking activity spreads to the cortex and evolves into electrographic seizures. Ictal periods recur every 3–5 min and finally lead to sustained discharges 50–60 min after the injection of pilocarpine. This pattern of electrographic activity lasts for several hours and may evolve to a pattern of periodic discharges on a relatively flat background.

Seizure frequency in the chronic period may vary considerably among epileptic rats, and several seizure patterns have been observed. Some pilocarpine-injected rats may present with a low seizure frequency throughout several weeks or months; others may have daily seizures; and some may present clusters of seizures in short periods of time. Such variability in seizure frequency patterns may represent a drawback for behavioral or antiepileptic drug (AED) studies. To assemble a homogeneous group, it is necessary to identify – through baseline monitoring – a group of rats with regular consistent seizure frequency.

It is important to stress that most behavioral or AED studies rely upon video monitoring to establish seizure frequency. Therefore, class 3–5 limbic seizures are preferentially detected, and less-severe ('asymptomatic') seizure stages (class 1 and 2) are frequently overlooked. This point is particularly relevant because many intractable complex partial seizures in humans rarely generalize, even when AEDs are tapered during video-EEG monitoring – and thus are the 'equivalent' of class 1 and 2 limbic seizures in rats. High-resolution video capturing coupled with EEG is necessary to detect subtle behavioral seizures correlated with, for example, focal ictal activity in the hippocampus or amygdala.

Response to AEDs and the Usefulness in Screening Tests

Several drugs have proved to efficiently suppress or attenuate pilocarpine-induced SE when injected either before or right after pilocarpine administration. For this reason, benzodiazepines and barbiturates have been widely used to prevent the relatively high mortality associated with prolonged seizures. Studies in which SE is attentuated (by both drugs) after different durations of SE have shown that early SE suppression can prevent spontaneous recurrent seizures. In addition, neuron loss is prevented if treatment is established with 30 min of SE. When administered before pilocarpine, clonazepan (90.35 mg kg^{-1}), phenobarbital (23.4 mg kg^{-1}), and valproic acid (286 mg kg^{-1}) prevent limbic seizures and protect against seizure-related neuron damage. Pretreatment with trimethadione (179 mg kg^{-1}) results in a moderate protection against pilocarpine-induced seizures, while phenytoin (10–200 mg kg^{-1}) and carbamazepine (10–50 mg kg^{-1}) have no effect and do not prevent pilocarpine-induced brain damage. The noncompetitive NMDA receptor antagonist MK-801, when given 20 min prior to pilocarpine (4 mg kg^{-1}), has no effect in blocking the onset of pilocarpine-induced SE; however, MK-801 pretreatment prevents later spontaneous recurrent seizures and protects against CA1 pyramidal-cell loss. Ketamine, another noncompetitive NMDA receptor antagonist, at a dose of 100 mg kg^{-1}, i.p., exerts a time-dependent protection of hippocampal cells and prevents late spontaneous seizures and specific motor deficits in the Morris water maze.

Drug testing in the latent period has a fundamental importance because several molecular changes occur in this phase that may contribute to the process of epileptogenesis. Thus, a compound with efficacy in inhibiting the development of spontaneous seizures may be considered a true antiepileptogenic drug. There is a growing body of evidence that suggests that there are differences between the mechanisms underlying the development of epileptogenesis and the mechanisms involved in maintaining the expression of seizures after they have established. Hence, it is reasonable to assume that compounds that prevent epileptogenesis may be quite different from classical AEDs. Drugs that regulate the expression of trophic factors involved in neuroprotection or plastic changes induced by damage may have an antiepileptogenic effect.

AEDs that have efficacy in suppressing pilocarpine-induced SE are not the same drugs that are effective in controlling spontaneous limbic seizures. Diazepam, phenobarbital, valproic acid, and trimethadione protect against pilocarpine-induced SE, while phenytoin and carbamazepine are ineffective. In the chronic phase, carbamazepine and phenytoin are effective against spontaneous seizures. Valproic acid is also effective at high doses (600 mg kg^{-1}), and ethosuximide does not prevent spontaneous seizures.

Neuropathology

Induction of SE by pilocarpine leads to severe and widespread cell loss in several brain areas. Dying cells can be assessed via a number of different techniques that characterize a given biochemical or structural aspect of the degenerating cells. Differences in the biochemical and morphological profile of dying cells may indicate whether the cell is suffering from an apoptotic or a necrotic degenerating process. As with a number of different pathological conditions, cell damage in the pilocarpine model has been described as to its necrotic or apoptotic nature. However, classifying cell damage according to these two categories may be confusing, and will therefore be avoided here. A more fruitful perspective is to consider that the excitotoxic insult triggered by pilocarpine-induced SE leads both to immediate cell damage – that takes place minutes to a few hours after its onset – and also results in a protracted process of neurodegeneration that may take weeks and months to develop.

The initial damage, occurring a few hours after the onset of SE, is most intense in the superficial layers of some neocortical areas, hilus of the hippocampus, endopiriform nucleus, piriform cortex, and claustrum. Eight hours after SE onset, damage has further intensified in those areas, and in addition, becomes significant in entorhinal cortex, amygdaloid nuclei, ventromedial nucleus of the hypothalamus, subiculum, and the bed nucleus of the stria terminalis. Damage in these distinct brain areas is time specific.

Damage is not restricted to the initial hours and days after SE, and tends to progressively involve other areas in the following months. To this end, damage to the thalamus is often found in animals sacrificed many months after the onset of pilocarpine-induced SE but is notably less intense (or even absent) in some thalamic nuclei at shorter survival times.

In addition to cell loss, there is also clear injury resulting in both morphological and functional pathology. Evidence of altered cell morphology in the pilocarpine model has been provided mostly for the hippocampus. Altered distribution of dendritic spines in dentate granule cells and distorted dendritic trees in putative GABAergic hippocampal interneurons are some of these changes. Additional morphological changes are more likely to be reactive rather than a direct consequence of the initial insult. In this sense, the emergence of axonal sprouting – the most notable being the supragranular mossy-fiber sprouting, granule-cell dispersion, increased rate of neurogenesis, and development of granule-cell basal dendrites – are among the morphological changes that are likely to represent a reactive response.

As with any other lesional model, pilocarpine-induced SE does not uniformly damage different cell groups. Here again, cell type-specific vulnerability has been best studied in the hippocampus. There is greater damage to principal cells, that is pyramidal and granule cells, in the hippocampal complex, but interneurons located in the other strata can also be damaged. Most notably, hilar mossy cells can be markedly damaged by pilocarpine-induced SE, but with large variation in the extent of damage between different animals. Damage to GABAergic neurons is also extensive throughout the hippocampus. However, not all GABAergic neurons in the hippocampal complex are equally vulnerable, with specific populations in different strata showing different rates of loss. In a recent study, the density of GAD65 mRNA-positive neuron profiles in layer III of the entorhinal cortex was similar in control and post-SE rats evaluated between 3 and 7 days after pilocarpine. Similar evaluations have not yet been provided for other brain areas, with the exception of a qualitative assessment of the neocortex.

Glial pathology in the pilocarpine model has not received the same level of attention as neuronal pathology. Nevertheless, there have been descriptions regarding the proliferation of astrocytes, as shown by the increased expression of glial fibrillary acidic protein (GFAP) and other glial markers. In addition to glial proliferation, it has been shown that in the CA1 area of the hippocampal complex of animals subjected to pilocarpine-induced SE, glial cells 'adapt' to permit rather large increases in extracellular potassium accumulation. Microglia and other

markers of inflammatory tissue reaction have also shown to be present in the early phases after pilocarpine-induced SE.

Challenges for the Future

Although there are many types of epilepsy, both genetic and acquired forms, TLE with hippocampal sclerosis is probably the most common human epilepsy and the one most intensely studied. Despite a wealth of descriptive data obtained from patient histories, imaging techniques, electroencephalographic recording, and histological studies, the epileptogenic process remains poorly understood. Progress toward understanding the etiology of an acquired neurological disorder is largely dependent on the degree to which experimental animal models reflect the human condition. The pilocarpine model of epilepsy has the potential to provide useful information about the pathophysiologic mechanism of human temporal epilepsy. In addition, demonstration of interictal disturbances of learning and other behaviors, as seen in this model, could be used to develop therapies for the interictal impairments that occur in human TLE. Finally, resistance to medical therapy is recognized as one of the major problems in epilepsy treatment today. The pilocarpine model of epilepsy could facilitate the use of modern state-of-the-art techniques in neurobiology to address critical questions in the pharmacoresistance of epilepsy.

The Tetanus Toxin Model of Temporal Lobe Epilepsy

J G R Jefferys and P Jiruska, University of Birmingham, Birmingham, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Temporal lobe epilepsy is the most common type of epilepsy in adults, and often proves resistant to drug treatment. Good experimental models provide a means to develop theories about the neural malfunctions responsible for the development of epileptic foci, and to test novel treatments. They have the important advantages over direct investigations in patients of being reproducible, and accessible to experimental procedures that would be unethical in humans. A major challenge is to find an appropriate model for each clinical condition of interest and specific research question.

The research outlined here on the intrahippocampal tetanus toxin model is aimed at:

1. Comparing the model with human temporal lobe epilepsy.
2. Identifying structural and functional abnormalities in the epileptic focus – that is, how the structure and function of tissue in the model differ from those of normal tissue.
3. Determining how epileptic seizures and interictal discharges are generated – and in particular, elucidating what mechanisms lead to the hypersynchrony and hyperactivity of hippocampal and related circuits.
4. Testing antiepileptic treatments.

Background

Experimental models of epilepsy have been around for over a century. Progress in the identification of the neuronal dysfunction that leads to epileptic activity gained real momentum in the last few decades of the twentieth century. Much of this work relied on models in which epilepsy-like activity was produced by applying convulsant drugs to normal brain tissue. This approach models human symptomatic seizures, but not epilepsy. Chronic models are needed in order to characterize cellular abnormalities associated with an epileptic focus. Such models also provide an experimental approach to understanding how epilepsy impacts on the whole organism.

Intracerebral injection of tetanus toxin was one of the earliest reported methods of triggering epileptic seizures, dating back to the late nineteenth century. In its modern incarnation as a model of temporal lobe epilepsy, a very small dose of toxin is injected directly into the hippocampus. The animal (usually a rat) will start to experience spontaneous, repeated, intermittent epileptic seizures after ~1 week. This model differs from the kindling model of temporal lobe epilepsy in readily producing spontaneous epileptic discharges. The appearance of spontaneous seizures is shared with the models that depend on an initial period of prolonged epileptic activity – status epilepticus – induced by injection of a drug (kainic acid – intracerebral or systemic, or pilocarpine (usually systemic)) or by prolonged electrical stimulation. Tetanus toxin differs from these other models in that it: lacks an initial period of severe/prolonged seizure activity, does not exhibit early gross lesions (e.g., as produced directly by a period of status epilepticus), and has a low mortality rate. The absence of early gross lesions following intrahippocampal tetanus toxin suggests that it is a particularly good model for nonlesional temporal lobe epilepsy in humans. The observation that about 10% of tetanus toxin-injected rats do develop hippocampal sclerosis suggests that the model is also relevant to lesional temporal lobe epilepsy – and that the hippocampal sclerosis seen clinically in many cases is a consequence of epileptic activity rather than its initial cause. If one accepts this possibility, then the tetanus toxin model may provide a good approximation of the early stages of mesiotemporal lobe epilepsy, and offer a useful system in which to study the mechanisms underlying the development of hippocampal sclerosis.

Practical Methodological Issues

Tetanus toxin is one of the most potent toxins known. It is the agent that causes spastic paralysis following infection of peripheral injuries with *Clostridium tetani* (a condition also known as 'lockjaw'). Tetanus toxin is a protein of about 150 kDa, comprising a light and a heavy chain. The light chain is a protease selective for a synaptic protein called vesicle associated membrane protein (VAMP, or synaptobrevin), and as a result of its action at this site, blocks synaptic transmission. However, the whole toxin is needed to induce experimental epileptic foci, which depends on the internalization, and probably the intraneuronal transport, of the toxin as well as the protease action.

To induce a temporal lobe epileptic focus, a few nanograms of toxin are injected, under stereotaxic control, directly into the hippocampus of an anesthetized animal. The injection target is near the end of the hippocampal fissure to ensure exposure of the CA3 region; dorsal and

ventral injections produce similar results. Injecting the toxin into the neocortex also produces an epileptic focus, but with different characteristics, resembling medically refractory epilepsia partialis continua. Recording electrodes may be implanted to monitor electrical activity from the hippocampus and other regions. After recovery from anesthesia, the animal is housed under normal conditions. Handling the toxin takes some care, both because of its toxicity and because it can be degraded in transit or by careless handling in the laboratory.

Investigations performed on these epileptic animals exploit a wide range of neuroscience methods. Much of the work outlined here uses hippocampal slices (usually 0.4 mm thick) prepared from the epileptic rats and maintained in vitro for several hours to allow electrophysiological investigation with microelectrodes. Chronic electrical recordings from implanted electrodes allow detection and characterization of electrographic seizures, while direct visual observation or video recording allows investigators to describe the behavioral correlates of seizures, and assess seizure severity and seizure types. Animals experiencing the fully developed epileptic syndrome may be used to test the behavioral consequences of the epilepsy, or serve in trials of antiepileptic drugs. At the end of the experiment, tissue should be prepared for terminal physiological, histological, and molecular investigations.

Results

Epileptic Syndrome

About a week after intrahippocampal injection, the rats start to have spontaneous and repeated seizures, developing a full-blown syndrome of temporal lobe epilepsy. The earliest electrographic abnormalities are occasional large spikes or brief burst discharges. When seizures start, they typically consist of a cluster of partial seizures, over a period of 1–2 days that culminate in a secondarily generalized seizure with motor signs. Seizure frequency typically peaks during the second week, at several to 20+ seizures per day. The electrographic picture in this model is characterized by interictal discharges and seizure activity of various patterns. In particular, seizure onsets can be either hypersynchronous or low-voltage fast, as in humans. Seizures usually start in the CA3 area – of either the injected or uninjected hippocampus – and spread into the entire hippocampus and to contralateral hippocampus and other parts of the brain (including cingulate and entorhinal cortices). Electrical activity during the seizure normally follows a sequence of frequencies, generally slowing as the seizure progresses (**Figure 1**); about one-third of seizures terminate with a period of 2–3 Hz activity. The behavioral correlates of the electrographic seizures resemble those described for other models of temporal lobe seizures, and mimic the seizures observed in human patients with mesiotemporal lobe epilepsy. Behaviorally, these seizures can be classified as complex partial, with behavioral arrest, staring, oroalimentary automatism (chewing), sniffing, vibrissal and facial twitching, and wet-dog shakes. Seizures can be followed by postictal confusion. Some seizures can progress to become secondary generalized, and are then characterized by fore-limb clonus, and rearing and falling convulsions. The seizures rarely last more than 2 min, and the rats maintain themselves in good condition. During the periods between seizures, modest behavioral disorders (e.g., hyperreactivity) can be found, but are less severe than in some other models, thus simplifying handling. Cognitive changes are discussed in the following sections.

Once the epilepsy is established in adult animals, then seizures recur intermittently for 6 weeks or so, after which the rats usually gain remission from seizures. This remission appears to be an active process for most hippocampal foci. In contrast, neocortical foci induced by tetanus toxin continue to discharge for the life of the animal – as do hippocampal foci if they are induced at postnatal day 10 (and also in a minority of hippocampal foci induced in adults).

In a pioneering series of studies on animals with hippocampal tetanus toxin foci, Mellanby found that the rats had enduring impairments on a range of tests of learning and memory, particularly on tasks known to depend on hippocampal function. These impairments cannot be attributed to epileptic seizures interrupting brain function, because they could be demonstrated after the rats gained seizure remission. They cannot be attributed also to medication (as corresponding changes in patients often are) because they occurred in the absence of any drugs. Finally, they cannot be due to gross morphological changes in hippocampus (such as neuronal loss or hippocampal sclerosis), since these pathologies are not present in the majority of animals. Therefore, these changes are primarily functional – and argue that the tetanus toxin model provides a unique opportunity to gain insights into the mechanisms of cognitive and memory dysfunctions observed in patients with mesiotemporal lobe epilepsy.

Cellular Mechanisms

Hippocampal slices and synaptosomes prepared from injected animals reveal a loss of inhibitory postsynaptic potentials (IPSPs) and calcium-dependent GABA release for ~1 week post toxin injection. Subsequently, the IPSPs and GABA release recover, at least in response to direct activation of inhibitory neurons or their terminals. However, inhibitory function continues to be impaired, in that stimulation of inhibitory neurons through excitatory synaptic pathways evokes very small 'disynaptic' IPSPs (**Figure 2**). This effect has parallels with the proposed function of 'dormant' basket cells, but differs in the absence of related neuronal loss; in the case of the tetanus

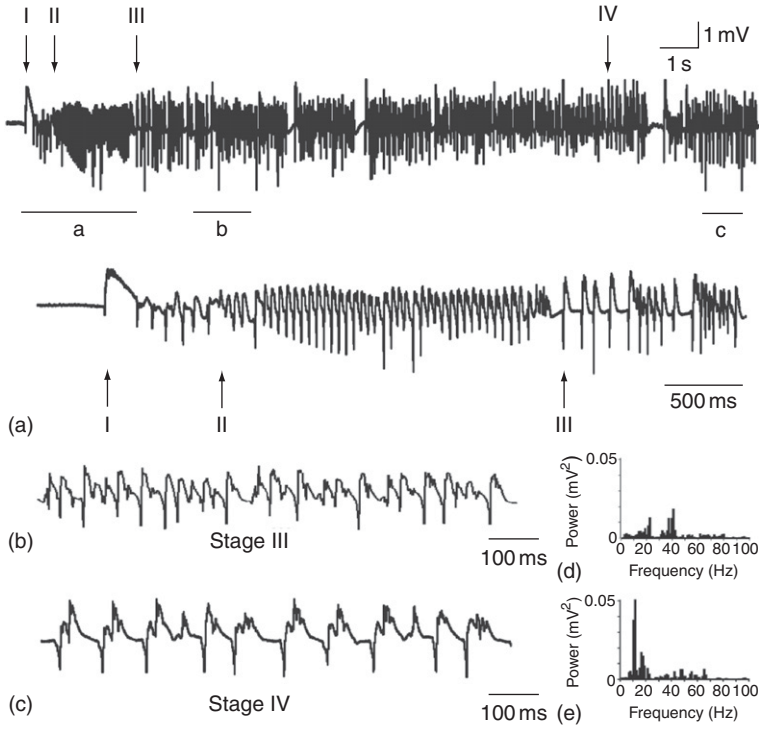

Figure 1 Recordings from a freely moving rat during a spontaneous epileptic seizure. Note the relatively high frequencies at the beginning and the progressive slowing as the seizure progresses. The top panel shows the full seizure until just before the onset of the motor component of the secondarily generalized seizure. The segments labeled (a), (b), and (c) are reproduced below. Panels (d) and (e) are power spectra of the signals in panels (b) and (c) respectively. Note the progressive slowing as the seizure develops. Reproduced from Finnerty GT and Jefferys JGR (2000) 9–16 Hz oscillation precedes secondary generalization of seizures in the rat tetanus toxin model of epilepsy. *Journal of Neurophysiology* 83: 2217–2226, with permission from American Physiological Society.

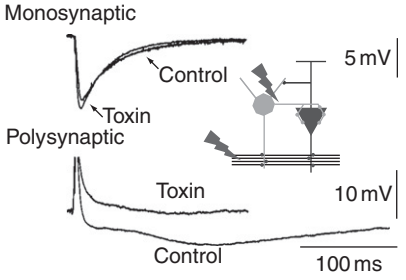

Figure 2 Functional dormancy during the active seizure phase of tetanus toxin model. 'Monosynaptic IPSPs' evoked by direct excitation of inhitory neurons, when excitatory synapses were blocked by drugs, were the same in tissue slices from epileptic and control rats, showing that GABA release mechanisms had recovered by (in this case) 2 weeks. 'Polysynaptic IPSPs' were substantially smaller in the epileptic rats when EPSPs were not blocked, that is before the glutamate receptor antagonists were added to the slice; the smaller stimuli used in these experiments activate inhibitory neurons via excitatory synapses. Cartoon illustrates mono- and poly-synaptic activation. Adapted from Whittington MA and Jefferys JGR (1994) Epileptic activity outlasts disinhibition after intrahippocampal tetanus toxin in the rat. *Journal of Physiology* 481: 593–604, with permission from Blackwell Publishing; see also Vreugdenhil M, Hack SP, Draguhn A, Jefferys JGR (2002) Tetanus toxin induces long-term changes in excitation and inhibition in the rat hippocampal CA1 area. *Neuroscience* 114: 983–994.

toxin model, 'dormancy' is functional rather than structural. Remarkably, this apparent interneuron malfunction persists for over 5 months, despite the rats gaining remission from their spontaneous seizures within that timeframe. Other changes found at the late stage of tetanus toxin-induced epileptogenicity, such as weakened synaptic excitation and reduced cellular excitability, may be part of the remission mechanism. These changes may also be responsible for the enduring impairments of learning and memory found in these animals (see explanation given earlier). Notably, a form of synaptic plasticity associated with learning and memory, long-term potentiation, is preserved in the epileptic rats, suggesting that impaired learning and memory in this case is due to a reduction in hippocampal responsiveness rather than in mechanisms of synaptic plasticity.

Histological changes in the tetanus toxin model are modest, at least when it is injected in the adult rat. About 10% of animals experience focal loss of hippocampal neurons with associated gliosis (not the same 10% that fail to gain remission from seizures). These structural changes often involve CA1 and extend up to 1–2 mm along the hippocampus. Selected classes of interneuron also can be lost, typically after many spontaneous seizures

over ~2 months. One consistent structural change is axonal sprouting, both in the dentate gyrus (mossy fibre sprouting shown by Timm staining) and in CA1 (shown electrophysiologically – antidromic responses can be evoked from stimulation in stratum radiatum which normally does not contain CA1 pyramidal cell axons). Axonal sprouting is one of the most consistent structural changes in temporal lobe epilepsy.

Tetanus toxin injected at a neonatal stage (postnatal day 10) produces a more intense seizure syndrome and disrupts cellular organization, but like the adult version of the model, results in minimal neuronal loss, recurrent seizures, and learning deficits.

The effects of antiepileptic drugs have been tested on both the neocortical and hippocampal foci induced by tetanus toxin. Neocortical foci appear medically refractory, at least to diazepam and phenytoin. Hippocampal foci do respond, with a significant reduction in seizure frequency, to both carbamazepine and levetiracetam. It remains to be determined whether these apparent differences in drug response are due to the site of the focus, to the drugs tested, or to other factors such as strain differences in the rats. It is worth noting that the intrahippocampal tetanus toxin model presents some difficulties if one plans to use it as a screen for antiepileptic drugs. While the spontaneity of the seizures makes the model more 'realistic,' it also makes quantifying the efficacy of antiepileptic treatments more difficult than in models with frequent seizures or seizures that can be triggered at will, (as is the case for kindling).

Future Challenges

Like other chronic models of focal epilepsy, the big challenge posed by the intrahippocampal tetanus toxin model for the neurophysiologist is the nature of the dysfunction of the neuronal circuits that leads to the generation of spontaneous epileptic seizures. The mechanisms that impair the excitation of inhibitory neurons need resolution and their interactions with other aspects of the focus (including axonal sprouting) need rigorous analysis. A distinctive feature of this model is the seizure remission gained by most rats. Previous work has provided circumstantial evidence of changes in excitatory transmission and in neuronal excitability, but these changes need to be investigated in more detail; in particular, it is important to determine which are missing in the minority of rats that do not gain seizure remission.

The main purpose, and challenge, for research on experimental models of epilepsy is to find improved treatments for epilepsy in humans. Understanding the cellular and local network mechanisms responsible both for establishing the epileptic focus and for seizure remission will provide clues for new treatments. The question of refractoriness to existing anticonvulsants needs to be addressed – in particular, whether rats fall into responder and nonresponder groups that can be used to determine mechanisms of drug resistance and methods of overcoming it. Finally, this model can be used for developing novel treatments, such as focal drug administration, local inactivation, and therapeutic electrical stimulation, and for developing improved methods for seizure prediction or detection.

The use of Cell Culture Models to Study Mechanisms Related to Epilepsy and Antiepileptic Drugs

M A Dichter, University of Pennsylvania, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction and Background

In order to understand the role of cell culture models in epilepsy research, it is useful to briefly examine the understanding of central nervous system (CNS), cellular physiology, and pharmacology that existed prior to the time that cell culture models were first 'invented' for the study of mammalian CNS. Much work had been performed in the 1960s and early 1970s, investigating the cellular phenomena occurring in the mammalian brain during interictal discharges and seizures. This research was developed in parallel to studies of neuronal and synaptic function in general. At that time, there was a basic understanding of neuronal physiology, still based on the Hodgkin and Huxley model of the squid giant axon, although even such elementary discoveries as the presence of Ca-dependent action potentials in mammalian neurons had not yet been made. In addition, there was a rudimentary understanding of synaptic physiology and pharmacology. The identities of the inhibitory neurotransmitters were just being discovered, and the identities of the excitatory transmitters were still somewhat of a mystery, as was even the basic physiology of excitatory synaptic potentials. All of the epilepsy research, until that time, had been performed in intact animals in which seizures were induced by either chemical or electrical stimulation. Mechanisms underlying the seizures were inferred from these in vivo experiments, and were based on the then understanding of neurophysiology. At the same time, relatively little was known about the mechanisms of action of any available antiepileptic drugs (AEDs).

In the early 1970s, it became clear that in order to begin to understand neurobiology at a cellular, and ultimately molecular level, in vitro preparations of mammalian CNS were needed. Almost simultaneously, a small number of investigators began to grow and maintain embryonic mammalian CNS in dissociated cell cultures, while others learned how to maintain viable sections of more mature CNS tissue in slice chambers (see Further Reading section). These discoveries led to a virtual explosion of new information about the physiology and pharmacology of mammalian CNS and, in parallel, to a great expansion of our knowledge of epilepsy mechanisms and the mechanisms of action of antiepileptic drugs. Thus, it is impossible to separate pure 'epilepsy research' using cell culture models from basic neurobiological research that led to major insights into epilepsy mechanisms.

This article briefly reviews techniques for establishing dissociated cell cultures of mammalian CNS that are most relevant to epilepsy studies. It then discusses the kinds of questions about epilepsy mechanisms and AEDs that can be best answered by studies employing this model system, using examples from the literature to illustrate how these strategies can produce important information. Finally, limitations of the model are addressed.

Cell Culture Methods

Dissociated cell cultures of central nervous system tissue can be prepared from essentially any mammalian species. The majority of cultures used to date, however, are derived from rat and mouse embryos or early postnatal animals. Data derived from the cultured tissue can be compared with comparable data from intact tissue, as rat and mouse brain slices are also commonly employed as experimental preparations. Interestingly, there is very little literature on potential differences between rat and mouse CNS neurons. Comparisons in culture would be extremely useful, given that clear differences between species, and among strains within each species, have been identified in intact systems.

Most forms of epilepsy occur in the archicortex or neocortex. As such, studies of cellular mechanisms most relevant to epilepsy or antiepileptic drugs have been performed on cultures developed from embryonic cortex or hippocampus. Other brain regions can also be studied, as dictated by specific research questions. In addition, many studies involving mechanisms of action of AEDs have utilized dissociated cultures of spinal cord or dorsal root ganglion (DRG); these regions produce large, relatively easily studied neurons with reproducible characteristics.

CNS neurons can be cultured in a variety of formats, depending on the desired experimental paradigm. For most physiological experiments, neurons are cocultured with glial cells, in a relatively enriched medium. For other experiments, neurons can be grown in an almost glial-free environment with carefully controlled and characterized media. Cells can be grown at varying densities, depending

on the nature of the experiment to be performed. For example, for routine physiology and pharmacology, neurons are often grown at relatively high density on top of proliferating astrocytes. These neurons are best studied at a density that allows identification of individual cells (soma and dendrites) in a microscopic field filled with many neurons. Under these conditions, the neurons are healthy, synapse formation is abundant, and small networks develop. For biochemical experiments, cultures such as these can be grown on the surface of large plates or in flasks.

One drawback of the usual 'high density' cultures is that finding pairs of synaptically connected neurons is difficult. In these cultures, all the neurons receive abundant synaptic inputs, but monosynaptic connections among neighboring neurons are rarely found. By growing cultures at very low densities, such that only two or three neurons are visible in a microscopic field, coupled pairs are easily found. An extreme example of this arrangement is found when neurons are cultured in isolation, often seeded at very low densities onto astrocytes or microdots of adherent substrate. Under these conditions, neurons form abundant autapses onto themselves. There are many subtle variations on the main methodological scheme employed to establish CNS cell cultures. These can best be obtained from either original papers or from texts devoted to CNS cell cultures.

Within hours of plating, most viable cells settle on the substrate, adhere, and begin extending processes. Even at this early time point, neurons can appear pyramidal, stellate, and bipolar. Whether these morphologies correspond to what the cells were destined to become in vivo has never been determined. By 3–5 days in vitro (DIV), the neurons have clearly differentiated and developed extensive processes. Synapses begin to appear at about 4–7 DIV and increase in density and complexity for days thereafter. Given the nature of the connectivity in the high density cultures, it is likely that axons extend fairly significant distances before synapses are made. Cultures of this kind can be maintained in a robust state for 4–6 weeks or longer. As the cultures age, there is a gradual decline in the number of viable neurons, although those that remain often are quite large, and have extensive dendritic trees and abundant spines.

When synaptic interactions are to be studied using paired recordings, cultures are often grown at a very low density. These cultures are maintained in lower volumes of media in high potassium (e.g., 20 mM). Under these conditions, glial cells grow very slowly and do not overgrow the cultures. The basic properties of the neurons in low density cultures appear similar or identical to those grown at higher density, although this similarity has not been rigorously studied.

Results – CNS Cell Cultures as a Model to Help Understand the Pathophysiology of Epilepsy and Mechanisms of Action of Antiepileptic Drugs

Neuronal and Synaptic Physiology and Pharmacology

Ionic currents underlying action potentials in cortical neurons

The physiological basis of the action potential (AP) in mammalian CNS is now well understood and was derived from pioneering studies of the squid giant axon and other similar preparations. Early studies in cell culture demonstrated that voltage-dependent Ca currents also contributed to AP generation in some mammalian neurons. These currents were first demonstrated in cultured dorsal root ganglion (DRG) neurons (a preparation that then became very useful for studying mechanisms by which neuromodulators were able to affect Ca currents), and later in mammalian cortical neurons both in slice preparations and in culture. Under baseline conditions, these currents were not apparent because of the rapid depolarization–repolarization sequence initiated by Na and K currents; however, when Na currents were inhibited, the cortical neurons developed slower, powerful Ca-dependent APs. Once the Ca APs were identified, it was noted that some neurons in cortex, hippocampus, and thalamus had quite prominent Ca APs and tended to fire bursts of action potentials when depolarized. These neurons appeared capable of acting as 'pacemaker' neurons for seizurelike discharges, and hypotheses about the origin of rhythmic discharges in cortex, hippocampus, and thalamocortical circuits were developed based on these findings.

Physiology and pharmacology of inhibitory synapses

Early in vivo studies had demonstrated that IPSPs were generated by opening of Cl channels, and were associated with an increase in membrane conductance. Studies in mammalian CNS cell culture demonstrated that GABA was the main, if not exclusive, neurotransmitter responsible for postsynaptic inhibition. These studies also showed that GABAergic inhibition was very labile at most synapses – declining rapidly with repetitive stimulation due mostly to presynaptic factors (i.e., not due to receptor desensitization or changes in Cl gradient). These discoveries in cell culture led to extensive examinations of the pharmacology of GABAergic synapses, including the elucidation of the mechanisms of action of some of the most important AEDs.

From both biochemical (e.g., receptor binding) studies on brain tissue and studies at the cellular level in cell culture, the $GABA_A$ receptor was recognized as a GABA

receptor *complex* (GRC). Studies utilizing cell cultures first described the allosteric modulation of the GRC by benzodiazepines, a group of drugs that was used extensively to treat status epilepticus and other forms of seizures, but whose mechanism of action had been unknown. Similar studies demonstrated that barbiturates, another class of AEDs, could allosterically modulate the GRC at a different site. Further, unlike the benzodiazepines, barbiturates at high concentrations could directly activate the GRC. Studies of membrane patches removed from cultured neurons demonstrated how these drugs worked at the single channel level.

GABA also activates other classes of receptors, most notably $GABA_B$ receptors that are found on both somas and axon terminals. Much of what we know of the physiology of $GABA_B$ receptors is derived from studies in cell culture. These receptors are G-proteins coupled to Ca channels in axon terminals, where they block Ca entry and thereby down-regulate neurotransmitter release; they are also found coupled to K channels on somas and dendrites, where they mediate slow and prolonged inhibition. Both of these sets of events have important implications for epileptiform mechanisms. Activation of $GABA_B$-mediated inhibition likely plays a role in the termination of interictal discharges and possibly in the termination of seizures. Increased activation of $GABA_B$ receptors is thought to contribute to enhanced bursting in thalamocortical relay neurons and the generation of spike-wave discharges in primary generalized epilepsy. Inhibition of GABA release by activation of $GABA_B$ receptors at GABAergic terminals has also been implicated in the reduction of inhibition seen with repetitive activation of inhibitory synapses. In addition, activation of $GABA_B$ receptors is likely to be responsible for the complex effects of two newer AEDs that were designed to increase GABA levels at inhibitory synapses – tiagabine (by blocking GABA uptake) and vigabatrin (by blocking GABA metabolism). Both of these agents are antiseizure drugs, effective against partial seizures. However, both can also enhance primary generalized absence seizures and possibly status epilepticus – presumably by allowing released GABA to act on presynaptic GABA terminals and paradoxically decreasing inhibition, or by enhancing hyperpolarization of thalamocortical neurons and thereby enhancing synchronized spike-wave activity.

Physiology and pharmacology of excitatory synapses

The physiology of excitatory synapses was much less understood than inhibitory synapses before the introduction of neuronal cell cultures. In culture, the response of neurons to applied glutamate was characterized; the odd *I–V* curve was determined to be due to a voltage-dependent block by Mg of a subpopulation of glutamate receptors; different glutamate receptor subtypes (e.g., AMPA, NMDA, kainate) were identified and characterized. Each of the advances in our understanding of the mechanisms of excitatory transmission had direct impact on epilepsy research. The nature of the large depolarizing events seen both during interictal discharges and ictal events was characterized within the framework of different glutamate receptor events. The role of NMDA receptors, especially, was emphasized as an important component of epileptiform activity. And the autoregenerative nature of NMDA-mediated synaptic events (with depolarization reducing the Mg block of NMDA receptors, which in turn promoted further depolarization by glutamate) became a critical part of the explanation for the all-or-nothing development of some forms of epileptic activity.

The characterization of excitatory synaptic transmission was also determined at the single channel level. AMPA receptors were demonstrated to have very rapid and unusual desensitization properties, such that they opened once in response to agonist and then desensitized until agonist was removed. NMDA receptor-coupled channels, however, continued to open and close for as long as glutamate remained present. In addition, it was demonstrated that NMDA receptors were very sensitive to changes in extracellular pH, becoming inhibited at acidic values and enhanced by alkalosis, within pH ranges that were found in the brain during physiological or pathological stimuli. Investigators also demonstrated that most AMPA receptors were permeable to only monovalent cations, whereas NMDA receptors were permeable to Ca as well. As the molecular biology of the receptors was further understood, AMPA receptors that lacked a properly edited version of the GluR2 subunit were found to be permeable to Ca. These channels occurred naturally on some inhibitory interneurons, and were proposed as a contributing component of some disease states. Each of these discoveries had great implications for our understanding of epileptic processes and for current theories of epileptogenesis. For example, the use of hyperventilation to stimulate epileptic changes in the EEG may be due to the brief metabolic alkalosis induced by this procedure. In addition, the vulnerability of subsets of inhibitory interneurons to hypoxia may be related to their Ca permeable AMPA receptors.

In addition to the fast depolarization mediated by ionotrophic glutamate receptors, it was also noted that glutamate could produce a slow and long-lasting change in neuronal properties due to activation of 'metabotropic' receptors. The discovery and characterization of these receptors also added significantly to our understanding of how epileptiform events could become established and propagate throughout the brain.

Synaptic Plasticity

Many studies of synaptic plasticity in the vertebrate CNS were performed using the preparation of in vitro brain slices, most commonly hippocampal slices. A vast literature

on long term potentiation and long term depression is derived from these studies. In general, with a few recent exceptions, such studies rely on pathway stimulation, and on single cell or field recordings to infer synaptic mechanisms. Parallel studies in cell cultures have allowed direct investigation of synaptic plasticity using intracellular or patch clamp recordings from both the pre- and postsynaptic elements of the synaptic pair. This approach provides more precise control over the relevant synaptic events. However, this preparation also has significant drawbacks for such studies. The cell culture tissue appears to be more immature than the tissue usually studied in slices; the nature of the synaptic interactions may be different from those that develop in the more complex CNS; and it may be very difficult or impossible to activate multiple inputs to the same postsynaptic neuron in culture preparations. In addition, some cellular mechanisms 'wash out' during the intracellular dialysis that occurs with whole cell patch clamp recordings (although this problem is not unique to cell culture preparations). The latter issue is particularly important when considering longer term changes in synaptic efficacy. Nevertheless, important observations about short term plasticity have been made utilizing cell culture preparations.

In general, when studied with paired recordings, inhibitory synapses that start out with a high probability of release almost always decrement when repetitively activated. After even a single action potential, the probability of release of GABA declines for as long as several seconds. With brief trains of action potentials, inhibitory synaptic efficacy may decline by more than 50%, all due to presynaptic factors independent of $GABA_B$ autoreceptor feedback. Such decreases in inhibitory efficacy may have profound implications for ictogenesis.

By contrast, excitatory neurons have different response characteristics to repetitive activation. They also often demonstrate a decrease in release of synaptic transmitter after single action potentials, but this decrease is much more variable than at inhibitory synapses. With trains of high frequency stimuli, some excitatory synaptic responses potentiate, some appear to remain stable, and some decrement. The net result is that if both excitatory and inhibitory synapses are part of a recurrent circuit, and if they are simultaneously activated repetitively, net inhibition will decline with respect to net excitation and the circuit will become unstable. This developing instability is likely one of the critical mechanisms underlying the development and spread of seizures through the brain.

Molecular Expression Profiling at the Level of Single Cells

One of the most widely employed techniques in molecular biology is expression profiling of various tissues under various physiological and pathological conditions. Changes in gene expression, as measured at the mRNA level, are often analyzed to determine how a specific group of cells reacts to a change in physiology. For the complicated CNS, such expression profiling is most informatively performed on single identified neurons (or at least on small groups of neurons) to attempt to understand how changes in gene expression produce changes in network behavior. Some of the earliest applications of single cell gene expression profiling were performed on identified neurons in cell culture. These studies were then extended to neurons identified in live brain slices. Subsequently, it was determined that RNA could be relatively faithfully amplified and analyzed even from fixed tissues.

Initial studies focused on molecular differences between identified inhibitory and excitatory neurons. Surprisingly little difference was found in the relative expressions of most channels and receptors. Even more surprising, however, was the finding of relatively large amounts of mRNA for glutamic acid decarboxylase (GAD), the enzyme responsible for the synthesis of the inhibitory neurotransmitter, GABA, in all excitatory neurons in culture. High levels of GAD mRNA were found, despite the fact that these neurons were not synthesizing GAD protein or GABA. Because of a concern for a possible artifact of neurons in culture, these observations were extended to more intact CNS tissues, where it was also found that excitatory pyramidal cells, and hippocampal and cerebellar granule cells contained relatively large amounts of GAD mRNA. These unexpected results led to the formulation of the 'standby neurotransmitter' hypothesis, that proposed that excitatory neurons could become inhibitory. Again unexpectedly, it was subsequently demonstrated that just such a switching on of GABA synthesis could occur during prolonged seizures! Dentate gyrus granule cells, which are normally excitatory, will exhibit dense staining for GAD and GABA, extending all the way into axon terminals, after prolonged seizures. These cells can then exert inhibitory effects on downstream neurons. Obviously, control of inhibitory elements in critical brain circuits may have a profound effect on excitability and seizure development and spread.

The application of single cell molecular profiling has been extended well beyond the early studies in cell culture. Much recent work focuses on changes in gene expression in different cells within the hippocampus after status epilepticus-induced or injury induced epileptogenesis. Changes in receptor numbers and subtypes, and alterations in ion channels, have been implicated in the development of the hyperexcitable state.

Excitotoxicity

The concept of excitotoxicity is so common at present that it is perhaps surprising to recognize that this hypothesis was only developed in the 1970s and 1980s. Although

initial observations by Olney and others were based on in vivo work, much of the subsequent progress in understanding underlying mechanisms proceeded in studies of CNS cell cultures. This understanding included insights into the roles played by the various glutamate receptor subtypes, the cellular mechanisms involved in both the necrotic and apoptotic components of cell death, and the effects of drugs on these processes.

Mechanisms of Action of AEDs

Almost all the currently available AEDs were developed based on animal screening models, and their mechanisms of action were unknown when the drugs were introduced. Studies in neuronal cell cultures have significantly contributed to an understanding of the mechanisms of many AEDs.

Na channel blockers

Several very potent AEDs have, as a primary mechanism of action, the ability to block voltage-dependent Na channels in a voltage- or use-dependent fashion. Using preparations of cultured spinal cord or cortex, several groups demonstrated that phenytoin, carbamazepine, lamotrigine, and zonisamide could block sustained repetitive firing (SRS). Early action potentials in the train were generally minimally affected, but as the neurons remained depolarized, the drugs were increasingly able to block more and more channels. Subsequent voltage clamp experiments demonstrated the voltage-dependent nature of the block.

GRC allosteric modulators

Several of our more commonly employed AEDs work as allosteric modulators of the GRC, mechanisms first elucidated by studies of cell cultures. Benzodiazepines enhance the affinity of GABA at the receptor and allow enhanced channel openings; barbiturates prolong channel openings and can produce channel openings even in the absence of GABA.

GABA uptake inhibitors

Tiagabine was developed as an inhibitor of GABA uptake. It was hypothesized that such inhibition would result in more GABA extracellularly, and thus there would be enhanced inhibition. Studies in cell culture have produced evidence that this assumption may reflect an oversimplification of the processes involved. More GABA at the synapse did not produce stronger inhibition at $GABA_A$ receptors. Paradoxically, the increased GABA primarily affected presynaptic $GABA_B$ receptors on axon terminals and down-regulated GABA release – thereby producing *less* inhibition. This surprising result may account for the complex response of some seizure types to tiagabine; absencelike seizures may be exacerbated and nonconvulsive status epilepticus may occur, even when partial seizures are reduced.

Similarly complex results were obtained when analyzing the effects of glutamate transport inhibitors on excitatory synaptic physiology. Instead of enhancing synaptic excitation, these agents often dampened excitatory synapses by an action of the excess synaptic glutamate on presynaptic mGluRs – which decreased transmitter release from excitatory terminals.

Circuit Behavior and Ictogenesis – 'Seizure-Like' Phenomena in Cell Cultures

Models of epilepsy in cell culture

When neurons from cortex or hippocampus are grown in dissociated cell culture, they form extensive synaptic interactions and local circuits. The nature of the circuitry has not been extensively examined but a few principles have emerged. Neurons in routine, high density culture do *not* tend to form synapses with nearest neighbors in culture, despite extensive overlap of processes. Instead, synapses are formed with more distant targets. Neurons in these cultures tend to fire in bursts at either irregular or occasionally regular intervals. These bursts, which resemble the paroxysmal depolarizing shifts seen in epileptic tissue in vivo, occur despite an *inability* of these neurons to generate endogenous bursts in response to depolarizing pulses (as opposed to some endogenous bursting neurons in intact cortex and hippocampus), and therefore appear to be driven by large EPSPs. When pairs of neurons in culture are recorded, it is very common for the neurons to exhibit synchronous bursting or synchronous activation – presumably driven by synaptic events originating elsewhere in the cultures. Thus, the circuit organization and synaptic interactions among neocortical and hippocampal neurons maintained in dissociated cell cultures spontaneously recreate the kinds of circuits needed to sustain epileptiform types of activity, even in the very simplified environment of a Petri dish and a two-dimensional substrate.

Synchronous bursting in the cultures can be enhanced by many of the same maneuvers that provoke epileptic activity in intact cortex (e.g., GABA receptor antagonists and NMDA receptor activators). Such epileptogenicity occurs in the absence of endogenous bursting cells, electrical interactions between the neurons, or ephaptic interactions among the neurons. This synchronous discharge can also occur when neurons are grown in the virtual absence of astrocytes. Surprisingly, this 'epileptic-type activity' and epileptogenic circuitry have been largely ignored by epilepsy researchers using cell cultures to study other aspects of cellular biophysics, physiology and pharmacology, or mechanisms of action of AEDs.

One prominent exception is the work of Delorenzo and colleagues, who have exploited the enhanced synchrony

produced by exposing the cultures to a low magnesium environment to create a cell culture model of epilepsy. Reducing Mg in the media in which neurons are bathed enhances activity of NMDA receptors and produces an increase in excitability of the cultures. When cells are maintained in this condition for more than 3 h, the cultures remain hyperexcitable for the life of the cells, even when normal Mg is restored. This group has carried out a number of experiments to support their view that this model simulates focal epileptogenesis – dependent on aberrant activation of NMDA receptors, and related to a disruption of calcium homeostasis, likely through alteration in calcium – and calmodulin kinase II activity.

Chronic cultures of dissociated neurons maintained on a chip

Another recent approach to analyzing epileptic-like events in cell culture has developed around an interesting new way of culturing the neurons. Cells can be grown on microchips with multiple exposed electrodes. When a neuron lands on one of these electrodes, an extracellular recording from that cell can be maintained, often for weeks at a time. Since the microchip contains many electrodes, many individual cells or small groups of neurons can be monitored simultaneously. Under these conditions, it has been shown that the neurons tend to fire in bursts, and that there are varying degrees of synchrony occurring in the cultures. Since the neurons can be monitored for weeks, this preparation has the potential for important studies of dynamic circuit behaviors, including the response of these synchronously discharging cells to antiepileptic drugs or other possible antiseizure therapies.

Limitations

Despite the extensive studies performed on dissociated cell cultures since they were first 'invented' in the early 1970s, there are a number of limitations that must be mentioned about 'models' of epilepsy developed with this approach. Many different laboratories now maintain cell cultures, and there is undoubtedly significant variability in cultures (methods of generation and maintenance, cell types, etc) from one lab to the other. For some types of experiments, this variability may be unimportant. However, for some studies that focus on epileptic-like events and conditions, such differences could be quite important – for example, a variation in the percent of inhibitory neurons(from 30 to 40% of the culture to less than 10% have been reported). Similarly, the presence or absence of astrocytes may be important for some kinds of studies.

Another issue that always arises with relation to cell cultures is how faithfully they mimic their in vivo counterparts. Surprisingly, for most properties studied, the resemblance is remarkable. However, for other properties, there may be very significant differences between cultured neurons and neurons in the intact brain. For example, one group of $GABA_B$ receptors (K channel-coupled $GABA_B$ receptors on cell bodies and dendrites) are absent from cultured neurons. Similarly, as we understand more about developmental expression of different ion channels and transmitter receptors, it will be necessary to validate culture studies with in vivo data. It is now clear that different mechanisms of epileptogenesis, seizure generation, and response to AEDs are characteristic of CNS neurons at different stages of maturity. It will therefore be important to determine what maturational level is reproduced in cell cultures before drawing general conclusions from culture data for the intact brain.

Perhaps the most interesting aspect of the comparison between cell cultures and the intact brain relates to the epileptiform activity expressed by neurons in culture. Do the circuits that form after cells are completely dissociated and then plated onto a two dimensional surface (covered with an artificial substrate) recreate the kinds of circuits that are capable of developing and sustaining epileptiform activity? Depending on how one defines 'epileptic,' it appears that cell cultures can do just that. What insights will this preparation provide about the developing brain and the response to injury? How will culture-determined properties of cells and circuits be useful for designing strategies to prevent seizures or the hyperexcitability that underlies human epilepsy?

Summary and Directions for Future Research

Insights into human epilepsy derived from studies of neuronal cell cultures

Studies utilizing the preparation of dissociated cell cultures have already provided significant insights into the basic physiology, pharmacology, and molecular biology of neocortical and hippocampal neurons and synapses, and have led to many advances in our understanding of epileptiform events. Such studies have contributed greatly to our current understanding of the mechanisms of action of AEDs. Further work on receptor (or channel) subtype-specific pharmacology will likely lead to new classes of AEDs that have more focused targets and (hopefully) better side-effect profiles. Other studies focusing on mechanisms underlying short term synaptic plasticity, and on the local circuitry involved in synchronous neuronal activation, may also lead to new strategies for suppressing seizures. Each of these areas may result in new targets for AED screening.

One of the main areas of neglect in epilepsy research is that of 'epileptogenesis.' Studies in cell culture on such issues as axonal sprouting, new synapse formation, and

altered molecular phenotype (e.g., in response to activity or injury) may provide new insights into these processes – and lead to new hypotheses about how to control them.

Introduction

Epileptic discharges are synchronized discharges of large populations of cortical neurons in the brain. The in vitro slice model, in particular, the CA3 neuronal circuit in the hippocampal slice has been useful in the elucidation of the mechanisms of synchronization. Studies in this preparation have focused on two major types of synchronized discharges. The first, a shorter-duration discharge (<500 ms) serves as a model for interictal spikes. The second, a more prolonged discharge (in the order of seconds) has been used to study the generation of ictal discharge and interictal-to-ictal transition.

Interictal-like spikes in hippocamapl slices can be elicited by the application of $GABA_A$ receptor antagonist. Ictal-like discharges can be activated in the same preparation by the addition of group I metabotropic glutamate receptor (mGluR) agonist (S3HPG or DHPG). mGluR agonist can elicit ictal-like discharges under two conditions. First, addition of mGluR agonists to hippocampal slices exhibiting interictal-like spikes (i.e., in the presence of $GABA_A$ receptor antagonist) causes a gradual prolongation of interictal spikes into ictal-like events (interictal–ictal transition). Secondly, mGluR agonist, when applied alone (without the presence of $GABA_A$ receptor inhibitor), causes the sequential appearance of short interictal-like discharges followed by prolonged ictal-like discharges. Recent studies reveal that, in addition to mGluR agonist, activation of synaptic mGluRs in the recurrent connections between CA3 pyramidal cells, under at least one pathological condition (that of Fragile X mental retardation syndrome, FXS), causes the generation of ictal-like discharges in the hippocampal CA3 population.

Epilepsy is a disorder of recurrent seizures. Epileptogenesis is the plasticity process by which a normal brain becomes epileptic. In this context, mGluR-induced, synchronized discharges in the CA3 population can be viewed as a model of epileptogenesis, because ictal-like discharges, once induced by agonist, persist for hours – even when the inducing agonist is washed out. Similarly, synaptically induced, mGluR-dependent, ictal-like discharges elicited in Fragile X Syndrome (FXS) model mouse preparations

are long-lasting events which persist for the duration of subsequent recording periods (over several hours). Recent studies suggest that mGluR-dependent epileptogenesis is probably the underlying cause of epilepsy suffered by FXS patients. In vivo studies show that FXS mice have increased propensity to audiogenically induced seizures. MPEP, a mGluR subtype (mGluR5) blocker, is uniquely effective in suppressing the seizure activity.

Methods

In vitro slices have been widely used for physiological studies of isolated brain regions. The hippocampal slice, with its easily identifiable regional demarcations, is a preparation of choice. The preparation was first used to study long-lasting potentiation (LTP) in the CA3–CA1 synapse and epileptiform discharges. The rapid and substantial progress in these two areas serves as a testimonial to the experimental advantages offered by this in vitro preparation.

After an initial developmental period, the hippocampal slice has become a relatively simple and reliable preparation to make. Subregions of the hippocampus, including CA3, CA1 or dentate gyrus areas, can be dissected out via visual guidance and studied in isolation. In addition, because of the largely separated location of the pyramidal cell soma and interneuron soma in the slice, the properties of interneurons can be examined independent of pyramidal cells using intracellular electrode recordings, either "blind" or using infrared, differential interference contrast microscopy (IR-DIC) to visualize isolated somata – including those of interneurons. Particularly for interneuron somata located close to the pyramidal cell body layer, the IR-DIC technique has proved to be particularly useful.

The identifiable and separated location of the dendrites and somata of pyramidal cells in subregions of the hippocampus also makes it possible to carry out detailed studies of pyramidal cell dendritic properties. Dendrites can be examined via intracellular recordings or they can be studied in isolation from the soma, using microdissection to separate dendrite from soma. The latter procedure has been useful in demonstrating the involvement of local dendritic mRNA translation in the induction of LTP.

The properties of the CA3 neuronal circuit have been extensively explored in studies on the basic mechanisms of epilepsy. The most powerful method for examining the recurrent synapses between CA3 pyramidal cells is paired intracellular recordings. Such studies provide data on the strength of recurrent connections between individual CA3 pyramidal cells, and the extent of connectivity within the network. Paired pyramidal cell–interneuron studies also provide opportunities to evaluate plasticity of inhibitory control, an issue of significant and ongoing inquiry relevant to epileptogenesis.

Recent studies have revealed the presence of axon-axonal gap junctions between principal cells in the hippocampus and dentate gyrus. The slice preparation will be useful for exploring the function of such axon-axonal gap junctions. The role of gap junctions in enhancing CA3 pyramidal cell synchrony, within a synchronized episode or in the generation of high frequency population oscillations, requires further attention.

Pharmacological tools are used to elicit epileptiform synchronized discharges in hippocampal slices. Generally, synchronized discharges are elicited in the hippocampal network via the excitatory connections between CA3 pyramidal cells. However, robust, prolonged, epileptiform discharges can also be elicited in the CA1 region by a number of manipulations, including the use of low divalent cation (Ca^{2+} and Mg^{2+}) solution for extracellular perfusion. In addition to pharmacological tools, detailed developmental profiles of synaptic connectivity have been carried out; some of these studies have focused on the prolonged synchronous discharges that are elicited in disinhibited, hippocampal slices from immature animals (compared to tissue from adult animals).

Synchronization Mechanisms for Interictal Spikes – Synaptic Activation of Ionotropic Glutamate Receptors and Network Simulation

Properties of CA3 pyramidal cells

Action potentials in CA3 pyramidal cells are followed by prominent depolarizing afterpotentials. Depolarizing afterpotentials often reach threshold to recruit additional action potentials, causing the firing of a cluster (burst) of 3–4 action potentials. Bursts of action potentials are a common form of spontaneous activity of CA3 pyramidal cells, recorded in vitro and in vivo. Burst firing can be viewed as a signal amplification process in that a single suprathreshold excitatory synaptic potential can trigger multiple action potentials from CA3 pyramidal cells.

In addition to somatic action potential firing, CA3 pyramidal cell dendrites can also generate independent bursts. The combined excitability of the soma-dendritic complex of CA3 pyramidal cell serves to increase the effectiveness of the recurrent synapses (between CA3 pyramidal cells) to synchronize the CA3 neuronal population (see below).

Properties of recurrent synapses between CA3 pyramidal cells

CA3 pyramidal cells are connected to each other via recurrent glutamatergic synapses. Recent in vitro data, using anatomical methods to trace the axon of single dye-filled CA3 pyramidal cells in hippocampal slices,

reveal that the recurrent network is the densest in the CA3a region, where each pyramidal cell axon makes up to 650 terminal contacts onto neighboring pyramidal cells. Data derived from paired recordings between CA3 pyramidal cells indicate that of unitary synaptic potentials have an average amplitude of 1.5 mV and synaptic conductance 1 nS. Recordings from CA3 pyramdical cells have also shown that the synaptic conductance underlying interictal-like synchronized discharges (recorded during disinhibition) is 70–300 nS (see below), indicating that single pyramidal cells receive 70–300 unitary excitatory synaptic inputs during the discharge. Given that each pyramidal cell can fire clusters of at least three action potentials during each interictal-like discharge, and that the recorded interictal-like event results from summation of synaptic potentials generated by these action potentials, a conductance of 70–300 nS for an interictal-like discharge suggests a lower limit of 23–100 presynaptic cell for each pyramidal cell; that is, on average, one pyramidal cell is functionally connected to 23–100 postsynaptic pyramidal cells.

Recurrent connections between CA3 pyramidal cells and interictal discharges

Recordings from pairs of CA3 pyramidal cells show that a burst generated in a single pyramidal cell has a 35% chance of causing action potential firing from its monosynaptically connected postsynaptic elements. Further, experimental and simulation studies show that, through the recurrent connection, single bursts in a pyramidal cell can initiate and pace synchronized discharges of the entire CA3 pyramidal cell population, when GABAergic inhibition is blocked. In addition to glutamatergic synapses between CA3 pyramidal cells, gap junctions, by enhancing cell–cell excitatory interaction and spiking activity, also significantly contribute to epileptic synchrony of the CA3 network.

Normally, the powerful synchronizing mechanism provided by the recurrent CA3 network is tightly controlled by feedforward and feedback inhibition mediated via local GABAergic interneurons. IPSPs are highly effective in stopping the spread of the excitatory wave in the recurrent network for two reasons: First, the conductance underlying unitary IPSPs (6–9 nS) is larger than that underlying the recurrent EPSPs (1 nS). Second, CA3 pyramidal cells are connected to GABAergic interneurons via a powerful monosynaptic excitatory connection; that is, a single action potential in a presynaptic pyramidal cell can elicit action potentials in postsynaptic GABAergic interneurons. An action potential in a single interneuron in turn elicits IPSPs in about 200 postsynaptic pyramidal cells. Thus, under normal circumstances, recurrent or feedforward inhibition serves to control excitatory spread within the CA3 pyramidal cell network and prevents the occurrence of hypersynchronized epileptiform discharges. This inhibitory control, and its variability in the face of a powerful recurrent excitatory network, is often viewed as a potential site of vulnerability that may lead to seizures.

Generation of Ictal-Like Discharges – Activation of Group I Metabotropic Glutamate Receptors (mGluRs)

Effects of mGluR activation on CA3 pyramidal cells

CA3 pyramidal cells normally generate spontaneous periodic bursts of 2–5 action potentials. The duration of a burst is less than 100 ms. Upon stimulation by a mGluR agonist, burst firing in CA3 pyramidal cells is significantly prolonged, reaching periods of 2–10 s. The prolongation in firing is caused by the activation of a voltage-dependent cationic current, $I_{\mathrm{mGluR(V)}}$. $I_{\mathrm{mGLuR(V)}}$ emerges following mGluR agonist exposure in CA3 pyramidal cells – but not in CA1 pyramidal cells. The current has a threshold around the resting potential of CA3 pyramidal cells (−65 mV) and its amplitude increases with depolarization. The current has a reversal potential of about −10 mV and shows no inactivation.

At the population level, mGluR agonist elicits ictal-like synchronized discharges of 2–10 s from the CA3 pyramidal cell population. mGluR-dependent ictal-like discharges have three notable properties. (1) As mentioned above, the discharge is long lasting. Further, once induced, ictal-like discharges persist for hours (invariably for the entire duration of recording time in an experiment) following the wash out of the inducing agonist. (2) Induction of mGluR-dependent ictal-like discharges is dependent on mRNA translation, and (3) $I_{\mathrm{mGluR(V)}}$ is a necessary cellular response underlying the expression of ictal-like discharges.

These data reveal that ictal-like discharges are elicited in CA3 population through mGluR agonist stimulation. The agonist changes the firing pattern of single CA3 pyramidal cells from burst firing of less than 100 ms to periodic prolonged firing of 2–10 s. Synchronization of mGluR activated CA3 pyramidal cells (with their altered mode of prolonged firing) via their powerful recurrent connection gives rise to ictal-like discharges.

Epileptogenesis: Synaptic Activation of mGluR-Dependent Ictal-Like Discharges

Application of DHPG stimulates synaptic and extrasynaptic mGluRs. For the mGluR-mediated epileptogenesis to be functionally relevant and activatable in the brain, the epileptogenesic process should be inducible by stimulation of synaptic mGluRs. Data obtained in wild type preparations show that, although mGluR-mediated epileptogenesis is elicited by DHPG, synaptic stimulation of mGluRs is not effective in inducing epileptogenesis. The reason for this apparent paradox is that, in wild type

preparations, synaptically stimulated mGluR-mediated mRNA translation is suppressed by fragile X mental retardation protein (FMRP), thereby preventing the induction of epileptogeneis. Absence of FMRP function is the cause of fragile X mental retardation syndrome (FXS). In a mouse model of FXS, in which FMRP is not functional, synaptic stimulation of mGluRs becomes effective in inducing epileptogenesis. In vivo studies show that FXS mice exhibit enhanced audiogenic seizure susceptibility that is sustained by exaggerated mGluR responses. The difference in DHPG versus synaptic stimulation of mGluR in wild type preparations, in terms of effectiveness in inducing epileptogenesis, is unclear. There are at least two explanations. First, FMRP may only regulate synaptically located mGluRs and not extrasynaptic mGluRs. Second, prolonged stimulation by DHPG (and not phasic synaptic stimulation) may cause proteolysis of FMRP via an activation of the ubiquitin-proteasome system, thereby abrogating the repressive effect of FMRP on mGluR-mediated mRNA translation (and thus enabling epileptogenesis).

Future Goals

The CA3 neuronal network has proved to be a useful tool for the study of basic mechanisms of epilepsy. Considerable understanding of the synchronization mechanisms underlying interictal discharges, and the process involved in ictal discharge generation, have been derived from in vitro preparations involving the CA3 neuronal network. In addition, the network provides a unique model for the study of signaling and plasticity mechanisms underlying one form of epileptogenesis – that of mGluR-dependent epileptogenesis. This mGluR-dependent process is likely to constitute a cause of epilepsy suffered by FXS patients. Efforts are now directed toward examining whether, and how, the mGluR form of epileptogensis can occur in subjects other than FXS patients. Regulation of the mGluR-stimulated translation process is a point of focus. In particular, vulnerability of the FMRP regulation sites will need to be explored and identified.

Although progress has been made mainly in the study of conventional 'chemical' synapses between CA3 neurons, recent studies suggest the presence of gap junctions between principal cells in hippocampal formation (i.e., between granule cells, and probably also between CA3 pyramidal cells). Both modeling and in vitro experimental data suggested that axonal gap junctions could account for very fast oscillations (>70 Hz), including ~200-Hz ripples, as well as play a critical role in the generation of persistent γ (30–70 Hz) and neocortical $\beta 2$ (20–30 Hz) oscillations. At present the function of gap junctions in neuronal synchronization in epilepsy is not well defined. That gap junctions may be important in epilepsy as has been suggested by EEG records showing high frequency oscillations (exceeding 100 Hz) that occur just before a seizure begins. More details are needed regarding the mechanisms by which gap junctions contribute to the very fast brain oscillations that can presage a seizure. Studies should also focus on whether attenuating or preventing these very fast oscillations can prevent seizures. Toward this end, preliminary in vitro studies have shown that carbenoxolone, a gap junction blocker, suppresses very fast oscillations and prevents subsequent epileptiform discharges.

Determinants of Neuronal Network Activity in Cultured Hippocampus

Introduction

Spontaneous network activity, expressed as synchronized, spreading bursts of action potential discharges over extended periods of time, is a typical attribute of all neuronal networks studied to date, both in vivo and in vitro. Intuitively, spontaneous activity is important for the development and refinement of connections among the neurons in the network, and may underlie the ability of the network to respond to afferent input in a dynamic fashion. Still, the mechanisms related to the triggering, spread, and the control of frequency, synchrony, and magnitude of the activity of the network remain elusive. Spontaneous network activity sometime goes astray, leading to the development of synchronized epileptic seizures. Such abnormal activity can last for the lifetime of the affected individual, and interferes with the person's ability to cope with the environment. Thus, understanding the mechanisms that regulate 'normal' network activity, while having its own merit, becomes extremely important as it may lead us to a better understanding of the conversion of network activity into an epileptic one.

Background

Several pertinent issues related to the generation of network activity have been dealt with only fragmentarily in recent years. One issue of major interest concerns the process of development and maturation of effective networks of synchronized activity. Among those issues, the questions related to network development are as follows: (1) Which are the crucial participants in network maturation? (2) Is activity in and of itself important for the organization of the network, or can the network develop in a situation where activity is blocked chronically? (3) Do excitatory or inhibitory synaptic activity speed up or slow down the development and activity of the network? (4) Since every neuronal network is composed of different cell types that are either intermingled (as is the case of the cerebral cortex) or are relatively clustered (as is the case of the hippocampus), what is the contribution of different cell types to the network activity? Finally and perhaps most importantly, is the network burst a collective behavior of many neurons, or are there 'master' neurons that entrain the network? In the latter case, who are these master neurons and what make them so unique?

A great deal of information has been gathered to characterize network activity in the intact brain. Cortical and hippocampal neuronal assemblies express different patterns of activity, associated with different 'states' of the organism, from slow delta rhythm (0.5–4 Hz), through theta (4–8 Hz), alpha (8–12 Hz) to fast gamma (12–80 Hz) oscillations. While it is quite clear that these rhythms involve synchronized activity of interneurons, the main issues that are pertinent to the understanding of the mechanisms of generation of these patterns remain elusive. A slow rhythmic bursting activity has been initially described in the developing hippocampus and later found in other brain areas, and this activity has been assumed to play a major role in the developmental organization of these structures. This rhythm is also present in the isolated hippocampus, indicating that the rhythm is genuinely intrinsic; however, the rules governing its generation are still elusive. It is virtually impossible to analyze these rules in the intact tissue, since it is hard to isolate

Introduction

Spontaneous network activity, expressed as synchronized, spreading bursts of action potential discharges over extended periods of time, is a typical attribute of all neuronal networks studied to date, both in vivo and in vitro. Intuitively, spontaneous activity is important for the development and refinement of connections among the neurons in the network, and may underlie the ability of the network to respond to afferent input in a dynamic fashion. Still, the mechanisms related to the triggering, spread, and the control of frequency, synchrony, and magnitude of the activity of the network remain elusive. Spontaneous network activity sometime goes astray, leading to the development of synchronized epileptic seizures. Such abnormal activity can last for the lifetime of the affected individual, and interferes with the person's ability to cope with the environment. Thus, understanding the mechanisms that regulate 'normal' network activity, while having its own merit, becomes extremely important as it may lead us to a better understanding of the conversion of network activity into an epileptic one.

Background

Several pertinent issues related to the generation of network activity have been dealt with only fragmentarily in recent years. One issue of major interest concerns the process of development and maturation of effective networks of synchronized activity. Among those issues, the questions related to network development are as follows: (1) Which are the crucial participants in network maturation? (2) Is activity in and of itself important for the organization of the network, or can the network develop in a situation where activity is blocked chronically? (3) Do excitatory or inhibitory synaptic activity speed up or slow down the development and activity of the network? (4) Since every neuronal network is composed of different cell types that are either intermingled (as is the case of the cerebral cortex) or are relatively clustered (as is the case of the hippocampus), what is the contribution of different cell types to the network activity? Finally and perhaps most importantly, is the network burst a collective behavior of many neurons, or are there 'master' neurons that entrain the network? In the latter case, who are these master neurons and what make them so unique?

A great deal of information has been gathered to characterize network activity in the intact brain. Cortical and hippocampal neuronal assemblies express different patterns of activity, associated with different 'states' of the organism, from slow delta rhythm (0.5–4 Hz), through theta (4–8 Hz), alpha (8–12 Hz) to fast gamma (12–80 Hz) oscillations. While it is quite clear that these rhythms involve synchronized activity of interneurons, the main issues that are pertinent to the understanding of the mechanisms of generation of these patterns remain elusive. A slow rhythmic bursting activity has been initially described in the developing hippocampus and later found in other brain areas, and this activity has been assumed to play a major role in the developmental organization of these structures. This rhythm is also present in the isolated hippocampus, indicating that the rhythm is genuinely intrinsic; however, the rules governing its generation are still elusive. It is virtually impossible to analyze these rules in the intact tissue, since it is hard to isolate

systematically the parameters that may contribute to the network activity and to study them later in isolation. For example, it is difficult to chronically expose intact tissue to drugs that block action potential discharges (e.g., tetrodotoxin), and study the effect on the maturation of the network. The few studies that employed such a method reported interesting observations on the outcome of a chronic blockade of cortical activity on hyperexcitability of the tissue. Also, it is impossible to vary systematically the proportion of excitatory and inhibitory neurons in a network in vivo.

The dissociated culture of cortical structures provides a convenient test system for the examination of the rules that govern the emergence, generation, and spread of network bursting in populations of densely interconnected neurons. Network activity can be recorded for extended periods of time in a noninvasive manner and with infinite time resolution using multielectrode arrays. Using such a method, spike activity of dozens of cells can be recorded simultaneously. However, even in this case, the recording is made of a select subpopulation of neurons, leaving the majority of neurons in the dish unseen. An alternative method involves imaging of action potential (spike)-associated changes in intracellular calcium concentrations of an entire network. This recording method, now used also in vivo, is limited to several hours after loading of the fluorophore; it can be used to detect changes in every cell and even specific compartments of the cell, but is limited by the sensitivity of the dye, the field of view of the objective, and the temporal resolution of the detection system (confocal microscope, high speed CCCD camera, etc). Needless to say, the dissociated culture is only an approximation of the network in vivo. It is raised in artificial growth medium, lacks blood supply and afferent innervation, and the cells may produce aberrant connections not found in vivo. Thus, whatever rules established in the dish need to be reexamined in vivo. Nonetheless, the ability to control the connectivity pattern of the cells and the growth conditions are unmatched in any in vivo experimental situation, allowing one to examine fundamental issues related to formation and operation of a small neuronal network. The following are illustrations of some of the issues relevant to neuron network study that can be tackled in cultured neurons.

Methods

Experiments are conducted with hippocampal or cortical neurons, dissociated from the brain of 1–3 day old pups and grown on glass coverslips, which were precoated with a glial bed (as detailed elsewhere). Recording of spontaneous electrical activity of individual neurons is made under an inverted, phase contrast microscopy, with a patch pipette, while imaging of population neuronal activity is made using the calcium sensitive dye Fluo-4AM. For these latter experiments, a high spatial and temporal resolution CCD camera is used to facilitate the detection and correlation of activities among several adjacent neurons in a spontaneously active neuronal network. Individual neurons can be recorded and stimulated while imaging all adjacent neurons at high resolution to detect presence and strength of connectivity between them.

Recent Results

The Development of Network Activity

When plated in a dish, most young neurons begin to express spontaneous action potential discharges almost as soon as they get attached to the surface and begin to send out processes. Following plating, cells develop morphological connections rather rapidly, and within 2 days in culture they already express networks of synaptic markers. However, at this early age, electrical activity is rather sporadic and little synchronicity among neurons can be found (**Figure 1**). It takes another day in culture before synchronized activity can be seen. Over the first week in culture, more neurons are recruited into the network, resulting in fully synchronized activity across neurons, likely to span the entire culture plate and endure for the entire life of the culture.

In assessing the importance of different neurotransmitter systems in the emergence of network activity and its maintenance, cultures were exposed to drugs that block excitatory synapses (DNQX), inhibitory synapses (bicuculline), or total action potential discharges (TTX). As expected, TTX and DNQX block ongoing activity. The GABAergic receptor antagonist has a peculiar effect; at early culture stages (up to one week in culture), blockade of GABA receptors causes silencing of any detectable spontaneous network activity, indicating that GABA possesses an excitatory drive, as suggested by previous work in acute slices. However at one week in culture, blockade of GABAergic receptors causes an enhancement of the burst discharge, indicating that GABA receptors are becoming inhibitory at this stage in culture.

A related issue concerns the role of excitatory and inhibitory neurotransmitters in the development of network activity. As indicated already, spontaneous network activity emerges between 3 and 7 days in culture, and matures over the following week. Will the blockade of all activity, or of only GABAergic or glutamatergic receptors, disrupt the emergence or maturation of the synchronized activity? To address this question, we exposed the cultures to a chronic (3 days) blockade of activity/receptors (from the day of plating), and found that neither blockade of specific receptors nor of action potential

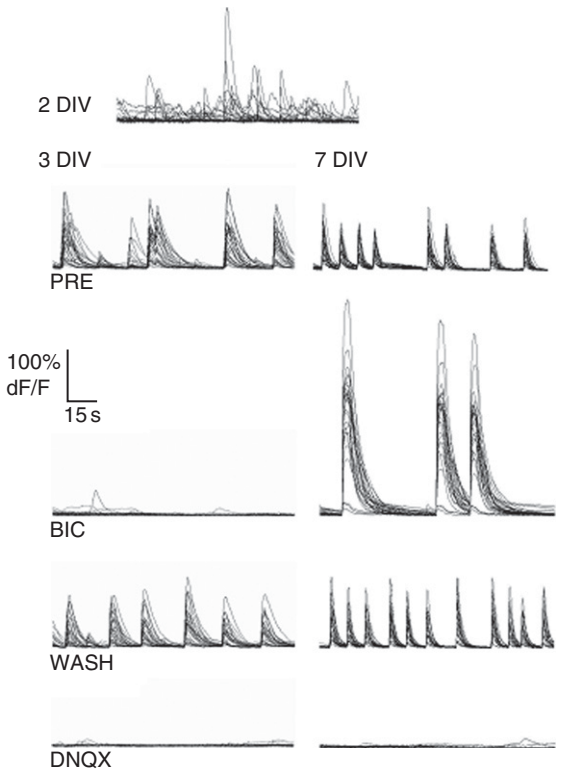

Figure 1 Development of network activity in culture. Cells were taken from the hippocampus of P1 pups, dissociated and grown in culture for 2–7 days. Activity of neurons in a 40× field of view of an inverted microscope was recorded using Fluo-4AM loaded neurons. Individual neurons were identified, and the variations in intracellular calcium concentrations, associated with action potential discharges, were recorded. In this and the following figures each line represents the calcium fluorescence in a single neuron, and the number of overlapping lines represent the number of cells in the field of view. At 2 days in vitro (2DIV) there is some spontaneous activity, but it is not synchronized. At 3 days in vitro, the activity is already partially synchronized, and each burst is long-lasting. At 7DIV more cells participate in a burst and each event is rather fast. Bicuculline, a GABA antagonist, blocks activity of a 3DIV culture, but enhances activity of a 7DIV culture. DNQX, a glutamate antagonist blocks network activity in both ages. Adapted from Cohen and Segal, in preparation.

generation prevented (or even delayed) the emergence of network activity. This result indicates that the initial growth of the dendrites/axons and the formation of functional connections are not dependent on ongoing activity of the neurons. The general issue of maturation of the activity is somewhat more complex, as the blockade of activity with TTX changes the morphology of the neurons, converts dendritic spines into long filopoda, and causes shrinkage of dendrites and eventual cell death. However, removal of TTX after a week of continuous blockade of activity allows spontaneous activity to reappear, as well as synchronization of the network (see later).

GABAergic interneurons play an important role in the synchronization of network activity and the timing of the individual bursts, as seen in vivo. The blockade of GABA receptors has been used traditionally, in many preparations, as a means for generating epileptic seizures, and indeed, blockade of GABAergic receptors produces a marked change in the behavior of the culture, in that bursts of activity are much larger and long-lasting than those of control cultures. However, synchronization persists in GABA-blocked cultures; in fact, the silent intervals between bursts become longer and more persistent. This observation suggests that other cellular mechanisms may assume control over the synchronization of activity when GABAergic transmission is blocked.

Generation and Spread of Activity

Two pertinent issues, important for the understanding the rules that govern network activity, concern the velocity of spread of the activity and the likelihood that activity is generated in only a small subset of neurons, To address these issues, we resorted to a one-dimensional culture that grows along a line in the culture dish. The advantage of such a network is that one can trace the origin of a burst of activity as well as the speed at which it spreads along the line, simplifying the more complex situation of a two-dimentional network where one cannot easily trace neither the origin of activity nor how it spreads. Imaging such network activity with Fluo-4 calcium sensitive dye (**Figure 2**), we were able to reach two important conclusions: First, network activity seems to originate in small, discrete regions along the length of the culture; these regions have a high probability of initiating bursts of activity. Although it is not yet clear what makes these 'trigger zones' so unique, it appears that the density of neurons in such a zone, as well as a high proportion of excitatory to inhibitory neurons, determine the likelihood that a burst will be initiated there. Second, the wave of activity spreads along the line of neurons in two modes: The first is a slow mode, which corresponds to slow synaptic connection, while the second is evident once the burst passes a local 'threshold,' after which it propagates rather rapidly. The speed of such a wave reflects both axonal and synaptic transmission along the line of neurons. The fast mode is within the range of the speed of transmission in typical unmyelinated fibers (**Figure 2**). The transmission of activity along the line of neurons in culture is also affected by local GABAergic inhibition such that GABA blockade speeds up the spread of the burst of activity.

Two more related experiments address the issue of how the network is 'driven' to produce spontaneous activity. The first study examines how many neurons in a network need to be interconnected in order to enable

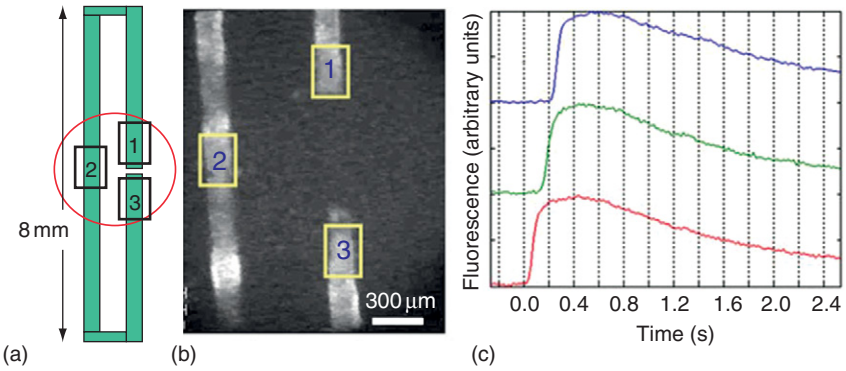

Figure 2 One-dimensional cultures used for the study of the origin and spread of network activity. (a). Illustration of a line of supportive material used to plate neurons, and the three regions of interest where activity, in the form of variations of calcium fluorescence, is recorded. (b) A close-up of these regions of interest. (c) A calcium transient recorded in regions 1–3, showing a distinct difference in latency to the event. The difference in threshold is used to calculate both the origin of the event and its spread. Adapted from Feinerman *et al*. (2007) Identification and dynamics of spontaneous burst initiation zones in unidimensional neuronal cultures. *Journal of Neurophysiology* 97: 2937–2948.

the expression of spontaneous synchronized activity. In other words, is there a 'critical mass' below which spontaneous activity will not be seen. The second study focuses on the question of whether a single neuron (rather than a mass of adjacent ones) can trigger a network burst? If so, what are the critical parameters needed for a neuron to be a 'master cell'? Furthermore, will the removal of this neuron affect the spontaneous activity of the rest of the network? These and other related questions are currently analyzed using small networks of neurons. Neurons are plated on islands of a glial bed, where the entire network can be visualized in the field of view of the microscope. The number of neurons in a small network varies between single cells and several hundreds of them. Spontaneous activity, as well as responses to spikes generated by depolarizing patch-clamped neurons, were visualized at high imaging frame rate of Fluo-4 dye loaded cells to enable the tracing of synaptic delays among the different cells in the field (**Figure 3**). The results can be tentatively summarized as follows: First, the larger the population of interconnected neurons, the more likely they are to express spontaneous network activity. The 'quality' of this network activity, expressed in the frequency of the burst activity and the magnitude of synchronicity among adjacent neurons, varies among the cultures – with the less dense cultures being more synchronized. Second, triggering a network event by stimulation of a single cell was negatively correlated with the number of neurons in the network. When the culture contains few neurons (10–100), the synaptic currents among them are large. In fact the largest synaptic currents are generated by autoptic synapses, in a single neuron culture (up to several µA, compared with 10–50 pA in a dense (10^5– 10^6 cells) culture. Thus, with few cells in a cluster, stimulation of one of them could evoke a large network burst, even if the network did not produce spontaneous events. With a larger network, synaptic currents between adjacent neurons are much smaller, and consequently, stimulation of one neuron could not trigger the generation of a network event.

The present series of studies indicate that spontaneous burst activity is an attribute of networks of neurons; that this, synchronous activity is an emergent property of the network that can appear even without 'training' of the network (i.e., in networks that were chronically silenced for several days after plating of dissociated neurons). Furthermore, the quality of the activity is correlated with the number of participating elements. We could not identify individual 'master' neurons that trigger activity to spread across the network; however, such a possibility cannot be ruled out. It is evident that small clusters of cells within the network can generate bursts of activity, which then spread across the entire network. Since our imaging method is not sensitive to synchronized subthreshold oscillations, we cannot rule out the possibility that such oscillations are responsible for the triggering of network discharge. This is subject for further explorations.

Network Activity – Kills or Heals

The dissociated culture can be used to address a fundamental question regarding the functional significance of network activity. On the one hand, neurons spend a great deal of energy to stay active in the absence of extrinsic afferent input. Given this situation, one would intuitively guess that spontaneous intrinsic activity has an instrumental role in maintaining survival of the neurons. On the other hand, small networks or even single neurons that do not express spontaneous network activity can be maintained for long periods of time in culture – so the significance of activity is not self evident. Enhancement of network activity – e.g., seizure activity that take place following blockade of

GABAergic synapses – leads to cell death both in vivo and in cultured hippocampal slices. Will enhanced activity of cells in dissociated culture result in neuronal death, and will cessation of activity salvage the hyperactive neurons?

To address these issues we exposed cultures to TTX for 1–2 weeks, and found that blockade of activity caused massive degeneration of the cultured neurons (**Figure 4**). In contrast, enhanced activity caused by blockade of

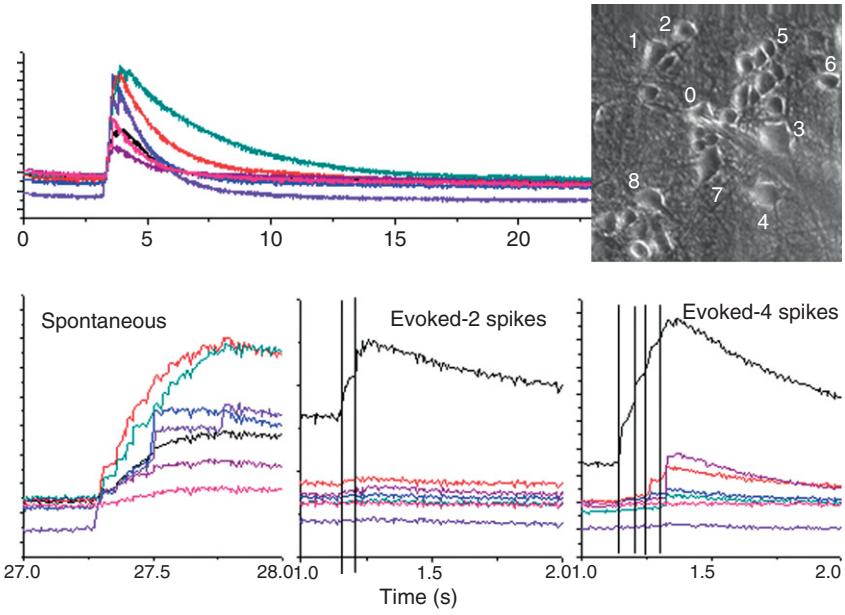

Figure 3 Calcium transients recorded at high resolution (200 Hz) of a population of neurons, in an attempt to identify threshold differences and to outline the spread of signals from one cell to another. Top image is a sample illustration of such a burst of activity, and a picture on the right illustrates the cells imaged and their sequence of firing. Below are one spontaneous event (left) and two events where one cell was recorded (illustrated above, patch in cell0) and stimulated to produce an action potential. Two action potentials did not evoke synaptic responses in the adjacent neurons, and 4 spikes (bottom right) produced a small response, but not a large synchronized burst, as seen in the spontaneous case (left). Adapted from Segal, unpublished observations.

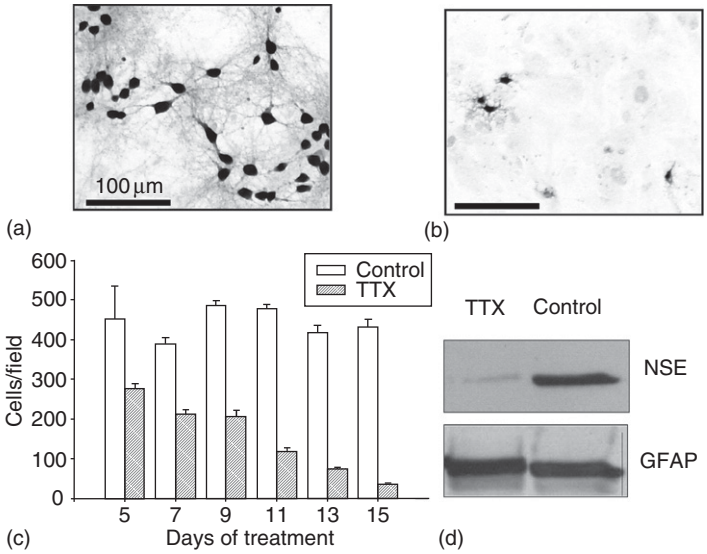

Figure 4 Tetrodotoxin kills neurons in culture, in a slow process. Cultured cortical neurons in control (a) and in TTX-treated culture (b). (c) The number of viable neurons is going down over 2 weeks of exposure to TTX, compared with controls. (d) Western blots to show that neuron specific enolase is drastically reduced, while GFAP, a glia marker, does not change. Adapted from Fishbein and Segal (2007) Miniature synaptic currents become neurotoxic to chronically silenced neurons. *Cerebral Cortex* 17: 1292–1306.

GABAergic receptors did not cause a significant cell loss. In an analysis of the causes of the cell death following secession of activity, we found that exposure to TTX caused a twofold increase in magnitude of miniature synaptic currents. Surprisingly, TTX-induced cell death was reversed by the addition of the AMPA receptor antagonist, DNQX, indicating that residual nonsynchronized activity (i.e., glutamate release in the absence of action potential discharge) is responsible for the cell death. Although we still analyze this unique action, it is obvious that network activity protects neurons from massive cell death, in the absence of supplementary growth factors and/or conditioning media.

Why is it that dissociated cultured neurons do not die during enhanced synchronized activity (epileptiform bursting discharge) caused by blockade of GABAergic receptors? There is no clear answer to this question. In fact, it is not entirely clear why neurons do die in other situations (e.g., via 'excitotoxicity'). After all, enhanced activity is supposed to cause a rather fast reduction in excitatory synaptic strength through a homeostatic mechanism. It is, of course, possible that this homeostatic plasticity is not sufficient to prevent continuous depolarization and influx of calcium in vivo, as hypothesized by some to underlie neuronal cell death. Other investigators have demonstrated that enhanced spontaneous activity in culture can last for hours, without the 'accommodation' expected from a homeostatic reduction in excitatory drive. One possibility is that neurons do not die as an immediate consequence of an increase in firing, or as a consequence of the depolarization leading to influx of calcium, but rather due to a downstream effect – e.g., an increase in reactive oxygen species. That latter change may not take place in cultured neurons because of the large extracellular space surrounding the neurons, which prevents the accumulation of hazardous diffusible chemicals in the neurons' immediate vicinity – unlike the neurons in vivo or in a slice, where the cells are densely packed and diffusion is slow.

Summary and Future Goals

Regardless of the possible causes of cell death in epilepsy, it is quite obvious that network activity per se supports survival of neurons, and that such activity can be maintained at high rates for months in dissociated cultured neurons that are deprived of extrinsic afferents. The rules that govern the generation and spread of network activity are being unveiled in these simple systems and are expected to shed light on similar, more complex systems of the intact brain. Future goals of this research include the identification of possible 'leader neurons' and the characterization of their biophysical, biochemical, and morphological properties. The use of more advanced molecular and imaging tools will allow investigators to activate and/or suppress selective neurons in a network, and to examine in more detail their effects on network properties. The role of trophic factors in the development and maintenance of network activity, and the balance of their effects on electrical activity and cell survival and elimination, should also be clarified. Finally, the sequence of molecular events leading to a slow, activity-regulated cell death, as well as the means for protecting cells from death, should be clarified.

Introduction

The co-existence of temporal lobe seizures in a patient with juvenile or childhood absence epilepsy is uncommon. This co-existence was reported to occur in <1% of the population with idiopathic generalized epilepsy. These clinical observations raise questions about how absence epilepsy and temporal lobe epilepsy might interact with each other so as to be mutually exclusive.

In line with these clinical observations, pharmacotherapy of given forms of epilepsy also suggests that cellular mechanisms of absence seizures differ from those of limbic focal seizures. Phenytoin, carbamazepin, oxcarbazepin, vigabatrin, and tiagabin are highly effective anticonvulsant agents in partial and/or secondary generalized focal seizures, whereas these agents may worsen typical absence and myoclonic seizures, and may trigger status epilepticus in patients with absence epilepsy.

Background

Increased basal levels of GABA have been demonstrated in the primary motor area of the cortex and in the ventrolateral thalamus of genetic absence epilepsy rats from Strasbourg (GAERS) when compared with those of non-epileptic Wistar controls. Further, the injection of $GABA_A$ or $GABA_B$ receptor agonists, and GABAergic drugs such as γ-vinyl GABA (an inhibitor of GABA transaminase) has been shown to increase the duration of spike-and-wave discharges in animal models of absence epilepsy as do drugs that increase GABAergic tonus in human absence patients. The exacerbation of absence seizures by excessive GABA-mediated activity is consistent with the hypothesis that this type of seizure is due to an imbalance between inhibition and excitation, with an abnormally strong inhibitory component. In contrast, neuropathological alterations in mesial temporal lobe epilepsy are associated with a relative increase in excitation, with an increased excitatory synaptic drive onto neurons and hyperexcitability of hippocampal cells. Enhanced glutamatergic activity is a main component of the hyperexcitability characteristic of epileptic discharge; cellular hyperexcitability of the hippocampal formation is one of the main processes underlying the progression of epileptogenesis in mesial temporal lobe epilepsy. For example, investigators have demonstrated that following a kindled seizure, there is a prolongation of *N*-methyl-D-aspartate (NMDA) channel openings in granule cells and enhanced NMDA receptor-mediated synaptic excitability for at least 60 days.

Taken together, the clinical, pharmacological and pathophysiological data suggest a critical difference in underlying mechanisms between mesial temporal lobe epilepsy and absence epilepsy. To show if or how these different seizure types might co-exist (or be mutually exclusive) it would be useful to have an animal paradigm. Studying such a paradigm could help elucidate interactions of different types of seizures in many clinical phenotypes, and help us understand the distinct mechanistic differences between focal secondary generalized convulsive and generalized non-convulsive seizures. Introduction

The co-existence of temporal lobe seizures in a patient with juvenile or childhood absence epilepsy is uncommon. This co-existence was reported to occur in <1% of the population with idiopathic generalized epilepsy. These clinical observations raise questions about how absence epilepsy and temporal lobe epilepsy might interact with each other so as to be mutually exclusive.

In line with these clinical observations, pharmacotherapy of given forms of epilepsy also suggests that cellular mechanisms of absence seizures differ from those of limbic focal seizures. Phenytoin, carbamazepin, oxcarbazepin, vigabatrin, and tiagabin are highly effective anticonvulsant agents in partial and/or secondary generalized focal seizures, whereas these agents may worsen typical absence and myoclonic seizures, and may trigger status epilepticus in patients with absence epilepsy.

Background

Increased basal levels of GABA have been demonstrated in the primary motor area of the cortex and in the ventrolateral thalamus of genetic absence epilepsy rats from Strasbourg (GAERS) when compared with those of non-epileptic Wistar controls. Further, the injection of $GABA_A$ or $GABA_B$ receptor agonists, and GABAergic drugs such as γ-vinyl GABA (an inhibitor of GABA transaminase) has been shown to increase the duration of spike-and-wave discharges in animal models of absence epilepsy as do drugs that increase GABAergic tonus in human absence patients. The exacerbation of absence seizures by excessive GABA-mediated activity is consistent with the hypothesis that this type of seizure is due to an imbalance between inhibition and excitation, with an abnormally strong inhibitory component. In contrast, neuropathological alterations in mesial temporal lobe epilepsy are associated with a relative increase in excitation, with an increased excitatory synaptic drive onto neurons and hyperexcitability of hippocampal cells. Enhanced glutamatergic activity is a main component of the hyperexcitability characteristic of epileptic discharge; cellular hyperexcitability of the hippocampal formation is one of the main processes underlying the progression of epileptogenesis in mesial temporal lobe epilepsy. For example, investigators have demonstrated that following a kindled seizure, there is a prolongation of *N*-methyl-D-aspartate (NMDA) channel openings in granule cells and enhanced NMDA receptor-mediated synaptic excitability for at least 60 days.

Taken together, the clinical, pharmacological and pathophysiological data suggest a critical difference in underlying mechanisms between mesial temporal lobe epilepsy and absence epilepsy. To show if or how these different seizure types might co-exist (or be mutually exclusive) it would be useful to have an animal paradigm. Studying such a paradigm could help elucidate interactions of different types of seizures in many clinical phenotypes, and help us understand the distinct mechanistic differences between focal secondary generalized convulsive and generalized non-convulsive seizures. Amygdala

kindling (with repetitive electrical stimulations) provides an animal model of focal epilepsy with secondary generalized limbic seizures; it is a well studied model of clinical mesial temporal lob seizures. Genetic absence epilepsy rat models, such as GAERS and Wistar Albino Glaxo Rats from Rijswijk (WAG/Rij), are among the best representatives of the human condition of typical absence epilepsy. We have investigated the course of kindling – an experimental model of temporal lobe epilepsy – in two well-validated genetic models of absence epilepsy: the GAERS, and the WAG/Rij. In addition, the effect of kindling on spike-and-wave discharges in these rat models was studied, the age-related effects of the kindling paradigm was investigated (conducting kindling in 30-day-old GAERS), and the effect of ethosuximide (a specific anti-absence agent) on kindling resistance was assessed in adult GAERS.

Methods

In the first group of experiments, we used adult non-epileptic control Wistar, GAERS, and WAG/Rij animals. Animals were equipped with stimulating/recording electrodes in the basolateral nucleus of the amygdala and recording electrodes in the fronto-parietal cortex bilaterally. After a recovery period of one week, animals were stimulated at their afterdischarge thresholds two times a day. The kindling stimulus, a rectangular current of 1 ms duration, at 60–80 Hz, was applied for 1–2 s. The EEG from amygdala and cortex were recorded continuously before and after the each stimulus. Racine's 5-stage scale was used for rating the behavioral development of kindling: stage 1, facial movements; stage 2, rhythmic head movements, head nodding; stage 3, unilateral forelimb clonus; stage 4, bilateral forelimb clonus and rearing; stage 5, bilateral forelimb clonus, loss of balance, and falling. Stages 1 and 2 are associated with focal limbic seizures, and stage 3, 4, and 5 are viewed as manifestations of generalized motor seizures. Animals showing two stage 5 seizures were accepted as kindled. If the animal did not reach stage 5 following the maximum number of 30 stimulations determined by the experimental protocol, electrical stimulation was terminated and the rat was labeled as 'kindling-resistant.'

In the second group of kindling experiments, adult GAERS were pretreated with intraperitoneal administration of ethosuximide (50 mg per kg, i.p.), which is known as a pure anti-absence drug and is not effective against kindling. The ethosuximide application was started after the determination of initial afterdischarge threshold on the first day of the experiment, and was then given 1 h before the electrical kindling stimulation. The effect of ethosuximide on the suppression of spike-and-wave activity was monitored from the cortical EEG.

In the third group, we applied kindling stimulations to postnatal 30-day-old GAERS. Spike-and-wave discharges in GAERS are first detected at about 30-days of age, and increased gradually with age to reach 100% at 3 months. The number and frequency of spike-and-wave discharges, and the duration of each complex, increased with age. Hence, we hypothesized that the immature animals – with immature spike-and-wave EEG activity – would provide an intriguing tool for investigating the effects on limbic kindling seizures on the development of thalamo-cortical activity (i.e., for the development of spike-and-wave generation). In these experiments, we used a kindling stimulus of 400 microA, 80 Hz alternate current, 1 ms pulse duration, 2 s train duration. The kindling stimulations were carried out at 90-min intervals (a maximum of 6 stimulations per day) in 30-day-old animals so that the experiments could be completed within a few days and thus avoid technical problems due to the ongoing head growth.

At the end of all three experiments, animals were killed and the electrode placements were checked for correct localization in the basolateral amygdala.

Recent Results

Kindling in Adult GAERS and WAG/Rij Animals

The afterdischarge thresholds of the groups were: 129 ± 7.1 μA in GAERS, 125 ± 17.1 μA in WAG/Rij, and 102 ± 14.2 μA in Wistar rats; there were no statistical differences among the groups ($P > 0.05$). The numbers of stimulations to reach stage 2 were comparable across groups, suggesting that the induction of the kindling process and of the limbic seizures was not different for the genetic absence epileptic and non-epileptic control animals. Interestingly, however, all GAERS and 3 of 12 WAG/Rij animals showed a resistance to the development of full kindling; they did not progress beyond stage 2 (**Figure 1**). Since they did not show any stage 3, 4, or 5 seizures when they were stimulated at their afterdischarge threshold, they were referred to as the kindling-resistant group; since all Wistar control animals and a group of WAG/Rij animals reached stage 5 and became kindled, they were referred to as kindling-prone. Importantly, once a WAG/Rij rat showed a stage 3 or 4 seizure, it quickly progressed to stage 5.

Our observations indicate that there is a resistance to generalization of limbic seizures in the absence epilepsy groups. This resistance was negatively correlated with the intensity (duration and number) of spike-and-wave discharges present on the baseline EEG of the GAERS and WAG/Rij animals. That is, GAERS and WAG/Rij rats having the highest number of spike-and-wave discharge in baseline EEG (before the kindling experiment started) were the least susceptible to kindling (**Figure 2**).

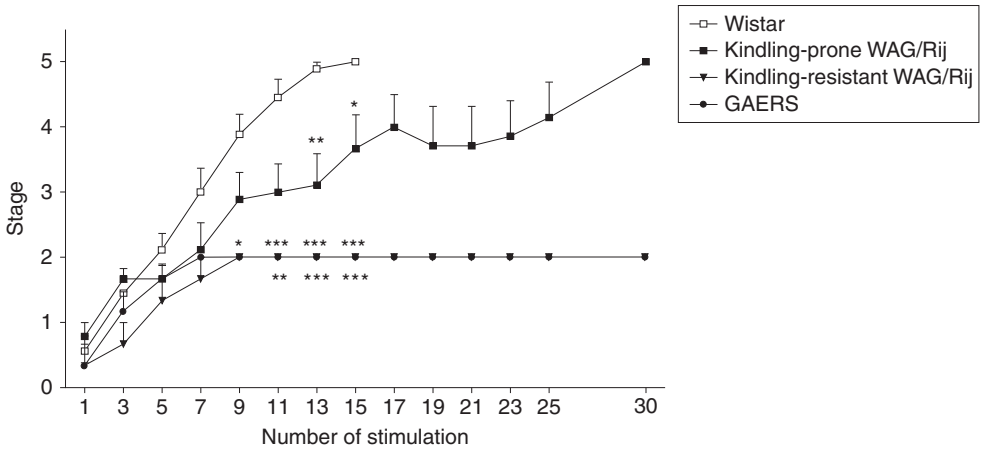

Figure 1 Seizure stages in non-epileptic Wistar control (n = 9), kindling-prone WAG/Rij (n = 9), kindling-resistant WAG/Rij (n = 3), and GAERS (n = 6) rats. Data are expressed as mean ± SEM. Two-way analysis of variance was performed for the first 15 stimulations of the groups because all the animals in the control Wistar group reached stage 5 seizures and were not stimulated beyond the 15th stimulation. *$p < 0.05$, **$p < 0.01$ and ***$p < 0.001$, significant differences between Wistar control and other groups.

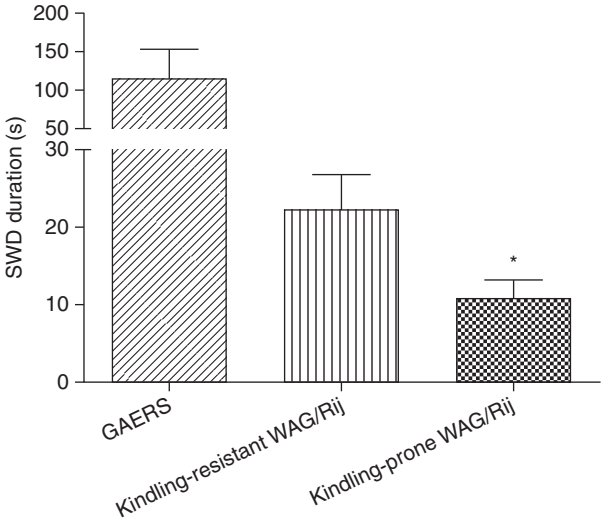

Figure 2 Basal spike-and-wave discharge (SWD) duration of GAERS (n = 6), kindling-resistant WAG/Rij (n = 3), kindling-prone WAG/Rij (n = 9) rats. Data are expressed as mean ± SEM of first five stimulations. *, $p < 0.05$, significant difference between GAERS and kindling-prone WAG/Rij. Modified from Onat *et al.* (2007) *Epilepsia* 48 (Suppl. 5): 150–156, with permission.

Other findings, such as decreased density of glutamate immunolabeling in mossy fiber terminals in the hilar region of GAERS compared to control rats, and reduced number of spike-and-wave discharges after intrahippocampal administration of tiagabine (an inhibitor of GABA reuptake) in the CA1–CA3 region of the dorsal hippocampus, also suggest that there is some limbic involvement in absence epilepsy. These results are consistent with imaging studies in these genetic models of absence, showing hippocampal activation associated with spike-and-wave discharge.

Kindling in Adult GAERS Pretreated with Ethosuximide

Since the resistance to kindling in absence epileptic animals showed a significant negative correlation ($r = -0.789$; $p < 0.001$) with spike-and-wave activity, we treated GAERS with ethosuximide (50 mg per kg, i.p.), an anti-absence drug, to see if this resistance could be broken-down by the pharmacological suppression of spike-and-wave activity. Ethosuximide effectively suppressed spike-and-wave activity in the EEG. Further, GAERS pretreated with ethosuximide progressed to stage 3 or 4, showing a partial drug effect on kindling resistance. Ethosuximide also delayed the development of kindling in Wistar control animals (**Figure 3**).

Kindling in 30-Day Old GAERS

We compared the resistance to amygdala kindling in 30-day-old non-epileptic Wistar rats vs. 30-day-old GAERS (an age when the first spike-and-wave discharges are observed) (**Figure 4**). All of the non-epileptic 30-day-old Wistar rats reached the stage 5 seizure state by the 18th stimulation. Of nine 30-day-old GAERS rats, seven animals reached stage 5 seizures by the 33th stimulation; two failed to reach stage 3, 4, or 5 seizures and stayed at stage 2, even after the application of 36 stimulations (**Figure 5(a)**). Statistical analysis showed a significant difference between the kindling rates of non-epileptic Wistar and the kindling-prone subgroup of GAERS ($p < 0.001$). The mean number of stimulations needed for the development of first stage 5 generalized seizure was 14.9 ± 1 for the non-epileptic Wistars and 29.6 ± 1.1 for the kindling-prone subgroup of GAERS. Statistical analysis revealed a significant difference in the mean number of stimulations for the development of

the first stage 3, 4, and 5 seizures between the non-epileptic control and the kindling-prone subgroup of GAERS rat groups ($p < 0.001$) (Figure 5(b)). No significant difference was found between the afterdischarge durations of 30-day-old GAERS and non-epileptic Wistars.

These findings suggest that resistance to kindling may be related to the existence of absence epilepsy and changes in the circuits that are responsible for the production of spike-and-wave activity. Taken together, the evidence indicates that pre-existing absence activity inhibits secondary generalization of the kindling progress in GAERS and the kindling-resistant WAG/Rij, and significantly retards kindling in the kindling-prone subpopulation of WAG/Rij animals. Absence activity appear to have an antagonistic effect on generalization of limbic seizures, suggesting an opposition between the mechanisms underlying limbic epilepsy and absence epilepsy (at least in our animal models). Interestingly, bilateral synchronization of the hippocampi during spike-and-wave discharges has recently been demonstrated in chemical absence epilepsy model in rat, showing a potential interplay between hippocampal (TLE-associated) circuits and those involved in absence seizure generation.

We have also shown that the spike-and-wave activity increases immediately after a kindling stimulation (i.e., during the 10 min poststimulation period) in kindling-prone WAG/Rij animals (Figure 6). This observation suggests that the kindling stimulations cause an activation of cortico-thalamo-cortical circuitry that is responsible for the production and maintenance of spike-and-wave activity. These results also suggest a reciprocal interaction between the secondary generalization of limbic seizures (e.g., during stage 3 kindling) and absence epilepsy.

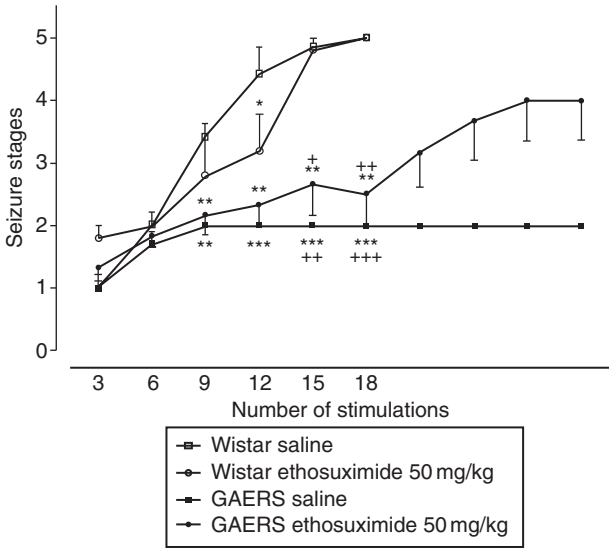

Figure 3 The effect of repeated kindling stimulations on seizure stage in Wistar and GAERS pretreated with saline or 50 mg per kg ethosuximide i.p. before each stimulation. Data are expressed as mean ± SEM. * ($p < 0.05$), ** ($p < 0.01$), *** ($p < 0.001$) indicate significant differences when compared with Wistar saline group; +($p < 0.05$), ++($p < 0.01$), +++($p < 0.001$) indicate significant differences when compared with Wistar ethosuximide 50 mg per kg pretreatment group with two-way analysis of variance fallowed by post hoc Bonferroni test.

Future Goals

These findings all point to interactions between the cortico-thalamo-cortical and the limbic circuits, but do not show how these interactions occur or in which parts of the brain the kindling resistance acts. Thus, there is a need to investigate further the links between absence epilepsy and limbic circuitry. One possibility link deserving attention is connection between the amygdala and the limbic nuclei of the thalamus (such as the mediodorsal, centromedial, and anterior nuclei). These nuclei have two-way connections to the rostral part of the thalamic reticular nucleus and to the limbic part of the reticular nucleus. It has recently been shown that this part of the thalamic reticular nucleus also receives hippocampal input. Thus, the thalamic reticular nucleus can receive excitatory input through its limbic connections from the amygdala, enthorhinal, and piriform cortices during kindling, and in turn might influence thalamo-cortical activity. These connections of the rostral thalamic reticular nucleus with limbic structures, through the limbic thalamic nuclei, may be particularly relevant for understanding the resistance to secondary generalized convulsive seizures in the genetic absence epilepsy models, or

elucidating the increases in spike-and-wave discharges induced by kindling.

Another possibility to explain this kindling resistance is the propagation of limbic seizures to cortical structures such as the parietal cortex. The spread of seizure activity to the somatosensory part of the parietal cortex would trigger cortico-thalamo-cortical activity, leading to an increase spike-and-wave activity in the poststimulation period. This cortical activation then could limit motor manifestations of limbic seizures through activation of the basal ganglia. A study of the role played by the limbic nuclei of the thalamus or by the basal ganglia in the kindling-resistance of genetic absence epilepsy models may prove to be an important study for the future.

Introduction

Limbic neuronal circuits are involved in normal brain functions (e.g., memory and learning) and in pathological processes such as the seizures occurring in TLE, a common form of partial epilepsy. Temporal lobe epilepsy is associated with a pattern of brain damage known as mesial temporal (also termed *Ammon's horn*) sclerosis that may significantly alter the modes of interaction among limbic areas. The sclerotic hippocampus presents with almost complete loss of CA1 neurons (the Sommer sector), especially at the boundary with the subiculum, as well as disappearance of hilar cells in the dentate gyrus (endfolium sclerosis). Neuronal cell loss is also found in the medial EC (especially in layer III) and in the amygdala. Recent evidence obtained from studies performed in animal models mimicking TLE suggests that the pattern of neuronal damage found in Ammon's horn sclerosis cuts off the normal physiological route of hippocampal network activity (the trisynaptic hippocampal pathway), thus reinforcing the activity of direct connections between EC-CA1 (when spared) and EC-subiculum. These findings have challenged the more traditional view that has emphasized the role played by dentate gyrus damage and consequent mossy fiber sprouting in epileptogenesis. Understanding the pathophysiogenesis of TLE remains an important challenge in epilepsy research.

Background

The parahippocampal region conveys information of neocortical origin into the hippocampus and redistributes back projections from the hippocampus into the temporal neocortex. The parahippocampal region includes the perirhinal/postrhinal cortex (PC), which borders the temporal neocortex, the EC interposed between the PC and the hippocampus proper (that is composed by the CA1, CA2, and CA3 subfields), and the subicular complex (in turn, consisting of pre- and parasubiculum and subiculum – although some authors consider the subiculum to be part of the hippocampus proper since it represents the most lateral extension of the CA1 region). The reciprocal connections between parahippocampal cortices, hippocampus, and temporal neocortex are highly preserved phylogenetically.

Introduction

Limbic neuronal circuits are involved in normal brain functions (e.g., memory and learning) and in pathological processes such as the seizures occurring in TLE, a common form of partial epilepsy. Temporal lobe epilepsy is associated with a pattern of brain damage known as mesial temporal (also termed *Ammon's horn*) sclerosis that may significantly alter the modes of interaction among limbic areas. The sclerotic hippocampus presents with almost complete loss of CA1 neurons (the Sommer sector), especially at the boundary with the subiculum, as well as disappearance of hilar cells in the dentate gyrus (endfolium sclerosis). Neuronal cell loss is also found in the medial EC (especially in layer III) and in the amygdala. Recent evidence obtained from studies performed in animal models mimicking TLE suggests that the pattern of neuronal damage found in Ammon's horn sclerosis cuts off the normal physiological route of hippocampal network activity (the trisynaptic hippocampal pathway), thus reinforcing the activity of direct connections between EC-CA1 (when spared) and EC-subiculum. These findings have challenged the more traditional view that has emphasized the role played by dentate gyrus damage and consequent mossy fiber sprouting in epileptogenesis. Understanding the pathophysiogenesis of TLE remains an important challenge in epilepsy research.

Background

The parahippocampal region conveys information of neocortical origin into the hippocampus and redistributes back projections from the hippocampus into the temporal neocortex. The parahippocampal region includes the perirhinal/postrhinal cortex (PC), which borders the temporal neocortex, the EC interposed between the PC and the hippocampus proper (that is composed by the CA1, CA2, and CA3 subfields), and the subicular complex (in turn, consisting of pre- and parasubiculum and subiculum – although some authors consider the subiculum to be part of the hippocampus proper since it represents the most lateral extension of the CA1 region). The reciprocal connections between parahippocampal cortices, hippocampus, and temporal neocortex are highly preserved phylogenetically.

Interactions within the parahippocampal region and between the parahippocampal region and the hippocampus

proper have been analyzed with electrophysiological techniques both in vivo and in vitro. Neurons in layers II and III of the EC target different subfields of the hippocampus, with different species specificity: In the rat and monkey, layer II connects the EC to the dentate gyrus and CA3, while layer III projects to CA1 and subiculum; however, in the mouse, EC layer II sends terminals to dentate gyrus only and the hippocampus is innervated by layer III. PC and EC are strictly and reciprocally interconnected.

Depth electroencephalographic (EEG) recordings in TLE patients have shown that epileptic discharges are recorded from the hippocampus and parahippocampal areas. Two different types of interaction between the hippocampus and EC have been identified. The first type is characterized by coupling between the EC and hippocampus, in which the latter is the 'leading' (i.e., seizure-initiating) structure. In this pattern of epileptic activity, seizures are initiated by low-frequency (<2 Hz) spikes – generated in the hippocampus, not in the EC – that are subsequently followed by fast activity. The second type of interaction consists of tonic discharges without preictal spiking, which appears simultaneously in the hippocampus and EC; in this type of activity, the EC more frequently takes the lead. Studies in animal models have demonstrated that preictal (defined as *interictal* in these studies) spiking activity can precede the ictal discharge. However, in these models, low-frequency stimulation that induces spiking activity was found to control, rather than to trigger, tonic (i.e., ictal) discharges. We will consider here these findings by addressing three main issues: (i) the contribution and the interaction of different limbic neuronal networks to epileptiform synchronization, (ii) the relationship between interictal and ictal activities, and (iii) the roles of subiculum and PC in controlling the spread of epileptiform discharges.

Methods

For studies on the whole isolated guinea pig brain, adult Hartley guinea pigs (150–200 g) were used according to standard procedures (see DeCurtis, this volume). Following anesthesia with sodium thiopental (125 mg kg^{-1} i.p.) and transcardial perfusion with a cold (10 °C) carboxygenated (95% O_2, 5% CO_2) saline solution (composition: 126 mM NaCl, 3 mM KCl, 1.2 mM KH_2PO_4, 1.3 mM $MgSO_4$, 2.4 mM $CaCl_2$, 26 mM $NaHCO_3$, 15 mM glucose, 2.1 mM HEPES, and 3% dextran M.W. 70 000, pH = 7.1), brains were dissected out, transferred into the recording chamber, and perfused with the saline solution (15 °C, pH = 7.3) via a cannula inserted into the basilar artery. Brain temperature was slowly raised to 32 °C to perform electrophysiological recordings that were obtained from different hippocampal–parahippocampal subfields with micropipettes or 16-channel silicon probes, positioned under direct visual control. Experiments in brain slices maintained in vitro were made according to standard procedures. Epileptiform activity was induced by drugs such as bicuculline or 4-aminopyridine, dissolved in the perfusate and applied via the resident arterial system (whole brain experiments) or to the bath (slices experiments).

Results

Region-Specific Propensity to Epileptiform Synchronization

Field recordings obtained from extended brain slice preparations (which include interconnected limbic structures, **Figure 1(a)**) have demonstrated the occurrence of several types of synchronous events during application of artificial cerebrospinal fluid containing convulsant drugs (such as 4-aminopyridine), nominally zero Mg^{2+}, or cholinergic agents (such as pilocarpine). The most impressive pattern (**Figure 1**, continuous lines in (a) and (b)) consists of a prolonged discharge – lasting several seconds – that is reminiscent of the EEG activity seen during a seizure in vivo (therefore, referred to as 'ictal discharge' in this article). This discharge is initiated by EC, PC, or amygdala networks. Other types of spontaneous epileptiform events have durations shorter than few seconds, thus resembling the interictal discharges occurring in epileptic patients between seizures. In these in vitro models of epilepsy, one type of interictal discharge (arrows in **Figure 1(a)** and **1(b)**) occurs at short intervals and is often confined to the hippocampus proper, where it originates in the CA3 area; the other type of interictal activity (asterisks in **Figure 1(a)** and **1(b)**) has a slower rate of occurrence, is recorded from all limbic areas, and often initiates outside the hippocampus. These two types of discharges will be referred to as 'CA3-driven' and 'slow' interictal discharge, respectively.

Ionotropic glutamatergic receptor-mediated mechanisms contribute to the interictal and ictal activity recorded from limbic networks in vitro. In addition, the generation of ictal events usually depends on NMDA receptor activation; in the EC, ictal generation appears to reside in the deep layers, in which a significant loss of interneurons occurs. Paradoxically, $GABA_A$ receptor-mediated conductances may also be required for the occurrence of ictal discharges (as shown in the 4-aminopyridine as well as in other models of epileptiform synchronization), suggesting that interneuronal networks actively participate in the initiation and the spreading of electrographic seizures.

Ictal–Interictal Relationships

Evidence emerging from in vitro studies indicates that interictal discharges can have both anti- and proseizure

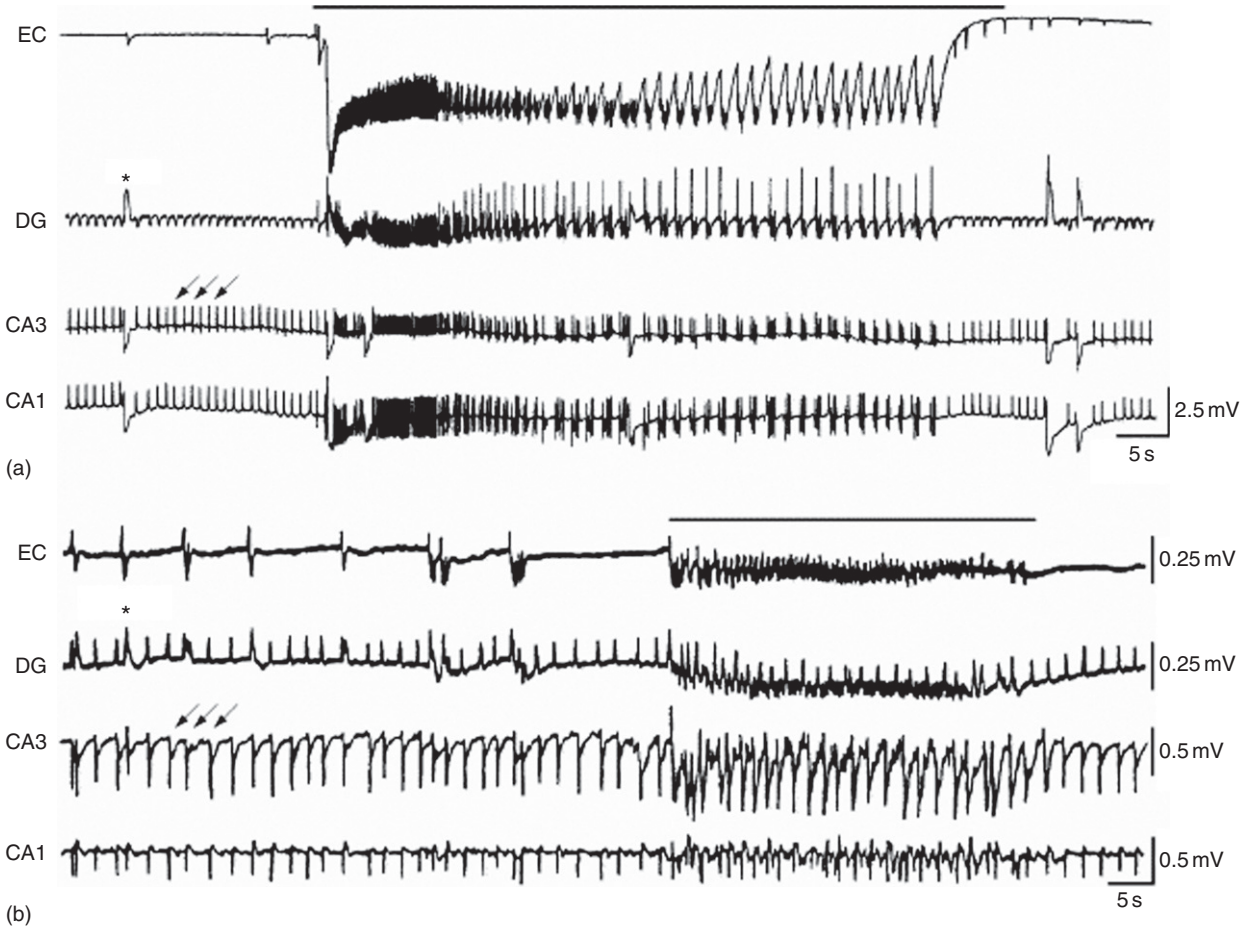

Figure 1 Synchronous epileptiform activities induced in hippocampus–entorhinal cortex slices that were obtained from adult rats during bath application of 4-aminopyridine (4-AP; 50 μM, (a)) or pilocarpine (10 μM, (b)). Note that in both cases three different types of discharges are evident. First, a continuous pattern of interictal discharges (arrows) that are confined to the hippocampus proper (note that their presence in the dentate gyrus reflects volume conduction of the signal generated by the CA3 network). Second, a slower type of interictal discharge that is seen in entorhinal cortex, dentate gyrus, and CA3 and CA1 subfields (asterisks). Third, a long-lasting discharge that resembles an ictal event and is recorded in all areas of the slice as well (continuous lines). EC, entorhinal cortex; DG, dentate gyrus. Reproduced from Avoli M, D'Antuono M, Louvel J, *et al*. (2002) Network and pharmacological mechanisms leading to epileptiform synchronization in the limbic system in vitro. *Progress in Neurobiology* 68: 167–207.

actions. As shown in **Figure 2(a)**, ictal discharges disappear in these brain slices within 1–2 h of treatment with proepileptic agents, while the CA3-driven interictal activity occurs throughout the experiment. Moreover, ictal discharges can be reestablished in these slices following a cut of the Schaffer collaterals, which connect CA3 to CA1. Transection of the Schaffer collaterals abolishes the propagation of CA3-driven interictal events to the EC (where ictal events are initiated) (**Figure 2(b)**). These experiments therefore demonstrate that interictal activity originating from the hippocampus proper can control, rather than sustain, the ability of EC networks to generate ictal events. Similar evidence has been obtained from brain slices that included the PC, the amygdala, or the insular cortex; in these experiments, CA3-driven interictal spikes prevented ictal generation in these other brain areas.

Further support for the view that CA3-driven interictal activity exerts antiseizure actions stems from experiments in which ictal discharges recorded in parahippocampal areas, following Schaffer collateral cut or surgical separation from the hippocampus, could be blocked by electrical stimuli at rates that are similar to those of the CA3-driven interictal activity (i.e., ~1 Hz). In addition, an inverse relationship between ictal and interictal discharges is seen in hippocampal slices when using pharmacological procedures (such as baclofen application) that depress interictal events. Epileptic rats and mice present with a significantly decreased frequency of interictal spikes. Finally, it has been reported in the in vitro isolated guinea pig brain that periodic interictal spiking in the piriform cortex prevents the involvement of this region in seizure-like (ictal) activity generated in the EC-hippocampus.

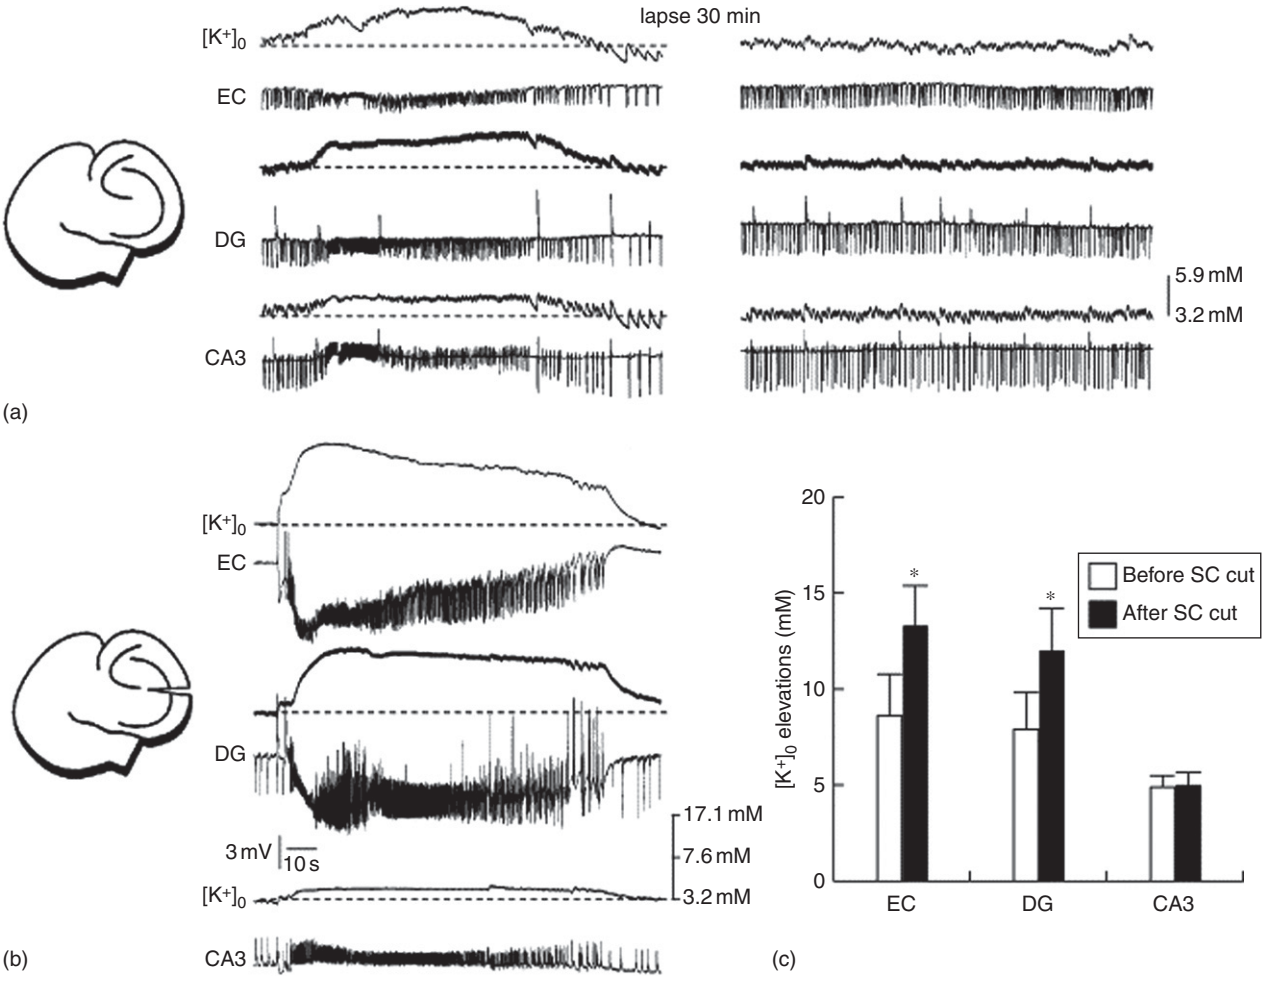

Figure 2 Effects induced by cutting the Schaffer collaterals on the 4-AP-induced epileptiform discharges and the associated $[K^+]_o$ rises in the EC, dentate, and CA3 areas. (a) Field and $[K^+]_o$ measurements of 4-AP-induced epileptiform activity in the intact hippocampus-EC slice before (left panel) and after (right panel) ictal discharges stop occurring. (b) After Schaffer collateral cut, ictal discharges are disclosed and their associated rises in $[K^+]_o$ are larger than prior to Schaffer collateral cut in the dentate gyrus and EC. Note the different calibrations of the $[K^+]_o$ before and after the cut. (c) Summary of effects of Schaffer collateral cut on $[K^+]_o$ rises associated with ictal activity in different limbic areas. Schaffer collateral cut results in both dentate and EC sectors in significant ($P < 0.05$, asterisks) increases in $[K^+]_o$ elevations associated with ictal discharges as compared with the intact slice preparation. Note also that the $[K^+]_o$ increases associated with ictal activity are comparable in the dentate and entorhinal cortex both before and after Schaffer collateral cut, and that they are significantly lower in CA3. Note also that Schaffer collateral cut does not affect the changes in $[K^+]_o$ associated with CA3 ictal discharge. Measurements were obtained from seven slices for dentate and EC and from five slices for CA3. Modified from Barbarosie M, Louvel J, Kurcewicz I and Avoli M (2000) CA3-released entorhinal seizures disclose dentate gyrus epileptogenicity and unmask a temporoammonic pathway. *Journal of Neurophysiology* 83(3): 1115–1124, with permission of the American Physiological Society.

The mechanisms responsible for the antiseizure action exerted by the fast CA3-driven interictal activity are unclear. Studies in animal models of epileptiform activity and in patients with neocortical epilepsy indicate that interictal spikes are followed by a prolonged period of inhibition during which the threshold for the generation of an epileptic discharge is increased; therefore, it is plausible that ongoing interictal activity can support a state of inhibition that is not favorable for the initiation or maintenance of ictal synchronization. Alternatively, a decrease in ictal discharge occurrence may result from activity-dependent (i.e., driven by the CA3-driven interictal events) changes in excitability that lead to depression of slow interictal discharge. Indeed, the slow interictal events are associated with transient elevations in $[K^+]_o$, and are often seen immediately preceding ictal onset; they are, therefore, hypothesized to play a critical role in initiation of electrographic seizure activity. Consistent with this view, data obtained in the 4-aminopyridine model suggest that the elevations in $[K^+]_o$ associated with the slow interictal discharges increase in amplitude once CA3-driven interictal events stop entering the EC

network (i.e., after cutting the Schaffer collaterals); in addition, increases in $[K^+]_o$ characterize the initial component of the ictal event (**Figure 2**). It is well established that extracellular K^+ can modulate neuronal excitability. Ictal discharge onset recorded intracellularly from EC neurons during 4-aminopyridine application is characterized by a long-lasting depolarizing event resembling the depolarization seen during a slow interictal event.

The Subiculum as a Gate of Hippocampal Input–Output Activity

GABAergic circuits within the subiculum control the spread of CA3-driven interictal events to the EC and to other parahippocampal areas. Hence, the subiculum does not represent a simple anatomical exit relay for hippocampal output activity, but rather a structure that can dynamically process the hippocampal outputs directed to downstream structures. This characteristic of the subiculum is relevant to understanding its role in the spread of seizures. For example, in patients where the epileptogenic focus has been localized to the hippocampus, any reduction in subicular inhibitory networks could provide a means for hippocampal seizures to generalize. However, if CA3-driven activity has the ability to reduce seizure occurrence (as discussed earlier), then changing levels of inhibition at the level of the subiculum will modulate the efficacy with which these CA3 discharges control ictal generation in parahippocampal areas.

It has also been shown that in combined hippocampus-EC slices obtained from chronically epileptic rodents, the subiculum supports EC ictogenesis, and can also provide a monosynaptic bypass for seizure activity to enter the hippocampus proper via the temporoammonic pathway. Although loss of principal cells in TLE brains is minimal in the subiculum, cellular and network reorganization within the epileptic subiculum may confer this structure with the propensity to sustain abnormal synchrony and hyperexcitability. Accordingly, in vitro studies in human epileptic tissue have demonstrated the presence of spontaneous interictal activity originating within the subiculum and spreading to adjacent hippocampal regions.

The Role of Perirhinal Cortex in Limbic Seizure Propagation

Seizure activity has been recorded in the parahippocampal region of the guinea pig isolated brain maintained in vitro, either using multiple extracellular electrodes or by analyzing optical signals measured after brain impregnation with voltage-sensitive dyes. These recordings have shown that reciprocal propagation of excitation between the PC and the EC is under the control of feed-forward inhibitory circuits. Stimulation of the neocortex or the PC, both in the in vitro isolated brain and in PC tangential rat slices, induced small-amplitude responses in the EC characterized by a prominent inhibition. The reciprocal propagation of activity from the EC to the PC is also highly regulated by intrinsic inhibitory connections. In vivo studies, in which spontaneous fast activities in EC and PC have been correlated, support the conclusion that these two regions show a low degree of functional interaction under conditions of normal excitability, even though they are directly connected.

To explore the effects of reduced inhibition on the interactions between EC and PC, experiments were carried out in which we injected $GABA_A$ receptor antagonists locally into these parahippocampal structures. $GABA_A$ receptor blockade resulted in enhanced propagation of activity from the PC to the EC. These studies revealed that the area responsible for the functional control of the interaction between these two regions resides in the lateral part of the EC and in area 35 of the PC. Local injections of bicuculline into these regions promoted propagation of synaptic responses evoked by local PC stimulation across the rhinal sulcus (Biella *et al.*, 2008; cf. citation at the end of this chapter). These findings strongly support the notion of a gating function of feed-forward inhibitory projections, in controlling PC-to-EC connectivity.

Notably, seizures induced by systemic application of bicuculline were initiated in the EC-hippocampus and did not show a tendency to propagate into the PC. The latter regions were recruited into the epileptiform discharge only after several seconds, when excitability built up to generate large-amplitude afterdischarges correlated with a highly synchronous activity throughout the hippocampus. Moreover, PC was progressively recruited when seizures were reiterated by repeated bicuculline applications, suggesting that an activity-dependent release/blockade of the inhibitory control between EC and PC developed over time, promoting the propagation of epileptiform discharges from the hippocampal-EC region to the PC (and from there to the neocortex) (**Figure 3**). That is, these findings suggest that an activity-dependent disinhibition may occur in the PC, as a consequence of complex dynamic changes in excitability supported by ictal discharges in the PC. The increasing involvement of PC during repetitive ictal discharges supports this hypothesis.

In vivo studies in the rat have shown that the rostral part of the PC, at the border of the insular cortex, is critical for the development of kindling, suggesting that this region is involved in the early stages of the establishment of an experimental temporal lobe epilepsy. In vitro recordings from the same rostral PC area support a distinct role for this region in ictal discharge initiation that is independent of activity generated in the hippocampus. Taken together, these experimental results lead to the hypothesis that a breakdown in the inhibition that characterizes the interactions between the PC and the EC may initiate hyperexcitability within these circuits, thus promoting limbic epileptogenesis.

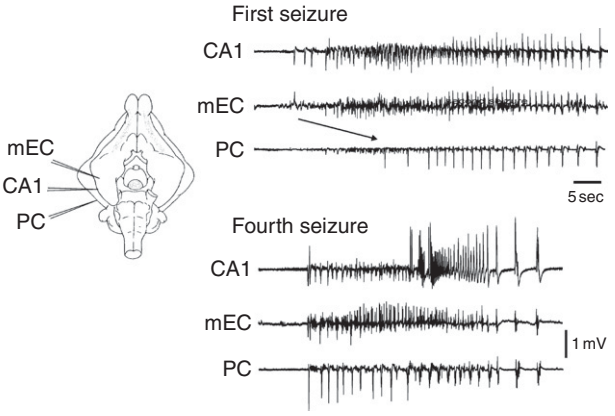

Figure 3 Simultaneous recordings from the hippocampus (area CA1), medial entorhinal cortex (mEC), and perirhinal cortex (PC) of the in vitro isolated guinea pig preparation during seizures induced by a single arterial perfusion of 50-μM bicuculline methiodide. Note that PC recruitment is stronger and occurs earlier when seizures are repeated within the same experiment (bottom panel).

Conclusions and Directions for Future Research

Evidence obtained to date indicates that neuronal networks in the hippocampus proper and in parahippocampal regions interact to produce synchronous patterns of epileptiform activity. Studies performed in in vitro brain slice preparations highlight a protective role played by hippocampal output with respect to seizure generation in parahippocampal areas. Such a mechanism may be relevant in TLE, a neurological condition where damage of hippocampal areas is a consistent finding. In this context, a pivotal role may be played by the subiculum, which appears to be the gate of hippocampal output activity. Moreover, it is increasingly clear that seizure generalization from parahippocampal structures to other regions of the brain requires the breakdown of inhibitory mechanisms controlled by the PC in the lateral EC.

These findings encourage the renewal of efforts to develop restorative approaches in the treatment of TLE associated with neuronal damage. One rationally guided goal would be the recovery of the inhibitory activity associated with hippocampal network synchronization at ~1 Hz. This pattern of neuronal activation is impaired in epileptic animals, and would be expected to be affected also in TLE patients who frequently present with a damaged CA3. Brain stimulation at low frequency, via implanted electrodes aimed at activating the subicular-EC networks, could be effective in suppressing ictal activity in patients, as demonstrated in animal models. This approach could represent an alternative to treating refractoriness to drug with purely surgical interventions.

Another alternative approach is to restore inhibitory mechanisms in parahippocampal regions involved in filtering the outgoing ictal activity generated in the limbic system. As epileptic foci are found in the hippocampus, EC, and amygdala of TLE patients, the PC appears to be a particularly likely brain region in which such restoration of inhibition could be effective. In fact, this area is interconnected with all the ictogenic regions discussed here, and could be targeted by specific interventions. However, only few data are available about changes affecting the PC in TLE patients and animal models. There does not appear to be extensive damage in PC, but there are no systematic studies to address the changes in specific cell populations – and in particular, in interneuron populations – in PC. These cells, especially parvalbumin-positive interneurons, are highly sensitive to seizure-induced damage and could be lost in areas extending beyond the hippocampal boundaries, as seen in the subiculum. Interneuron replacement in rat brains damaged after status epilepticus represents a novel and promising approach to reinforcing inhibition in neuronal networks in which inhibition has been compromised.

Recurrent Synaptic Actions and the Genesis of Epileptiform activity

C Le Duigou, G Huberfeld, and R Miles, INSERM U739, Paris, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Intracellular recordings were crucial in unraveling the circuits underlying epileptiform activities. The first records of epileptiform activity were made by Spencer and Kandel from the hippocampus of cats during focal application of penicillin. Penicillin suppresses γ-aminobutyric acid (GABA) receptor signaling and acts as a convulsant, provoking repetitive interictal EEG spikes. Pyramidal cells near the focus were found to fire in high-frequency burst discharges synchronous between most cells in a local region. During these synchronous bursts, neurons depolarize nearly simultaneously in a paroxysmal shift associated with EEG spikes. Some years later, Schwartzkroin and Prince showed that penicillin produces similar synchronous depolarizing shifts in the then-new hippocampal slice.

The cellular or synaptic origin of the paroxysmal depolarizing shift (PDS) was pursued in the slice. The discovery of calcium-mediated action potentials with similar, slow kinetics to those of an EEG spike and records from dendrites where these calcium spikes were initiated supported a cellular origin. But why should large numbers of pyramidal cells generate such events simultaneously? Maybe synaptic transmission was also needed. Evidence that the PDS reflected synaptic activity came from the voltage clamp records of Johnston and Brown, which revealed large synaptic currents associated with depolarizing shifts in CA3 pyramidal cells. These currents occurred rhythmically and were independent of cellular membrane potential, suggesting that they depended on synaptic signaling.

Background and Experimental Methods

If interictal activity corresponds, in part, to a giant excitatory postsynaptic potential (EPSP), where does the EPSP come from? Interictal events in disinhibited hippocampal slices were clearly generated in the CA3 region (**Figure 1**), but they could be initiated by stimulating any pathway afferent to the region, or could occur spontaneously in the absence of any stimulus. Computer modeling helped to identify the origin of the EPSP. Traub and Wong made a model of an isolated network of 100 cells, with a sparse connectivity. They argued that if each cell excited just a few of its neighbors strongly enough that they fired, the size of the group of firing cells would increase with time and so generate a local population synchrony. Sparse but strong connections could also explain a delay of several 10 s of milliseconds that was sometimes seen between afferent stimulation and an interictal event.

A delay of several 10 s of milliseconds does not reflect monosynaptic input, consistent with the observation that the giant EPSP was not specific to any afferent fiber system. The architecture of the Wong and Traub model consisted of synaptically connected pyramidal cells in a single array. The biological correlate of this connectivity was suggested to be recurrent excitatory synapses

Recurrent Synaptic Actions and the Genesis of Epileptiform activity

C Le Duigou, G Huberfeld, and R Miles, INSERM U739, Paris, France

Introduction

Intracellular recordings were crucial in unraveling the circuits underlying epileptiform activities. The first records of epileptiform activity were made by Spencer and Kandel from the hippocampus of cats during focal application of penicillin. Penicillin suppresses γ-aminobutyric acid (GABA) receptor signaling and acts as a convulsant, provoking repetitive interictal EEG spikes. Pyramidal cells near the focus were found to fire in high-frequency burst discharges synchronous between most cells in a local region. During these synchronous bursts, neurons depolarize nearly simultaneously in a paroxysmal shift associated with EEG spikes. Some years later, Schwartzkroin and Prince showed that penicillin produces similar synchronous depolarizing shifts in the then-new hippocampal slice.

The cellular or synaptic origin of the paroxysmal depolarizing shift (PDS) was pursued in the slice. The discovery of calcium-mediated action potentials with similar, slow kinetics to those of an EEG spike and records from dendrites where these calcium spikes were initiated supported a cellular origin. But why should large numbers of pyramidal cells generate such events simultaneously? Maybe synaptic transmission was also needed. Evidence that the PDS reflected synaptic activity came from the voltage clamp records of Johnston and Brown, which revealed large synaptic currents associated with depolarizing shifts in CA3 pyramidal cells. These currents occurred rhythmically and were independent of cellular membrane potential, suggesting that they depended on synaptic signaling.

Background and Experimental Methods

If interictal activity corresponds, in part, to a giant excitatory postsynaptic potential (EPSP), where does the EPSP come from? Interictal events in disinhibited hippocampal slices were clearly generated in the CA3 region (**Figure 1**), but they could be initiated by stimulating any pathway afferent to the region, or could occur spontaneously in the absence of any stimulus. Computer modeling helped to identify the origin of the EPSP. Traub and Wong made a model of an isolated network of 100 cells, with a sparse connectivity. They argued that if each cell excited just a few of its neighbors strongly enough that they fired, the size of the group of firing cells would increase with time and so generate a local population synchrony. Sparse but strong connections could also explain a delay of several 10 s of milliseconds that was sometimes seen between afferent stimulation and an interictal event.

A delay of several 10 s of milliseconds does not reflect monosynaptic input, consistent with the observation that the giant EPSP was not specific to any afferent fiber system. The architecture of the Wong and Traub model consisted of synaptically connected pyramidal cells in a single array. The biological correlate of this connectivity was suggested to be recurrent excitatory synapses

between pyramidal cells of the CA3 region. The model predicted such recurrent excitatory connections, but no data were available on whether pyramidal cell axon terminals contacted other pyramidal cells in the CA3 region. And the technique of stimulating afferent pathways while recording from a single cell, transferred to the slice from work on the spinal cord, gave no insights into local recurrent synaptic circuits.

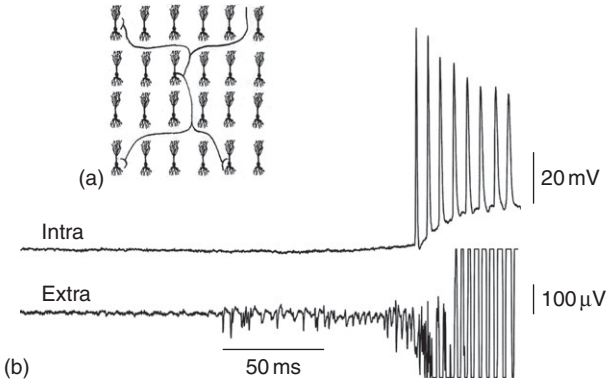

Figure 1 Interictal-like activity in the CA3 region of disinhibited slices. (a) Sparse but strong recurrent connectivity within a single pyramidal cell population is suggested to underlie interictal-like bursts in disinhibited slices. (b) Extracellular records show burst initiation is associated with an acceleration of the frequency of multiunit activity. It is correlated intracellularly with a barrage of temporally summating EPSPs that lead to action potential firing together with the extracellular field potential.

A different technique and a lucky experiment supported the idea that recurrent circuits were crucial in the genesis of epileptiform synchrony in the disinhibited CA3 region. The approach was borrowed from work in invertebrate preparations on the entrainment of rhythmic motor activities by single-cell firing. It consisted in showing that firing induced in one cell could, in some cases, affect the timing of spontaneously generated population events. These experiments showed that the CA3 recurrent excitatory connectivity was high enough that action potential discharge of a single cell could entrain or initiate population discharges. A delay of several 10 s of milliseconds between single-cell firing and an epileptiform burst was a striking vindication of the modeling work.

While it seemed possible that interictal-like population activities might depend on local synaptic interactions in the CA3 region, the existence of recurrent connections between CA3 pyramidal cells was not proven, and it was not clear why suppressing inhibition favored epileptiform bursting. Simultaneous records from CA3 cell pairs were needed to resolve these points.

Simultaneous recordings from pairs of pyramidal cells confirmed the existence of recurrent excitatory synapses in the CA3 region (**Figure 2**). Morphological data show that CA3 pyramidal cell axons arborize extensively, mostly within the CA3 stratum oriens and radiatum,

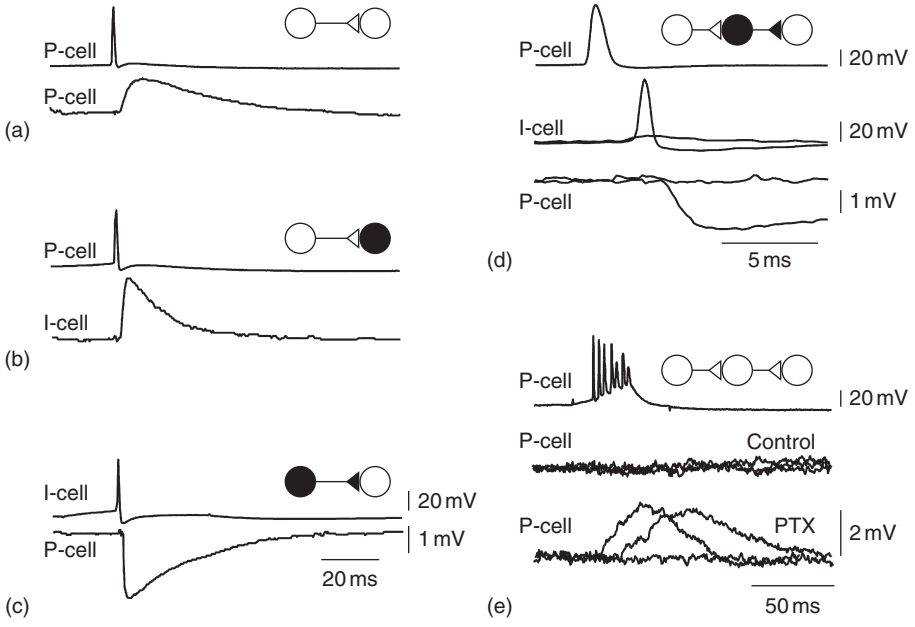

Figure 2 Synaptic circuits for interictal activity in the CA3 region of the hippocampus. (a) Monosynaptic recurrent excitatory interaction between two pyramidal cells. (b) Excitation of interneurons occurs via unitary events that are faster and larger than at connections with pyramidal cells. (c) Inhibitory interaction between an interneuron and a pyramidal cell. (d) Interactions underlying a short-latency disynaptic inhibition. Single pyramidal cell EPSPs can make single interneurons fire and so initiate a disynaptic IPSP. (e) Loss of inhibitory control induced by blocking $GABA_A$ receptors with their antagonist picrotxin, PTX, reveals latent polysynaptic excitatory connections between previously uncoupled pyramidal cells.

with an interterminal distance of 5–10 μm. The probability that two cells in a slice are connected via synapses established by these axon collaterals is about 2–5%. A connection between two CA3 pyramidal cells may be mediated by few – maybe only one or two – terminals. Unitary synaptic events at recurrent synapses have amplitudes at resting potential of 0.1–1.2 mV and a time to peak in the range 5–10 ms. These synaptic events decay with time constants on the order of 15–30 ms, and may be prolonged by the activation of inward postsynaptic currents at near-threshold potentials. Some synaptic events fail – that is, some presynaptic action potentials evoke no postsynaptic response – probably due to the stochastic nature of transmitter liberation. With these synaptic properties, firing in a single pyramidal cell can sometimes induce firing in a postsynaptic partner – as predicted by the simulation studies.

Characterization of unitary inhibitory postsynaptic events, in simultaneous records from a GABAergic interneuron and a pyramidal cell, illuminated how suppressing inhibition might favor epileptiform activity. Inhibitory synaptic connectivity can be very high in a local region, and inhibitory connections may comprise multiple synaptic contacts. Unitary inhibitory synaptic events have mean amplitudes in the range 0.3–3 mV at resting potential. Their time to peak is in the range 3–8 ms and decay in the range 20–40 ms. Inhibitory synaptic events rarely fail. There is an exquisite precision and great variability in sites of inhibitory synapses established between different interneurons and the pyramidal cells that they contact. Some interneurons inhibit dendritic sites, others synapse with postsynaptic somata, and still others contact the initial parts of pyramidal cell axons. These differences presumably underlie different functions. For example, perisomatically terminating interneurons might control pyramidal cell output, whereas inhibitory cells that target dendrites might counter specific excitatory inputs or dendritic electrogenesis. Suppression of both these functions probably contributes to the disinhibition-induced synchrony.

Dual records from interneurons and pyramidal cells revealed that synapses that excite inhibitory cells have distinct properties from those that excite pyramidal cells. Synaptic events are larger, with mean amplitudes in the range 0.5–3 mV at resting potential. Their rise time is faster (2–5 ms) and EPSPs also decay faster, with a time constant of 10–15 ms. Two differences between interneurons and CA3 pyramidal cells may be responsible for these striking differences in the excitatory events recorded from the respective cell types. The subunit composition of AMPA receptors expressed by interneurons tends not to include the GluR2 subunit, so giving rise to synaptic currents that are faster and larger than those of pyramidal cells. Furthermore, excitatory synaptic depolarizations activate fast, intrinsic K-currents that curtail EPSPs in interneurons but not pyramid cells. Functionally, these differences, together with the relatively depolarized interneuron resting potential, assure that pyramidal cell firing can synaptically initiate firing in an interneuron at latencies of 2–8 ms. In contrast, latencies for synaptic transmission of firing between monosynaptically connected pyramidal cells are in the range 5–25 ms.

This difference in latencies for synaptically induced firing at recurrent excitatory connections with interneurons and with pyramidal cells helps explain how the suppression of fast synaptic inhibition leads to the initiation of interictal synchrony. Firing of a CA3 pyramidal cell can spread if postsynaptic cells can be made to fire, and in turn induce firing in further generations of postsynaptic cells to generate an interictal spike. As fast inhibition acts to suppress the transmission of firing between pyramidal cells, it prevents the development of interictal population activities. Inhibitory circuits are more efficient than excitatory circuits (1) at the synaptic level, with less failures and larger conductance events; (2) within the network because of more densely arborizing axons; and (3) functionally, with a more efficient and shorter latency transmission of firing. Subsequent experiments proved that inhibition controls the spread of activity in recurrent circuits by showing that suppressing inhibition uncovered 'latent' polysynaptic pathways between previously uncoupled pyramidal cells.

Recent Results

If the initiation of interictal bursts depends on the spread of neuronal discharge mediated via recurrent excitatory synapses between CA3 pyramidal cells, the properties of these connections may influence population events in other ways. The duration of interictal events has been suggested to depend on the depletion of transmitter at recurrent synapses following high-frequency release. The replenishment of release-ready vesicles takes 5–15 s and this process, occurring across the population of CA3 recurrent excitatory synapses, seems to control the interval between interictal bursts.

How does epileptiform bursting emerge? Single CA3 cells normally discharge spontaneously in bursts that are not synchronous with bursts in other cells. Suppressing inhibition enables transmission in polysynaptic, excitatory pathways. New traffic in these latent polysynaptic circuits is responsible for the synchronization of CA3 pyramidal cell firing. Recent multiunit studies on the transition between asynchronous firing and interictal synchrony have shown that rhythmic burst discharges emerge, and grow in amplitude and coherence, before fully synchronous firing is established. Multiunit activity during an emerging interictal event consists of increased firing of some but not all cells in a local region; this emerging interictal event stops before developing into a fully epileptiform

event. The interictal field potential corresponding to an interictal event has a spike-and-wave shape, with the wave component corresponding to the cessation of unit-firing; intracellular records suggest that this cessation of firing is due to a $GABA_B$-mediated IPSP. Thus, interictal rhythmicity emerges from events mediated by sequences of glutamatergic and $GABA_B$-mediated signals.

What determines the timing of an interictal burst? While the replenishment of synaptic vesicles controls the interval between population events, distinct active processes may be involved in the precise timing of burst initiation. Multiunit recordings revealed a distinct acceleration in activity before interictal firing. The observation that firing frequency is higher just before a burst than at any other point in the interburst cycle suggests that firing frequency must exceed a certain threshold to initiate a burst. This idea might explain how single pyramidal cell firing can sometimes initiate firing in the larger CA3 population. If population activity induced via polysynaptic pathways activated by the stimulated pyramidal cell exceeded a threshold level, a population burst should be initiated. Reducing either neuronal excitability or excitatory synaptic strength reduces population firing and increases the time to reach burst threshold. The frequency of population events is reduced and eventually spontaneous events are suppressed. Small reductions in excitatory synaptic efficacy reveal partial population events curtailed by intracellular $GABA_B$-mediated hyperpolarizations, similar to the 'partial' events seen during the emergence of synchrony. These results show that two synaptic processes are engaged during interictal-like population bursts: one excitatory process, mediated by glutamatergic receptors, acts to recruit cells into the synchronous discharge; the other inhibitory process, mediated via $GABA_B$ receptors, tends to stop recruitment into these bursts. The opposition of two such processes, like the inward and outward currents engaged during action potential generation in a single neuron, may be an essential feature of systems with a threshold.

Interictal Synchrony in Slices from the Temporal Lobe of Epileptic Patients

It is essential, at some point, to confront models of disease with the human pathology that they model. Since pharmacotherapies for focal temporal lobe epilepsies may be ineffective, the best therapeutic option for some patients is to excise the damaged tissue. Epilepsies of the temporal lobe are one of the rare neurological diseases where human tissue can be available for physiological comparison with tissue from model systems. Recordings made from slices of human tissue (obtained after careful surgical excision of epileptic tissue from the temporal lobe) have sometimes – although not always – revealed a spontaneous interictal-like activity. Interestingly, GABAergic synaptic mechanisms seem to contribute to this population activity, which consists of recurring spontaneous field potentials of similar frequency, amplitude, and duration to those generated by disinhibition in the CA3 region of guinea-pig slices.

Human temporal lobe epilepsies are often associated with a hippocampal sclerosis consisting of a mild to severe cell loss in the CA3 and CA1 regions. In tissue from such patients, we have found that an interictal-like activity, similar in frequency to that observed in intracranial EEG records from the same patients, occurs spontaneously at frequencies in the range 0.3–2 Hz. It is generated in the subiculum, an output region of the hippocampus that has suffered little cell loss but that is presumably severely deafferented because of sclerosis in the CA1 region. The interictal activity is suppressed by antagonists at either glutamate or GABA receptors.

The unexpected involvement of GABAergic signaling seems to depend on a depolarized reversal potential for GABAergic events in a minority (about 20%) of subicular pyramidal cells. A depolarized reversal potential for normally inhibitory GABAergic events points to a defect in homeostatic mechanisms that control intracellular chloride. Such responses are rare in the normal adult cortex, but do occur during early development before full expression of the K-Cl cotransporter, KCC2, which acts to extrude chloride. Possibly the denervation of the subiculum due to CA1 cell death induces a replay of developmental mechanisms with proepileptic consequences. Combining biocytin staining of recorded cells with immunostaining showed that KCC2 expression was perturbed in some of the subicular cells with depolarizing responses to GABA.

Comparison of Human Interictal-Like Synchrony and Disinhibition Induced Synchrony

Slices of human subiculum that generate interictal activity are larger (about 3×5 mm) than those of the guinea-pig CA3 region (about 1.5×2 mm) that generate an interictal-like activity upon disinhibition (**Figure 3**). Perhaps because of the larger cell population involved, attempts to affect the interictal rhythm in human tissue, by single-cell stimulation, are unsuccessful. Comparison of the timing of events recorded by spatially segregated electrodes suggests that multiple pacemaker zones often exist in human slices. In contrast, interictal-like events are always initiated in the CA3a region of disinhibited guinea-pig slices. The interval between population events in human subiculum (0.3–2 s) is notably shorter than that (4–12 s) between interictal-like firing in disinhibited guinea-pig CA3 region. The form and duration of interictal field potentials, filtered in the same way, is very similar across preparations.

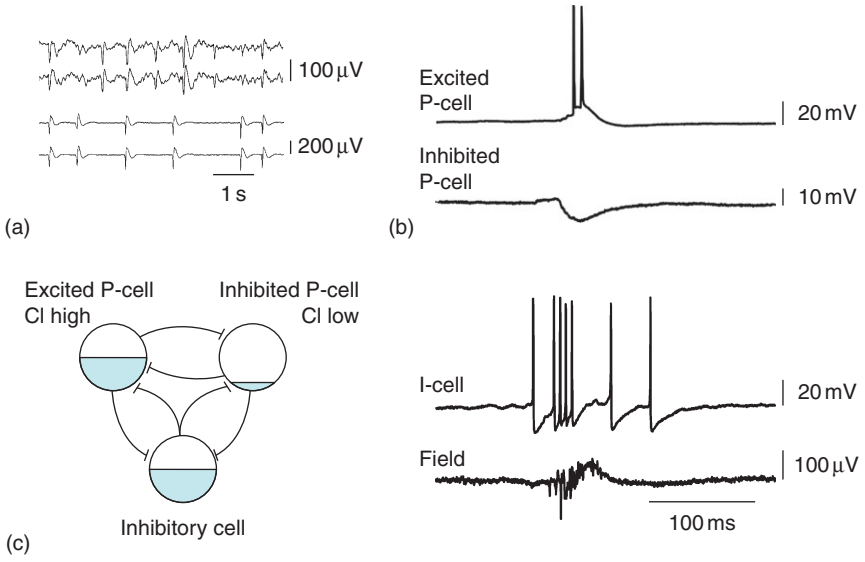

Figure 3 Interictal-like activity generated by the human subiculum. (a) Comparison of interictal activity recorded in situ, with intracranial electrodes, and in vitro, with extracellular electrodes. (b) Distinct patterns of activity simultaneous with interictal-like activity in vitro, recorded from an excited pyramidal cell, an inhibited pyramidal cell and an interneuron. (c) Possible circuit diagram for human subicular interictal activity. The two types of pyramidal cells and interneurons are all connected to each other. Internal Cl, indicated by a horizontal line in each cell symbol, is high in excited pyramidal cells and interneurons.

Some comparison of the mechanisms involved may be useful. While interictal bursts in disinhibited guinea-pig slices seem to be initiated by a local acceleration in pyramidal cell firing, in human subiculum interneurons consistently discharge before interictal events. While neither mechanism has been confirmed, early-firing subicular interneurons could be synchronized by electrical coupling or perhaps by GABAergic signaling, which is not strikingly inhibitory in human tissue. With GABAergic reversal potentials distributed between positive values for a minority of pyramidal cells, and values hyperpolarizing from resting potential in the majority, the same interneuron should excite some and inhibit other postsynaptic cells. These depolarizing GABAergic signals might fulfill the same role as recurrent excitation between pyramidal cells in the guinea-pig CA3 region: to transmit firing within an interconnected population. However, some points argue against such a role. The driving force for depolarizing GABAergic events is small, not more than about 15 mV, and shunting effects may oppose action potential generation in target cells. If interneurons do not initiate human interictal synchrony, subicular pyramidal cells that possess a respectable recurrent connectivity may fill this role. In the human subiculum, recurrent synaptic excitation would have to generate synchrony in the presence of a partial disinhibition due to the perturbation of Cl-homeostasis and the resulting effects on GABAergic signaling. In contrast, in the disinhibited CA3 region of guinea-pig slices, recurrent excitatory systems generate synchrony in the absence of resistance from $GABA_A$ receptor-mediated signals.

Future Goals

The shape and kinetics of interictal-like field potentials, in slices from both human and animal tissue, are not very different from those of field potentials that have been called sharp-waves in EEG records from non-anaesthetized animals. In the sleeping or resting rodent, sharp-waves have been associated with processes of memory consolidation, and are generated in the CA3 region, possibly by recurrent synaptic mechanisms similar to those involved in generating the synchrony observed in disinhibited slices. Clinically however the term sharp-wave is used to describe an anomalous epileptiform event recorded from the temporal cortex during interictal periods. Since intrahippocampal EEG records are rarely made from healthy humans, it is not clear whether sharp-wave-like events are generated in more physiological conditions. The lack of a clear nomenclature should be clarified. Possibly a reasonable criterion to distinguish between such population events could be made from estimates of the proportion of simultaneously discharging pyramidal cells. In the disinhibited slices from the guinea-pig, probably 100% of pyramidal cells fire synchronously. Approximately 20% of pyramidal cells seem to suffice to generate the interictal-like activity in slices of subiculum from epileptic patients. Estimates from in vivo records with tetrodes suggest that 5–10% of the CA3 population may discharge quasisimultaneously in a sharp-wave of a sleeping animal.

Another question to be resolved is the origin of the perturbed chloride homeostasis, which appears to

contribute to human interictal-like activity. The molecule or molecules involved in this perturbation must be identified, as must the signaling pathways involved in pathological changes to their function. The discovery of other cellular modifications correlated with depolarizing GABAergic signaling in a fraction of subicular cells might help to clarify this point. More work is also needed to understand how these and other reactive changes contribute to the initiation of seizure-like activity in human temporal lobe tissue.

Introduction

Epilepsy is a chronic disease characterized by the regular alternation of short synchronous oscillations and long-lasting interictal periods (with or without EEG abnormalities). These periods without seizures can vary from a few hours to several months. This alternation of ictal and interictal conditions suggests the existence of both passive conditions and active processes that control the occurrence of seizures. Control mechanisms of epileptic seizures may involve existing circuits or processes that are capable of controlling physiological oscillations in the brain. Such mechanisms may also develop in parallel with epileptogenesis, and may constitute an adaptative response to the development of epileptic circuits.

Our knowledge about the mechanisms that control epileptogenesis and/or epileptic seizures has improved during the last decades, but remains very partial.

The study of such mechanisms is critical to better understand not only the development of the epileptic state (epileptogenesis), but also (once the seizures are established) the transitions between normal and paroxysmal activities of the epileptic networks. Insight into these processes should offer the possibility to develop innovative therapeutical strategies, and also the opportunity to better understand brain mechanisms that control synchronized oscillations in general (whether physiological or pathological).

Several lines of evidence from experimental studies in animal models have suggested that different structures of the BG are critical in the control of epilepsies. Indeed, in addition to their strong involvement in the control of movement, the BG also contribute to a wider set of functions, including cognitive and motivational aspects of behavior. In particular, the BG have a critical position in the CNS, with connections to a large set of forebrain structures known to be involved in the generation of seizures and, more generally, in the emergence of large-scale synchronized normal and pathological oscillations. Although the BG do not by themselves generate epileptic discharges, they may well provide a subcortical system that controls the alternation between interictal and ictal cortical activity.

Background

Functional Anatomy of the BG Circuits

The BG have a privileged position in the brain to control circuits involved in the generation of seizures, as they are connected to the cerebral cortex, limbic areas, and thalamic relay nuclei through several multisynaptic loop circuits. Through glutamatergic afferent projections, the striatum – one of the BG input nuclei – processes information from all areas of the cerebral cortex, the midline and intralaminar thalamic nuclei, the amygdala, and the hippocampus. The glutamatergic inputs to the subthalamic nucleus (STN) arise from a more restricted part of the cortex, involving the motor, premotor, and prefrontal areas and from the parafascicular thalamic nucleus. In turn, the two outputs of the BG, the substantia nigra pars reticulata (SNR) and the internal segment of the globus pallidus (or the entopeduncular nucleus in the rodent), project to a diversity of thalamic and brain stem nuclei. Through the thalamic nuclei, the BG influence mainly the frontal cortex. They also affect, via nigral GABAergic projections, the intermediate and deep layers of the superior colliculus and the pedunculo-pontine nucleus. Via the ascending projections of these brain stem structures, the BG can also indirectly influence widespread areas of the cerebral cortex. A conceptual model of BG circuits and their relationships with the cerebral cortex has been proposed, where by cortical information is transmitted via three main pathways: (i) a direct striatonigral pathway, (ii) a direct subthalamo-nigral pathway, and (iii) an indirect striato-pallido-subthalamo-nigral pathway (see Further Reading). Since the striatal projection neurons are GABAergic whereas STN neurons are glutamatergic, the trans-striatal and trans-subthalamic pathways exert opposite effects, respectively inhibitory and excitatory, on output neurons (i.e., the GABAergic nigral projection cells). According to this model, electrical stimulation of the cortex induces in these BG neurons a sequence of synaptic events consisting of an inhibition, preceded or not by an early excitation, and followed or not by a late excitatory event. Since the BG output neurons are GABAergic and tonically active, their inhibition by the direct striatal pathway leads to a *disinhibition* of the BG targets like the thalamic or the brain stem nuclei. Conversely, the trans-STN circuits reinforce the inhibitory influence that BG exerts on their targets (see **Figure 1**, middle panel).

The BG as a Generator of Seizures?

Although the BG circuits are known to generate spontaneous oscillatory activities in several physiological as well as pathophysiological conditions, that they will initiate epileptic seizures appears quite unlikely. Indeed, oscillatory activities observed in BG circuits have very low frequencies; when recorded during seizures, activity in BG appears to result from propagated influences. Furthermore, electrical or chemical stimulations of the BG structures rarely initiate seizures, and their lesions never abolish the occurrence of seizures (see Further Reading). On the contrary, changes in neuronal activity revealed by EEG, measures of glucose metabolism, or expression of immediate early genes studies suggest that the BG circuits rather «detect» the beginning, the localization, and/or the intensity of a seizure. It is thus conceivable that changes of activity of these BG circuits may have some consequences on the development of ongoing seizures.

Early Evidence of a Gating System for the Control of Epileptic Seizures

In 1980, Gale and Iadarola were the first to associate an increase of GABA in the substantia reticulata (SNR) with antiepileptic effects. Since then, several studies showed that the potentiation of the GABAergic neurotransmission within the SNR, by bilateral microinjections of GABAmimetic drugs, suppressed seizures in a large variety of models of generalized seizures in the rat. Inhibition of the SNR, obtained by blockade of the glutamatergic input from the STN, also suppressed seizures. More recently, it was shown that 60–130 Hz stimulation applied to the SNR can interrupt seizures in several models. The critical nigral projection(s) involved in these antiepileptic effects remain(s) to be determined. Disinhibition of neurons of the superior colliculus, one of the main targets of

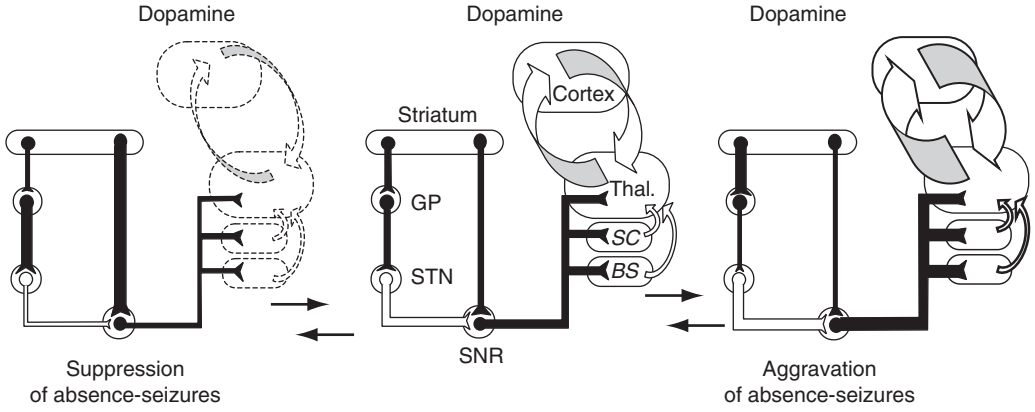

Figure 1 Effects of pharmacological manipulations of the basal ganglia structure. Schematic representations of the connectivity within the basal ganglia system thought to be involved in the control of absence-seizures in GAERS. Thickness of neuronal outputs is proportional to the activity of the projection, as modified following intracerebral pharmacological manipulations. An increased activity in the striatal dopaminergic tone has antiepileptic effects (left panel), whereas a decreased activity in the dopaminergic tone has proepileptic effects (right panel). For instance, dopamine at the striatal level is thought to simultaneously potentiate the inhibitory influence of the trans-striatal direct pathway and decrease the excitatory influence of the trans-striatal indirect pathway through D1 and D2 dopaminergic receptors, respectively. BS: brain stem; GP: globus pallidus; SC: superior colliculus; SNR: substantia nigra pars reticulata; STN: subthalamic nucleus; Thal: thalamus.

the SNR, appears to play a significant role in their mediation, at least in some forms of seizures. The projection towards thalamic nuclei could also be involved in this control circuit.

Methods

Most of the data presented below were collected from in vivo experimental studies performed in rodent models of epilepsy. They were mainly obtained using intracerebral pharmacological manipulations and electrophysiological recordings, with subsequent histological analyses.

Results

Role of the Different BG Pathways in the Control of Seizures (see Figure 1)

Involvement of the direct striatonigral pathway

The possibility that the direct GABAergic striatonigral pathway could modulate seizures – through inhibition of the SNR – was first suggested by experiments showing that intranigral injection of GABA agonists have antiepileptic effects in most models of seizure in the rat. Later, activation of neurons in the striatum, by glutamate or D1 agonists, which results in release of GABA in the SNR and decrease of SNR neuronal activity, was also shown to suppress seizures. This effect could be reversed by a subsequent injection of a GABA antagonist into the SNR. These effects, however, appear to vary according to the model used and type of seizures. In addition, these antiepileptic effects appear to be region-dependent within the striatum, suggesting that different circuits are involved depending on the type of seizures.

Involvement of the direct subthalamo-nigral pathway

The glutamatergic input from the STN is critical in the maintenance of the SNR neuronal activity; bilateral injections of a GABA agonist into the STN, or high-frequency stimulation of this structure, decreases the activity of nigral neurons. In the genetic model of absence epilepsy in the rat (GAERS), we showed that these manipulations suppress seizures without behavioral side-effects. This observation is consistent with our previous findings showing that blockade of NMDA receptors in the SNR has antiepileptic effects. The antiepileptic effects of pharmacological STN inhibition have been confirmed in different models of generalized convulsive seizures. Similarly, 130 Hz stimulation of the STN was recently reported to protect against different forms of convulsive seizures.

Involvement of the indirect striato-pallido-subthalamo-nigral pathway

The involvement of the GABAergic input from the pallidum to the STN has been investigated in only a few models of convulsive epilepsy, but these studies support the view that this projection could be part of a circuit involved in propagation of seizure activity during secondary generalization. In the GAERS, we showed that disinhibition of the globus pallidus or the ventral pallidum, by $GABA_A$ antagonists, suppresses absence seizures, an effect which was correlated with a decrease in glutamate levels in the SNR measured by microdialysis. These results suggest that the antiepileptic effect is mediated, at least in part, through a reduction in activity of the STN. Conversely, an increase in the occurrence of absence-seizures was observed following inhibition of the ventral pallidum.

The involvement of the pallidum in the control circuit of seizures is consistent with data obtained following intrastriatal injection of dopaminergic agonists of the D2 receptors (see below). Although still debated, several sets of results have suggested that these receptors are preferentially located on neurons projecting to the globus pallidus, and that their activation leads to disinhibition of pallidal neurons. Injections of D2 agonists into the striatum block convulsive or nonconvulsive seizures, whereas injections of their antagonists have aggravating effects. An additive suppression of absence-seizures was obtained in the GAERS with combined injections of low doses of a D1 and a D2 agonists into the striatum, and more precisely into the core of the accumbens. This result is similar to the potentiation of antiepileptic effects observed after combined injection of a $GABA_A$ agonist and an NMDA antagonist into the SNR, at doses shown to have no effect by themselves. These data suggest that the trans-striatal and trans-subthalamic pathways could cooperate in the suppression of absence seizures, and that striatal dopaminergic transmission could play a key role in the modulation of epileptic seizures by the BG (see below).

Evidence for an Endogenous Control System by the Basal Ganglia Circuits

Electrophysiological recordings of the BG circuits

The data reported in the different models of generalized epilepsy have lead to the hypothesis that some BG circuits may act as an endogenous control system capable of interrupting epileptic seizures and/or of modulating their occurrence. Accordingly, changes of neuronal activity within the BG should be associated with the occurrence and/or interruption of seizures. Indeed, changes in basal activity is always observed in the BG concomitantly with an epileptic discharge, in both human patients and animal models. In animal models, data were mainly collected during pharmacologically or electrically induced seizures, and the «endogenous» nature of the observed changes of activity was thus difficult to determine. To investigate the possible relationships between unit activities in the BG and the cortical EEG during ictal and interictal periods, the genetic models with spontaneous seizures are preferred. In particular, single unit recordings in immobilized GAERS (maintained under neuroleptanalgesia) indicated that SNR and STN neurons increase their firing rate concomitantly with the occurrence of spike-and-wave discharges, whereas dopaminergic neurons of the substantia nigra pars compacta (SNC) tend to decrease their activity. Conversely, at the end of the seizure, SNR and STN neurons decrease their firing rate, whereas dopaminergic neurons of the SNC display a transient overactive state. Furthermore, multiunit recordings with a chronically implanted movable tetrode, in the freely moving GAERS, revealed that the frequency of discharge of the SNR neurons increased and action potentials became organized into bursts during an epileptic spike–wave discharge (see **Figure 2**). These SNR bursts always followed the spike component (of each spike-and-wave element) by a few milliseconds. In addition, a few seconds before the end of the EEG discharge, a decrease in SNR neuronal activity was often observed. The delay observed between the occurrence of the cortical EEG spikes and the burst of action potentials suggests that the SNR is involved in the propagation rather than the generation of the seizure. In addition, the decrease of unit activity observed before the end of the seizure, suggests that inhibition of SNR neurons could participate in the blockade of an ongoing seizure. The nature and the temporal pattern of these changes are in agreement with what could be predicted from the pharmacological data, and suggest that these events could contribute to the antiepileptic effects resulting from a physiological triggering of the control system.

The involvement of the BG was further supported by recent in vivo extracellular and intracellular recordings, performed in GAERS, at different levels of the circuit. The propagation of the electrical discharges in corticostriatal and corticosubthalamic neurons induced a feed-forward inhibition of the GABAergic striatonigral neurons and synchronized rhythmic bursting activity in the glutamatergic subthalamo-nigral neurons, respectively. This rhythmic activity in subthalamo-nigral neurons, together with an imbalance between excitation and inhibition within the SNR, lead in turn to synchronized burst firing in GABAergic nigrothalamic neurons, in phase with the spike-and-wave complexes in the EEG. This circuit activation pattern is likely to reflect an endogenous mechanism controlling (positively) the maintenance and the duration of the seizure. The rebound of excitation observed in most of striatal output neurons at the end of a spike-and-wave discharge, and in parallel with the decrease of SNR activity, may have a negative modulatory effect on spike-and-waves and thus contribute to the interruption of an ongoing absence-seizure.

As compared to the other thalamic nuclei, neurons of the ventromedial thalamus – the main thalamic output target of the SNR – display an increase in rhythmic bursts of action potentials during seizures. Pharmacological blockade of excitatory inputs to nigrothalamic neurons led to a transient interruption of spike–wave discharges, correlated with a change in the activity of thalamic cells, which was increased in frequency and converted into a sustained arrhythmic firing pattern. Simultaneously, cortical neurons exhibit a decrease in their firing rate that was associated with an increase in membrane polarization and a decrease in input resistance. These findings demonstrate that an inhibition of SNR neurons changes the activity of their thalamic targets, which in turn could

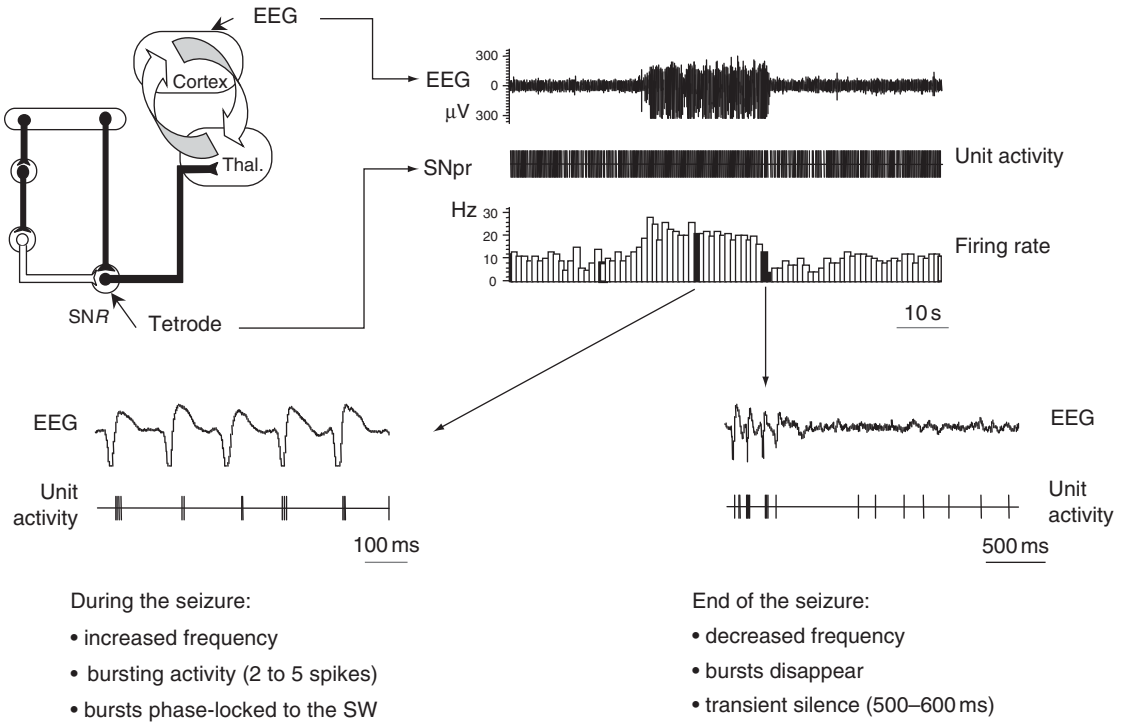

Figure 2 Changes in extracellular unit recordings in the SNR in a freely behaving GAERS. Cortical EEG and unit activity obtained from a freely behaving rat equipped with a movable tetrode chronically implanted within the substantia nigra *pars reticulata*. The lower panels display an enlargement of spike-and-wave complexes with simultaneous bursts of action potentials (*left panel*) and changes occurring at the end of an absence-seizure (*right panel*).

affect cortical neuron excitability, and consequently, the generation of cortical epileptic discharges. Thus, the nigro-thalamo-cortical pathway may provide an online system control of absence seizures.

Role of the dopaminergic neurotransmission

As mentioned above, pharmacological and electrophysiological studies have revealed a critical role of the striatal dopaminergic neurotransmission in the control of seizures. It is well known that dopamimetic drugs have antiepileptic effects, in general, in both human and in animals. In addition, changes in dopaminergic markers have been reported in animal models as well as in some human patients. These changes may result from the recurrent involvement of dopaminergic neurotransmission to control seizures, and may represent compensatory processes. Investigation of the expression of different dopaminergic transcripts in the striatum of GAERS revealed an increased level of D3 mRNA expression in neurons of the nucleus accumbens in adult GAERS (as compared to nonepileptic control rats). This change was specific to D3 receptors (there was no change in the expression of mRNAs coding for other neuronal dopaminergic markers, such as tyrosine hydroxylase, membraneous and vesicular dopamine transporters, or D1, D2 or D5 receptors). Because D3 transcripts were not increased in 21-days juvenile GAERS (i.e., at a time when no absence seizures had yet occurred), these data suggest that this transcriptional change represents either a part of the epileptogenesis process or an adaptive response to repeated seizures. Although the functional consequences of an upregulation of D3 transcripts on neurons of the n. accumbens are still unknown, it is likely to be related to the overactivity of the dopaminergic neurons observed at the end of the absence seizure (see above). Since changes in dopaminergic markers occur in chronic epileptic animals, and since dopamine is thought to be involved in the fine tuning of seizure interruption, changes in dopaminergic tone are likely to occur and further influence the epileptogenesis process and how seizure recurrence develops.

Future Goals

The experimental data reviewed in this article support the idea that changes in the activity of BG circuits influence the occurrence and/or cessation of epileptic seizures. In addition, the dynamic changes observed in neurons of these circuits suggest that the BG stand at a pivotal point, not only to detect but also to interfere with an ongoing seizure activity. Yet, further studies are required to complete the characterization of these

circuits. In particular, the projections and the mechanisms involved in the cessation of seizures remain to be specified. From the few data reported, it appears very likely that these mechanisms differ according to seizures type, and therefore with the circuits that generate the seizure. The possibility that the BG interrupt seizures or control their occurrence via a change in cortical excitability and/or synchronization capacities appears to be the most likely hypothesis, and our laboratory is currently testing this hypothesis. The role of dopaminergic transmission, and its possible plasticity throughout the course of epileptogenesis, are other important issues for further study, using models of epilepsy with spontaneous seizures as well as investigating epilepsy patients with dopaminergic deficits. Finally, experimental studies with different animal models have led to initial clinical trials using high-frequency stimulation of the STN in epileptic patients. Clinical studies are under way to better determine whether this type of stimulation can be used as a possible treatment in patients with drug-resistant seizures, who cannot undergo resective surgery. The precise targets, as well as the stimulation parameters and protocol of stimulations – currently derived from studies in patients with Parkinson disease – will certainly need to be adapted for control of epileptic seizures, and possibly customized to each epileptic patient.

Introduction

Most seizures are self-limited events as they stop within minutes. Status epilepticus (SE) is relatively rare. These observations suggest that within the brain, there are intrinsic networks that prevent seizures from continuing indefinitely. Clinical and experimental studies have identified several possible networks, remote to the seizure focus, which may help suppress their initiation, abort the spread of seizures, or even lead to their termination. These intrinsic seizure-controlling networks appear to be operant in many seizure syndromes, suggestive of a commonality in the endogenous systems involved in seizure control. By determining the degree of functionality of the seizure suppressing systems in various epileptic conditions, targeted strategies can be designed to stop

circuits. In particular, the projections and the mechanisms involved in the cessation of seizures remain to be specified. Introduction

Most seizures are self-limited events as they stop within minutes. Status epilepticus (SE) is relatively rare. These observations suggest that within the brain, there are intrinsic networks that prevent seizures from continuing indefinitely. Clinical and experimental studies have identified several possible networks, remote to the seizure focus, which may help suppress their initiation, abort the spread of seizures, or even lead to their termination. These intrinsic seizure-controlling networks appear to be operant in many seizure syndromes, suggestive of a commonality in the endogenous systems involved in seizure control. By determining the degree of functionality of the seizure suppressing systems in various epileptic conditions, targeted strategies can be designed to stop

seizures acutely and to prevent seizure recurrences. Indeed, the idea that there may be specific networks that are involved in the control of seizures is very exciting, since genetic or epigenetic factors or damage to these networks may explain why some patients respond to anticonvulsant therapy whereas others do not (despite having the same seizure syndrome). Furthermore, the ability of the endogenous systems to effectively influence seizure severity or duration may be age-dependent and sex-dependent, and may be influenced by prior experience to seizures. In this laboratory, we have focused our investigations on the identification of seizure controlling circuits that involve the basal ganglia and especially the substantia nigra pars reticulata (SNR), as a function of age and sex.

Background

The notion that the basal ganglia may participate in the expression and control of seizures is long standing. Initial studies focused on striatal–thalamocortical interactions. Subsequent experimental studies suggested that basal ganglia networks that involve the subthalamic nucleus and the SNR are critically involved in the control of seizures. Further, in humans, there is emerging evidence that stimulation of the subthalamic nucleus may have beneficial effects in some patients with intractable epilepsy. The effects of subthalamic nucleus stimulation are mediated through the SNR which is one of its major output targets.

To fully appreciate how the SN may act as a seizure controller, we must first detail some of the important aspects of its functional anatomy. The SN is composed of two distinct parts, the pars compacta (SNC) comprised of dopaminergic neurons, and the SNR, which is the larger subdivision and is predominantly populated by GABAergic neurons with high baseline firing rates. The SN is part of the basal ganglia, which is composed of the striatum (caudate/putamen complex), the globus pallidus, the entopeduncular nucleus, and the subthalamic nucleus. These nuclei have widespread connections with the cerebral cortex, thalamus, and brainstem (**Figure 1(a)**), and are associated with a variety of functions including motor control, cognition, emotions, and learning. The striatum integrates inputs originating from the cortex with those from limbic and extrapyramidal circuits, and conveys this information to the subthalamic nucleus and the SNR through two different routes, the 'direct' (striatonigral) and 'indirect' (striato-pallido-subthalamo-nigral) pathways. The SNR then directs information either to the thalamus, superior colliculus, brainstem, or back to the striatum. Indeed, the SNR has been proposed to 'influence widespread cerebral mechanisms in synchronization and excitability.'

The experimental evidence that the SN may be a critical site in the control of seizures has emerged over the last 35 years, initially from studies in adult male

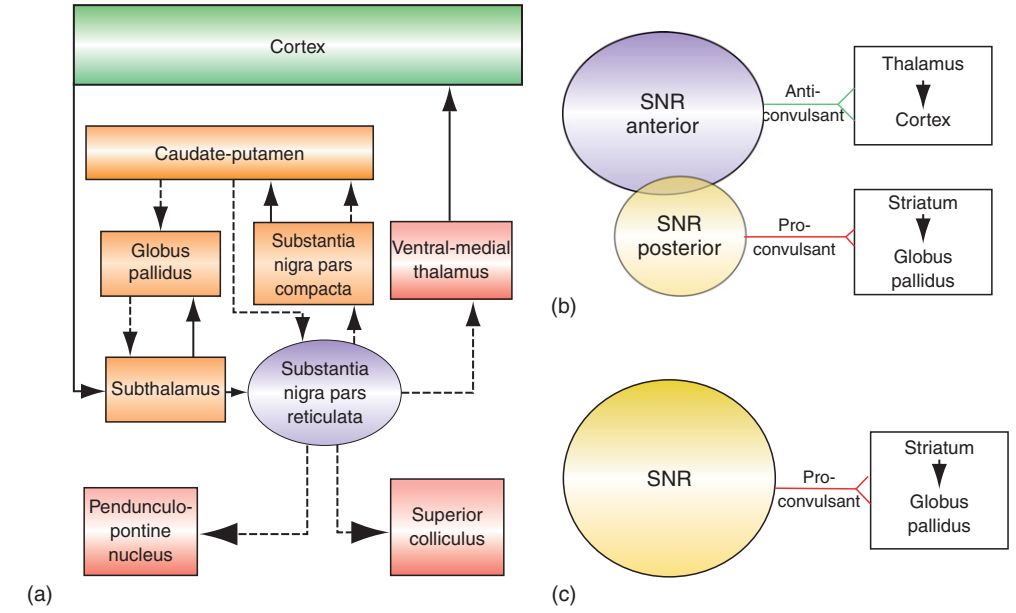

Figure 1 (a) Connections of the substantia nigra pars reticulata (SNR). Solid arrows = excitatory connections, broken arrows = inhibitory connections. (b) and (c) are a representation of the proposed $GABA_A$-sensitive SNR networks involved in seizures as a function of age. Panel (b) shows the adult SNR and the efferent networks whereas panel (c) shows the SNR efferent networks of a P15 male pup. Note that in the P15 male pup there is no topographic segregation of the effects of muscimol infusions in the SNR. This is also the case in P15 females, but in this case muscimol infusions do alter the seizure thresholds. In older female rats, the $SNR_{anterior}$ mediates $GABA_A$ sensitive anticonvulsant effects while the $SNR_{posterior}$ is ineffective.

animals. One pivotal experimental study, using the kindling model of epilepsy, reported that during a kindled seizure, the electrical activity propagated to involve the substantia nigra bilaterally; this observation supported the view that the SNR is involved in the generalization of limbic seizures, either as a facilitator or a suppressor. This conclusion was also supported by a subsequent study, using the [^{14}C]-2-deoxyglucose (2DG) technique, which showed striking increases in the metabolic activity of the SNR bilaterally during generalized kindled seizures. Increased metabolic activity of the SNR was similarly reported in other animal models of epilepsy, especially (but not exclusively) when the animal experienced generalized seizures. Subsequently, in a series of elegant studies, Iadarola and Gale showed that pharmacological treatments that increase GABAergic transmission in the SNR bilaterally suppressed a variety of experimentally-induced seizures in adult rats. At about that time, we showed in this laboratory that the metabolic changes that occur in the SN during seizures were age-dependent. Furthermore, the enhancement of GABAergic transmission in the SNR in postnatal day (P) 15 male rats facilitates the development of seizures – in contrast to its seizure suppressing effects in adult male rats. Over the years, we have provided further evidence that the ability of the SNR to control the expression of seizures in rats is age-dependent and sex-dependent, and influenced by prior history of seizures, especially the occurrence of SE early in life.

Methods

In our laboratory, we have used several methodological approaches to investigate the role of the SNR in the control of seizures as a function of age and sex which are summarized below.

Flurothyl-Induced Seizures

Flurothyl is a volatile convulsant agent which has been used in this laboratory for more than 20 years to establish the age-specific and sex-specific effects of the SNR on seizures. Rats are placed in an airtight 9.2 l chamber, and the liquid flurothyl is delivered via a Harvard pump at the constant rate of 20 μl min^{-1} onto a filter pad from which it vaporizes. An advantage of this model is that flurothyl-induced seizures always occur, in all animals. As flurothyl is constantly infused, changes in latency mirror the amount of flurothyl administered. Therefore, the clonic and tonic seizure thresholds are determined by calculating the amount of flurothyl used to induce seizures (latency x rate of infusion). Changes in the threshold and seizure severity can readily distinguish whether any given pharmacological manipulation produce a facilitation or partial suppression (delay) of convulsions.

Intracranial Drug Administration

Rats are anesthetized with a combination of ketamine and xylazine i.p., and implanted with cannulae that target the $SNR_{anterior}$ or $SNR_{posterior}$. Rats recover from the surgery for 2 days. For all infusions made via these cannulae, the injected volume is 0.25 μl; the injection time is 2 min per site to minimize drug spread.

[^{14}C]-2-Deoxyglucose (2DG) Technique

We determine glucose uptake (GU) from autoradiograms of brain sections, using a modification of Sokoloff's method. GU reflects general neural activity, with likely contributions from several neural elements. The method uses a radiolabeled glucose analog, [^{14}C] 2-deoxy-D-glucose, as a marker for GU and phosphorylation in the brain.

In Situ Hybridization

Both radioactive and nonradioactive in situ hybridization methods are used to determine changes in $GABA_A$ receptor subunit and NKCC1 and KCC2 mRNAs in the SNR. Signal densitometry with the Scion Image 1.62c software (NIH) is used to compare expression across individual cells.

In Vitro Electrophysiology

To study synaptic $GABA_A$ergic PSCs, we use gramicidin-perforated patch clamp recordings of synaptically stimulated SNR neurons, in the presence of glutamate receptor antagonists (AP5 50 μM, CNQX 10 μM). This method does not perturb the chloride gradient during the recordings. Studies also include characterization of the SNR GABAergic neurons and calcium imaging.

Intracranial Single Neuron Recordings in Freely-Moving Rats

A homemade microelectrode/cannula system is advanced slowly to detect action potentials in the $SNR_{anterior}$. Extracellular signals are amplified 10 000× and filtered between 300 Hz and 10 kHz, displayed both on an oscilloscope and digitized on the computer screen. Digitized signals are acquired, processed, and stored using SciWorks 4.0 (Datawave Technologies). After a stable firing baseline is established, muscimol or other $GABA_A$ergic agents are infused into the SNR via the cannula. The recording is resumed 15 min after the cessation of the microinfusion (to allow for resolution of any changes that are directly produced by the infused volume – e.g., change in position of neurons relatively to the recording microwires – that might affect apparent neuronal activity due to mechanical/topography reasons). The recording continues for the next 45 min to determine the drug effects on neuronal activity in $SNR_{anterior}$. Individual action potentials from different

neurons are distinguished based on several parameters, including action potential amplitudes, relative latencies of the negative and positive component peaks, and interspike interval. We create firing rate histograms for the cells over time following $GABA_A$ergic drug infusions.

Quantitative Real-Time-PCR

qRT-PCR reactions are carried out using specific primers for the $GABA_A$ receptor subunits (α1–α6, β1–β3, γ1, γ2l, γ3, δ, ε, π, θ), the $GABA_C$ receptor subunits ρ1–ρ3, the chloride cotransporters and channels NKCC1, KCC1, KCC2, and ClC-2, and the carbonic anhydrase VII (Car-7). We use the ABI Prism 7000 real-time PCR and gene-specific qRT-PCR expression assays developed and standardized by Applied Biosystems.

Immunocytochemistry

Immunochemistry for a variety of $GABA_A$ receptor subunits, parvalbumin, tyrosine hydroxylase, and chloride cotransporters are performed with established protocols to determine the expression of these proteins. Cell counts are performed and signal densitometries are done using the Scion Image NIH 2.62c software.

Results

Studies in Adult Rats

In adult male rats, the involvement of the SNR in seizures was recognized from metabolic mapping studies using 2DG. Among brain structures, the increase in GU in the SNR during different types of seizures is especially striking. While the regional patterns of 2DG uptake vary in different seizure models, the SNR is always activated in adult rats, especially during generalized seizures. Studies using localized drug applications into the SN in rodents have been the bedrock for gaining an understanding of the subcortical mechanisms regulating seizures. Many agents have been infused into the SNR and the results are summarized in Table 1.

In the adult SNR, bilateral microinfusions of the $GABA_A$ agonist muscimol into the SNR revealed the presence of two functionally distinct regions, $SNR_{anterior}$ and $SNR_{posterior}$, that may have different roles in seizure control that are gender-specific (Figure 2). In adult male rats, microinfusions of muscimol into the $SNR_{anterior}$ produce anticonvulsant effects, whereas microinfusions into the $SNR_{posterior}$ are proconvulsant. It should be emphasized that the infusions must be administered bilaterally into the SNR; unilateral infusions are without any effect. Indeed, in adult male rats, a 2DG metabolic study showed that during the evolution of a generalized seizure, the posterior part of the SNR ($SNR_{posterior}$) becomes involved

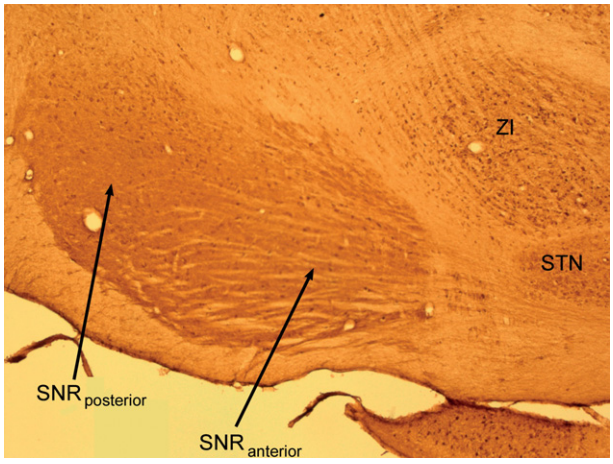

Figure 2 The two SNR regions ($SNR_{anterior}$ and $SNR_{posterior}$) are depicted on a sagittal section stained with GAD67. ZI = zona incerta; STN = subthalamic nucleus.

Table 1 Site-specific effects of various treatments in SNR on flurothyl seizures comparing the effects of various agents on seizures in adult and immature male rats

Agent	*Adult $SNR_{anterior}$*	*Adult $SNR_{posterior}$*	*PN 15 SNR*
Muscimol	Anticonvulsant	Proconvulsant	Proconvulsant
ZAPA	Anticonvulsant	Proconvulsant	Biphasic effects
Bicuculline	Proconvulsant	No effect	Proconvulsant
Zolpidem	Anticonvulsant	No effect	Anticonvulsant
GVG	Anticonvulsant	Proconvulsant	Anticonvulsant
Baclofen	No effect	Not tested	Anticonvulsant
CGP 35 348	No effect	Not tested	Proconvulsant
AP7	Anticonvulsant	Proconvulsant	No effect
Electrical stimulation	Anticonvulsant	No effect	Anticonvulsant

Muscimol, $GABA_A$ receptor agonist at high-affinity and low-affinity sites; THIP, 4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol, $GABA_A$ receptor agonist at high-affinity site; Bicuculline, $GABA_A$ receptor antagonist at low-affinity site; ZAPA ((*Z*)-3-[(aminoiminomethyl)thio] prop-2-enoic acid), $GABA_A$ receptor agonist predominantly at low-affinity site and weakly at high-affinity site; Baclofen, $GABA_B$ receptor agonist; CGP 35348, $GABA_B$ receptor antagonist; GVG (γ vinyl-GABA), increases GABA levels by inhibiting GABA transaminase; Zolpidem, agonist at the benzodiazepine receptor site, linked to the low-affinity site; AP-7 (DL-2-amino-7-phosphonoheptanoic acid).

just before the expression of the seizure, while the anterior part ($SNR_{anterior}$) is activated during the seizure – perhaps signaling the imminent termination of the seizure. 2DG autoradiography shows that the pathways by which the two SNR regions mediate their effects are different (**Figure 1(b)**). In the $SNR_{anterior}$, muscimol infusions decrease 2DG uptake in the striatum, sensorimotor cortex, and ventromedial thalamus. In contrast, when muscimol is infused into the $SNR_{posterior}$, glucose utilization in the dorsal striatum and globus pallidus is increased and glucose utilization in thalamus decreases. In female rats, muscimol produces anticonvulsant effects when infused in $SNR_{anterior}$ but does not change the seizure threshold when infused in the $SNR_{posterior}$.

The prevailing hypothesis to explain the effects of $SNR_{anterior}$ on seizures is that during a clonic seizure there is increased GABA release from striatonigral terminals which silences SNR neurons and leads to disinhibition of SNR output systems, resulting in suppression of the ongoing seizure. This hypothesis is consistent with anticonvulsant effects of bilateral, strictly local injections of $GABA_A$ receptor agonists in the $SNR_{anterior}$, and with the results of nigral lesions. Suppression of the SNR glutamatergic input from the subthalamic nucleus, by local microinfusions of glutamate receptor antagonists (e.g., AP7, an *N*-methyl-D-aspartate [NMDA] receptor antagonist) into the SNR, decreases the firing rate of SNR neurons and induces anticonvulsant effects.

Disinhibition of the nigral output systems, such as the superior colliculus and the pedunculopontine tegmental nucleus, is essential for the muscimol induced $SNR_{anterior}$ anticonvulsant effect. Accordingly, bicuculline infusions in the superior colliculus or pedunculopontine nucleus are anticonvulsant but localized muscimol infusions or lesions are proconvulsant.

Age and Sex Specific Effects

The functional difference (with respect to seizure control) between the $SNR_{anterior}$ and $SNR_{posterior}$ is not seen early in life. Studies have shown that the SNR goes through many anatomical and functional changes throughout development, leading to different age-related and sex-related effects on seizure control. For example, in P15 male rats the SNR does not show any increase in 2DG uptake during seizures; these animals have a high propensity to develop SE, suggesting that the 'adult-like' homeostatic mechanisms involved in seizure control are not properly functioning. Indeed, in P15 and P21 rats of both sexes, there is only one $GABA_A$ sensitive functional region. The functionality of the SNR on seizure control at these ages is sex-specific; infusions of muscimol are proconvulsant in males and have no effect on seizure in females in the flurothyl model. The functional separation occurs at about P25 in both sexes. The adult patterns of the SNR effects on seizures are already present at P25 in females and emerge at P30 in males.

Our findings also support the view that the dynamic changes occurring in the SNR throughout development are sex-specific. In our laboratory we have further evaluated the possible involvement of sex hormones in these sex-specific developmental changes that affect the SNR-mediated seizure control. Testosterone has been shown to play a key role in the development of the male SNR phenotype at distinct developmental stages. It is well recognized that in rats there is a surge of testosterone perinatally, followed by relatively stable levels up to the end of third postnatal week when the testosterone levels drop. From P25, testosterone levels start rising again continuously up to adulthood. The role of perinatal testosterone in the development of the SNR proconvulsant region is supported by experiments that prevent the effect of testosterone by neonatal castration in males, or by blocking endogenous androgen receptor (AR) activation by the AR antagonist flutamide in newborn male rats. Male rats that are castrated on the day of birth (to avoid the postnatal surge of testosterone) or treated with flutamide at P0–2 develop the female phenotype (no muscimol mediated effect of the SNR on seizure thresholds at P15). In females or neonatally castrated males, exogenous treatment with testosterone, or its metabolites dihydrotestosterone and estrogen, during the first postnatal week (and especially during the first 3 days after birth) results in the development of the male SNR phenotype. Importantly, the effects of testosterone change with maturation and are biphasic. Testosterone administration in male rats between P18 and P25 (during the period when natural testosterone levels drop) accelerates the onset of the anticonvulsant SNR region, suggesting that at later developmental stages, testosterone regulates the normal, later appearing maturational pattern of the $SNR_{anterior}$.

$GABA_A$ Receptor Changes Early in Life

It is likely that the sex-related effects of muscimol may be influenced by the specific subunit composition of SNR $GABA_A$ receptors during development. In situ hybridization studies found distinct developmental and spatial patterns of $\alpha 1$ and $\gamma 2L$ $GABA_A$ receptor subunit mRNA expression in the SNR in male rats. In adult male rats, neurons located in the $SNR_{anterior}$ contain higher amounts of $\alpha 1$ and $\gamma 2L$ mRNA hybridization grains and have a higher GABA content per neuron than neurons in the $SNR_{posterior}$. At P15, the labeling of neurons is relatively more diffused throughout the anterior and posterior SNR regions, with cells showing moderate numbers of hybridization grains for both subunits. The finding of age-related, differential distribution of $\alpha 1$ and $\gamma 2L$

subunit mRNAs in the SNR suggests that $GABA_A$ receptor heterogeneity may play a role in the age-specific and site-specific effects of $GABA_A$ergic agents in the SNR on seizures. Subsequent studies showed that in P15 and P30 rats, the $GABA_A$ α1 subunit mRNA expression and GABA immunoreactivity (IR) in the SNR were higher in female rats than in male rats. A regional difference in the $GABA_A$ α1 subunit mRNA expression and GABA IR with regards to $SNR_{anterior}$ versus $SNR_{posterior}$ was not observed in P15 rats, but at P30 the $GABA_A$α1 subunit mRNA expression and GABA IR was higher in the $SNR_{anterior}$ in both male and female rats.

Another important factor in the development of the GABAergic system is the influence of the potassium chloride cotransporters (**Figure 3**). The potassium chloride cotransporter type 2 (KCC2) is known to play a pivotal role in the developmental switch of GABA chloride channel conductance. In the immature brain, GABA has a depolarizing action, which results from the efflux of chloride from the intracellular compartment upon activation of $GABA_A$ receptors. This depolarization results in the activation of voltage-sensitive calcium channels (VSCCs) leading to a large influx of calcium into the cell – which in turn activates calcium-sensitive intracellular events that promote differentiation and regulate gene transcription. During development, the amount of KCC2 present on neuronal cells increases. The developmental increase in KCC2 expression decreases intracellular chloride, via outward cotransport of K^+ and Cl^-, and switches the $GABA_A$ receptor response from depolarizing to hyperpolarizing. In addition to the developmental changes in $GABA_A$ receptor makeup, the accompanying changes in KCC2 expression can also influence the responsiveness of SNR neurons to $GABA_A$ergic agents.

Recently the expression profile of KCC2 in the SNR has been detailed. Several variables, including age, sex, SNR region, and hormonal milieu, were shown to affect the expression of KCC2. Using in situ hybridization, it has been shown that KCC2 mRNA increased between P15 and P30 in both males and females. In males there were no regional SNR differences at P15, but by P30 and in adulthood there was a consistently greater amount of KCC2 mRNA in the $SNR_{anterior}$ than in the $SNR_{posterior}$. Females exhibited similar developmental change as the males, with no anterior–posterior difference at P15, but a greater amount of KCC2 mRNA in the $SNR_{anterior}$ compared to the $SNR_{posterior}$ by P30. Overall, females had greater KCC2 mRNA (both regions of the SNR) compared to males. To determine the source of this gender difference, additional studies examined the role of sex hormones on the developmental profile of KCC2 expression. In P15 rats, KCC2 expression was examined after systemic treatment (4 or 52 h) with testosterone, dihydrotestosterone, and 17β-estradiol. Both testosterone and dihydrotestosterone increased KCC2 expression in male and female rats at both time points. The effects of 17β-estradiol were sex-specific. In males, it decreased KCC2 expression whereas in females there was no effect on

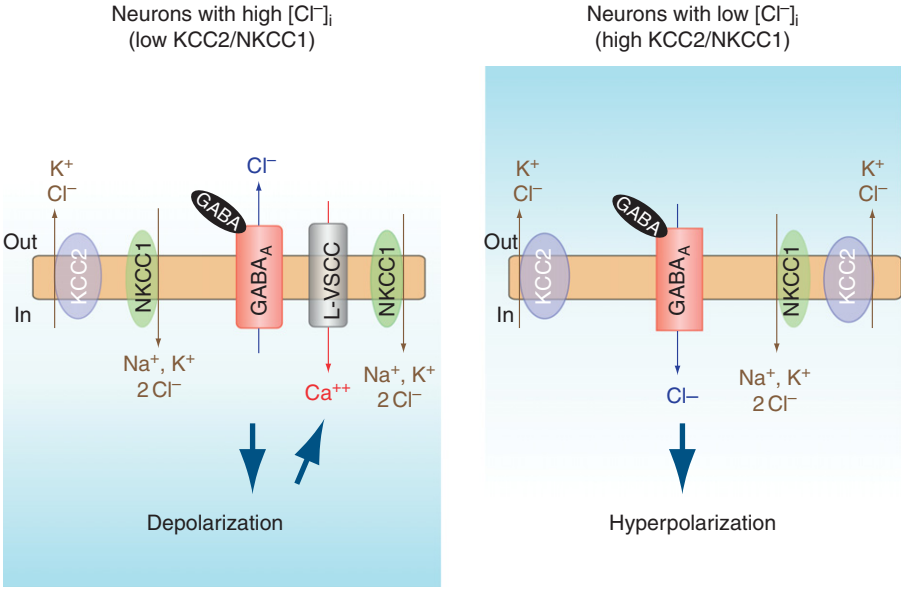

Figure 3 The developmental switch in $GABA_A$ signaling is driven by shifts in the balance of the activity of potassium chloride cotransporters, KCC2 and NKCC1. *Left panel:* In immature neurons, there is high relative expression of NKCC1 over KCC2 which allows the intracellular accumulation of Cl^-. As a result, $GABA_A$ receptor activation leads to depolarizing neuronal responses and activation of L-type VSCCs (L-VSCC) increasing intracellular calcium and activating calcium-signaling processes. *Right panel*: In more mature neurons, KCC2 expression increases and overrides NKCC1 effects, decreasing intracellular $[Cl^-]_i$. As a result, $GABA_A$ receptor activation hyperpolarizes neurons, but cannot activate L-VSCCs or calcium signaling processes.

KCC2 expression. Pretreating SNR neurons with specific inhibitors for either $GABA_A$ receptors or L-VSCCs, it has been shown that the sex-specific patterns of KCC2 regulation by estradiol were linked to the sexually dimorphic $GABA_A$ receptor signaling pathway. Specifically, estradiol decreased KCC2 mRNA only in neurons in which $GABA_A$ receptor activation caused depolarization and activation of L-VSCC, but not in those cells that were hyperpolarized by $GABA_A$ receptor agonists. This differential expression of KCC2 may play a role in the functional compartmentalization of the developing SNR.

Considering the dynamic changes in sex steroid receptors, $GABA_A$ receptors, and KCC2 expression during development, it is apparent that the SNR is a sexually dimorphic brain region. These changes in part reflect the in vivo differences in seizure threshold and susceptibility found between the sexes and during development. Although these differences are readily seen in the flurothyl seizure threshold testing, it is important to further examine the functional effects of these changes at the cellular level. To determine if these sex-related changes are indeed causing functional aberrations in the developing SNR, cellular electrophysiological and calcium imaging experiments have been used. In the SNR, GABAergic neurons of both sexes show spontaneous repetitive firing. These cells also do not show any time-dependent inward rectification to hyperpolarizing current steps, and may in fact also show a sag and inward current of lower amplitude compared to dopaminergic cells. At P14–17, when the male SNR has proconvulsant effects on seizure threshold and females have no effect, SNR neurons were recorded with the gramicidin-perforated patch clamp technique (**Figure 4**). Both males and females had similar resting membrane potentials, spontaneous firing rates, and responses to depolarizing and hyperpolarizing current injections. When the SNR was exposed to muscimol, male SNR cells showed a depolarizing response while female SNR neurons became hyperpolarized. In addition, calcium-imaging data showed that male SNR neurons have an associated increase in intracellular calcium when they depolarize. These results match well with the lower KCC2 expression in males at P15.

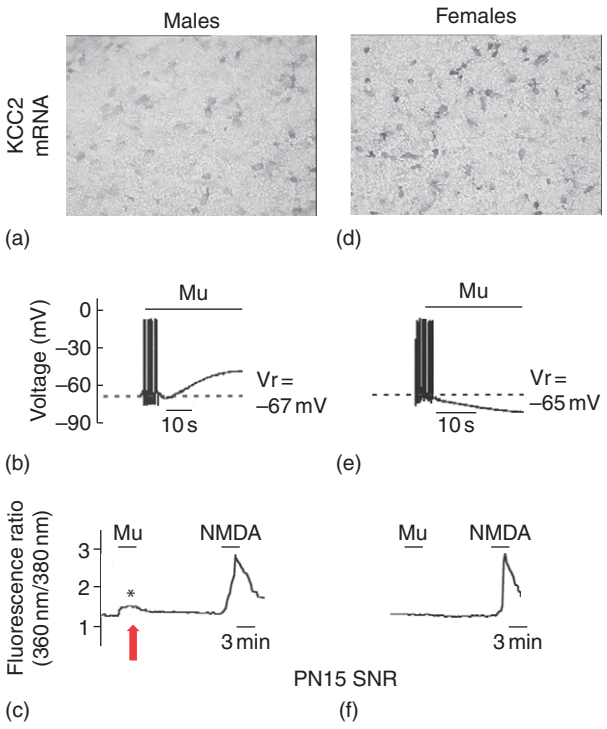

Figure 4 Sex differences in $GABA_A$ signaling in GABAergic neurons of the PN15 rat SNR. The low expression of KCC2 in rat P15 male SNR (a: in situ hybridization) leads to depolarizing responses to muscimol (Mu) (b: gramicidin-perforated patch clamp) and increments in intracellular calcium (red arrow in c: fura-2AM imaging). Female P15 rat GABAergic SNR neurons have higher KCC2 expression (d: in situ hybridization), which triggers muscimol-induced hyperpolarizations (e: gramicidin-perforated patch clamp), without altering calcium intracellularly (f: fura-2AM imaging). In the fura-2AM experiments, NMDA application triggered calcium rises in both male and female neurons. Future Directions

Given that the SNR is a principal player in the endogenous mechanisms for seizure control, it follows that a deviation from normal developmental processes of the SNR may have profound influences on long-term outcomes on seizure control. Epidemiological studies suggest that early in life (particularly in the neonatal period), the brain is highly susceptible to seizures and especially SE. The increased propensity of the developing brain to experience SE may be related to immaturity of the networks (such as the SNR-based network) that can suppress recurrent seizures in adults. Understanding the spectrum and progressive nature of SE-induced changes in brain function may have important implications in the design of treatments aimed at disease modification. These treatments can potentially be used over relative short periods, thus avoiding the potentially detrimental effects of long-term drug administration.

However, the mechanisms available to terminate seizures in otherwise normal healthy brain may not be available to terminate seizures in a brain that has already experienced seizures. The effectiveness of the SNR to influence seizure duration and recurrences appears to be dependent on previous seizure history. In adult male rats, amygdala kindling modifies the firing pattern of SNR neurons, switching them into a burst firing mode. Also, in adult male rats, SE induced by various

means (flurothyl, pentylenetetrazol, lithium–pilocarpine) results in acute SNR lesions. Long-term studies in the lithium–pilocarpine model show that, during the latent phase prior to the emergence of spontaneous seizures, there are marked, chronic increases in SNR metabolic activity. This observation suggests that the SNR may be involved in the chronic reorganization of brain circuits leading to the development of spontaneous seizures.

Preliminary data from our laboratory indicate that the development of the $SNR_{anterior}$ is distorted if infant rats experiencing three episodes of kainic acid induced SE (3SE) prior to P6 (irrespective of sex) by preventing the emergence of the $SNR_{anterior}$ $GABA_A$-sensitive anticonvulsant region at P30, as revealed by localized microinfusions of muscimol or zolpidem. Three SE are not associated with acute neuronal injury in SNR. However, in the SNR, 3SE rats increase the expression of the chloride cotransporter KCC2 mRNA; accelerate the sex-specific switch of synaptic $GABA_A$-ergic responses from depolarizing to hyperpolarizing (referred to here as E_{GABA} switch); induce changes in $GABA_A$ receptor subunit expression, with downregulation of the expression of $\alpha 1$ and $\gamma 1$ subunits at P30; and attenuate the responsiveness of $SNR_{anterior}$ neurons to $GABA_A$ agents in vivo and in vitro at P30. If 3SE are induced in P14-16 male rats (a period during which the E_{GABA} switch naturally occurs), the $SNR_{anterior}$ $GABA_A$-sensitive anticonvulsant region develops normally. The depolarizing effects of GABA are important for neuronal differentiation. The data suggest that, during a specific developmental window, the 3SE-induced increases in KCC2 expression and the resultant early appearance of E_{GABA} switch may shorten the period during which the normal GABA-mediated differentiation of SNR occurs. Further, the data imply that the detrimental effects of 3SE occur within days after SE and provide a possible means for intervention based on short-duration treatments that may prevent or revert the 3SE-induced increases in KCC2 expression.

Thus, the challenge for the future will be to identify early life insults that can potentially alter the normal development of SNR seizure controlling networks. Accomplishing this goal would constitute a major advance in the study of the critical role of the SNR as an endogenous seizure controller, and would permit us to address some of the mechanisms by which remote early life events can lead to reduced seizure thresholds and chronic epilepsy – issues that are currently poorly understood. To translate the experimental data to clinical practice, it is important to perform studies to identify the contribution of the SN in seizures in humans, especially early in life. To achieve this goal, imaging techniques with better than currently available resolution are needed to determine the role of the SN before, during, or after seizures. To date, PET imaging and NMR spectroscopy are two techniques that have been used to study the role of the basal ganglia networks in the control of generalized seizures in adults only; there are many limitations in carrying out such studies in infants and children, including issues related to sedation. Progress in technology is a much needed step to better understand the role of the diffuse systems involved in the control of seizures (such as the SN) and thus institute age-specific and possibly sex-specific interventions.

Our current research has provided mechanistic explanations for the age-specific and possibly sex-specific effects of neuroprotective/disease modifying agents that can be used to prevent or restore some of the detrimental effects of early life SE on an endogenous system involved in seizure control. These studies, to understand the function of the SNR during development in the male and female brain, should also offer significant insights to the field of developmental biology as it pertains to epigenetic influences on the development of the SNR, a sexually dimorphic structure. We hope that our studies will lead to a better understanding of the role of the SNR in the expression of comorbidities associated with epilepsy. Indeed, the SN may play a significant role in depression, integration of cognition, and expression of movement disorders such as stereotypies. The latter is a prominent feature of autism, a condition in which seizures frequently coexist.

Introduction

It was long believed that no new cells were born in the adult brain, and as a result, injury and neurodegeneration were irremediable. Evidence slowly accumulating over the past 40 years has overturned this dogma and suggests a role for adult-born cells both in normal cognition and after brain injury. Germinative zones persist in the adult mammalian forebrain subventricular zone (SVZ) and hippocampal dentate gyrus (DG). These areas contain neural progenitors that continue to generate neurons, as well as glia, throughout life. Adult-born neurons migrate long distances from the SVZ to the otherwise mature olfactory bulb, or a short distance within the DG, and integrate into neural circuits probably involved in olfactory function, and learning and memory, respectively. Normal aging decreases but does not extinguish this process, and decreased neurogenesis has been implicated as a potential mechanism involved in depression and dementia. Further, brain injuries as diverse as stroke, trauma, and seizure stimulate neuronal production and subsequent migration to sites of damage. Adult neurogenesis thus represents a novel mechanism for brain plasticity which not only modifies neural activity but also may rejuvenate or repair the injured brain.

Introduction

It was long believed that no new cells were born in the adult brain, and as a result, injury and neurodegeneration were irremediable. Evidence slowly accumulating over the past 40 years has overturned this dogma and suggests a role for adult-born cells both in normal cognition and after brain injury. Germinative zones persist in the adult mammalian forebrain subventricular zone (SVZ) and hippocampal dentate gyrus (DG). These areas contain neural progenitors that continue to generate neurons, as well as glia, throughout life. Adult-born neurons migrate long distances from the SVZ to the otherwise mature olfactory bulb, or a short distance within the DG, and integrate into neural circuits probably involved in olfactory function, and learning and memory, respectively. Normal aging decreases but does not extinguish this process, and decreased neurogenesis has been implicated as a potential mechanism involved in depression and dementia. Further, brain injuries as diverse as stroke, trauma, and seizure stimulate neuronal production and subsequent migration to sites of damage. Adult neurogenesis thus represents a novel mechanism for brain plasticity which not only modifies neural activity but also may rejuvenate or repair the injured brain.

The causes and pathophysiology of mesial temporal lobe epilepsy (mTLE) are poorly understood. Because this disorder involves a region of persistent neuronal birth (the DG), study of mTLE provides a unique opportunity to examine not only how injury influences adult neurogenesis but also the resulting consequences for neural plasticity, disease pathophysiology, and functional recovery. mTLE is a progressive disorder that is associated with intractable complex partial seizures and disturbed short-term memory. In many cases, the epileptic focus is presumed to be located in the hippocampus and consequently may involve the population of neural progenitors in the DG. The epileptic focus, further, is commonly marked by mesial temporal sclerosis, with loss of neurons in the Cornu Ammonis (CA) and dentate hilus. Seizures are known to acutely stimulate adult neurogenesis, so neural proliferation has been implicated in mTLE – but whether its role is causative, reactive, or compensatory is unclear. Seizures may trigger aberrant adult neurogenesis, recruiting new/immature cells to epileptogenic neural pathways. Alternatively, increased adult neurogenesis may be merely reactive (or even vestigial), responding ineffectively to cell damage. Also possible, and indeed the best of alternatives, is that adult neurogenesis may represent an attempt by the brain to replenish damaged populations and improve recovery. Elucidating how neurogenesis and epilepsy are related, therefore, has the potential to elucidate, counteract, and even prevent epileptogenesis, as well as to clarify how epilepsy impairs learning and memory.

Background

Adult Neurogenesis in the SVZ and DG

The earliest report of adult neurogenesis dates to the early twentieth century, when mitotic figures in the adult rodent brain were identified as evidence of proliferating neural progenitors. In the mid-1960s, mitotic labeling with tritiated thymidine suggested cells in the SVZ and DG continue to proliferate in the adult rodent, and electron microscopy later confirmed these newborn cells as neurons. Since then, adult neurogenesis has been found in the DG and SVZ of every mammalian species examined, including humans, but most data are based on rodent studies. In these DG and SVZ regions, neural progenitors compose a defined population of small, radial glia-like cells. In the DG, these stem like cells send out long processes that may help guide migrating neuroblasts or the outgrowth of their processes. At any given time, only a small proportion of progenitors are actively dividing. This proliferation appears tightly regulated in vivo and is likely modulated by a number of growth and neurotrophic factors, among other stimuli.

Although the SVZ and DG both support germinative zones, the plasticity of adult-born cells differs widely at each site. Adult neurogenesis occurs extensively along the rostral SVZ of the lateral ventricles. From this niche, neuroblasts migrate tangentially through the rostral migratory stream to the olfactory bulb. In the bulb, they disperse and differentiate into granular and periglomerular interneurons. This prolific process substitutes as much as 3% of the olfactory interneuron population daily. Further, SVZ progenitors are true neural stem cells (NSCs), displaying multipotentiality in vitro. Stroke and other neurological insults recruit neuroblasts from the ipsilateral and contralateral SVZ to areas of injury, where they may survive and integrate in damaged neural circuits.

By comparison, neurogenesis in the DG is restricted to the subgranular zone. Neuroblasts subsequently migrate a short distance to the granule cell layer where they mature as dentate granule cells (DGCs). Proliferation occurs at a much lower rate in the DG than in the SVZ, replacing a mere 0.05% of dentate granule cells daily. And while injury similarly stimulates neurogenesis in the DG, adult-born neurons are confined to the hippocampus and only appear capable of differentiating into DGCs and not other neuronal subtypes. Whereas SVZ neuroblasts are thought to participate in olfactory discrimination and memory, dentate neuroblasts are implicated in hippocampal learning and memory.

Aberrant Neurogenesis in mTLE

Rodent models of mTLE show a dramatic increase in DGC neurogenesis (5–10 fold) after chemoconvulsant- or electrically induced status epilepticus (SE). After a latent period of several days, the newborn neurons migrate, differentiate, and display markers of mature DGCs. Many of the DGCs generated after SE survive for months to years. At the same time, seizure-related excitotoxicity causes extensive damage and neuronal loss, and the epileptic hippocampus undergoes considerable network reorganization. As a result, the relationship between dentate neurogenesis and neural plasticity has been the focus of considerable research.

Seizure-induced DGC neurogenesis is associated with at least three forms of aberrant plasticity during epileptogenesis. The first is mossy fiber sprouting, the remodeling of DGC axons (mossy fibers) into the supragranular molecular layer of the DG. This remodeling is believed to result in recurrent excitatory circuits and subsequent hippocampal hyperexcitability. Although initially implicated in sprouting, the role of newborn cells in this process appears to be more complex than originally suspected (see below). Another form of plasticity, one that seems to involve only adult-born cells, is the persistence of hilar basal dendrites. Mature DGCs typically extend only a single apical dendrite into the molecular layer, but in experimental mTLE models, a much larger percentage show basal dendrites. Recent work suggests that these are

all adult-born DGCs, and the basal dendrites persist indefinitely. A third form (or two unrelated forms) of abnormal plasticity involves DGC layer dispersion and the finding of DGCs in ectopic locations in the dentate hilus and molecular layer after an epileptogenic insult. At least in the latter instance, the heterotopic appearance of DGCs appears limited to effects on DGC progenitors. Ongoing investigations in these areas are discussed under the 'Recent Results' section.

Methodological Approaches

The study of adult NSCs and neurogenesis first and foremost involves the ability to identify proliferating and migrating cells. The simplest way to label dividing cells is to immunostain them, using an antibody that recognizes a protein expressed only during active cell cycling, such as Ki67, proliferating cell nuclear antigen (PCNA), or mini-chromosome maintenance protein-2 (MCM-2). This approach, however, only allows a single 'snapshot' of the dividing cells and does not allow one to determine their eventual phenotypes. The time-honored approach for labeling dividing cells, then and determining their phenotypes after they differentiate, has been labeling with tritiated thymidine, a hydrogen radionuclide-labeled nucleotide that is incorporated into the DNA of dividing cells and can later be detected by autoradiography. This approach proved cumbersome and insensitive, however, and was largely replaced by the development of an antibody to the thymidine analog, bromodeoxyuridine (BrdU). BrdU also is taken up in dividing cells but is more easily identified using immunohistochemistry, with an anti-BrdU antibody. To 'see' the BrdU, DNA must first be denatured to single strands, usually by hydrochloric acid treatment so that the antibody can bind to the BrdU. BrdU can be used to 'pulse' label dividing cells, by injecting it and looking at the cells within hours. Alternatively, one can use a 'chase' period in which one waits days to weeks after the BrdU is administered to identify cells that had earlier incorporated the BrdU; this approach also allows the investigator to determine the cell types into which the newborn cells developed after becoming postmitotic.

A major disadvantage of tritiated thymidine or BrdU labeling of dividing cells is that only the nuclei of labeled cells are visualized, and thus no information on cell morphology is available. In the nervous system, therefore, the cell bodies, axons, and dendrites of recently dividing cells cannot be visualized. Several strategies have been developed more recently to overcome this limitation. The first is the use of retroviral reporter labeling. Retroviruses only infect dividing cells because they require dissolution of the nuclear envelope to incorporate into the genome. A retrovirus can be engineered to carry a reporter gene, such as green fluorescent protein (GFP) that will label the entire cell within a few days. Because the retrovirus integrates into the genome, it is faithfully passed on to each generation such that all progeny of the initially infected, dividing cell are labeled. One potential disadvantage of this approach is that some retroviral promoters are silenced, or turned off, over time so that the cells can no longer be tracked. This problem has been overcome by using strong internal promoters that are less likely to be silenced for driving expression of GFP (or other reporter genes). In conjunction with the definitive identification of neurons by immunohistochemistry, therefore, the location, differentiation, migration, and regulation of adult-born neurons are now subject to investigation.

Several other new techniques have led to advances in NSC biology and adult neurogenesis. One technique is cell culture to isolate neural progenitors from adult brain, creating neurospheres that display self-renewal and are multipotent in vitro. Another recently developed and powerful approach is to label NSCs and their progeny during embryonic or adult life using transgenic mouse technology. Mice have been generated in which neural progenitor cell- or immature neuron-specific promoters drive reporter gene expression (**Figure 1**). If this technique is combined with inducible gene recombination (e.g., using the Cre–LoxP system), one can permanently and specifically label NSCs and all their progeny in the adult. Such transgenic mice have proven very useful for labeling neural progenitors or adult-born neurons in the mature brain. This approach, which also allows for the specific deletion of 'floxed' genes in these same cells, combined with the retroviral reporter gene method, likely

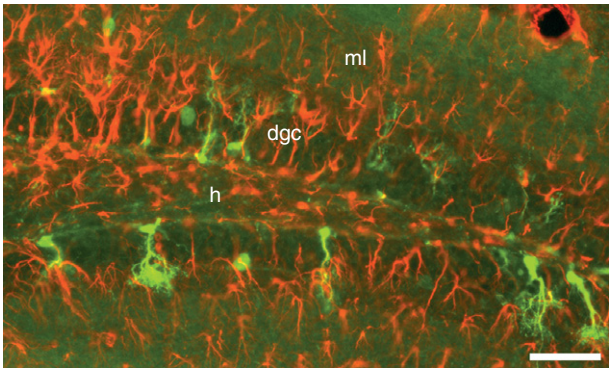

Figure 1 This photomicrograph shows immunofluorescence double labeling for GFP (green) and glial fibrillary acidic protein (GFAP; red) in a coronal brain section through the hippocampal DG of an adult nestin-GFP transgenic reporter mouse. GFP-labeled (green) neural stem cells appear in the dentate subgranular zone and inner DGC layer. GFAP labels astrocytes and neural stem cells, and many of the GFP-positive cells have slightly yellow processes because they also express low levels of GFAP. DGC, dentate granule cell layer; h, hilus; m, molecular layer. Scale bar, 50 μm.

will usher in tremendous advances in the field of adult neurogenesis over the next decade.

Recent Results

Using the adult rat pilocarpine-induced SE model of mTLE, our group first investigated the role of dentate neurogenesis in relation to aberrant mossy fiber sprouting to the molecular layer of the DG and within area CA3. As increased DGC neurogenesis precedes mossy fiber remodeling in rodent seizure models, and the differentiation of newborn neurons occurs in parallel with axonal reorganization, it is plausible that newborn DGCs lead to mossy fiber sprouting. Inhibition of neurogenesis by irradiation prior to SE, however, fails to inhibit mossy fiber remodeling at four weeks after pilocarpine treatment. These data indicate that although newborn neurons may contribute to mossy fiber sprouting, preexisting DGCs are predominantly responsible for these aberrant fibers (and associated synapses). Interestingly, recent work using retroviral reporter labeling of adult-born DGCs, before or after SE, showed that (consistent with our radiation findings) cells labeled after SE did not contribute to sprouting. Those labeled 4 weeks prior to SE, however, did show mossy fiber sprouting, suggesting that differentiating 'juvenile' DGCs (i.e., those born shortly before the SE insult) respond to injury by reorganizing their axons. The fact whether fully mature DGCs are also capable of sprouting remains to be determined. In contrast, hilar basal dendrite formation and the ectopic migration of DGC progenitors appear to be limited to DGCs generated just before or after SE. These abnormalities also may form continually during chronic epilepsy rather than just during the acute epileptogenic phase.

Recent research has explored more closely the role of aberrant neurogenesis in granule cell layer dispersion and migration of adult-born DGCs to ectopic locations in the hilus and molecular layer. This disruption of the normal hippocampal architecture may contribute to the formation of aberrant excitatory circuits. Within 2 weeks of chemoconvulsant-induced SE in adult rodents, DGCs appear in ectopic locations in the DG, accumulating for at least several weeks (**Figure 2**). Rather than migrating from the SGZ to the GCL, chains of neuroblasts extend to the hilus and, to a lesser degree, molecular layer. Of note, the degree of GCL dispersion in human mTLE correlates with decreased expression of mRNA for reelin. Reelin is a secreted neuronal migration guidance cue that is important for embryonic cortical development; it is expressed in the adult cortex and hippocampus for unknown reasons. We have found that reelin protein expression also decreases in experimental mTLE in association with ectopic migration of neuroblasts, and that reelin directly influences chain migration of DG neuroblasts grown in tissue culture. Thus, altered developmental molecules that persist in the adult may contribute to abnormalities of persistent neurogenesis in mTLE.

What is the functional effect of adult-born ectopic DGCs in terms of hippocampal network function after an epileptogenic insult? On a structural level, ectopic

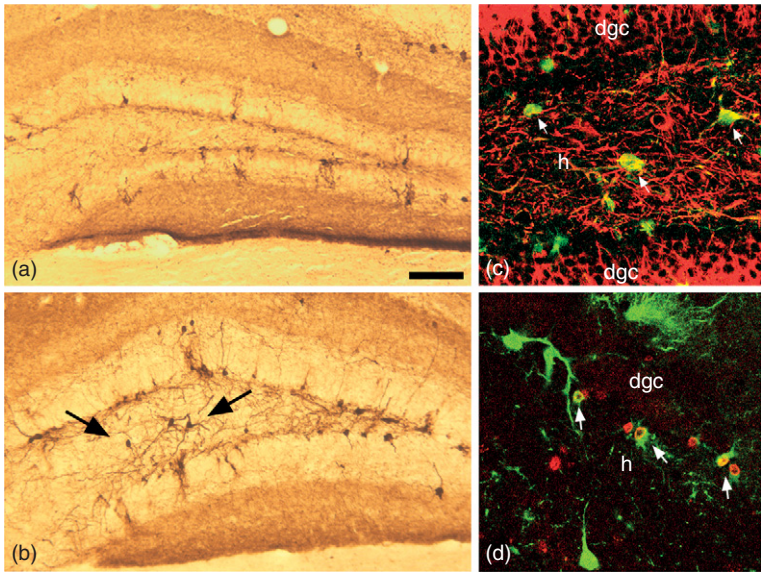

Figure 2 (a, b) Peroxidase immunohistochemistry for GFP in nestin-GFP transgenic mice treated with saline (a) or 2 weeks after pilocarpine-induced SE (b). Note the increase in GFP expression after seizures, especially in the hilus (arrows in b). DGCs possess more persistent basal dendrites and excitatory synaptic inputs than normal granule neurons, supporting a hyperexcitable phenotype of newborn cells in experimental mTLE. The abnormal hilar basal dendrites appear to receive remarkably increased numbers of excitatory inputs compared to typical DGC dendrites. On an electrophysiological level, study of acute hippocampal slices obtained from rats following chemoconvulsant-induced SE confirms the integration of hilar granule-like neurons in hippocampal circuits. In contrast to normal DGCs, however, these granule-like neurons demonstrate abnormal burst firing in synchrony with CA3 pyramidal cells, contributing to a possible epileptic pathway. In support of this idea, recent data indicate that inhibition of neurogenesis (with continuous infusion of an antimitotic agent) inhibits ectopic granule cell formation and reduces spontaneous seizure frequency after SE-induced injury. The antimitotic agent, however, also depletes DGC progenitors that develop normally within the layer (see below) and also has important nonspecific effects. Nonetheless, mounting evidence suggests that increased dentate neurogenesis after experimental SE leads to ectopic, dysfunctional DGCs that likely contribute to epileptogenesis.

Several considerations serve as caveats to the above conclusion. First, one group has shown that adult-born DGCs that develop normally in the DGC layer after electrically induced SE contribute to recurrent inhibition and may restore lost inhibitory tone. In addition, some investigators find that after chronic hippocampal injury in rodent epilepsy models, dentate neurogenesis declines severely, suggesting the DGC progenitor population is depleted or suppressed. Therefore, a competition of aberrant and compensatory DGC neurogenesis may occur in early epileptogenesis; however, in chronic epilepsy the suppression of neurogenesis may have additional functional significance.

Challenges for the Future

A number of questions remain to be addressed regarding the causes and consequences of seizure-induced neurogenesis. First, knowledge of the normal molecular regulation of adult hippocampal neurogenesis is incomplete, and the mechanisms underlying seizure-induced neurogenesis are even less clear. Some evidence points to the involvement of neuropeptides in modulating the increased neurogenesis seen after seizures. Many other important regulators undoubtedly will be uncovered. In addition, the causes of ectopic migration and hilar basal dendrite formation are poorly understood. As described above, existing evidence implicates reelin in ectopic migration, but other factors probably play a role. Levels of brain-derived neurotrophic factor, for example, increase after seizures and this neurotrophin is a prime candidate for stimulating both ectopic migration and abnormal dendritic development. The neural stem cell niche or local environment influences neural stem cells and neurogenesis, and almost certainly also is involved in altered neurogenesis after injury. The niche includes endothelial cells, astrocytes, and – with injury – microglia. These cell types are implicated in modulating NSCs and neurogenesis in both normal and disease states.

Another key area requiring further exploration is the functional consequences of seizure-induced neurogenesis. One approach of current research is to selectively ablate adult-born neurons and determine how this lesion impacts the development of epilepsy. Even more useful will be the development of an approach to block only *aberrant* neurogenesis and perhaps leave potentially compensatory neuronal birth unaffected. This strategy, when accomplished, will allow for a determination of whether abnormal neurogenesis contributes to epileptogenesis. A third question relates to effects of the probable exhaustion of the neural stem cell pool in chronic epilepsy as mentioned above. If DGC neurogenesis is involved in hippocampus-dependent learning and memory, the lack of neurogenesis may explain the disabling memory disturbances seen in mTLE. Careful behavioral testing in experimental mTLE models will be necessary to sort out how aberrant or depleted neurogenesis impacts cognitive function.

Finally, evidence of impaired neurogenesis in human mTLE exists but is not strong. Better techniques for identifying NSCs and neurogenesis in human hippocampus, both histologically and non-invasively, will be required to examine this problem. Once the role aberrant neurogenesis plays in epilepsy development or cognitive comorbidity is defined in the human disorder, novel stem cell-based therapies to prevent or alleviate mTLE may be forthcoming.

Introduction

New neurons develop in the adult mammalian brain in several locations, but primarily within the subventricular zone and the dentate gyrus. In the dentate gyrus, most progenitors are thought to arise from the subgranular zone, a thin layer just below the granule cell layer. The majority of these progenitors become granule cells, and most migrate to the granule cell layer and become integrated into the normal circuitry. Earlier studies of granule cells born in the adult brain suggested that many of these new cells did not survive for long periods of time, which led to questions related to their functional importance. However, more recent experiments suggest that these newly born cells have a role in basic hippocampal functions such as learning and memory.

The process of dentate gyrus neurogenesis is not static in the mature animal. Many stimuli can influence the rate of proliferation, the cell type specificity of newly born cells, and their survival. Neuronal activity typically increases the rate of proliferation, as does exercise, environmental enrichment, and various growth factors and neuropeptides such as BDNF (brain-dervied neurotrophic factor), VEGF (vascular endothelial growth factor), and neuropeptide Y. The rate of neurogenesis also changes in various neurological disorders and psychiatric illnesses. For example, in depression, neurogenesis is decreased and antidepressant medication may alleviate symptoms by increasing neurogenesis.

Seizures appear to be a robust stimulus that increases the rate of neurogenesis. Remarkably, almost every type of seizure-like event that has been examined to date has this effect. After discharges, electroconvulsive shock and other brief seizures have been reported to increase the rate of dentate gyrus neurogenesis, and appear to do so in diverse species. Status epilepticus leads to perhaps the most marked increase in dentate gyrus neurogenesis, possibly because it is the most severe and most prolonged of the types of experimental seizures that have been studied. However, the relationship between seizures and neurogenesis is not necessarily as simple as this statement might imply. Stronger and more prolonged seizures may increase proliferation more than milder seizures, but the increase in neurogenesis may be different; seizure-induced damage is greater as the severity and duration of a seizure increases, and this effect can lead to fewer surviving progenitors, and may damage the subgranular zone pool of precursors. For example, unilateral

Introduction

New neurons develop in the adult mammalian brain in several locations, but primarily within the subventricular zone and the dentate gyrus. In the dentate gyrus, most progenitors are thought to arise from the subgranular zone, a thin layer just below the granule cell layer. The majority of these progenitors become granule cells, and most migrate to the granule cell layer and become integrated into the normal circuitry. Earlier studies of granule cells born in the adult brain suggested that many of these new cells did not survive for long periods of time, which led to questions related to their functional importance. However, more recent experiments suggest that these newly born cells have a role in basic hippocampal functions such as learning and memory.

The process of dentate gyrus neurogenesis is not static in the mature animal. Many stimuli can influence the rate of proliferation, the cell type specificity of newly born cells, and their survival. Neuronal activity typically increases the rate of proliferation, as does exercise, environmental enrichment, and various growth factors and neuropeptides such as BDNF (brain-dervied neurotrophic factor), VEGF (vascular endothelial growth factor), and neuropeptide Y. The rate of neurogenesis also changes in various neurological disorders and psychiatric illnesses. For example, in depression, neurogenesis is decreased and antidepressant medication may alleviate symptoms by increasing neurogenesis.

Seizures appear to be a robust stimulus that increases the rate of neurogenesis. Remarkably, almost every type of seizure-like event that has been examined to date has this effect. After discharges, electroconvulsive shock and other brief seizures have been reported to increase the rate of dentate gyrus neurogenesis, and appear to do so in diverse species. Status epilepticus leads to perhaps the most marked increase in dentate gyrus neurogenesis, possibly because it is the most severe and most prolonged of the types of experimental seizures that have been studied. However, the relationship between seizures and neurogenesis is not necessarily as simple as this statement might imply. Stronger and more prolonged seizures may increase proliferation more than milder seizures, but the increase in neurogenesis may be different; seizure-induced damage is greater as the severity and duration of a seizure increases, and this effect can lead to fewer surviving progenitors, and may damage the subgranular zone pool of precursors. For example, unilateral

hippocampal kainic acid infusion has been shown to increase dentate gyrus *proliferation* bilaterally, but *neurogenesis* was only increased contralateral to the infusion site, where the least damage occurred.

In light of the robust nature of seizure-induced neurogenesis, a great deal of attention has been paid to its implications. Do the new neurons play a role in epilepsy? Do they contribute to network excitability, either by increasing it or decreasing it? These questions have become the focus of current studies.

Background

There are several suggestions for the role that new neurons in the dentate gyrus might play in epilepsy. Most of these possibilities are germane to TLE, since the hippocampus is often involved in TLE.

How might new neurons contribute to TLE? The fact that there is generally more plasticity in newly generated neurons than in mature neurons makes seizure-induced neurogenesis a potential explanation for several abnormal anatomical findings that are associated with TLE. For example, newly born granule cells could be responsible for the outgrowth of the granule cell axons (mossy fibers) in abnormal locations (mossy fiber sprouting) or the emergence of basal dendrites in granule cells of the granule cell layer. It is also possible that the dispersion of the granule cell layer in epileptic tissue is due to the inability of adult-generated granule cells to terminate in the exact location of the normal granule cell. However, irradiation that reduces seizure-induced neurogenesis does not abolish mossy fiber sprouting. Regarding granule cell dispersion, new data suggest a role of seizure-induced reduction in reelin, which normally hinders granule cell migration outside the boundaries of the granule cell layer. Therefore, new neurons may not necessarily play a seminal role in mossy fiber sprouting or granule cell dispersion.

There are other ways that seizure-induced neurogenesis could play a role in TLE. For example, an initial precipitating insult (which many believe initiates epileptogenesis) might stimulate neurogenesis in the dentate gyrus, contributing to abnormal structure and/or function associated with epileptogenesis (**Figure 1**). New neurons might promote increased excitability, because they are more excitable (at least in the normal rodent brain) than are granule cells born during development. It might also be the case that seizures occur chronically in TLE because new neurons are born after each seizure – and each time this neurogenesis occurs, excitability increases further. It is important to note, however, that some new neurons do not exhibit characteristics associated with increased excitability, suggesting that dentate gyrus neurogenesis may not always lead to changes that promote seizures. Indeed, it is possible that the net effect of new neurons is not directly related to seizures, but to cognitive or mood-related changes. The new neurons may simply disrupt normal circuitry, because they change the normal network connectivity, and in so doing impair cognitive function. This disruption could be relevant to the defects in learning and memory, and depression, which have been observed in TLE.

Note that seizure-induced changes in neurogenesis may change over time. It appears that the rate of neurogenesis increases soon after an initial precipiating event (such as status epilepticus); however, several weeks later, when chronic recurrent seizures develop, data from animal models of TLE and patients with intractable TLE suggest that the rate of neurogenesis declined below normal. The initial rise in neurogenesis could stimulate epileptogenesis, and the chronic decline could be responsible for cogntive and mood-related changes.

A contrasting perspective is that seizure-induced neurogenesis is not a factor in epileptogenesis or cognitive dysfunction at all, but actually is restorative (**Figure 1**). In other words, neurogenesis may be a compensatory mechanism to replenish neurons, because the initial precipitating event leads to neuronal loss. Other effects of seizures, independent of neurogenesis, would be responsible for increased excitability and cognitive effects.

Methods

If one wanted to study seizure-induced neurogenesis, what would be the ideal approach? The answer to that question depends on the goal of the study. If the goal is to examine potential mechanisms of TLE, using an animal model of TLE is appropriate. Which model? Of those that have been developed, models that use status epilepticus as an initial precipitating insult appear to lead to the most reliable induction of spontaneous seizures. However, status epilepticus leads to severe brain damage, and the degree of damage often appears to be more than that occurs in TLE. Therefore, a modification to reduce status-induced brain damage, but maintain the spontaneous seizures, is ideal. Toward that end, many laboratories administer an anticonvulsant drug to limit status epilepticus. When diazepam is administered one hour after the onset of pilocarpine- or kainic acid-induced status epilepticus, neuronal damage is decreased greatly, but animals still develop robust spontaneous seizures after several weeks, and structural changes such as mossy fiber sprouting and granule cell dispersion are robust.

How does one study new granule cells? Many laboratories use a combination of approaches to distinguish neurons that are born after status from those that were born during development. A useful tool is the granule cell marker, Prox1, which does not label other hippocampal neurons. In addition, intracellular labeling is useful to establish granule cell characteristics, including the

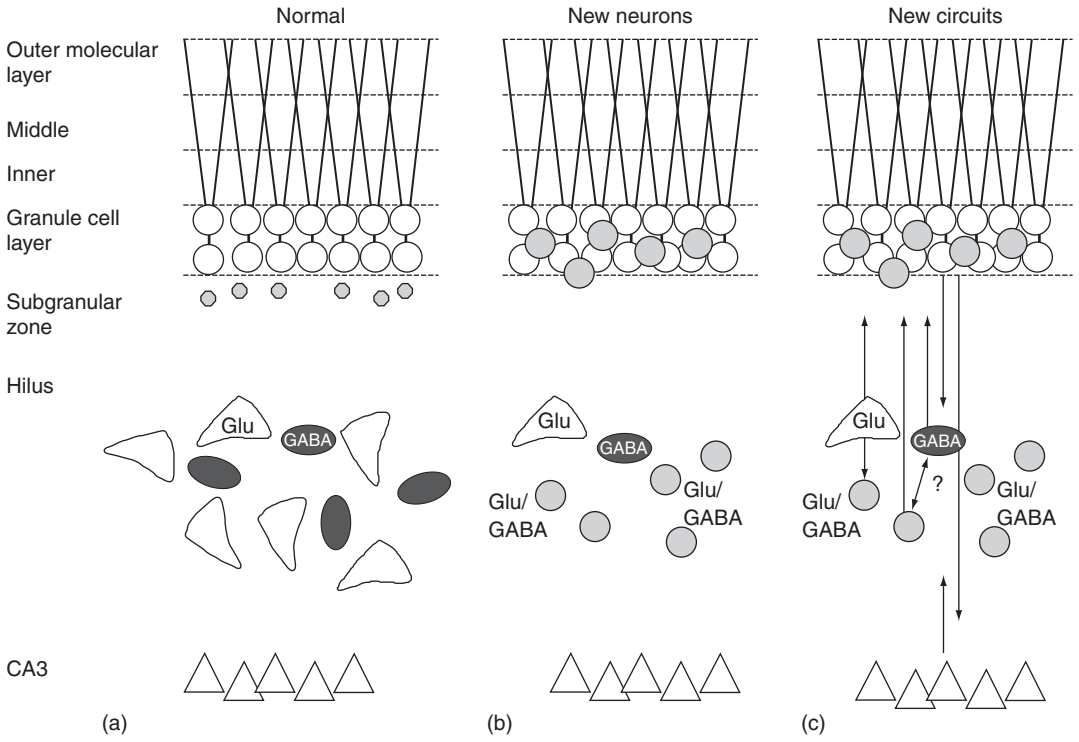

Figure 1 Seizure-induced neurogenesis after status and its potential influence on excitability in the dentate–CA3 network. (a) A schematic of the dentate gyrus illustrates the laminar organization of the dentate gyrus and several of the prominent neuronal subtypes in the normal adult rodent. White indicates glutamatergic cells, which are granule cells and mossy cells. Black indicates inhibitory neurons, which use GABA as a primary neurotransmitter. (b) After status in animal models of TLE, new neurons develop from progenitors in the subgranular zone and migrate into the cell layer as well as ectopic locations, such as the hilus. The new neurons, like granule cells in the granule cell layer, synthesize glutamate as their primary transmitter, but also synthesize GABA and potentially have inhibitory actions. Many of the normal hilar neurons are lost after status-induced damage occurs. (c) Circuitry involving newly generated neurons after status include glutamatergic and GABAergic pathways. Electrophysiological recordings in slices of animals after status have shown that hilar cells often develop epileptiform bursts, synchronized with area CA3 pyramidal cells, and the generator appears to be within CA3. These bursts appear to influence granule cells primarily by hilar projections to the granule cells.

granule cell axon or 'mossy fiber,' which has unique specializations and projections. The mitotic marker, bromodeoxyuridine (BrdU) is taken up into dividing cells for approximately 2 h after peripheral injection, leading to BrdU uptake into newly generated cells that could subsequently be identified by immunocytochemistry using an antibody to BrdU. The use of BrdU, though common, has its pitfalls in studies of seizures. A seizure that opens the blood brain barrier could increase brain BrdU to a greater extent than the rise in BrdU that would occur in a control animal. Some investigators have argued that BrdU uptake by damaged cells occurs during DNA repair, although studies in culture have indicated that this problem does not occur in practice as much as might be expected.

Alternatives to the use of BrdU involve viral vectors that specifically target newly born neurons and label them with green fluorescent protein (GFP) so that they can be visualized. One drawback is that all new cells may not be labeled. Another problem with this approach is that the injection required to introduce the viral vector into the dentate gyrus lead to injury and reactive changes which are confounding.

Recent Results

Seizure-Induced Neurogenesis of Granule Cells: Does it Contribute to Epileptogenesis or is it Restorative?

There are several lines of evidence that support a proexcitatory role of adult neurogenesis in the dentate gyrus under normal conditions, as well as in the context of epilepsy. Under normal conditions, electrophysiological studies have identified characteristics of granule cells that are consistent with increased excitability, such as depolarizing responses to GABA. In addition, it appears that newly generated granule cells contribute to perforant path-induced LTP, whereas granule cells that are born during development play a more limited role.

In animal models of TLE, there also is evidence that the neurons born in the adult brain are proexcitatory, and could be epileptogenic. Support comes from studies of the new granule cells that do not migrate correctly. These granule cells migrate into the hilar region after status, and do so in robust numbers. The 'ectopic' hilar granule cells develop independently of how status was induced – i.e.,

following pilocarpine, kainic acid, lithium followed by pilocarpine, or stimulation using implanted electrodes (**Figure 1**).

The cells that are located ectopically in the hilus have some characteristics of normal granule cells, despite their abnormal location. For example, they are labeled by calbindin and Prox1. Electrophysiological studies have shown that their intrinsic properties are similar to normal granule cells. The axon forms a mossy fiber that innervates CA3 pyramidal cells in stratum lucidum, as well as targeting diverse hilar neurons and granule cells located in the cell layer. The fact that the ectopic granule cells innervate the granule cells of the cell layer, and do so by sending axon collaterals into the inner molecular layer, suggests that ectopic hilar granule cells contribute to mossy fiber sprouting. The axonal projections of ectopic granule cells within the hilus are also potentially important, since they are likely to be a part of additional recurrent excitatory circuits that are not present normally (**Figure 1**). It is also possible that the ectopic neurons innervate inhibitory neurons, but evidence for such inhibitory circuits is not available to date.

Despite the fact that the axon arbor of ectopic hilar granule cells is so similar to granule cells of the granule cell layer, and the expression of calbindin and Prox1 is similar, ectopic hilar granule cells are distinct in some ways. The most striking distinction is the dendritic tree, which is highly polarized for the typical granule cell in the granule cell layer, but rarely polarized in ectopic hilar granule cells.

Despite the structural distinctions of dendrites between ectopic and correctly positioned granule cells, their response to inputs such as the perforant path are similarly robust. The dendrites of ectopic hilar granule cells are covered with synapses, showing that they are well integrated into the network. Studies of c-fos expression in animal models of TLE have also supported this perspective, because c-fos is expressed shortly after a seizure in ectopic hilar granule cells, as well as adjacent hilar neurons. Interestingly, the delay from a spontaneous seizure to c-fos expression is similar, whether the hilar cell is an ectopic hilar granule cell or another hilar cell type (such as parvalbumin- or neuropeptide Y-immunoreactive GABAergic neurons). Yet, the granule cell layer in the same animals typically shows c-fos weak immunoreactivity. These data suggest that hilar ectopic granule cells behave like hilar neurons when a seizure occurs, but in other ways are structurally and functionally similar to granule cells of the granule cell layer.

Interestingly, recordings from hilar ectopic granule cells during the weeks and months after pilocarpine-induced status, we have shown that many develop burst discharges that occur spontaneously, an abnormal characteristic for a granule cell. These bursts are 20–50 ms in duration, typically involve 3–5 action potentials, and are synchronous with spontaneous, rhythmic CA3 pyramidal cell bursts that occur at frequencies up to 0.25 Hz. Simultaneous recordings of dentate neurons and CA3 pyramidal neurons showed that CA3 pyramidal cells discharge first, suggesting that they are generators of the epileptiform activity. Other recordings demonstrate that subsequent to the bursts of these hilar cells, granule cells in the granule cell layer typically exhibit subthreshold synaptic potentials, usually EPSPs (but IPSPs can also occur). These recordings have important implications, because they show that the ectopic hilar neurons may contribute to a local network discharge in epileptic animals. Because ectopic granule cell bursts precede EPSPs or action potentials in granule cells of the cell layer with a single synaptic delay, it is reasonable to hypothesize that ectopic granule cells may contribute to the effects of the CA3 burst discharge on granule cells of the granule cell layer,. However, other hilar neurons are also likely to contribute to effects on granule cells; many of these hilar neurons innervate the granule cell dendrites in the molecular layer or somata/axon hillock.

The inhibitory interneurons in the hilus also have burst discharges synchronized with CA3 and other hilar neurons, and they may serve as a brake on the ability of CA3 to initiate epileptiform activity in the dentate gyrus. Interestingly, ectopic granule cells might also be inhibitory under some conditions, if they synthesize GABA. It is likely that GABA synthesis occurs in ectopic granule cells, because granule cells within the granule cell layer express GABA after seizures. A prediction based on these findings is that the dentate-hilus-CA3 network could become a seizure focus for the spontaneous seizures that occur in the animal that has had status, particularly under conditions that would 'unmask' the excitatory network by reducing inhibitory function. Furthermore, the presence of ectopic granule cells might facilitate the development of a focus, if they are primarily excitatory. However, these ectopic cells could also inhibit the formation of a focus – if they are primarily GABAergic and/or primarily activate GABAergic neurons. Support for the hypothesis that they are proconvulsant comes from studies showing that they innervate glutamatergic neurons (granule cells, mossy cells, pyramidal cells). In other experiments, the numbers of ectopic granule cells was reduced by infusion of arabinoside C after status and spontaneous seizures decreased. However, because arabinoside C is a general mitotic inhibitor, there were other effects of arabinoside C besides decreasing ectopic hilar neurons. Therefore, the more cautious interpretation of this experiment is that neurogenesis can contribute to epileptic seizures in an animal model of TLE, but a critical role of ectopic hilar granule cells in epileptogenesis or chronic epilepsy is not yet clear.

Interestingly, specimens from patients with intractable TLE exhibit ectopic hilar granule cells also. However, not all studies of patients with pharmacoresistant TLE have reported ectopic granule cells. One reason could be that ectopic granule cells are not detected (e.g., because a

granule cell specific marker, such as Prox1, has not always been used). Calbindin is a good marker of normal granule cells, and is often used in human specimens, but it can be downregulated in granule cells after seizures. Indeed, some studies have suggested a limited influence of neurogenesis in TLE because markers of proliferating neurons – examined without granule cell specific marker – were expressed at low levels. Furthermore, human tissue specimens typically are obtained at the end stage of a chronic disease process, at a time when proliferation may be reduced or ectopic granule cells may have died. Indeed, in chronic seizures in animal models of TLE, proliferation in the dentate gyrus appears to be downregulated, and there is evidence that progressive neuronal loss occurs in TLE.

There are other arguments against a role of neurogenesis in TLE. For example, febrile seizures in immature rats do not initiate a rise in neurogenesis, but animals exhibit a lower seizure threshold and many develop spontaneous electrographic seizures. Intrahippocampal kainic acid in the mouse, a different model of TLE, also shows little evidence of increased dentate gyrus proliferation, although this finding could simply reflect the severe damage at the injection site. In the kindling model, ectopic granule cells are a less robust phenomenon than in status models of TLE, but animals that have been kindled to the point of spontaneous seizures have not yet been explored. It is possible that seizure-induced neurogenesis plays an important role in some types of TLE but not in others, and the diversity of findings in animal models reflects the clinical variation.

Future Goals

The ultimate effect of new neurons in the adult brain, particularly the epileptic dentate gyrus, is a subject of debate. Studies of ectopic hilar granule cells suggest a proconvulsant or epileptogenic role, but experiments that have been conducted on new granule cells in the cell layer – those that develop after status – have led to the conclusion that seizure-induced neurogenesis may be a homeostatic mechanism. In fact, both views may be correct. Neurons born in the adult brain that migrate correctly could be important to maintain normal function, but those that migrate to ectopic locations could lead to dysfunction. Indeed, genes that regulate migration are often critical to normal function, a lesson learned from studies of transgenic animals and clinical research.

Whether neurogenesis is 'curative' or whether it leads to impaired function will require advanced tools to selectively ablate new neurons in the adult brain. For example, silencing or killing ectopic neurons, without influencing the new neurons that migrate correctly, would be a powerful approach to address the current questions about seizure-induced neurogenesis. Such approaches may ultimately be useful as novel therapeutic strategies.

Newborn Neurons Mitigate Synaptic Excitability in Epileptic Brain

M Kokaia and O Lindvall, University of Lund, Lund, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Experimental animals that experience pharmacologically or electrically induced status epilepticus (SE) start to exhibit spontaneous unprovoked epileptic seizures a few weeks later. This pattern is paralleled by cell death, neuronal circuit reorganization, and chronic inflammation in the hippocampal formation and other brain areas, as well as increased neurogenesis in the dentate gyrus. Whether and how these events are involved in the mechanisms of epileptogenesis is not well understood. In particular, it is not known what the role of increased neurogenesis in epileptogenesis is.

Background

Some data indicate that a certain subpopulation of SE-induced neuroblasts migrates into the hilus of the dentate gyrus, where they differentiate into ectopic granule cells. These cells seem to receive excitatory synaptic connections from sprouted axons (mossy fibers) of granule cells in the granule cell layer, as well as excitatory afferents from entorhinal cortex. These afferents have been proposed to create abnormal excitatory circuits, promote increased excitability of the dentate gyrus, and thus contribute to epileptogenesis. However, aberrant granule cell formation appears to be associated with a particular pharmacological model of SE, and therefore may have limited impact on epileptogenesis induced by other (e.g., electrical) models or in the human epileptic brain. Moreover, the majority of newborn cells generated after SE migrate appropriately into the granule cell layer, and differentiate into morphologically normal granule cells. Whether these cells, which have been born in a pathological environment, also receive abnormal excitatory or inhibitory afferents remains to be elucidated. Our recent data indicate that the afferent connections to the newly formed granule cells located in the granule cell layer develop in such way that they mitigate the increased excitability of the epileptic hippocampus.

Methods

Status epilepticus was induced in rats by electrical stimulation of the ventral hippocampus. As a control for increased neurogenesis after SE, a separate group of animals was exercised on a running wheel in their home cages. The latter procedure leads to increased neurogenesis without any significant pathological changes in the hippocampus. To label newly born granule cells, a retroviral vector carrying the GFP gene was injected into the dentate gyrus one week after SE or running. Four to six weeks later, acute hippocampal slices were prepared for whole-cell patch-clamp recordings from the prospectively identified GFP-labeled newborn granule cells. The slices were maintained in an artificial cerebrospinal fluid (aCSF) gassed with a mixture of 95% O_2 and 5% CO_2. Whole-cell recordings were made with patch-clamp pipettes filled with solutions specifically designed for certain experimental requirements, resulting in pipette tip resistances of 4–6 MΩ. Whole cell currents or potentials were amplified with patch-clamp amplifier (HEKA Elektronik, Germany), and recordings were saved for off-line analysis on the computer. IgorPro and FITMASTER software were used for off-line analysis, and appropriate statistical tests were applied for group comparisons. Detailed method description can be found elsewhere (see Further Reading).

Recent Results

Status epilepticus induced pronounced changes in the hippocampus of the animals, leading to neuronal degeneration in hilus (**Figure 1(a)**, upper panel) and CA1 and CA3 regions, as revealed by Fluoro-Jade staining, and increased inflammation (**Figure 1(a)** lower panel) as judged by counting activated Iba1-positive microglia. In 'runners,' no cell death was observed, and the number of activated microglia was significantly lower. Moreover, EEG recordings in SE animals displayed interictal spikes, and animals were noted to experience spontaneous seizures, none of which was seen in the runner group. These data confirmed that the new cells in SE animals were born in a pathological environment, while the new cells in runners were not. The intrinsic properties of the new cells in SE animals were not different from those of cells born after running, maintaining normal passive membrane properties and characteristics of depolarization-induced action potentials (**Figure 1(b)**). Newly born cells were identified by GFP labeling and verified by simultaneous staining for biocytin, which diffused into the cells during whole-cell recordings (**Figure 1(c)**).

The newborn cells in SE animals, however, were substantially different from their counterparts in animals

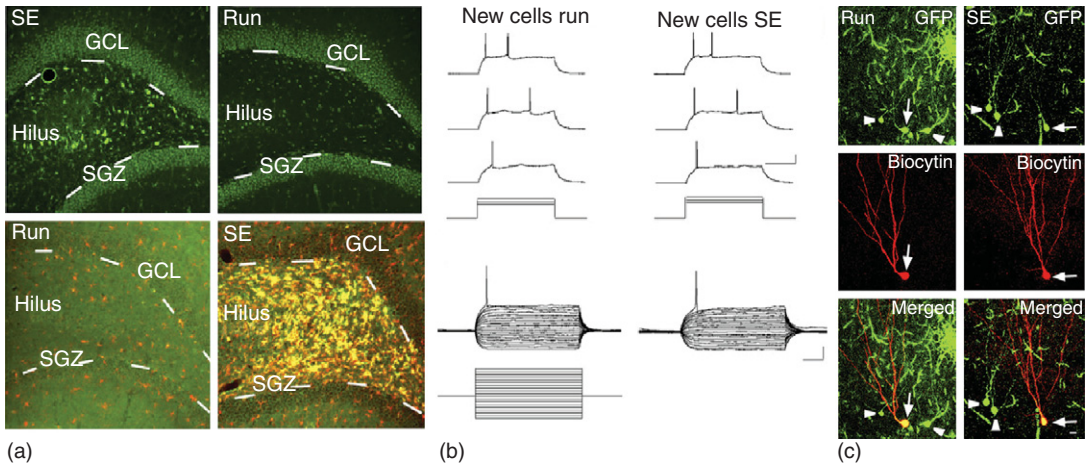

Figure 1 Intrinsic membrane properties of newborn cells in SE environment is unaltered. (a) Upper panels: Fluoro-Jade-stained, degenerating neurons in the hilus of dentate gyrus at 1 week after SE or running; Lower panels: Number and distribution of microglia (Iba1+ = red, depicts all microglia; ED1+ = green, shows activated, phagocytic microglia) in dentate gyrus at 1 week after SE or running. (b) Upper panels: Depolarization-induced action potentials in newly born cells in runners and SE animals. Scale = 200 ms, 10 mV; Lower panels: Voltage responses in new cells born after running or SE recorded in current-clamp mode at resting membrane potential (77.1 ± 6 1.4 mV, $n = 10$, and 79.0 ± 6 1.8 mV, $n = 8$). Scale bar = 100 ms, 20 mV. Recordings were performed 4.5–5 weeks after RV-GFP injection; 500 ms duration current steps with 15 pA increments. (c) Confocal images of cells in runners and SE animals. Cells expressing only GFP (not recorded) are indicated with arrowheads, and GFP-expressing, recorded cells filled with biocytin are depicted by arrows. Merged images show coexpression of GFP and biocytin in recorded cells.

that experienced only running in terms of their synaptic integration. This difference was revealed by analyzing in detail the excitatory and inhibitory drive on these cells, using spontaneous and miniature EPSCs [s(m)EPSCs] and IPSCs [s(m)IPSCs]. Such analysis demonstrated significantly lowered frequency of sEPSCs (**Figure 2(a)–2(c)**) and increased frequency of sIPSCs (**Figure 2(d)** and **2(e)**) in newborn cells in SE as compared to that in runners. In both cases, altered synaptic drive onto the newborn cells in SE animals seemed to be mostly due to presynaptic features: lower sEPSC frequency was a result of decreased overall release probability of glutamate, as estimated by the rate of NMDA receptor-generated EPSC blockade by MK-801 (an NMDA receptor activity-dependent blocker); increased sIPSC frequency was due to decreased sensitivity/expression of presynaptic $GABA_B$ receptors, as measured by changes in paired-pulse depression of monosynaptic IPSCs induced by baclofen.

These findings suggest that newborn cells in the SE environment somehow 'sense' increased excitability and/or inflammation in the dentate gyrus, and by retrograde messenger modulate the functional properties of the presynaptic terminals of the sprouted axons of the existing cells in the neuronal network (**Figure 3**). In this scenario, the overall synaptic excitability of these newborn cells would be decreased. Therefore, taken together, these data suggest that those granule cells that are born in an epileptic environment, and migrate and differentiate in the granule cell layer, integrate into the neuronal circuitry in such a way that they mitigate pathological hyperexcitability. Indeed, in case these newborn cells become active part of the granule cell-CA3 neuronal network, the overall excitatory drive of the whole dentate gyrus output (synapsing onto the CA3 cells) will be relatively diminished, and therefore these new cells would strengthen the inhibitory 'gate' function of dentate gyrus against incoming seizure activity.

Future Goals

Our findings raise a number of questions that are directly related to the possible functional outcome of increased neurogenesis in the epileptic dentate gyrus. One of the main questions is how newborn cells sense the pathological environment. It is not clear at the moment whether seizure activity per se, or inflammatory processes associated with seizures are the main factors signaling to newborn cells to adjust their synaptic integration according to the needs of neuronal networks for normalizing their excitability. Furthermore, it is not known whether the synaptic outputs of the newborn cells also possess adaptive properties, and can be modified by an epileptic environment. Most importantly, it will be central to determine if neurogenesis is capable of becoming a possible therapeutic target for brain repair, and particularly for epilepsy treatment. To address these questions, future research will require a broad approach and intense efforts in the field of normal brain function as well as in the animal models for various diseases in the brain. In this regard, experimental epilepsy could provide a fruitful platform, since studying animal models of seizures and epileptogenesis not only reveals pathological processes associated with abnormal excitability of neurons and

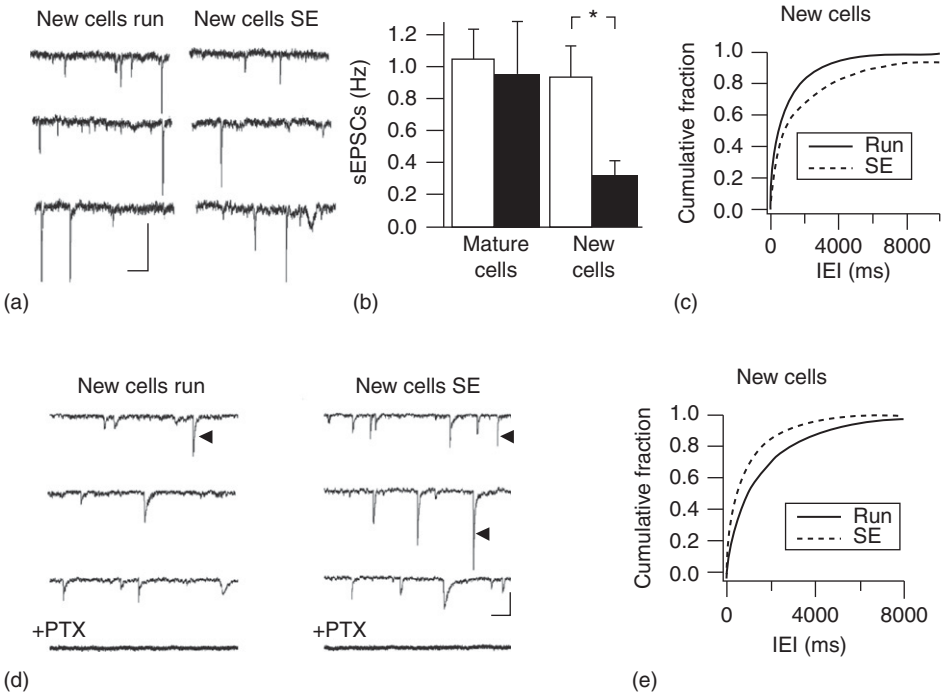

Figure 2 Decreased excitatory and increased inhibitory drive on newborn granule cells in SE animals. (a) Examples of sEPSCs in cells born after running and SE. Note fewer sEPSCs in traces from SE animals. Scale bar = 200 ms, 10 pA. (b) Average frequency of sEPSCs in new and mature cells from runners (white) and SE (black) animals. Frequency of sEPSCs was lower in new cells born after SE than in those born after running (*$p < 0.05$, Student's unpaired *t*-test, $n = 7$ and 6 cells, respectively), but similar in mature cells in runners and SE animals ($p > 0.05$, $n = 10$ and 6 cells, respectively). (c) Cumulative fraction curves of interevent intervals (IEIs) for sEPSCs in new cells showing longer IEIs in cells born after SE compared with those born after running ($p < 0.05$, K–S test). (d) Examples of sIPSCs in cells born after running and SE. The sIPSCs were blocked by PTX, confirming that they were mediated by GABAA receptor activation (+PTX). Note the larger, more frequent sIPSCs in the cells from SE animals. Scale bar = 200 ms, 50 pA. (e) Cumulative fraction curves of IEIs for sIPSCs recorded in new cells in SE animals and runners. The IEIs were shorter in new cells from SE animals compared with runners.

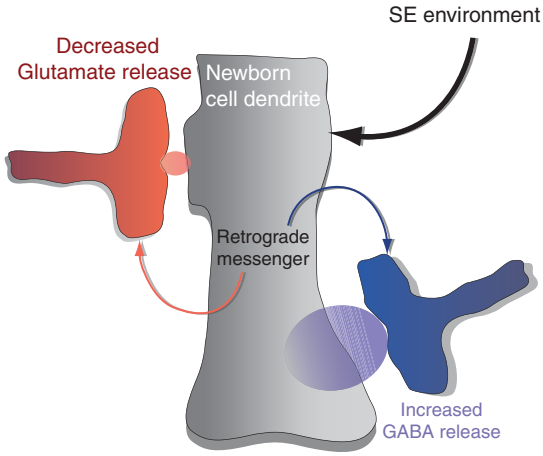

Figure 3 Cartoon depicting overall changes in synaptic drive onto the new granulce cells in SE animals. Newborn granule cells 'sense' environmental cues (black arrow) that guide formation of new functional synapses in network-normalizing manner. This is likely to be achieved by retrograde transporter (red and blue arrows selective for excitatory and inhibitory synapses, respectively) from the new granule cells that travel to the arriving or newly established synaptic endings of existing neurons to alter their functional properties during the final synaptogenesis.

neuronal networks, but also provides a basis for better understanding of normal brain function.

Seizures and Adult Neurogenesis

S Jessberger, Institute of Cell Biology, ETH Zurich, Zurich, Switzerland
G Kempermann, Center for Regenerative Therapies Dresden, Dresden, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Mesial temporal lobe epilepsy (mTLE) is one of the most common idiopathic epilepsies of the adult. The syndrome of mTLE frequently involves changes in cognitive function, leading to substantial learning and memory disabilities and marked reduction of life quality. Although antiepileptic drug treatment often leads to substantial seizure control, lasting cognitive disturbance remains a frequent clinical feature of mTLE. A large variety of animal models of TLE have been established over the last decades, in which investigators can study the progression from an initial insult to the development of epilepsy, a process called 'epileptogenesis.' In most rodent models, the initial insult is a prolonged seizure called 'status epilepticus' (SE), which is commonly induced by chemoconvulsants such as kainic acid (KA) or pilocarpine. Importantly, SE not only affects mature structures in the adult brain but also leads to a marked increase in the number of newborn cells generated in the subventricular zone of the lateral ventricles and the dentate gyrus (DG) of the hippocampus. Interestingly, many of the newborn neurons in the dentate extend aberrant basal dendrites and migrate ectopically into the hilus – two features of adult neurogenesis that are absent under normal conditions. The functional association between neurogenesis and mTLE remains unclear and there is an ongoing debate if seizure-induced neurogenesis represents an attempt of the injured brain for repair or if newborn neurons after SE participate in the disease process.

Background

Hippocampal neurogenesis is a dynamically regulated process and the number of newborn neurons is increased or decreased by a large number of factors. In the 1990s several laboratories showed in parallel that seizure activity strongly increases the number of new granule cells born in the DG. Early on it was noted that SE leads to marked alterations in granule cell localization and morphology, as many cells born after SE migrate into the hilus and extend abnormal dendrites. This observation has led to the hypothesis that seizure-generated neurons (i) might interfere with synaptic transmission through the hippocampal circuitry, leading to cognitive impairment associated with SE, and (ii) might contribute to epileptogenesis by forming aberrant recurrent excitatory networks with area CA3. Several studies showed that inhibition of seizure-induced neurogenesis was associated with improved hippocampus-dependent learning and less seizure activity in the chronic phase of the disease, supporting a functional link between newborn cells and the epileptic disease process. However, there is also recent evidence showing that seizure-generated granule cells receive more inhibitory input compared to new granule

Introduction

Mesial temporal lobe epilepsy (mTLE) is one of the most common idiopathic epilepsies of the adult. The syndrome of mTLE frequently involves changes in cognitive function, leading to substantial learning and memory disabilities and marked reduction of life quality. Although antiepileptic drug treatment often leads to substantial seizure control, lasting cognitive disturbance remains a frequent clinical feature of mTLE. A large variety of animal models of TLE have been established over the last decades, in which investigators can study the progression from an initial insult to the development of epilepsy, a process called 'epileptogenesis.' In most rodent models, the initial insult is a prolonged seizure called 'status epilepticus' (SE), which is commonly induced by chemoconvulsants such as kainic acid (KA) or pilocarpine. Importantly, SE not only affects mature structures in the adult brain but also leads to a marked increase in the number of newborn cells generated in the subventricular zone of the lateral ventricles and the dentate gyrus (DG) of the hippocampus. Interestingly, many of the newborn neurons in the dentate extend aberrant basal dendrites and migrate ectopically into the hilus – two features of adult neurogenesis that are absent under normal conditions. The functional association between neurogenesis and mTLE remains unclear and there is an ongoing debate if seizure-induced neurogenesis represents an attempt of the injured brain for repair or if newborn neurons after SE participate in the disease process.

Background

Hippocampal neurogenesis is a dynamically regulated process and the number of newborn neurons is increased or decreased by a large number of factors. In the 1990s several laboratories showed in parallel that seizure activity strongly increases the number of new granule cells born in the DG. Early on it was noted that SE leads to marked alterations in granule cell localization and morphology, as many cells born after SE migrate into the hilus and extend abnormal dendrites. This observation has led to the hypothesis that seizure-generated neurons (i) might interfere with synaptic transmission through the hippocampal circuitry, leading to cognitive impairment associated with SE, and (ii) might contribute to epileptogenesis by forming aberrant recurrent excitatory networks with area CA3. Several studies showed that inhibition of seizure-induced neurogenesis was associated with improved hippocampus-dependent learning and less seizure activity in the chronic phase of the disease, supporting a functional link between newborn cells and the epileptic disease process. However, there is also recent evidence showing that seizure-generated granule cells receive more inhibitory input compared to new granule

cells born under normal conditions. Thus, it is also possible that the function of newborn neurons that are born after SE might be to decrease overall excess excitation in the epileptic hippocampus. In the following sections, we will discuss the effects of SE on hippocampal neurogenesis and the potential contribution of seizure-generated granule cells to epileptogenesis.

Methods

Several approaches are used to study the effects of SE on cell proliferation, differentiation, neuronal migration, and functional integration of hippocampal granule cells born after SE. Dividing cell and their progeny can be either labeled with the thymidine-analogue, bromo-deoxyuridine (BrdU) – alone or in combination with transgenic markers of hippocampal precursor cells. In addition, several laboratories use retroviral vectors that specifically label dividing cells and their progeny in order to study the effects of SE on the morphology and synaptic integration of seizure-generated granule cells. Furthermore, video-EEG monitoring and hippocampus-dependent behavioral tasks have been used to analyze the contribution of seizure-associated neurogenesis to impairment of hippocamapal function after SE.

There are various rodent models of mTLE. The most popular models involve systemic injections of chemoconvulsants (such as kainic acid or pilocarpine) to induce SE, but electrical stimulation has also been used. Differences in the choice of model (i.e., which method is used to induce SE), of rodent species (e.g., mouse or rat), strain, age, and gender may lead to markedly different results. This range of options between different laboratories undoubtedly accounts for many of the apparent discrepancies in the field. Even though it is reasonable to choose a rodent model in which one can reproduce the pathological changes seen in human mTLE brains (such as hippocampal sclerosis), we are then faced with the problem that the human phenomenology – largely determined from brain samples obtained following surgery or post-mortem – might represent only the structural end point of the disease. The human samples from which the neuropathological hallmarks of mTLE have been derived, in most cases, had experienced a very long disease history, often several years or longer. Thus, rodent models that reproduce this morphological stage of disease within days – as seen, for example, with intrahippocampal KA injections – might not be ideal for studying epileptogenesis as it occurs in humans.

On the basis of these considerations we have used two different seizure models in our studies. To characterize the progenitor cell type that is activated in response to seizures, we used transgenic mice expressing green fluorescent protein under the nestin promoter; such animals provide an experimental means of dissociating subtypes of progenitors in the adult hippocampus. In these experiments, intraperitoneal injections of KA were used to induce SE. However, we chose a mouse strain – C57Bl/6 – that does not develop spontaneous recurrent seizures and is resistant to KA-induced excitotoxicity. Thus, while KA injections into C57Bl/6 mice are not well suited to study epileptogenesis and mechanisms of the chronic disease phase of epilepsy, they are ideal for studying the impact and long-term consequences of single bouts of seizures. In our later studies that were designed to investigate the effects of SE on cognition and lasting morphological alterations of newborn granule cells, we switched to an animal model that better reflects a chronic epileptic condition; these studies were carried out using adult rats that were injected with KA, leading to the development of spontaneous recurrent seizures and seizure-associated cognitive impairment.

Recent Results

The work of several laboratories has provided an astoundingly sound picture describing the phenotype of dividing cells in the DG, and the morphological maturation of newborn granule cells. Our initial experiments tried to answer the question of which precursor mediates the massive increase in cell proliferation following SE. Toward this end, we used a transgenic animal expressing green fluorescent protein under the control of the nestin promoter (which is active in hippocampal precursors). This approach enabled us to identify doublecortin (DCX)-expressing neuroblasts (type-3 cells) as a major contributor to increased cell proliferation 1 week after SE. Furthermore, SE led to the dispersion of cells expressing DCX (which is also expressed during later stages of neuronal maturation) compared to newborn DCX-expressing cells under control conditions (**Figure 1(a)**). Together with earlier results from other laboratories, these experiments pointed towards a marked alteration in the behavior of granule cells born after SE. We next used a retroviral strategy, which allowed us to visualize whole cells, so that we could analyze potential morphological alterations of newborn granule cells. Using this approach, we confirmed the previously described ectopic migration and synaptic integration of aberrant granule cells in the hilus. We showed that some of the newborn granule cells extended aberrant basal dendrites towards the hilus, became stably integrated into the DG circuitry, and made ectopic synaptic connections (**Figure 1(b)**). These new connections altered DG connectivity. Furthermore, we determined that granule cells born 4 weeks prior to SE are the cells that participate in SE-induced axonal sprouting (mossy fiber sprouting into the molecular layer); these findings supported previous reports that granule cells born after SE do not contribute to mossy fiber sprouting. We also found that only granule cells born after SE were those that extended hilar basal dendrites.

Even though the cellular events and morphological effects of SE on dentate granule cell neurogenesis are

quite well described, many of the molecular mechanisms responsible for increased neurogenesis and seizure-induced structural alterations, and many of the consequences of SE-induced neurogenesis remain largely unknown. We were interested in studying the possibility that neurogenesis contributes to the cognitive changes seen in mTLE. To carry out these studies, we treated animals with valproic acid (VPA). This histone deacetylase inhibitor – one of the most commonly used antiepileptic drugs – has a marked effect on the proliferation and differentiation of hippocampal precursor cells. We used VPA to analyze the contribution of seizure-generated granule cells to SE-associated cognitive impairment. In the VPA-treated groups we started to inject VPA (150 mg kg^{-1}) 5 h after the initial SE, and rats of the VPA groups received two injections per day throughout the entire length of the experiment. VPA proved to be a potent inhibitor of seizure-induced cell proliferation (judged by the numbers of BrdU positive cells in animals that were killed immediately after 5 days of daily BrdU injections) and net neurogenesis (judged by the numbers of BrdU positive cells in animals that were killed 4 weeks after 5 days of daily BrdU injections). VPA treatment also reduced the formation of basal dendrites extending from newborn granule cells born after SE compared with seizure animals that had not received VPA injections. Next we asked if the reduction of seizure-generated neurons in VPA-treated rats (compared to seizure animals without VPA treatment) affected behavior depending on proper hippocampal function. To this end, we used a well-established hippocampus-dependent object recognition memory task, with a delay of 3 h between the familiarization and testing phase. Similar to previous reports, we found an impairment in the object recognition task in seizure rats that had not received VPA injections. Strikingly, VPA-mediated inhibition of aberrant neurogenesis after SE attenuated the hippocampus-dependent behavioral deficits (seen in non-VPA treated, seizure control animals), supporting the notion that seizure-induced neurogenesis might contribute to the epileptic disease process.

Future Goals

Even though the initial reports on seizure-induced adult neurogenesis were published more than ten years ago, many basic questions remain unanswered: (1) how is seizure-activity 'translated' into increased cell proliferation? (2) what are the molecular mechanisms that lead to the ectopic migration of newborn granule cells and aberrant

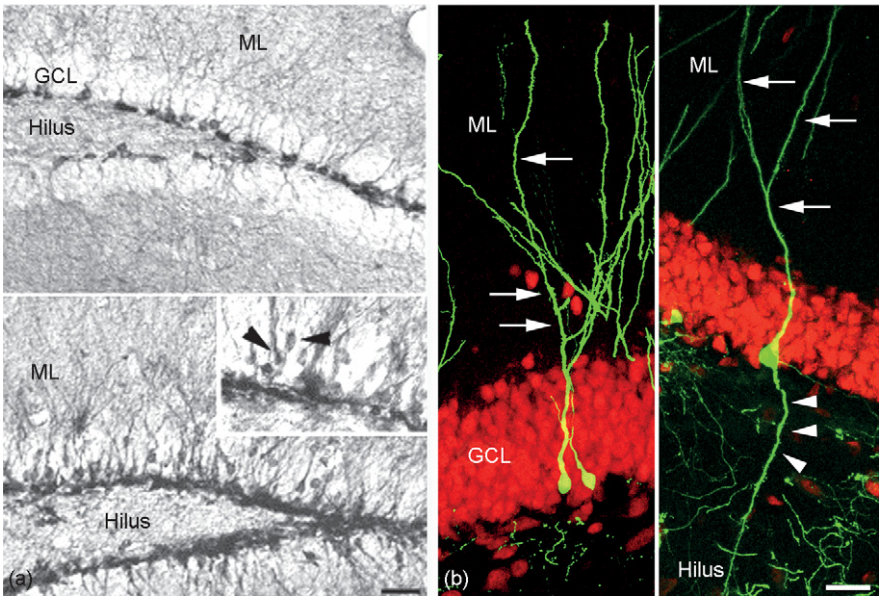

Figure 1 Aberrant neurogenesis after SE. Newborn cells expressing the microtubuli-associated protein doublecortin (DCX) line up along the inner parts of the granule cell layer (GCL) under control conditions (a, upper panel). One week after KA-induced seizures the number of DCX-expressing cells is greatly increased (a, lower panel). New neuronal cells born after seizures also migrate further into the GCL compared to control conditions (see high power view in the inset in panel a). Retrovirus-labeled, 4-weeks old granule cells born under control conditions have a highly polarized architecture with an apical dendrite (arrows in panel b) extending towards the molecular layer (ML; b, left panel). In contrast, 4-weeks old virus-labeled granule cells born two months after SE commonly extend an additional basal dendrite towards the hilus (arrowheads in b; b, right panel) and that synaptically integrate into the preexisting dentate circuitry. ML, molecular layer; GCL, granule cell layer. Scale bars in panel a: 50 μm, in panel b: 20 μm. **Figure 1a** is adapted from Jessberger S, Romer B, Babu H, and Kempermann G (2005) Seizures induce proliferation and dispersion of doublecortin-positive hippocampal progenitor cells. *Experimental Neurology* 196: 342–351, with permission from Elsevier. **Figure 1b** is adapted from Jessberger S, Zhao C, Toni N, Clemenson GD, Jr., Li Y, and Gage FH (2007) Seizure-associated, aberrant neurogenesis in adult rats characterized with retrovirus-mediated cell labeling. *Journal of Neuroscience* 27: 9400–9407, with permission from society for Neuroscience.

extension of basal dendrites? (3) what are the functional consequences of seizure-induced neurogenesis?

The fact that SE leads to dramatic increase in cell proliferation in the DG is unquestioned. Furthermore, it seems clear that excitation alone is sufficient to increase cell proliferation and that SE-associated cell death is not required for the proliferative response. Previous reports suggested that neural precursors appear to 'sense' excitation, influencing proliferation and differentiation behavior. Furthermore, proliferative activity of dividing precursor cells in the adult DG is regulated by synaptic GABA transmission. Clearly, excitatory activity and GABA-mediated currents are altered in the course of epileptogenesis, suggesting a role for these activity-dependent processes in seizure-induced neurogenesis. However, future experiments manipulating those activity-sensing mechanisms – specifically in dividing and newborn immature cells – are needed to understand the molecular mechanisms of seizure-induced cell proliferation. In addition to changes in neurotransmitter concentrations in the DG after SE, there is an emerging understanding for the role for neuropeptides such as neuropeptide Y in the pro-proliferative effects of SE.

Another exciting question is how newborn cells in the DG find their correct position. What are the signals that regulate migration and that direct dendritic and axonal growth? Knowledge regarding mechanisms of neurite extension and pathfinding remains scant, even for normal conditions. The first contributions towards understanding the molecular mechanisms underlying ectopic migration of granule cells after SE were only recently published. The mechanistic hypothesis derived from these data is that the expression of the secreted glycoprotein reelin, which is a critical neuronal guidance molecule during development, is dramatically decreased after SE, and that this decrease might help explain the ectopic migration of granule cells following SE. Without a doubt, however, additional factors will be involved in ectopic migration and aberrant dendrite extension. Potential candidates include, for example, cdk5/p35 signaling and growth factor (e.g., VEGF and BDNF) signaling.

As adult neurogenesis obviously occurs in the midst of a mature neural structure, it seems reasonable to speculate that the environmental niche is a critical factor in governing distinct aspects of progenitor proliferation and neuronal maturation. This consideration is probably particularly important within the context of the extensive structural alterations that occur in the DG after SE. To date, the distinction between cell-autonomous effects within the domains of dividing precursors and immature neurons, in contrast to changes within the neurogenic niche of the hippocampus, is not clear.

Probably the currently most debated question in this field is whether seizure-generated granule cells are an attempt of self-repair or exert additional pathologic influences on the epileptic hippocampus. Current evidence actually points toward both possibilities. Four weeks after they were born, seizure-generated granule cells were found to have intrinsic electrophysiological properties similar to cells that were born in running animals, but appeared to receive less excitatory input. These results suggested that the SE brain was attempting to 'balance' surplus excitation. Along the same lines, another study showed that brain irradiation – which suppresses adult neurogenesis – transiently increased excitation after SE. In contrast, extensive analyses strongly suggest that ectopic granule cells are part of a recurrent excitatory circuitry with area CA3, which might contribute to epileptogenesis. Similarly, the basal dendrites extending from seizure-generated granule cells might be at least partially responsible for DG hyperexcitability observed after SE. We and others have found that inhibition of aberrant neurogenesis attenuates seizure-associated deficits in hippocampus-dependent learning and memory. Thus, it seems probable that seizure-induced neurogenesis might have both positive and negative effects on the integrity of the DG circuitry. The challenge will be to design experiments that specifically target seizure-generated granule cells in isolation from the rest of the DG circuitry.

The involvement of neurogenesis in the epileptic disease process might also be dependent on the disease stage. Although early stages of the disease apparently lead to aberrant newborn granule cells that might interfere with proper hippocampal function caused by ectopic synaptic integration, there is emerging evidence that the levels of adult neurogenesis might be strongly decreased (compared to control animals) in the chronic phase of the disease process. Such decline of neurogenesis might account for cognitive or affective clinical syndromes at later stages of the disease. With this possibility in mind, it is interesting to consider the possibility that stimulation of endogenous neurogenesis (or the addition of transplanted precursors) might be a future strategy to treat epileptic syndromes.

Even though the molecular basics remain largely unclear and the functional significance of seizure-induced neurogenesis is to some extent controversial, there is no doubt that newborn cells after SE do change the dentate circuitry. Seizure-generated granule cells integrate synaptically and make contacts with neural structures that are not targeted by cells born under normal conditions. Understanding the cause for these changes, and identifying the stages of the disease process in which new neurons may be good or bad for the epileptic brain, will require the concerted effort of molecular biologists, electrophysiologists, behavioral biologists, and clinical neurologists.

Introduction

Endogenous ACh acts on several subtypes of nicotinic and muscarinic receptors. The brain is rich in cholinergic receptors, including those areas, like hippocampus and cortex, that have a low threshold for the generation of seizures. The importance of this neurotransmitter for cognitive function has been established by findings in neurodegenerative diseases, where cognitive and behavioral dysfunction is accompanied by abnormalities in the cholinergic system.

There is substantial evidence that early life seizures influence brain development. Moreover, the probability of

long-lasting effects is associated with the characteristics of the seizure. In addition, epidemiologic evidence shows that the incidence of seizures, in a variety of syndromes associated with cognitive dysfunction or deterioration, is significantly higher than in the general population – indicating either a common cause or a causative link between the two. These findings, taken together with those implicating ACh in cognitive processes, suggest that this neurotransmitter is a very good candidate if one wants to investigate the cellular mechanisms linking seizures to (long-term) cognitive function, and more particularly, early life seizures to brain development.

We have had two major targets for our research program. First, we have designed studies to examine whether there is evidence to implicate cholinergic mechanisms in the generation of epileptiform discharges in immature brain, and to examine whether the occurrence of early seizures had any long-lasting effects on adult cholinergic responses. We chose a model within which we could provoke generalized and relatively long-lasting convulsions, since the severity and duration of seizures are both factors positively correlated with the appearance of long-lasting effects. Our second target was to determine whether adult (brain) cholinergic responses differed in animals that had experienced early convulsions (vs. age-matched controls), and if so, to investigate the cellular/synaptic basis for this difference. This latter aim has been investigated with a variety of approaches, including electrophysiology, cell and molecular biology, and behavioral testing.

Background

Cholinergic agents have been extensively used in electrophysiological recordings in vitro to manipulate synaptic potentials and/or neuronal membrane properties. Thus, we have gained to date substantial insight into their mechanism(s) of action and their probable effects on the integrated neuronal activity, that is, brain function. Muscarinic agents mostly inhibit synaptic activity by acting on presynaptic receptors that decrease transmitter release, but on the other hand, also exert excitatory effects by blocking K^+ channels and also by facilitating intracellular Ca^+ accumulation (see Further Reading section). Several reports have suggested their potential in modulating epileptiform discharges in a way that would add up to the excitatory process. Nicotinic receptors exert mostly excitatory effects although there is less evidence linking them to epileptic paradigms (see Further Reading section).

Cholinergic agonists have been effectively used in vivo for the provocation of convulsions, in immature as well as in adult animals. In this respect, they are not different from many neuroactive agents with varying mechanisms of action, where administration at a sufficiently high dose may provoke seizures. Pilocarpine, in particular, has been extensively used, often in combination with lithium (which reduces animal mortality – although with a still unresolved mechanism). Because of the uncertainties associated with pilocarpine's actions, we have used the $GABA_A$ receptor antagonist, pentylenetetrazol (PTZ) for our studies; this drug is eliminated within 24 h of injection from the animal's system, and has no known toxic or long-lasting effects of its own.

A number of reports have examined the effects of experimental seizures on brain cholinergic neurotransmission, with attention to post seizure ACh release, changes in the number of cholinergic terminals, and changes in receptor subtypes. Fewer studies have examined post seizure electrophysiological cholinergic effects. Findings from these reports are not easily comparable for three reasons: (1) Differences in the age and species in which convulsions were provoked; (2) Differences in the experimental protocol, including the choice of pharmacological agent used, method of administration, dose, and the resulting type of convulsion (severity, duration, single vs. repetitive); (3) Differences in timing – that is, interval between 'conditioning' (seizure provocation) and assessment. This third factor is critical, since many studies have shown that long-term effects of brain insults of varying etiology, including seizures and stroke, differ from those observed in the short term. Indeed, changes assessed immediately or at a short interval after the seizure are often not evident in the long term, and changes assessed after a long interval are not evident in the short term. Short-term effects in cell physiology often dissipate with time, while some long-term effects are not detectable shortly after the insult, indicating that the initial insult starts a cascade of 'mostly unknown,' events leading to the long-term alteration. The time interval between the initial insult and the appearance of long-term (permanent) effects is called the 'silent period' precisely because no changes are seen within this time window; this period may vary in length, depending on the type of insult and the specific effect (i.e., change in physiology) to be investigated.

Methods

Sprague–Dawley rat pups of postnatal day (P) 10 or 20 were subjected to generalized and sustained convulsions (>20 min duration, a model for status epilepticus, SE), provoked by i.p. injection of pentylenetetrazol (PTZ, 70–80 mg kg^{-1}); some pups of each litter were used as controls. After a period of at least 40 days, the (adult) conditioned animals were decapitated under volatile agent anesthesia, and the brains were either frozen for the assays described in the later sections, or used for the

preparation of hippocampal slices for electrophysiological recordings. We measured the frequency of occurrence of spontaneous synchronous bursts and the features (amplitude, duration, etc.) of evoked potentials in vitro, using either extracellular or intracellular recording techniques.

Whole brain or hippocampal tissue obtained 40 days post seizure was used to determine ACh innervation density (using choline acetyltransferase immunocytochemistry) and endogenous ACh and GABA content by high-performance liquid chromatography (HPLC) electrospray ionization mass spectrometry, a technique that allows the measurement of small concentrations of endogenous substances (nM) from small volume samples. Whole brain sections were used for (i) quantitative radioligand binding autoradiography, (ii) in situ hybridization, and (iii) [^{35}S]GTPγS autoradiography, to assess the properties of hippocampal and neocortical muscarinic receptors.

Results

In the first set of experiments, we sought to determine whether cholinergic receptors played any role in the generation of epileptiform activity in immature brain, by recording extra- and intracellularly from P10–P20 hippocampal slices. We found that cholinergic agonists greatly increased the frequency of spontaneous epileptiform discharges when $GABA_A$-mediated inhibition was blocked, but did not have such an effect when $GABA_A$-mediated inhibition was intact (**Figure 1**). This result suggested that cholinergic receptors played a facilitatory but not a generating role, since another excitatory condition (i.e., the $GABA_A$ receptor block) was a prerequisite. This cholinergic effect was completely reversed by the mucarinic antagonist atropine, and was also mimicked by several muscarinic agonists. Interestingly, the anticholinesterase eserine (which inhibits the catabolism of

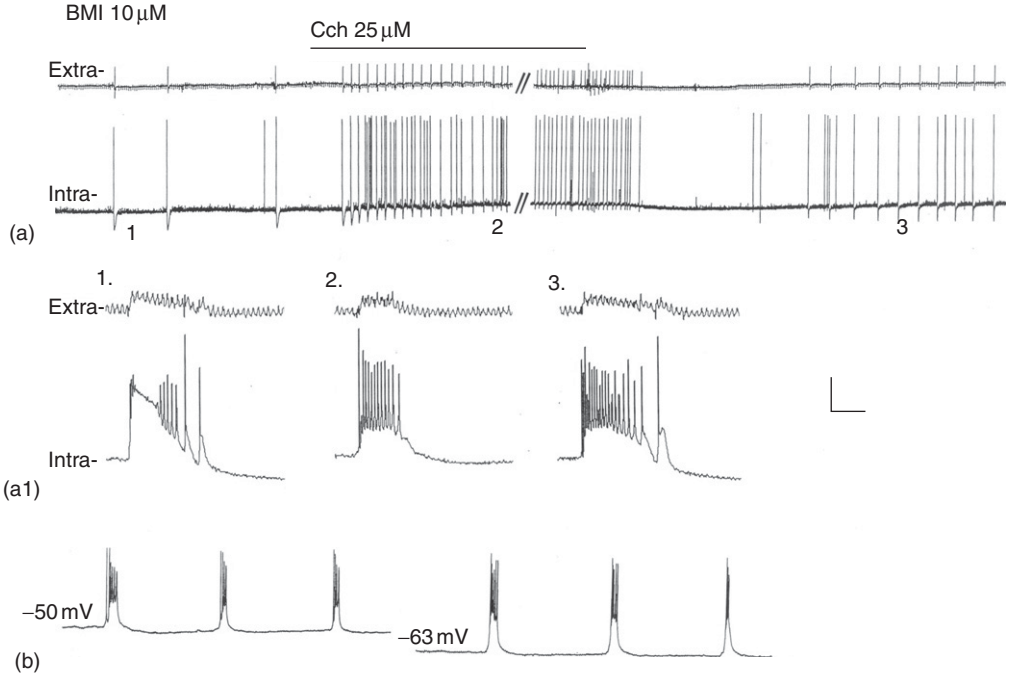

Figure 1 Effects of CCh on spontaneous synchronous activity in the presence of BMI. (a) A P14 CA3 neuron (RMP −57 mV) responded to the application of 10 μM BMI with rare synchronous discharges corresponding to intracellular bursts (freq. 0.012 Hz). Perfusion with BMI had started 14 min before the beginning of – and lasted throughout – the trace shown here, so the rate of occurrence of spontaneous discharges was maximal, under these conditions. Addition of CCh (25 μM) to the perfusion medium depolarized the neuron by 4 mV and increased the frequency of synchronous discharges to 0.202 Hz (16.83 times the original frequency). These effects of CCh were reversible upon wash. Three of the discharges recorded extra- and intracellularly (marked with numbers 1, 2, 3) are depicted at a higher speed in (a1). (a1) The amplitude and duration of the synchronous spontaneous discharges recorded in BMI (1) was reduced by the addition Cch (2), an effect that was reversible upon CCh wash (3). CCh also reduced the number of APs associated with the burst, an effect evident when comparing traces 3 and 2, but not 2 and 1. The reason for that is the high amplitude of the burst in 1, resulting in AP block at its peak. (b) Intracellular recording from another P14 neuron in the presence of 10 μM BMI and 25 μM CCh. The amplitude but not the frequency of the spontaneous bursts recorded at RMP (−50 mV) changed following artificial hyperpolarization by dc current injection to −63 mV. Calibration bars: 4 mV (extra-), 20 mV (intra-in a, a1, b), 40 s (a), 100 ms (a1), 285 ms (b) Reproduced from Psarropoulou C and Dallaire F (1998) Activation of muscarinic receptors during blockade of $GABA_A$-mediated inhibition induces synchronous epileptiform activity in immature rat hippocampus. *Neuroscience* 82: 1067–1077, with permission from Elsevier.

endogenous ACh) had effects similar to those of exogenous agonists under the same conditions of $GABA_A$ receptor blockade, suggesting that elevations in endogenous ACh would presumably suffice to play this role in vivo. This effect of eserine was manifested after P10 but not earlier (**Figure 2**), suggesting a developmental onset for this synergistic excitatory effect. P10 in a rat pup is comparable to a human neonate, according to some earlier studies comparing some biochemical indices and anatomical data. Taken together, these data suggest that endogenous ACh could play a significant role (as a co-factor) in precipitating seizures in neonates or infants.

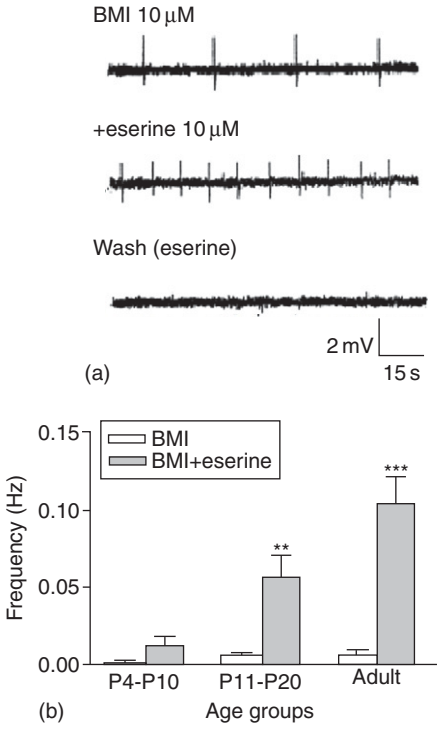

Figure 2 (a) Effects of eserine 10 mM on the frequency of the synchronous spontaneous discharges recorded extracellularly during blockade of the inhibitory GABA-mediated potentials by BMI 10 mM. *Upper trace*: BMI induced infrequent synchronous spontaneous discharges in the CA3 area of a hippocampal slice from a P10 rat pup. In this and all slices tested, no synchronous spontaneous discharges were recorded in control ACSF. *Middle trace*: Addition of eserine more than doubled the frequency of synchronous spontaneous discharges. *Lower trace*: The effects of eserine were reversible. (b) Bar chart showing the mean frequencies in Hz of the spontaneous synchronous discharges recorded in 10 mM BMI as well as following the addition of 10 mM eserine. All slices tested were included in the graph and 0 Hz was entered if no synchronous discharges were recorded. Standard errors of the mean values are shown on top of each bar. BMI versus BMI-eserine data were compared by the paired Student's *t*-test; significant differences in the mean values are marked by asterisks p 0.01, p 0.001. Reproduced from Gruslin E, Descombes S, and Psarropoulou C (1999) Epileptiform activity generated by endogenous acetylcholine during blockade of GABAergic inhibition in immature and adult rat hippocampus. *Brain Research* 835: 290–297, with permission from Elsevier.

Although the cholinergic excitatory effects appeared to be muscarinic, we conducted a separate in vitro study to determine whether nicotinic agonists displayed similar activity in the same paradigm. We found that nicotinic agonists did not increase significantly the frequency of spontaneous field discharges recorded during $GABA_A$ receptor block.

We then investigated whether the provocation of seizures in vivo, by a similar mechanism (blockade of $GABA_A$ synaptic inhibition by PTZ) would provoke any long-term changes in central cholinergic responses. We found that a PTZ-induced generalized convulsion in P10 or P20 rat pups had led to an apparent hypersensitivity to cholinergic stimulation in hippocampal slices from adult rats (40 days or more after the convulsion). That is, following perfusion of the slice with eserine, we recorded synchronous, interical-like epileptiform discharges that were atropine-sensitive; no such activity was seen in slices from naïve (i.e., not exposed to PTZ) littermates. And no such spontaneous field activity was recorded from these same slices when they were perfused with standard ACSF (i.e., without eserine), that would suggest a generalized increase in excitability. Inhibition appeared normal; IPSPs ($GABA_A$- and $GABA_B$-dependent, mono- or polysynaptic) measured intracellularly were similar in slices from PTZ and naive rats. The spontaneous discharges provoked by eserine were not observed if the PTZ convulsion was blocked by prior injection of pentobarbital, suggesting that this effect was linked to the convulsion and not the PTZ injection.

In the same set of experiments, we compared young (P10, P20) and adult animals (>P60) with regard to this long-lasting post-convulsion effect; comparisons were made between animals with convulsions of similar duration. Interestingly, when animals were young (P10 or P20) at the time of seizure induction, the cholinergic supersensitivity was found both in the short term (10 days) and in the long term (>40 days) after the convulsion. In contrast, when animals were adult (P60) at the time of seizure induction, the cholinergic supersensitivity was found only in the short term (10 days) but not in the long term (>40 days), indicating a temporary and reversible change. These findings differentiate immature and adult animals with regard to seizure-induced effects on cholinergic neurotransmission, and moreover suggest a mechanism by which, early life seizures may influence later life brain functions that depend on cholinergic neurotransmission (cognitive, behavioral). Within a broader context, this increased cholinergic sensitivity represents an activity-dependent developmental change – that is, a paradigm of activity dependent immature brain plasticity.

This cholinergic sensitivity was not the result of (i) decreased synaptic inhibition or GABA content,

(ii) increased ACh content, (iii) proliferation of cholinergic terminals, or (iv) changes in the number and/or subtype of muscarinic receptors. Instead, it was associated with a marked increase in the cholinergic-stimulated [^{35}S]GTPγS incorporation, leading to an increase in the efficacy of G-protein coupling to muscarinic receptors (Figure 3). We do not know the pathway leading to this functional change; however, it may be a seizure-induced modification in the regulation of one or more genes in a muscarinic receptor (M1?) signaling cascade. In terms of function, this increase in the efficacy of G-protein coupling may act as an equivalent of, for example, reduced receptor desensitization.

Associated with this identification of seizure-induced increased G-protein coupling, we discovered a trend toward a higher level of total [^{35}S]GTPγS binding in female compared to male PTZ-exposed rats. Although this finding may be explained by the higher basal level of [^{35}S]GTPγS incorporation in females compared to males, it illustrates how seizures may amplify naturally occurring gender differences. Indeed, some G-protein-coupled receptors have been reported to be differently regulated in females and males, and thus may result in some of the gender-specific characteristics seen in some forms of epilepsy. To date, we have also observed this male–female difference in a number of experimental protocols involving cholinergic function.

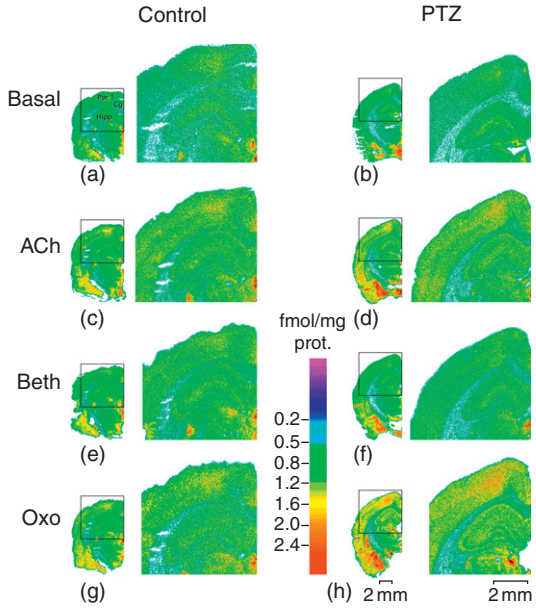

Figure 3 Color-coded autoradiographs illustrating the basal and agonist-stimulated [^{35}S]GTPγS incorporation in the cerebral cortex and hippocampus of control (a, c, e, and g) and pentylenetetrazole (PTZ)-treated rats (b, d, f, and h), at a transverse level near stereotaxic plane A 4.7 mm according to Paxinos and Watson (1986). The rat brain in stereotaxic coordinates, 2nd edition, Academic Press, Sydney. The enlarged area includes the Par1 (primary somatosensory) region of cerebral cortex and dorsal hippocampus. ACh, acetylcholine; Beth, bethanechol; Oxo, oxotremorine. There are noticeable increases in [^{35}S]GTPγS incorporation in both the cerebral cortex and hippocampus of PTZ-treated compared with control rats after stimulation by ACh and Oxo. Reproduced from Potier SSJ, Chabot J-G, Psarropoulou C, and Descarries L (2005) A pentylenetetrazole-induced generalized seizure in early life enhances the efficacy of muscarinic receptor coupling to G-protein in hippocampus and neocortex of adult rat. *European Journal of Neuroscience* 21: 1828–1836, with permission from Wiley-Blackwell.

Directions for Future Research

The accumulated evidence shows that the CNS cholinergic-muscarinic system undergoes a functional change following an early life prolonged and generalized convulsion. Seizures of this type are considered to model status epilepticus (SE), a condition that is associated with long term effects in brain anatomy and function. It is possible, but not yet proved, that this change in the cholinergic system may contribute to changes in these animals' response to environmental stimuli. It is also conceivable that this change may play a role only in specific conditions – for example, in behavioral or pathophysiologic conditions that increase endogenous ACh release. Several such conditions have been reported in the literature. These findings provoke a number of further questions that have guided our current efforts. For example:

What may be the consequences of this cholinergic system change on the animal's general behavioral phenotype and/or the animal's susceptibility to future insults? Is this alteration in the ACh system simply an adaptive and/or compensatory change, or does it facilitate the precipitation of future seizures ('seizures beget seizures')? In an effort to find out, whether the early life SE episode and the ensuing cholinergic change were associated with any phenotypical changes, we carried out a series of behavioral tests for assessing the animal's reaction to novelty or to different aspects of memory and learning. We found statistically significant differences in behavioral responses, not only between control and PTZ-treated rats of the same sex, but also between male and female rats of the same group (control or PTZ-treated). In the open field test, spontaneous motor activity was estimated as an index of the animal's reaction to a novel environment. Female PTZ-treated rats had significantly reduced spontaneous motor activity as compared to controls, a finding that was not replicated in the male PTZ-treated rats. In the object recognition test, which models nonspatial memory and learning, both male and female PTZ-treated rats performed significantly worse compared to controls. In the water maze test modeling spatial memory and learning, only male PTZ-treated rats

performed worse than controls. Overall, male PTZ-treated rats displayed impaired performance related to memory and learning abilities as compared to female PTZ-treated rats. These preliminary results suggest that even a single, sustained, generalized early life seizure may induce long-term consequences related to novelty behavior, spatial and nonspatial learning, and memory, which appear to be sex-specific (E. Papalexi, C. Psarropoulou, and K. Antoniou, unpublished data). Whether these findings are directly associated with the changes observed in cholinergic neurotransmission or not remains to be seen.

Is there a specific muscarinic receptor subtype that is primarily affected by the seizure insult? Our findings so far point to the M1 muscarinic receptor, but do not exclude other types. It is noteworthy, however, that disruption of the m1 gene (the pharmacologically defined M1 receptor coincides with the genetically defined m1 gene) can disrupt the muscarinic receptor-dependent M current regulation, and leads to seizure activity in mice.

How does this functional change in muscarinic receptors affect neuronal output in terms of responses to synaptic and intrinsic stimuli? By answering this question, we can elucidate the pathway leading from the seizure-dependent modification of cholinergic neurotransmission to animal behavior. It will also permit us to predict the types of effects, other than those already observed, that may stem from such a modification. This question can be answered by electrophysiological in vitro recordings, where the extracellular or intracellular neuronal environment can be manipulated to mimic different in vivo conditions.

Does this functional change in muscarinic receptors also affect the output of other neurotransmitter systems that act in synergy? Neurotransmitter systems often share metabolic pathways or interact via receptors that can be regulated by common mechanisms. Therefore, changes in any given neurotransmitter system may indirectly affect the output of another. For example, it has been shown that activation of m1 muscarinic receptors potentiates NMDA-receptor currents in hippocampal pyramidal cells. Taking our cue from this work, we examined whether the NMDA-receptor mediated excitability would differ in brain tissue of adult conditioned versus naive animals. We provoked spontaneous NMDA-receptor mediated epileptiform discharges by bathing the tissue from PTZ-treated and naïve rats in ACSF without added Mg^{+2}, and recorded from the CA3 area. We found that the rates of epileptiform discharges were significantly higher in slices from PTZ-treated animals (PTZ slices) in both the male group ($n = 55$ control slices, $n = 61$ PTZ slices, Student's t-test $p = 0.0008$) and in the female group ($n = 43$, $n = 112$, $p = 0.01$) compared to sex-matched controls. Interestingly, female slices showed significantly higher frequencies compared to male slices, in all recording locations (CA1, CA3, dentate gyrus), within both the control and the PTZ group (B. Foadjo Awoumé and C. Psarropoulou, unpublished data). The latter finding may be explained by the reported interaction between ACh, NMDA, and estrogen receptors.

Is the cholinergic change functionally important for all, or only some brain regions? The output of each region or brain formation depends on its structural (neuronal types, connections) and functional (receptor types, neurotransmitter systems) features. For example, it is known that hippocampal excitability differs along the septotemporal axis, with the temporal pole reported as 'more excitable.' It is, therefore, possible that this muscarinic receptor functional change would differentially influence the output of septal versus temporal hippocampal regions. Using septal and temporal hippocampal slices from PTZ-treated or control animals, and slice perfusion with ACSF with no added Mg^{+2}, we have tested the cholinergic modification of NMDA-mediated epileptiform discharges. Our preliminary findings indeed suggest that the degree of the ACh-mediated frequency increase of the NMDA-dependent epileptiform discharges differs along the septo-temporal hippocampal axis (A. Mikroulis and C. Psarropoulou, unpublished data).

What mechanisms lead from the seizure to the cholinergic neurotransmission changes? What is the sequence of events leading up to the establishment of long-term effects? Are there any interventions that could reverse these changes or lessen their impact? The increased cholinergic sensitivity was recorded in both immature and adult animals 10 days after the PTZ seizure, indicating that it was developed within this 10 day time window – that is, a relatively short latency response. Longer interval recordings showed, however, that this change is reversed (no longer recordable) in animals that had the seizure in adult life, but persists in animals that had the seizure during CNS maturation. Thus, it appears that the better question is not "how/when does this cholinergic change appear?", but rather "what are the factors that are responsible for its dissipation in adult the brain or its maintenance in the immature brain?"

And finally, one can add the gender factor in all these questions, especially since gender differences in G-protein receptors occur naturally, and they may be stressed or increased following seizures, as shown by our preliminary data. Because of the naturally occurring gender differences in G-protein receptors, muscarinic and other such receptors may be good candidates in which to investigate gender-related seizure phenomena

(e.g., catamenial epilepsy), and also any gender associated short- or long-term seizure effects.

Introduction

Synapses regulate their own neurotransmitter supply. Once released, neurotransmitter is recycled, both through direct reuptake and by processing through the astrocytic glutamate–glutamine cycle. Inhibitory synapses exhibit tight, activity-dependent coupling of the GABA supply to the activity of the glutamate–glutamine cycle. Interrupting the glutamine cycle rapidly depletes GABA supply at active inhibitory synapses – which in turn may mediate synaptic scaling, allowing the inhibitory efficacy to ramp up during periods of high excitatory synaptic activity, thus maintaining circuit regulation. In epileptogenic foci in hippocampus resected from patients with temporal lobe epilepsy, the keystone enzyme in the glutamine cycle, glutamine synthetase, is significantly downregulated in reactive astrocytes. GABA supply will also be deficient in this tissue, causing disinhibition and a lack of circuit regulation. This condition could contribute to seizure initiation and/or propagation. Therefore,

(e.g., catamenial epilepsy), and also any gender associated short- or long-term seizure effects.

Consequences of Diminished Function of the Glutamine Cycle on Inhibitory Function in the Epileptic Brain

D A Coulter, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Synapses regulate their own neurotransmitter supply. Once released, neurotransmitter is recycled, both through direct reuptake and by processing through the astrocytic glutamate–glutamine cycle. Inhibitory synapses exhibit tight, activity-dependent coupling of the GABA supply to the activity of the glutamate–glutamine cycle. Interrupting the glutamine cycle rapidly depletes GABA supply at active inhibitory synapses – which in turn may mediate synaptic scaling, allowing the inhibitory efficacy to ramp up during periods of high excitatory synaptic activity, thus maintaining circuit regulation. In epileptogenic foci in hippocampus resected from patients with temporal lobe epilepsy, the keystone enzyme in the glutamine cycle, glutamine synthetase, is significantly downregulated in reactive astrocytes. GABA supply will also be deficient in this tissue, causing disinhibition and a lack of circuit regulation. This condition could contribute to seizure initiation and/or propagation. Therefore,

therapeutic intervention strategies targeted towards restoring the glutamine cycle and GABA levels in epileptic brain appear promising.

Background

Synapses as Autonomous Structures

Synapses are compartmentalized structures, geographically isolated from regulation by the neuronal soma. For synapses releasing small molecule neurotransmitters, complex metabolic machinery exists to recycle and package neurotransmitter from amino acid precursors. This local regulation of neurotransmitter supply is an absolute necessity for the efficient regulation of synaptic function. If it were necessary for neurotransmitter-containing synaptic vesicles to be synthesized in the Golgi apparatus (in the cell soma) and transported down axons for release at synapses, the resulting delay in supply and demand signaling would preclude economical up- or downregulation of neurotransmitter supply based on the recent history of synaptic activity.

The specialized machinery required for local neurotransmitter recycling and synthesis resides both within synapses themselves, and within the astrocytic processes investing synapses. Specialized neurotransmitter transporters are localized within presynaptic terminals, allowing for the immediate recycling of released neurotransmitters, the most efficient form of recycling. This type of recycling occurs at inhibitory synapses, where GABA transporters (GAT-1) and glutamate transporters (EAAC-1) (glutamate serving as a precursor for GABA synthesis) are localized to the presynaptic terminal membrane. However, this direct recycling capability is not predominant at excitatory synapses, where little or no glutamate is transported directly back into the presynaptic terminal following release. At these synapses, astrocytic uptake (via glutamate transporters such as GLT-1) accounts for 80–90% of glutamate sequestration.

The Astrocytic Glutamate–Glutamine Cycle

Once transported into astrocytes, the potent neurotoxin glutamate is efficiently inactivated by conversion into the nontoxic amino acid, glutamine. This conversion is accomplished by glutamine synthetase, an enzyme whose expression is astrocyte-specific in brain. However, if all amino acid transmitters were rapidly, unidirectionally, and irreversibly absorbed into astrocytes following release, synaptic transmission would rapidly fail in the absence of a supply of neurotransmitter precursors. Alternatively, neurons would be required to synthesize large amounts of neurotransmitter de novo and in an ongoing manner, a hugely expensive metabolic endeavor. To avoid this failure or metabolic cost, an additional set of transporters is localized both in astrocyte and neuron membranes, to efficiently recycle glutamine back into neurons.

Glutamine exits astrocytes through the activity of a specialized set of transporters, termed system N transporters. It is then taken up by neurons by the activity of a second set of transporters, termed system A transporters. Once inside neurons, glutamine is then converted to glutamate by the mitochondrial enzyme, glutaminase. In excitatory neurons, glutamate can then be re-packaged into synaptic vesicles by vesicular glutamate transporters. In inhibitory neurons, the glutamate must be transformed into GABA by glutamic acid decarboxylase (GAD) before packaging into synaptic vesicles by vesicular GABA transport (via the vesicular inhibitory amino acid transporter, VIAAT). This neurotransmitter recycling pathway is summarized in **Figure 1**.

The primary methodology utilized in studies characterizing the dynamics of localized neurotransmitter flux through the recycling pathway described earlier has been radiotracer flux assays. Years of research in this arena has shown that the preferred substrate for GABA synthesis is glutamine. In brains of animals infused with radiolabeled glutamine or glutamate, a significant fraction of label rapidly appears in GABA, suggesting that inhibitory neurons rely on the glutamine cycle to a significant extent for neurotransmitter synthesis. We were interested in determining how glutamine cycle dynamics regulate inhibitory synaptic function – the final, biologically significant readout regulated by neurotransmitter recycling.

Methods and Results

Regulation of Hippocampal Inhibitory Synaptic Transmission by the Astrocytic Glutamate–Glutamine Cycle

By definition, neurotransmitter recycling requires that there be ongoing activity to necessitate vesicle refilling for subsequent release. Static, inactive inhibitory synapses should not exhibit much in the way of recycling requirements, while active inhibitory synapses should experience significant demand to regenerate GABA for subsequent vesicular release. In order to assess this prediction experimentally, we utilized patch clamp recording techniques in hippocampal slices to examine the potential role of the glutamine cycle in regulating inhibitory synaptic transmission, under both static and active conditions. The glutamine cycle was perturbed at several distinct steps by perfusion of the slices with various pharmacological antagonists, including the astrocytic glutamate uptake blocker dihydrokainate (DHK), the glutamine synthetase inhibitor, methionine sulfoxamine (MSO), and the System A neuronal glutamine transport inhibitor, α-(methylamino) isobutyrate (MeAIB) (see **Figure 1**). Activity was generated by synaptic stimulation at varying frequencies, and activity

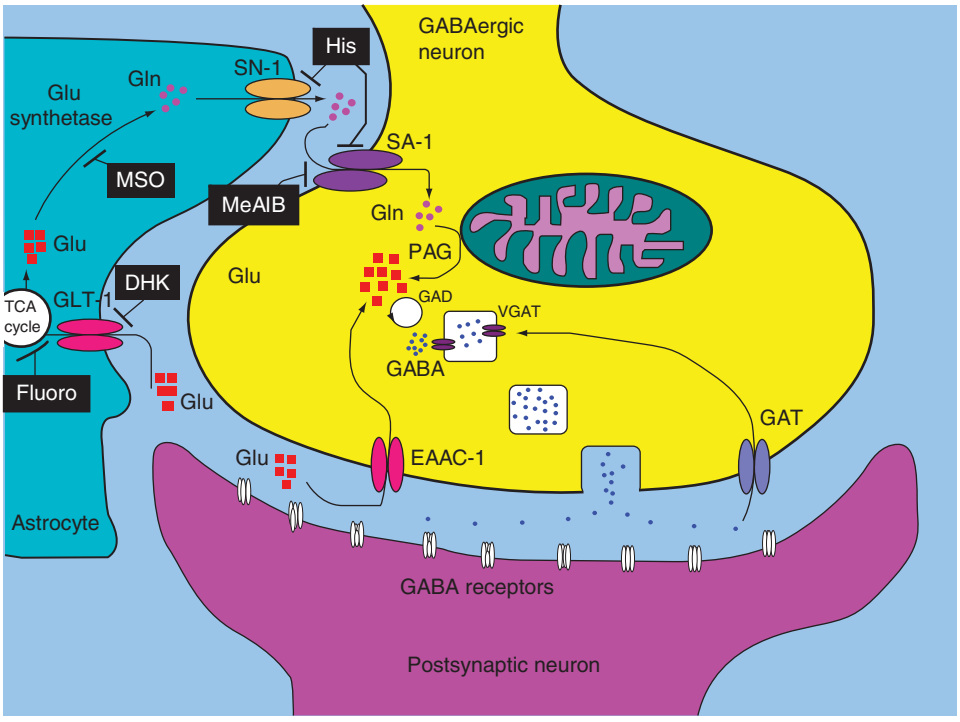

Figure 1 Schematic of the major functional players determining glutamate-glutamine cycle contributions to vesicular GABA content, and pharmacological antagonists targeting these players. Extracellular space is in blue, the presynaptic GABA terminal is in yellow, and an astrocyte is in green/turquoise. GAD, glutamic acid decarboxylase; GAT, GABA transporter; EAAC-1 and GLT-1; neuronal and glial glutamate transporters, respectively; VGAT, vesicular GABA transporter (also known as vesicular inhibitory amino acid transporter, VIAAT); SN-1 and SA-1, glial and neuronal (system N and A) glutamine transporters, respectively; PAG, phosphate-activated glutaminase; DHK, dihydrokainate; MeAIB, α-(methylamino)isobutyrate; MSO, methionine sulfoximine; his, histidine; fluoro, fluoroacetate (TCA cycle inhibitor).

was retarded in some experiments using sodium channel blockers and excitatory amino acid receptor antagonists.

In keeping with the obvious potential for an activity-dependent role of the glutamate–glutamine cycle in regulating inhibition, we found that blocking the glutamine cycle had no effect on inhibitory synaptic transmission in hippocampal neurons in the absence of activity (in medium containing sodium channel and excitatory amino acid receptor blockers). Under these conditions, little or no neurotransmitter recycling occurs. Antagonists blocking glutamine uptake into neurons (MeAIB), or enzyme antagonists targeting glutamine synthetase (MSO), had no effect on spontaneous inhibitory synaptic responses recorded in the absence of activity (miniature IPSCs, or mIPSCs, reflecting spontaneous, activity-independent vesicle fusion). Under these static conditions, in the presence of the sodium channel blocker, tetrodotoxin, neuronal glutamate uptake via EAAC-1 (localized in inhibitory terminals) and GABA reuptake via GAT-1 were responsible for maintaining GABA vesicle levels. Targeting either of these processes (by antisense oligonucleotides targeting EAAC-1, or blockade of GAT-1 by NO-711) resulted in reduced mIPSC amplitudes, slower mIPSC kinetics, and the appearance of peak mIPSC augmentation effects by benzodiazepines. The latter phenomenon is thought to reflect the lack of postsynaptic receptor saturation, due to decreased release of GABA. These data are consistent with the idea that vesicle GABA content in inactive synapses is predominantly mediated by direct recycling of glutamate and GABA, with no significant role of glutamine provided by the astrocytic glutamate–glutamine cycle.

In marked contrast to the earlier data, when we began to examine synapses under higher activity conditions (generated by sustained stimulation protocols), we found that 60–80% of synaptically released GABA was derived from the astrocytic glutamate glutamine cycle. To examine this process, we activated inhibitory synapses with a 15 min period of stimulation, consisting of a 4-pulse burst every 20 s, in normal media, and in media containing various astrocytic glutamate–glutamine cycle blockers. In control media, this stimulus protocol induced transient synaptic potentiation consisting of a 20–30% increase in inhibitory postsynaptic current amplitude, which persisted for 10–15 min. This potentiation was due to a presynaptic increase in the probability of release in the stimulated inhibitory terminals. In contrast, in media containing a glutamine cycle antagonist (either an astrocytic glutamate uptake inhibitor, dihydrokainate, a glutamine synthetase inhibitor, MSO, or a System A transport blocker, MeAIB), synapses showed a marked depression (60–80% reduction compared with the

potentiated response) in inhibitory synaptic efficacy, which gradually recovered over the next 20–40 min. This depression was due to decreased vesicular release of GABA, and occurred despite the fact that inhibitory synapses still showed an increased probability of release when stimulated in the presence of glutamine cycle blockers (assessed with paired pulse stimulation protocols, or by decreased failure rates in quantal analysis). The addition of exogenous glutamine could restore inhibitory synaptic efficacy during perfusion with MSO, but not MeAIB, supporting the concept that inhibition decreased because of glutamine depletion, and neuronal uptake of glutamine occurred through MeAIB-sensitive transporters.

Similar studies to those described earlier have been conducted by the Nicoll laboratory in hippocampal excitatory synapses, both in slices and in culture. In contrast to effects on inhibitory neurotransmitter supply, the glutamine cycle was found to play a much more indirect role in regulating glutamate neurotransmitter supply. Supply of exogenous glutamine, or blockade of the glutamine cycle with MSO, had little effect on excitatory synaptic responses in the short term (minutes to hours). Only after prolonged treatment were effects evident, consistent with the known dichotomy in cytoplasmic glutamate levels in excitatory and inhibitory neurons. Excitatory neurons have high cytoplasmic glutamate levels (mM), which would serve to provide a reserve neurotransmitter supply. Inhibitory neurons exhibit several orders of magnitude lower glutamate levels in cytoplasm.

Taken together, these data strongly support the concept that inhibitory (but not excitatory) synaptic terminals rely heavily on the astrocytic glutamate–glutamine cycle to replenish neurotransmitter stores depleted by synaptic activity. Although this concept was postulated on the basis of amino acid flux studies, these experiments provide the first demonstration that the glutamine cycle can directly regulate the inhibitory synaptic efficacy in a local, dynamic, and immediate manner. These results lead immediately to the hypothesis that any perturbation of the glutamine cycle, triggered as a consequence of either normal or pathological mechanisms, should have a direct consequence on the inhibitory efficacy, which in turn would alter circuit excitability. Thus, the regulation of the glutamate–glutamine cycle may constitute a novel mechanism for circuit plasticity, and also may be significant in pathophysiological states involving abnormal brain function, such as epilepsy.

Implications of Glutamine Cycle Coupling to Inhibitory Synaptic Efficacy: Scaling Inhibition to Regulate Enhanced Excitatory Synaptic Activity Levels

There is an intriguing implication derived from the prominent role played by the glutamate–glutamine cycle in providing neurotransmitter precursors for local GABA synthesis in inhibitory synapses: This process may directly couple the ability of these synapses to sustain activity to the immediately preceding levels of excitatory activity. That is, inhibitory synaptic power should be directly coupled to excitatory activity via the glutamine cycle. Such a synaptic scaling mechanism would be energetically efficient, and esthetically appealing. According to this scenario, inhibitory synapses will be able to release neurotransmitter in a more sustained manner during periods of elevated glutamatergic activity, and potentially release more neurotransmitter per vesicle (if vesicular content is not saturated). Similarly, during low activity states, GABAergic synapses would synthesize less transmitter, and potentially conserve energy. These combined processes of up- and downregulation of inhibitory efficacy during high and low network activity states, respectively, should stabilize network excitability through regulation of neurotransmitter supply. What might happen to network stability if the glutamate–glutamine cycle were compromised? One such state where ubiquitous disruptions in astrocytic function are evident is temporal lobe epilepsy, a disease characterized by network instability, manifested as seizures.

Loss of Glutamine Synthetase and GLT-1 in Reactive Astrocytes of the Epileptic Brain: Implications for Regulation of Network Excitability

Reactive astrocytosis is a hallmark of mesial temporal lobe epilepsy. Astrocytes in an epileptogenic focus within the human hippocampus, surgically resected from patients with temporal lobe epilepsy, exhibit dramatic changes in their anatomy and biology. Among the vast array of changes that have been described in these cells, downregulation of key proteins involved in the glutamate–glutamine cycle is notable. There is a virtually complete downregulation in the expression of the keystone astrocytic enzyme in the glutamine cycle, glutamine synthetase. This loss of glutamine synthetase is restricted to astrocytes within epileptogenic hippocampal areas – even immediately adjacent, nonepileptogenic areas (such as area CA2 and subiculum) retain the expression of this enzyme, despites its complete absence from sclerotic hippocampal cell areas, such as CA1, CA3, and the dentate gyrus. There is also a reduced expression of glutamate transporters in astrocytes from epileptic human hippocampus, accompanied by a loss of interglial gap junction coupling.

A loss of these keystone glutamine cycle enzymes and transporters in astrocytes from epileptic hippocampus has obvious implications for the regulation of circuit excitability. Neurotransmitter supply at inhibitory synapses in epileptic hippocampus would be expected to be significantly compromised. In addition, the capability of glutamine cycle-dependent synaptic scaling to maintain circuit

equilibrium in the face of changing activity levels would be lost. This condition has the potential to generate basal, steady state disinhibition in the epileptic hippocampus, which would be exacerbated during periods of elevated activity, including seizure initiation and/or propagation. Thus, a loss of glutamine cycle enzymes and transporters could contribute significantly to circuit disequilibrium and seizure susceptibility.

Directions and Challenges for the Future

Potential Novel Therapeutic Strategies Targeting the Glutamine Cycle in Epilepsy

Compromised neurotransmitter supply at inhibitory synapses in epileptogenic brain areas is a potential novel therapeutic target for seizure control. Since reactive (glutamine synthetase-lacking) astrocytes are restricted to focal epileptogenic regions, strategies to augment the glutamine supply should exhibit activity only in these pathologically modified regions, and have little effect on normal areas of brain not exhibiting gliosis. This specificity would make such strategies less prone to side effects derived from undesired actions on nonpathologic structures. Glutamine itself is innocuous, and is tolerated at high millimolar concentrations by brain and peripheral tissues without overt adverse activity. Gavage studies in rodents have shown effects on brain glutamine dialysate levels following an oral administration of high concentrations of this amino acid. Therefore, dietary intervention to augment brain glutamine levels could be a useful strategy to augment inhibition specifically in focal epileptogenic regions of brain. Since many anticonvulsant drugs target inhibitory synapses (often postsynaptic GABA receptors) as a mechanism of action, dietary supplements could increase the effectiveness of conventional antiepileptic drugs by augmenting synaptic GABA release specifically in the seizure focus, enhancing the activity of the receptors targeted by the antiepileptic medication, without effects in other brain areas. This strategy is a logical therapeutic approach deserving further attention and corroboration through a combination of basic and clinical studies.

Potential Interactions of Glutamine Cycle Deficits with Existing Therapeutic Strategies

Ameliorating glutamine cycle-mediated deficits in inhibitory synaptic transmission in the epileptic brain may be an as-yet-uncharacterized mechanism of the action of metabolic therapies in epilepsy, including the ketogenic diet. This diet is known to enhance GABA levels (although there are other, significant, potentially antiepileptic effects of this diet as well). This GABA effect is produced by the presence of high ketone body levels, which retards glutamate-to-aspartate flux and thus increases precursors for GABA synthesis. Thus, ketosis induced by the ketogenic diet may specifically augment GABA, particularly in the seizure focus where there is insufficient GABA due to glutamine cycle deficits. The effects of elevated ketones would presumably be less significant in nonfocal brain areas, where GABA levels are normal. Understanding the precise intermediaries of metabolic therapies that lead to this GABA effect (and to seizure control) could more specifically target dietary efforts to control seizures, without the difficulties involved in the ketogenic diet (which restricts patient compliance). This area deserves further research attention.

Gliosis

Clearly, understanding the role gliosis may play in epilepsy is an area of growing interest. Defining the precise consequences of neurotransmitter recycling deficits on synaptic and circuit function in focal epileptogenic brain regions is a formidable challenge worthy of considerable additional research activity. These efforts have the added benefit that they are likely to translate into significant clinical advances toward improving patient care. In a broader context, it is important to define the mechanisms mediating gliosis, so as to gain a better understanding of the origin of reactive astrocytes as well as the anatomical, molecular, and physiological plasticity occurring in these cells; the effects of these astrocyte changes on neuronal circuit function constitute a critical area about which little is known. Gliosis is a ubiquitous finding in myriad neurological and psychiatric conditions, and better understanding of how this phenomenon regulates the brain function should be a significant, relevant focus of future research.

Introduction

The prefrontal cortex is composed of cortical areas in the most anterior regions of the frontal lobe. This area plays an important role in governing a number of behaviors, including motivation, emotion, and learning and memory. Patients with epilepsy often have frontal lobe dysfunction. Neuropsychological studies have shown that epileptic patients have impairments of attention, episodic memory, and executive function, suggestive of frontal cortex involvement. These deficits are particularly apparent in frontal lobe epilepsy, but differences in memory processing are also seen in temporal lobe epilepsy. The deficits underlying epilepsy-associated frontal lobe dysfunction have been suggested to be intrinsic to the frontal lobe and/or due to spread of epileptiform activity from the temporal region. The neurochemical changes subserving altered cognitive functioning are unclear, but may involve changes in neuromodulatory systems involving dopamine.

Prefrontal cortex receives inputs from widespread cortical and subcortical regions, including sensorimotor and limbic areas. Integration of information from these inputs has been specifically implicated in cognitive and neuropsychiatric processes. Prefrontal cortex has a pivotal role in working memory, the ability to process information 'online.' Working memory in primates, often studied using delayed response tasks, is associated with sustained increases in firing of neurons in prefrontal cortex during the delay periods. Similarly, unit activity recorded in rats during delayed performance indicates that rodent prefrontal cortex is also involved in short-term or working memory. The local networks present in prefrontal cortex consist of interconnected inhibitory and excitatory neurons. The balance between recurrent excitation and inhibition in these local networks is important for the stabilization of ongoing activity and proper circuit functioning.

Selective lesions of the cortical dopamine input impair working memory in both primates and rats. Clinical and experimental studies have implicated dopamine in the pathogenesis of a number of neurological and psychiatric disorders, including epilepsy. Dopaminergic mechanisms contribute to excitability increases induced by transcranial direct current stimulation in human cortex, and dopamine receptor binding is decreased in temporal lobe epilepsy patients. How dopamine modulates working memory and cortical excitability is still unclear. Understanding the basic mechanisms underlying dopamine's modulation of synaptic activity in local cortical networks is critical for insights into how modulatory systems contribute to changes in frontal lobe functioning in epilepsy.

Background

Dopamine Innervation of Prefrontal Cortex

In rats, prefrontal cortex has been defined as the part of cortex that receives inputs from the mediodorsal nucleus of the thalamus and from the dopaminergic cell groups localized in the ventral tegmental area. Immunohistochemical studies in rat and primate cortex have shown that dopamine terminals, together with glutamatergic axon terminals, form so-called synaptic triads on dendritic spines of pyramidal neurons. Dopamine receptor activation can gate excitatory synaptic inputs to pyramidal neurons. Moreover, dendritic spines and shafts of pyramidal cells, along with dendrites of GABAergic interneurons, receive symmetric contacts from dopamine axon terminals. Introduction

The prefrontal cortex is composed of cortical areas in the most anterior regions of the frontal lobe. This area plays an important role in governing a number of behaviors, including motivation, emotion, and learning and memory. Patients with epilepsy often have frontal lobe dysfunction. Neuropsychological studies have shown that epileptic patients have impairments of attention, episodic memory, and executive function, suggestive of frontal cortex involvement. These deficits are particularly apparent in frontal lobe epilepsy, but differences in memory processing are also seen in temporal lobe epilepsy. The deficits underlying epilepsy-associated frontal lobe dysfunction have been suggested to be intrinsic to the frontal lobe and/or due to spread of epileptiform activity from the temporal region. The neurochemical changes subserving altered cognitive functioning are unclear, but may involve changes in neuromodulatory systems involving dopamine.

Prefrontal cortex receives inputs from widespread cortical and subcortical regions, including sensorimotor and limbic areas. Integration of information from these inputs has been specifically implicated in cognitive and neuropsychiatric processes. Prefrontal cortex has a pivotal role in working memory, the ability to process information 'online.' Working memory in primates, often studied using delayed response tasks, is associated with sustained increases in firing of neurons in prefrontal cortex during the delay periods. Similarly, unit activity recorded in rats during delayed performance indicates that rodent prefrontal cortex is also involved in short-term or working memory. The local networks present in prefrontal cortex consist of interconnected inhibitory and excitatory neurons. The balance between recurrent excitation and inhibition in these local networks is important for the stabilization of ongoing activity and proper circuit functioning.

Selective lesions of the cortical dopamine input impair working memory in both primates and rats. Clinical and experimental studies have implicated dopamine in the pathogenesis of a number of neurological and psychiatric disorders, including epilepsy. Dopaminergic mechanisms contribute to excitability increases induced by transcranial direct current stimulation in human cortex, and dopamine receptor binding is decreased in temporal lobe epilepsy patients. How dopamine modulates working memory and cortical excitability is still unclear. Understanding the basic mechanisms underlying dopamine's modulation of synaptic activity in local cortical networks is critical for insights into how modulatory systems contribute to changes in frontal lobe functioning in epilepsy.

Background

Dopamine Innervation of Prefrontal Cortex

In rats, prefrontal cortex has been defined as the part of cortex that receives inputs from the mediodorsal nucleus of the thalamus and from the dopaminergic cell groups localized in the ventral tegmental area. Immunohistochemical studies in rat and primate cortex have shown that dopamine terminals, together with glutamatergic axon terminals, form so-called synaptic triads on dendritic spines of pyramidal neurons. Dopamine receptor activation can gate excitatory synaptic inputs to pyramidal neurons. Moreover, dendritic spines and shafts of pyramidal cells, along with dendrites of GABAergic interneurons, receive symmetric contacts from dopamine axon terminals. Pyramidal neurons and interneurons express

multiple different subtypes of dopamine receptors, providing a means for differential dopamine modulation of cortical neurons. Dopaminergic activation may shift, in a complex way, the balance between excitation and inhibition in neuronal circuits, providing a wide range of possibilities for neuronal modulation in prefrontal cortex.

Dopamine Modulation of Synaptic Activity

Dopamine's action in the brain at the cellular and network level is still under investigation. Dopamine can both increase and decrease spontaneous firing of neocortical neurons in vivo. Long-lasting transitions of prefrontal cortex neurons to a more excitable *up* (depolarized) state are enhanced by dopamine. During short-term working memory processing, firing of groups of prefrontal cortex neurons increases in a dopamine-dependent manner. In vitro electrophysiological experiments suggest that dopamine has multiple effects on prefrontal cortex neurons. Both increases and decreases in postsynaptic excitability of pyramidal neurons have been reported following D1 receptor activation. In addition, changes in excitability mediated by D2 receptors have been reported. Complex effects of dopamine on synaptic responses are also present and may be layer- and species-specific. AMPA receptor-mediated excitatory postsynaptic currents (EPSCs) in layer V pyramidal cells are depressed by a D1 receptor mediated effect of dopamine, whereas NMDA responses have been reported to be both enhanced and depressed. EPSCs in layers II/III are enhanced by dopamine in rats but decreased in primates.

Anatomical and electrophysiological studies have shown that axons of layer II/III pyramidal cells make excitatory connections with each other via local axon collaterals. This circuit could provide a substrate for the sustained increase in firing seen during delayed response tasks. We have described dopamine-mediated increases in EPSCs in these cortical circuits. An important question, which has received little attention, is whether excitatory synapses onto GABAergic interneurons in various cortical layers are also potentiated. Inhibition is important for controlling the timing of neuronal activity and shaping the temporal flow of information in prefrontal cortex. The mechanisms underlying spatial working memory have been shown to depend upon $GABA_A$-receptor dependent inhibition. Dopamine-induced increases or decreases in excitatory input to inhibitory interneurons could thus affect working memory.

Given the complexity and microheterogeneity of dopamine's effects, the net action of dopamine modulation of local circuits in prefrontal cortex is not easily predicted. The presence of massive recurrent excitatory connections, which are powerfully regulated by inhibitory mechanisms, has been implicated in the susceptibility of both neocortex and hippocampus to the development of epileptiform activity and seizures. Modulatory influences strongly influence activity in thalamocortical and neocortical circuits. A shift of the balance towards excitation by neuromodulators may lead to the generation of epileptiform activity, whereas an enhanced inhibitory tone could dampen excitability.

Dopamine Regulation of Activity in Neocortical Circuits

Local neocortical circuits are formed by synaptic connections between pyramidal cells and interneurons. Excitatory connections are predominant, with 85% of synaptic connections within the gray matter being excitatory; most of these connections originate from cortical neurons. Pyramidal cells and interneurons in prefrontal cortex display correlated discharges over time-scales that range from millisecond action potential synchronization to hundreds of millisecond covariation in firing rates. Experimental and modeling studies have shown that circuits containing recurrent excitatory connections, like those among layer II/III pyramidal neurons, are inherently unstable. Feedback inhibition provided by GABAergic interneurons provides a stabilizing influence and prevents runaway excitation. In our laboratory, we have been using in vitro slices of rat neocortex to explore the role of dopamine receptors in maintaining the balance between inhibition and excitation necessary for normal functioning of neocortical circuits.

Methods

Our laboratory has been using in vitro studies of rat prefrontal cortex to study modification of synaptic activity by a variety of neuromodulators. We study both normal synaptic activity and epileptiform activity in chronic models of epilepsy. The focus in this article is on dopamine receptors, but the approach is applicable to a variety of neurotransmitters. Slices containing the anterior cingulate cortex and the shoulder (or Fr2 region) of the frontal cortex are used for recording, as these regions receive a dense dopaminergic innervation. We use a two-pronged approach in our studies. The first component exploits the power of the visualized neuron brain slice preparation. Using infrared illumination and Nomarski differential interference contrast microscopy, it is possible to record from identified cell types within prefrontal cortex. We use this method to study the effects of neuromodulators on intrinsic excitability of neurons and the changes induced by these modulators in synaptic activity. The second method used is the voltage-sensitive dye recording technique. Although single cell recordings provide useful information on biophysical properties of individual cells and synapses, they cannot simultaneously monitor vertical and horizontal spread of activity in local neocortical

circuits, an important issue in epilepsy research. Voltage sensitive dyes can be used to reliably monitor the initiation, distribution, and spread of activity in the neocortex in vitro. Modern optical methods allow reproducible detection of dye signals in single trials and without serious photo-bleaching or toxicity. We have shown that the changes in dye signals (i.e., fluorescence changes) – in response to alterations in extracellular calcium, addition of tetrodotoxin, or application of excitatory amino acid receptor antagonists – correlate well with established electrophysiological measures of electrical activity. We use this method to correlate effects seen at the local circuit level with observations made using single cell voltage-clamp recordings. Our studies have examined changes in intrinsic cell excitability, synaptic activity, and spread of activity after bath application of known concentrations of D1- and D2 receptor specific agonists and antagonists.

Results

Photomicrographs of neurons visualized during recording are shown in **Figure 1(a)**. The left-hand panel shows the oval cell body of a GABAergic interneuron in layer I, whereas the right-hand panel shows a group of pyramidal cells in layer II/III. An approaching patch electrode can be seen. Including biocytin in the recording pipette allows unequivocal identification of these cells. Camera lucida reconstructions of a layer I interneuron and a pyramidal cell are shown in **Figure 1(b)**. An important early observation was that dopamine had different effects on interneurons and pyramidal cells. Due to our ability to make recordings from GABAergic interneurons, we were able to determine that dopamine directly depolarizes the majority of cortical interneurons in frontal and cingulate areas by enhancing the hyperpolarization-activated, non-specific, cationic current I_h. This action leads to increased interneuron excitability and increased spike firing, as shown on the left part of **Figure 1(c)**. Excitability of the pyramidal cell (shown on the right part of **Figure 1(c)**) was moderately decreased, but overall there was no significant effect on resting potential or intrinsic excitability of pyramidal cells. In additional studies, we have shown that spontaneous and evoked IPSCs appear to be differentially regulated by dopamine. Spontaneous IPSCs are increased in frequency, presumably due to the enhanced interneuron excitability; however, dopamine can inhibit evoked IPSCs in layer II/III pyramidal cells. This effect appears to be mediated via a presynaptic mechanism in GABAergic nerve terminals, apparently involving D1-like receptor stimulation of an adenylate cyclase-protein kinase A-mediated process. These diverse effects raise the possibility that dopamine could decrease overall cortical excitability by enhancing GABAergic tone via an increase in spontaneous IPSCs, while at the same time facilitating specific inputs by reducing evoked IPSCs. Such differential effects could be important for control of circuit excitability in epilepsy.

Our results using single cell recordings are summarized in **Figure 2**. This illustration makes the point that dopamine can act at multiple sites within neocortex. Complex effects on inhibition and excitation are present, as are cell type specific changes in intrinsic excitability. D1 receptors seem to underlie many of the observed effects, although other investigators have shown that D2 receptors have important effects in deeper cortical layers. These studies have, in large part, used a reductionist approach where a particular cell, synapse or receptor subtype was isolated for investigation. An important issue in epilepsy is the *net effect* of a neuromodulator on cortical excitability. We turned to voltage-sensitive dye studies to examine the net effect of dopamine on normal cortical excitability.

In our recent work, we have used optical imaging with the voltage-sensitive dye RH 414 to study how spatiotemporal patterns of activity were modulated by dopamine under conditions of normal synaptic transmission. **Figure 3** (upper) shows a pseudocolor map of dye signals recorded from a prefrontal cortical slice after a single intracortical stimulation under control conditions. It can be seen that stimulation results in activation of a small area of the slice. Activity was most prominent in upper cortical layers and extended laterally for up to 900 μm. The interval between each map in **Figure 3** was 15 ms, showing that activity spreads laterally to adjacent areas and persists for ~60 ms. After application of 30 μM dopamine for 10 min, activity in response to the same stimulation was decreased (**Figure 3(a)**, bottom). To quantify these changes, peak signal amplitudes – before and after dopamine application – were calculated for diodes lying on a line corresponding to the region of the slice showing the highest levels of activity. These amplitudes were normalized to the highest peak amplitude and plotted as a function of distance from the diode showing the highest peak dye signal (**Figure 3(b)**). Our results show that peak dye signals and lateral spread of activity were decreased after dopamine application. The level of background activity is indicated by the dotted line. Taken together with results from whole cell recording, the voltage-sensitive dye imaging suggests that dopamine's net effect is to increase inhibition under these control conditions. Acting via D1-like receptors, dopamine restricts spatiotemporal spread of synaptic activity in local neocortical networks.

Future Directions

For a more complete understanding of the nature of dopamine's modulatory role in epilepsy, it is necessary

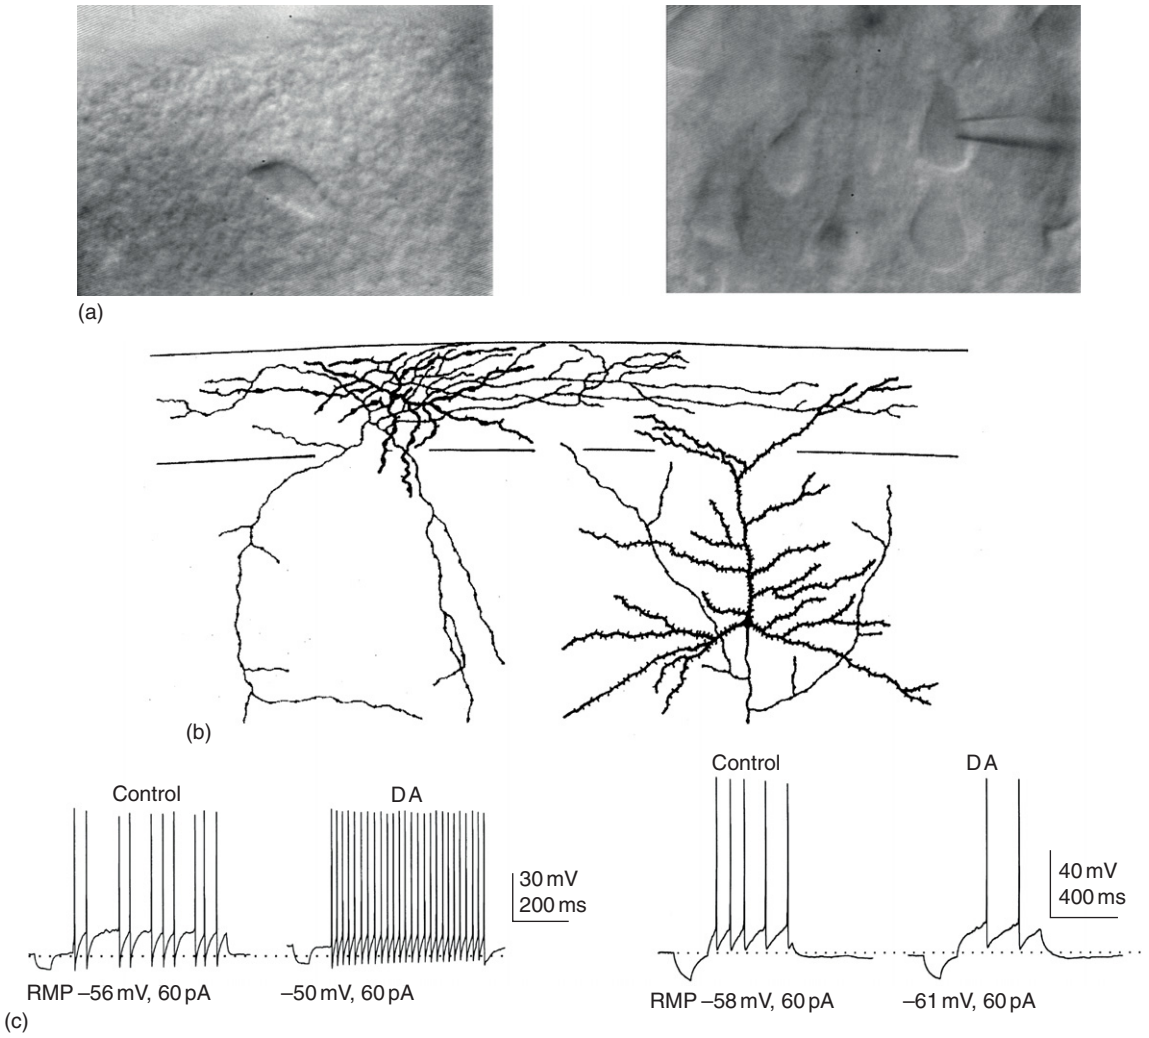

Figure 1 Effects of dopamine on intrinsic excitability of identified cells in rat prefrontal cortex. (a) Infrared Nomarski differential interference contrast images of layer I (left) and pyramidal (right) neurons, as seen during recording. The patch pipette can be seen approaching a pyramidal cell from the right. (b) Camera lucida reconstructions of the biocytin labeled neurons. Pial surface is up in all cases. (c) Dopamine increases interneuron excitability but decreases pyramidal neuron excitability. Recordings were made in the presence of 10 μM bicuculline methiodide (Bic), 20 μM D(−)2-amino-5-phosphonovaleric acid (D-APV), and 10 μM 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) to block $GABA_A$, NMDA, and AMPA receptors, respectively. Left: in a layer I neuron, bath application of 40 μM DA induced a depolarization of ~6 mV and increased the number of spikes evoked by 60-pA depolarizing current pulses. Input resistance, monitored by a current pulse of −40 pA, was also increased from 230 MΩ in control to 280 MΩ in DA. Right: in a pyramidal neuron, bath application of 40 μM DA induced a hyperpolarization of ~3 mV and decreased the spikes evoked by injecting 60-pA depolarizing current pulses. Input resistance, monitored by a current pulse of −60 pA, was also decreased from 270 MΩ in control to 225 MΩ in DA. In both cells, DA effects were partly reversed on wash. Reproduced from Zhou FM and Hablitz JJ (1999) Dopamine modulation of membrane and synaptic properties of interneurons in rat cerebral cortex. *Journal of Neurophysiology* 81: 967–976, with permission from American Physiological Society.

to understand how this neurotransmitter alters activity in local neuronal networks in intact animals. The in vitro studies described here document the ability of dopamine to sharpen activation patterns by enhancing inhibition. More information is needed about the effects of endogenously released dopamine on activity in local circuits. This information could be obtained in experiments in intact animals, involving stimulation of cortically projecting dopaminergic fibers in the ventral tegmental area. Recent studies have examined the spatiotemporal dynamics of cortical sensory responses in vivo using voltage-sensitive dye imaging combined with whole-cell voltage recordings and neuron reconstructions. Similar approaches would be a powerful means of understanding dopamine modulation in intact animals.

Advances in this area will also come about by establishing the effects of dopamine agonists and antagonists in chronic animal models of epilepsy. By chronically altering dopamine levels via systemic or local administration of agents selective for activating or inhibiting specific

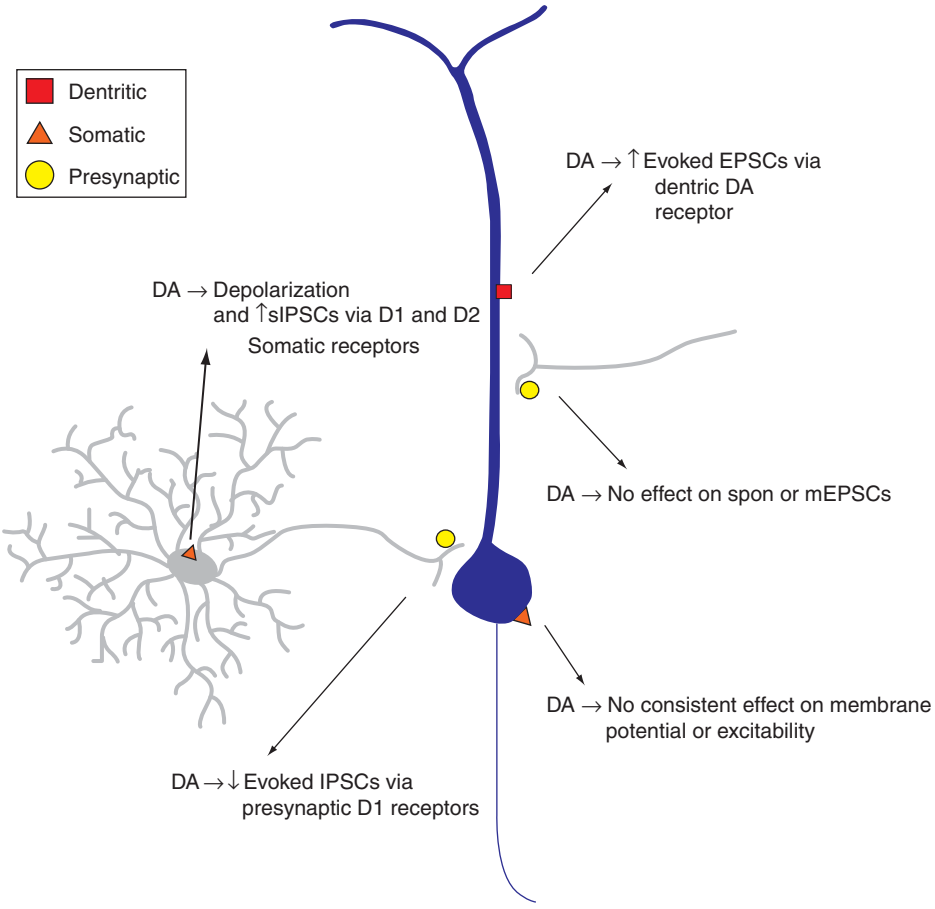

Figure 2 Schematic diagram showing the multiple sites of action and effects of dopamine in rat frontal cortex. Dopamine receptors are located both on GABAergic interneurons (gray) and pyramidal cells (blue). These receptors can be either somatic (orange triangle) or dendritic (yellow circle) or on presynaptic terminals (red box). Not indicated is the additional complexity of variability in dopamine receptor subtype (D1- or D2-like) at each location.

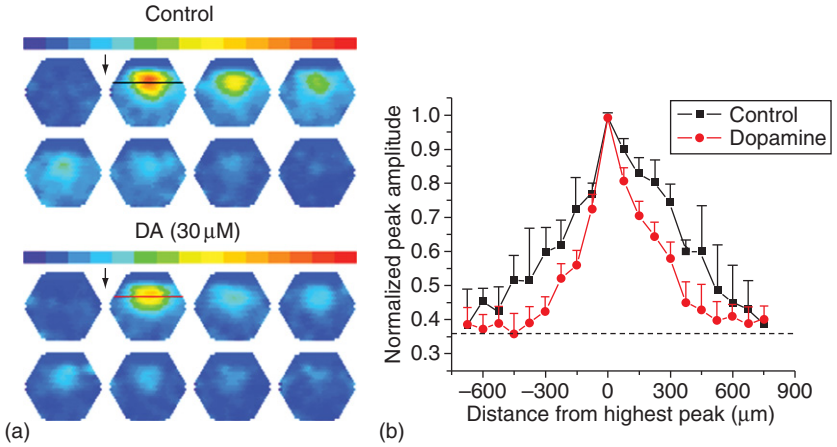

Figure 3 Dopamine decreases spatiotemporal spread of activity evoked by intracortical stimulation in prefrontal cortex under conditions of normal synaptic transmission. (a) Pseudocolor maps of activity evoked in a prefrontal cortical slice (pial surface up) by a single intracortical stimulation (↓, time of stimulation) before and 10 min after application of dopamine (30 μM) in bath. Fixed pseudocolor scale was used for all frames. A frame interval of 15 ms was used. (b) Normalized peak dye signal amplitudes measured along a line drawn across the diode array (as shown in (a)) plotted as a function of distance from the diode showing highest peak dye signal. Dye signals were normalized to the highest peak dye signal. Error bars indicate SE ($n = 9$). Dashed line indicates the level of background noise. Reproduced from Bandyopadhyay S and Hablitz JJ (2007) Dopaminergic modulation of local network activity in rat prefrontal cortex. *Journal of Neurophysiology* 97: 4120–4128, with permission from American Physiological Society.

dopamine receptor subtypes, the time to develop seizures and/or the frequency and severity of established seizures could be examined. A variety of models, including those involving both hippocampus and neocortex, should be considered, because given the heterogeneity of dopamine effects, differential outcomes might occur.

Dopamine is but one modulatory system in the neocortex. Innervation by serotonergic and noradrenergic fibers is also prominent. Considerable controversy exists concerning whether antidepressant drugs, which affect these modulatory systems, are anticonvulsant or proconvulsant. Application of techniques outlined above for study of dopamine could also be profitably applied to serotonergic and noradrenergic systems, leading to a more complete understanding of the role of modulatory systems in epilepsy.

Impact of Norepinephrine on Epileptogenesis

Introduction

The impact of neurotransmitters, neuropeptides, and other endogenous chemicals on the development and expression of epileptic seizures is of great clinical and experimental/theoretical interest. Indeed, as convulsive seizures are recruited in the brain, it is quite likely that nearly all neural networks in most structures are engaged differentially in the seizure, depending upon many factors, including genetic background. In this article, I present some of the evidence concerning the involvement of norepinephrine (NE) in epilepsy, where its major impact appears to be on epileptogenesis – i.e., the development of seizures, rather than on modulation of the chronic condition of epilepsy – i.e., the epileptic state. If epilepsy is the pathological offspring of otherwise normal brain mechanisms, as has been suggested by others like Graham Goddard, the normal mechanisms that are likely usurped during epileptogenesis are probably involved in the neuroplasticity of learning; further, the network changes that subsequently represent the epileptic state are likely realized through the usurped mechanisms of memory, where the epileptic state represents the engram of the neuroplastic, epileptogenic process.

Background

The role of NE in the expression of seizures has a long and distinguished history. Although relatively less work has been done recently in this regard, NE historically has

dopamine receptor subtypes, the time to develop seizures and/or the frequency and severity of established seizures could be examined. A variety of models, including those involving both hippocampus and neocortex, should be considered, because given the heterogeneity of dopamine effects, differential outcomes might occur.

Dopamine is but one modulatory system in the neocortex. Innervation by serotonergic and noradrenergic fibers is also prominent. Considerable controversy exists concerning whether antidepressant drugs, which affect these modulatory systems, are anticonvulsant or proconvulsant. Application of techniques outlined above for study of dopamine could also be profitably applied to serotonergic and noradrenergic systems, leading to a more complete understanding of the role of modulatory systems in epilepsy.

Impact of Norepinephrine on Epileptogenesis

D C McIntyre, Carleton University, Ottawa, ON, Canada

Introduction

The impact of neurotransmitters, neuropeptides, and other endogenous chemicals on the development and expression of epileptic seizures is of great clinical and experimental/theoretical interest. Indeed, as convulsive seizures are recruited in the brain, it is quite likely that nearly all neural networks in most structures are engaged differentially in the seizure, depending upon many factors, including genetic background. In this article, I present some of the evidence concerning the involvement of norepinephrine (NE) in epilepsy, where its major impact appears to be on epileptogenesis – i.e., the development of seizures, rather than on modulation of the chronic condition of epilepsy – i.e., the epileptic state. If epilepsy is the pathological offspring of otherwise normal brain mechanisms, as has been suggested by others like Graham Goddard, the normal mechanisms that are likely usurped during epileptogenesis are probably involved in the neuroplasticity of learning; further, the network changes that subsequently represent the epileptic state are likely realized through the usurped mechanisms of memory, where the epileptic state represents the engram of the neuroplastic, epileptogenic process.

Background

The role of NE in the expression of seizures has a long and distinguished history. Although relatively less work has been done recently in this regard, NE historically has

shown one of the most profound suppressive effects ever recorded on the development of epilepsy. Thus, the neuroplasticity associated with epileptogenesis may be associated with the period in which NE exerts the majority of its antiepileptic effect. Although NE exerts its antiepileptic effect in a variety of experimental paradigms, including systemic pentylenetetrazol and electroshock, its most robust action has been recorded in the kindling paradigm.

Originally, Racine's group demonstrated that suppression of catecholamine activity facilitated the development of amygdala kindling. In their experiment, they administered (systemically) reserpine (a nonselective catecholamine depleting agent) and 6-hydroxydopamine (6-OHDA; a nonspecific monoamine neurotoxin) that depleted both NE and dopamine. Subsequently, they showed that the effects of this 6-OHDA treatment depended on the loss of NE-containing neurons; if 6-OHDA administration was preceded by systemic administration of desmethylimipramine (DMI) (a NE reuptake inhibitor that selectively protects NE neurons from 6-OHDA), 6-OHDA killed only DA neurons. These NE protected rats now kindled similarly to saline controls. In a reciprocal fashion, increasing NE availability with antecedent systemic DMI injections alone or by locus coeruleus (LC) stimulation significantly delayed the kindling process.

The involvement of NE in epileptogenesis was also supported by the demonstration that transplants of fetal LC cells into the hippocampus or amygdala-piriform area of 6-OHDA-pretreated rats significantly slowed kindling from the hippocampus and amygdala, respectively (compared to 6-OHDA-pretreated rats without fetal LC grafts). The grafts produced robust sprouting of NE terminals in the area of the transplant, which spontaneously released NE and clearly affected local epileptogenesis. Importantly, when the grafts were implanted into previously kindled rats, they had no discernible effect on the triggering or the form (i.e., the expression profiles, including latencies and durations of convulsive events) of the kindled seizures. Thus, as shown with other manipulations, NE applied after kindling had little impact on the triggering or expression of already kindled limbic seizures.

Methods

In our laboratory, we have questioned NE involvement in epileptogenesis and the epileptic state in several different ways. First, we have examined the effect of NE on local circuitry in the limbic system that is known to be critically important in the convulsive expression of seizures. This circuitry is manifested heavily in the parahippocampal cortices, especially the piriform, perirhinal, insular, and entorhinal areas. The convulsive expression can be directly driven by electrical stimulation of perirhinal and insular neurons that project robustly to the frontal motor fields, where the convulsive motor event seems to originate. Second, we selectively bred rats to be natively seizure prone or seizure resistant to the kindling process. With these rats, we have asked how their NE system responds to kindling and other natural stressors, and to NE manipulations that affect epileptogenesis and its expression. Third, we have performed microdialysis studies to measure the release of NE and other transmitters in the amygdala during the early stages of kindling epileptogenesis, using different stimulation protocols (i.e., distributed or traditional once-daily electrical kindling versus massed stimulation kindling procedures).

Recent Results

In developing a coronal slice preparation of the amygdala/piriform/perirhinal area, we showed that this temporal lobe area is intrinsically excitable and readily shows spontaneous burst discharges in vitro after being excised from either amygdala or hippocampal kindled rats. The in vitro perirhinal/insular area taken from naïve rats showed small burst discharges without kindling, but antecedent kindling augmented the bursting, promoting increased spontaneous discharge frequencies and durations in the network. The burst activity in naïve, control slices could be significantly dampened by perfusion of the slices with NE. The effect of NE on kindled slices, however, was much less robust – much like the results obtained from intact kindled animals, where NE had lost its suppressive efficacy.

Selective NE agonists and antagonists to slices from control tissue indicated that the $\alpha 1$ NE agonist, L-phenylephrine, had little effect on the burst responses, but the $\alpha 2$ agonist, clonidine, duplicated the suppressive effects of NE itself. In contrast, the β agonist, isoproteronol, augmented burst responses. Clearly, in this in vitro preparation with manipulation of NE receptor subtypes, NE itself has the potential to either promote suppression or enhancement of triggered or spontaneous burst events, depending upon the compliment of receptor subtypes it activates and the networks in which they reside. Since these different receptors have differential affinities for NE, we have hypothesized that these differential effects of NE might be a result of dose-dependent actions, where low doses of NE could activate the network (assuming the β receptors have a greater affinity), while higher doses (acting on the postsynaptic $\alpha 2$ receptors) could suppress it; this hypothesis has not yet been tested.

Extrapolating this hypothesis to the whole animal, one might predict that low levels of NE (conditions of low arousal) would potentiate responsiveness to stimulation,

while higher levels of NE (during higher arousal) would 'channelize' responsiveness (information) by suppressing competitive but less intensely activated networks, and focusing activity/attention. The suppressive postsynaptic action of the α2 agonist can be seen in whole animals deprived of their presynaptic NE machinery, where clonidine suppressed the development of amygdala kindling in 6-OHDA-pretreated rats in a manner similar to intact controls.

When outbred rats from a Wistar and Long-Evans hooded cross were selectively bred to be seizure prone or seizure resistant to amygdala kindling (based on their Fast or Slow rates of kindling development to stage-5 convulsive seizures), a number of important observations were made concerning NE and associated behaviors. The fast kindling strain in their naïve state showed higher postmortem levels of NE activity (3-methoxy-4-hydroxyphenolglycol, MHPG) in several limbic structures compared with the Slow strain, in the presence of various stressors or aversive conditioning procedures. This result was corroborated in microdalysis experiments, where the levels of NE in the amygdala/piriform area in Fast rats rose to higher levels than in Slow rats when the animals were 'challenged' by amygdala kindling procedures. The unique importance of the NE system to Fast rats was further suggested when Fast and Slow rats were subjected to intraventricular 6-OHDA administration, as described earlier. The amygdala kindling rates of both Fast and Slow rat groups significantly decreased following depletion of NE by 6-OHDA; however, the NE depletion was catastrophic for the behavior of Fast rats, where most Fast rats experienced full stage-5 seizures on their first kindling stimulation compared with the much more resistant kindling profiles in the 6-OHDA-pretreated Slow rats (Mean ± SEM kindling rates: Fast controls = 7.9 ± 1.1; Fast 6-OHDA = 1.2 ± 0.1; Slow controls = 32.6 ± 3.8; Slow 6-OHDA = 8.0 ± 1.2; $N = 8$ in all groups). Clearly, with a similar reduction of NE levels in Fast and Slow rats (94–97% reduction compared with their controls), Slow rats had other effective inhibitory mechanisms in place against epileptogenesis that were not evident in Fast rats. Our studies suggest that the residual inhibition in Slow rats, that attenuated their amygdala kindling rates compared with Fast rats after the loss of NE, was likely to be GABAergic in nature.

Using a different kindling paradigm, additional information about NE involvement in epileptogenesis can be obtained. If one mass stimulates (MS treatment) the amygdala (with interstimulation intervals, ISI, of 10 min or less) above threshold for triggering afterdischarges (ADs), very little kindling occurs in outbred rats (e.g., Long-Evans hooded). In contrast, such short ISIs tend to facilitate or promote kindling from the hippocampus. Clearly, different neural networks respond differentially when challenged in this manner. When stimulating the amygdala in rats given the α2 NE receptor blocker, yohimbine, we found that a significant increase in the expression of generalized seizures was triggered throughout the 50 stimulation experiments (a 5-min ISI). In contrast, the β blocker propanolol marginally reduced the triggered seizure activity, by shortening the evoked ADs (so that there was no concomitant behavioral seizure expression). When a similar MS treatment was applied to naïve Fast and Slow rats, paradoxically perhaps, Fast rats had a greater release of NE in their amygdala/piriform area compared with Slow rats (as seen with microdialysis), yet they also exhibited intermittently several strong generalized seizures. There were no such enhanced responses in Slow rats. Clearly, the greater focal release of NE in Fast rats was not able to suppress the intermittently stronger seizure response (compared with Slow rats); however, this increased NE release was associated with a phasic elevation of AD thresholds that rarely was seen in the Slow rats or outbred controls.

Pharmacological manipulation of the NE system of Fast and Slow rats during MS, and its impact on subsequent daily amygdala kindling, was also informative. The α2 antagonist, idazoxan, greatly increased the AD durations of Slow rats during the MS procedure, and several of these discharges were accompanied by generalized seizures; yet idazoxan had very little effect on Fast rats. In contrast, an α2 agonist, guanfacine, facilitated the appearance of generalized convulsive seizures during MS in Fast rats, with little effect on Slow rats. The enhanced responsiveness of Slow rats to idazoxan during MS treatment supports the earlier demonstration, in distributed stimulation paradigms, that activation of the postsynaptic α2 NE receptors provides considerable suppressive effect on the kindling epileptogenesis in outbred rats. This action was clearly the case during MS treatment in Slow rats, but not in Fast rats. By contrast, Fast rats during the MS treatment showed little local amygdala sensitivity to either of the two α2 NE manipulations, but did show an increase in the number of recruited generalized convulsive seizures in the presence of guanfacine. These observations suggest that the various NE receptor subtypes, their distribution, pre- or postsynaptic expression, or efficacy in several brain areas are different between Fast and Slow rats.

Data from such pharmacological studies might involve activation of pre-versus postsynaptic α2 NE receptors to create these differential effects on seizure behavior in the two strains; however, this possibility must be interpreted with caution, as variations in methodology may often lead to conflicting results. For example, differences in the distribution of NE receptors between species, strain, and brain regions are possible; further, different receptor subtypes are likely to influence the selectivity and binding properties for various agonists and antagonists, all of which may depend on dosage of the drug, as suggested earlier. Because different α2 agonists can produce opposite responses (proconvulsant and anticonvulsant) in the

same or different animals, Szot et al. have argued, based on their data with clonidine and guanfacine, that these two agonists have different affinities for pre-versus postsynaptic α_2A receptors; further, other α2 phenotypes exist (e.g., α2C). In fact, we have reported significant elevations of α2C mRNA expression in naïve, unkindled Slow rats compared with Fast rats in several brain regions, including nucleus accumbens, dentate gyrus, cerebellum, cingulate gyrus, and neocortex layer II.

Future Directions

At the present time, the involvement of the α2C receptor in NE activity is unknown, as is the extent of the effect that kindling has on mRNA expression in Fast and Slow strains; analyses of these issues should provide an interesting avenue for future investigation. Previous studies have shown that α2A receptors are approximately 10× more abundant than α2C receptors in many areas of the brain, and likely responsible for the rapid inhibition of NE release. The α2C receptor subtype is interesting, as it is located both in the intracellular compartment and on the plasma membrane but with the vast majority of receptors found intracellularly. Although both α2A and α2C receptors are present pre- and postsynaptically, MS of the amygdala may potentially alter, differentially, the expression and/or localization of receptors in Fast and Slow rats. In the present study, differences in pre-versus postsynaptic properties in Fast versus Slow rats could easily be the case, especially since guanfacine did not affect focal AD characteristics (like AD thresholds and durations) in the amygdala of either strain, but facilitated the occasional recruitment of the convulsive motor network in Fast rats. This result was surprising, since several studies have reported guanfacine to be anticonvulsant against a number of seizure models in adult outbred animals; however, it would explain Fast rat behavior if guanfacine was only effective presynaptically in these animals, and only before kindling.

Although we had postulated that idazoxan might have a preferential affinity for postsynaptic α2 receptors, it can also block presynaptic α2 autoreceptors and additionally bind to α1 and β receptors. Further, numerous reports have shown that idazoxan binds at high affinity to non-adrenoceptor idazoxan binding sites. It has been suggested that occupation of these sites by idazoxan may counteract the proconvulsant effects of postsynaptic α2 adrenoceptor blockade. If this is the case, it is possible that MS of the amygdala may have increased the number of these non-NE idazoxan binding sites in Fast rats compared with Slow rats. Higher NE levels in Fast rats during MS would facilitate binding of idazoxan to these other receptors, and depending upon their location and function, could impact other neurotransmitter systems and the release of other inhibitory transmitters such as GABA or serotonin.

Finally, the fact that chronic activation of postsynaptic α_2 noradrenergic receptors via distributed kindling protocols or by drug administration can presumably regulate NE receptors, it is possible that the first few stimulations of the MS protocol effected such a change in the amygdala area in Fast but not Slow rats, rendering their amygdala area insensitive to the NE manipulations. If such a downregulation occurred largely in the local amygdala/neocortical network, application of the systemic α2 agonist, guanfacine, should have reached the LC, and with presynaptic agonistic efficacy, reduced forebrain NE, making Fast rats more seizure prone. This result was, indeed, the behavioral outcome of the treatment. By contrast, Slow rats maintained considerable sensitivity to the α2 antagonist, idazoxan, throughout the MS protocol, as well as through the completion of the distributed kindling phase that followed the MS treatment, suggesting that they might be less subject to changes in NE receptor regulation in the face of frequent activation.

In the 2 weeks following MS treatment, all rats had their AD thresholds checked once weekly. Fast rats in all treatment groups showed very progressive and large increases in their AD durations compared with Slow rats that exhibited relatively short, stable discharges over that period. Interestingly, previously guanfacine-treated Fast rats showed the greatest AD growth during MS treatment, and were the fastest kindlers, requiring the fewest stimulations to develop their first stage-5 seizure after the MS treatment. It was also found that both idazoxan and guanfacine administered during the MS treatment slightly facilitated the daily distributed kindling rates of Slow rats compared with saline controls, but perhaps for different reasons.

The correlative data indicate that rats with the greatest number of long ADs during the MS treatment subsequently kindled the fastest (i.e., experienced the most positive transfer between the two protocols). It appeared, therefore, that if one can create long ADs during the MS treatment, independent of other considerations, the long ADs will recruit broadly throughout the network and enduringly alter synaptic efficacy. The network modifications affected by those long discharges, when accessed subsequently with daily kindling, result in rapid, spatially broad recruitment and faster generalization. This outcome leads quickly to reliable stage-5 generalized seizure expression. Short AD durations during MS treatment did not seem to affect such changes. Perhaps this effect of prolonged AD helps to explain why the long seizures of limbic status epilepticus so readily and reliably promote spontaneous generalized convulsive behavior.

Once an outbred rat is fully kindled, NE manipulations historically have had little effect on the kindled state. Thus, it was surprising that idazoxan resulted in an increase in the duration of motor convulsions of fully

kindled Slow rats, but was without a significant concomitant increase in their associated AD durations. This result suggested that the α2 noradrenergic receptors in the recruited motor network were still capable of modulating seizure expression after kindling (i.e., could be rendered less effective by the antagonist). Noteworthy, idazoxan did not affect the seizure profile of kindled Fast rats, a result that was consistent with earlier lack of response to idazoxan before kindling during the MS treatment. However, guanfacine, which failed to significantly affect the naïve Slow rats during MS treatment, now increased the duration of their kindled amygdala AD without influencing the concomitant convulsion. It is not obvious how to explain this result, unless amygdala kindling in the Slow rats altered the expression of α2 receptors or their subtypes in that local area, where they interface with other transmitter systems (e.g., GABA) to altered GABA release. Guanfacine, which affected the expression of convulsive seizures in Fast rats during the MS treatment, was without effect once Fast rats were kindled. Thus, the seizure behavior of Fast rats after amygdala kindling is consistent with the notion that kindling makes the rat insensitive to NE treatments, similar to outbred rats. This outcome did not occur in the Slow rats that maintained sensitivity (albeit slightly altered) to α2 manipulations after amygdala kindling.

Clearly, the expression of α2 NE receptors in the Fast and Slow rats, and their alteration with MS treatment and subsequent distributed kindling, needs to be explored in detail to more fully explain the unique patterns of results described here. The binding studies have indicated that Fast and Slow rats have similar distributions and labeling for the NE α2A receptor. Thus, activation of the α2A receptor might not be critical in differentiating the Fast versus Slow seizure phenotypes. Certainly, the α2 C receptor mRNA expression is quite different between the two strains. In general, Fast rats had significantly lower levels of α2 C expression than Slow rats in several limbic and motor structures. How NE affects that receptor subtype, and its consequences for excitability of the network, is unknown but should provide a fertile area for future research. Most importantly in that context, the two different strains should be viewed as modeling two different 'people' who have been exposed to an event (e.g., an injury) that could lead to epileptogenesis. This prelude begs the research question concerning differential treatment of those 'individuals,' involving the NE systems and its receptor subtypes, which might be appropriate for those two different natural predilections for development of the disorder. Certainly, manipulations that appear to be good for one strain are not necessarily good for the other. Therapeutically, such information should be quite valuable.

Introduction

Epilepsy is a multifactorial disease with debilitating effects. Its quintessence, the synchronization of neuronal networks, is generated at least in part through the inappropriate release of, or response to, neurotransmitters (NT). This article focuses on the molecules that control presynaptic NT release. We seek to understand the molecular mechanisms accounting for the heightened release of NT seen in epilepsy. Identification of the pathways and associated regulatory proteins involved in this process may illuminate potentially useful therapeutic targets to control NT release, and perhaps to mitigate or even abort seizure activity. Given the advances in genetic methods and small molecule inhibitor design, a mechanistic understanding of NT release is required to focus the search on new classes of anticonvulsant or antiepileptogenic agents.

Background

Kindling and the Dysregulation of NT Release

Kindling is a useful animal model of epilepsy and epileptogenesis. It is a progressive process, in response to repeated subconvulsive electrical or chemical stimulation, yielding a permanent intensification of epileptiform afterdischarges that culminates in generalized seizures. Many kindling studies have focused on the deregulation of NT release, particularly glutamate, as a mechanism of epileptogenesis. Several studies have used microdialysis techniques to show that increased glutamate release precedes seizures. We have shown that entorhinal kindling induces a permanent increase in K^+-evoked, Ca^{2+}-dependent release of glutamate from the hippocampus. Similar results are seen in hippocampal slices after Schaffer collateral-commissural kindling, in hippocampal and amygdalar slices of amygdalar-kindled rats, in cerebral cortical synaptosomes, and in hippocampus after septal kindling. Increased excitatory NT release has been measured in several different systems, and although the underlying molecular mechanisms accounting for it are still undefined, it is clear that increased release is a chronic change that once established is permanent in kindled animals.

Certainly, epileptic convulsions can result from defective release of inhibitory NTs; however, it is not clear whether long-term changes of GABA release play a role in epileptogenesis. Conversely, GABA systems themselves can be modified by seizure activity; these changes may provide compensatory augmentation or even an epilepsy-enhancing attenuation (e.g., with loss of inhibitory neurons in association with mesial temporal sclerosis). In our studies, there was no increase of K^+-evoked Ca^{2+}-dependent GABA release in hippocampus following entorhinal kindling; similar findings have been reported in amygdala following amygdala kindling. In contrast, others have shown increased K^+-evoked GABA release in hippocampal slices of hippocampal-kindled animals. Furthermore, there are microdialysis studies of human epilepsy patients showing increased GABA release with stimulation. These observations suggest that during epileptogenesis, alterations in GABA release are likely compensatory mechanisms; however, they could reflect molecular changes in the secretory machinery that would be subject to targeted modification.

Basic Machinery of NT Release

Neurotransmitters are stored in synaptic vesicles (SV) and their extracellular release is facilitated by the fusion of the SV with the presynaptic plasma membrane. SVs are cycled in the presynaptic area, where they are either held in a reserve position, poised for release (ready release pool), or recycling from the plasma membrane following fusion. The ready release pool is thought to represent a stage in which the final step of membrane fusion is fully engaged but not consummated. In fact, the two membranes (synaptic vesicle and active zone membranes) are thought to exist in a hemi-fused state in which the cytoplasmic faces of the two bilayers have already mixed. Many of the proteins, now known to affect NT release, appear to affect the formation or stability of the ready release pool.

Membrane fusion is mediated by the soluble *N*-ethylmaleimide sensitive factor (NSF) attachment protein (SNAP) receptors or SNAREs. These integral membrane proteins are the minimal elements required for membrane fusion. In neurons, there are two classes of SNAREs that can be distinguished based on their localization. The t-SNAREs, or target membrane SNAREs, are found in the plasma membrane and fall into two

categories, syntaxins and SNAP-25-like. The vesicle SNAREs, (v-SNAREs, also known as vesicle associated membrane proteins (VAMPs)) are localized to the SV membranes. Each SNARE contains at least one SNARE motif (SNAP-25 has two), which contains heptad repeats in which the A and D position are hydrophobic amino acids. Repeats from the three SNAREs form a parallel, coiled-coil that buries these hydrophobic residues. Such a complex is known as the 7S SNARE complex due to its hydrodynamic properties in centrifugation experiments. This structure is quite stable, requiring $>75\,^{\circ}C$ to denature (this property is exploited in our assays for SNARE complex formation). Such stability is thought to contribute thermodynamically to the membrane fusion process when the SNARE complex is in a trans-membrane configuration. Disassembly of the postfusion, *cis*-SNARE complex requires the action of the ATP-dependent chaperone, NSF, and is essential for further NT release.

Regulation of SNARE Interactions

The trans-membrane SNARE complex at the apposition of the synaptic vesicle and active zone membranes is the basic element required for membrane fusion. The stability of the SNARE complex, a potential source of energy for membrane fusion, poses mechanistic problems both for SNARE complex disassembly (which is required for recycling SNAREs) and for complex assembly (which is required for promoting fusion events). As alluded to above, the ATPase/chaperone NSF and its adaptor protein, α-SNAP, are required for disassembly and the recycling of the spent SNARE complexes in the *cis* configuration. NSF participation in this disassembly appears to be essential, because loss-of-function mutants of NSF cause an activation-dependent loss of NT release in *Drosophila*. Several reports suggest that NSF activity may be regulated via posttranslational modifications such as nitrosylation, serine/threonine, or tyrosine phosphorylation. Other studies have suggested that NSF RNA and protein levels are affected during epileptogenesis. At this time, it is unclear if/how control of NSF activity affects epilepsy.

Assembly of the *trans*-SNARE complex represents a key step through which NT release can be regulated. The function of most SNARE regulators is to bind the individual SNARE proteins, thereby controlling their access to each other. Thus, the SNARE regulators act as chaperones and/or matchmakers, affecting where and when SNAREs can bind to facilitate membrane fusion. From the analysis of the known effectors, controlling syntaxins appears to be a pivotal step for controlling membrane fusion – as suggested by the various conformational changes in syntaxin that occur as it becomes competent to interact with the other SNAREs. In its 'closed' conformation, the SNARE motif in syntaxin 1 is thought to be masked by the folding back and binding of the N-terminal H_{abc} domain. In syntaxin's 'open' conformation, its SNARE motif is exposed and thus available to interaction with the SNARE motifs of SNAP-25 and VAMP-2 to form the SNARE complex for membrane fusion.

Munc18

One of the first identified syntaxin regulators was the nSec1/Munc18 family. Munc18s have high affinity for syntaxins and were first purified by affinity chromatography on immobilized GST-syntaxin. Three Munc18 isoforms are present in mammalian tissues – a, b, and c – and each shows specificity in its syntaxin binding. In neurons, the most relevant isoform is Munc18a which interacts with syntaxin 1. The role of this Munc18 family in regulating syntaxin is confusing because of the varied effects of overexpression and deletion. Overexpression studies and in vitro binding experiments suggest that Munc18s are negative regulators, affecting syntaxin binding to other SNAREs. However, this view is inconsistent with the phenotypes of Munc18a$^{-/-}$ mice, or conditional mutants in yeast (Sec1p,) and *Caenorhabditis elegans* (unc18p), where Munc18s are required for secretion. One explanation for these latter results is that Munc18s are regulated chaperones required to maintain syntaxins in an 'activated' conformation at a specific site. Thus, overexpression may be inhibitory, because more Munc18 disrupts the dynamic balance between syntaxin binding and release, which is required for exocytosis. What is clear from all the data is that Munc18 must 'pass' syntaxins to their cognate SNARE partners to propagate membrane fusion. While the terms 'release or pass' are used, it may be more a conformational change in the interaction between Munc18 and syntaxin that denotes Munc18 function.

As Munc18s have multiple kinase recognition sites, phosphorylation could trigger syntaxin 'release.' This interpretation is consistent with in vivo studies showing that phosphorylation of Munc18a (at Ser313) decreases its affinity for syntaxin 1, but does not completely inhibit binding. Based on these observations, Munc18 phosphorylation could be a priming step that promotes 'release' of syntaxins. Such a hypothesis is supported by the recent findings which suggest that PKC phosphorylation of Munc18a is critical for vesicle priming at a step upstream of Munc13–1.

Munc13

The Munc13 family has at least four isoforms (1–4). Munc13 proteins show a bipartite structure, with a diverse N-terminal region and a more conserved C-terminal region. The C-terminus contains two C2 domains and two conserved Munc13 Homology Domains (MHD). The diverse N-terminus can contain a third C2 domain, one C1 domain and a calmodulin binding site. The C2

domains are homologous to the calcium-dependent phospholipid binding domains of PKC. The C1 domain is significant because it is homologous to the diacylglycerol (DAG) binding domain of PKC. While the N-terminus contains domains that might be responsive to signals, the C-terminal region contains some of the key interaction domains. The MHD contains a DOC2 interaction domain (DID) that is important for binding DOC2. Overexpression of this domain inhibits secretion from PC12 cells. This same region is important for binding to syntaxins, specifically, the N-terminal helices of syntaxin (H_{abc}) that do not form the coiled-coil structure of the SNARE complex.

Munc13–1 is required for maintenance of the ready release pool of synaptic vesicles in neurons. It acts as a priming factor accelerating the transfer of docked, unprimed vesicles to the ready releasable pool, and therefore increasing their fusion competence. Calmodulin (CaM) binding to Munc13–1 is an important component of this priming, and loss of CaM binding slows the transfer rate. The C1 domain is also critical. Knock-in mice expressing a mutant of Munc13–1 (H567K, which fails to bind DAG or phorbol esters) had a lethal phenotype similar to the Munc13–1 knockouts. Explanted neurons from these animals failed to respond to phorbol esters, suggesting that Munc13–1 is, along with PKC, a major site of phorbol esters' enhancing effects on neurotransmission.

It should be pointed out that DOC2s and syntaxins share a similar binding site on Munc13, and Munc13–1 and Munc18a share a common binding site on syntaxin 1. The overlapping binding sites are of interest, as recent reports suggest dynamic in vivo interactions between syntaxins, Munc13s, and Munc18s. Overexpression of Munc13–1 suppressed the inhibitory effect of Munc18a expression on syntaxin activity; this action also led to an increased association of SNAP-25 with the plasma membrane, consistent with an increase in SNARE complex formation. Expression of an 'open' conformation mutant of syntaxin 1 (that does not bind Munc18) suppressed the deletion of Munc13 in *C. elegans*. These observations show that these proteins – syntaxin, Munc13, and Munc18 (and perhaps DOC2) – are involved in a pathway of protein–protein interactions which could promote SNARE pairing and perhaps membrane fusion.

Tomosyn

Tomosyn is a 130-kDa protein originally purified from brain. Structurally, tomosyn contains 14 WD40 repeats arranged in two 7-bladed propeller domains and a C-terminal domain that mimics the SNARE motif of v-SNAREs. This motif allows tomosyn to interact with t-SNARE heterodimers to form a heterotrimer very similar to the SNARE complex. The complex can be disassembled by SNAP and NSF, suggesting another mechanism by which NSF could control secretion. Functionally, tomosyn appears to affect vesicle priming prior to membrane fusion; however, the precise mechanism is confusing. As with Munc18t's, tomosyn is needed for NT release in neurons and secretion in yeast, but overexpression inhibits release – suggesting that tomosyn and Munc13 play antagonistic roles, the former exerting negative and the latter positive effects on vesicle priming. In a model proposed by McEwen et al., tomosyn is a place-holder for the v-SNARE and is displaced by activated Munc13. Thus, NT release is controlled by balancing tomosyn binding of the t-SNARE heterodimer, and Munc13 activation of the SNAREs for membrane fusion.

SV2

Although the specific molecular role(s) of the SV2s (A, B, or C) are debated, they appear to be a key control element for neurotransmitter and neuroendocrine release. In hippocampal slices, action potential-dependent release of GABA (operationally defining the 'ready release' pool of vesicles) is reduced in $SV2A^{-/-}$ mice. In these knockouts, the frequency and amplitude of spontaneous inhibitory postsynaptic currents (IPSC) is decreased, whereas miniature IPSCs measured in the presence of tetrodotoxin are no different from wild type mice. This observation suggests a role for SV2A in controlling assembly of SNARE complexes, but not in membrane fusion. Consistent with this view, analyses of brain tissue from $SV2A^{-/-}$ animals show a 50% decrease in SNARE complexes. These data suggest that SV2A is important for maintaining SNARE complexes but is perhaps not essential for complex formation.

Lynch *et al.* demonstrated that the antiepileptic drug, levetiracetam (LEV) binds stereospecifically, saturably, and reversibly to SV2A. These data suggest that LEV's anti-epileptic effects may be through the modulation of SV2A. LEV does not acutely affect the electrophysiology of normal tissue, and recent data show that prolonged treatment with LEV is required before presynaptic neurotransmission defects can be observed. These results suggest that LEV may affect some aspect of SV2 synthesis or transit to the synapse, but not its acute function. Further analysis will be needed to address this point.

Methods

Kindling

Kindling can be induced by electrical or chemical stimulation of many brain sites, especially in limbic areas (e.g., amygdala, hippocampus, and entorhinal cortex). The development of limbic kindling is characterized by electrographic discharges and behavioral seizure stages 1–5. An animal is considered fully kindled once enhanced sensitivity to an initial subthreshold stimulus has developed, as evidenced by a full (Racine) stage 5 seizure

(rearing and falling). Kindling is a particularly valuable technique to study chronic epilepsy because the site of stimulation is known, and no other disturbances are introduced (in contrast to status epilepticus models which are associated with widespread unilateral or bilateral limbic damage caused by cell death). Analysis of the electrophysiology of kindling, including observations that continued stimulation (i.e., the over-kindled state) leads to the occurrence of spontaneous seizures, suggests that kindling represents a permanent alteration which parallels changes seen in some human epilepsies.

Quantitative Western Blotting

The ability to better quantify proteins by western blotting has come with the advent of new detection systems, specifically those based on fluorescence imaging. Such readouts offer broader linear ranges and the ability to probe multiple proteins on the same membrane. One challenge in such analyses was to overcome the potential for animal-to-animal variation. We have solved this problem by using ratio measurements, comparing ipsilateral and contralateral hemispheres; in this way, each animal serves as its own control. We have validated this methods by showing that in naïve and surgical-control animals, the ipsilateral/contralateral ratio of SNARE complexes is consistently close to unity. Deviation from unity consistently appears as an increase in ipsilateral complexes in kindled animals. As would be expected, it does not occur with electroshock seizures; we have not measured this ratio in any other models of epileptogenesis.

Important Results to Date

Asymmetric Accumulation of SNARE Complexes

We have examined the state of the SNARE proteins and several of the SNARE regulators in hippocampi from kindled animals. Initial studies showed an asymmetric accumulation of SNARE complexes in ipsilateral hippocampal synaptosomes prepared from animals kindled by entorhinal stimulation. Control experiments suggest that this ispsilateral buildup of SNARE complexes is a marker of some basic biochemical change occurring during kindling and is indicative of epileptogenesis (see Figure 1(a) and below). Asymmetric accumulation cannot be induced by electroconvulsive shock nor is it seen in synaptosomes prepared from tissues outside of the limbic system (e.g., cerebellum or occipital cortex). This asymmetry can be induced by stimulating at several different sites, including entorhinal cortex, septal region, and amygdala; it develops in the ipsilateral hippocampus regardless of whether the right or left hemisphere is stimulated. As with kindling, asymmetric SNARE complex accumulation requires time to evolve and only occurs with stimulation within a frequency range that promotes kindling. The accumulation occurs gradually during kindling, mirroring the progression of Racine behavioral stages (Figure 1(a)), but it is persistent and can still be detected up to one year after the animal has attained a minimally kindled state (defined as two successive stage 5 seizures). It appears that a certain minimal level of kindling induction is necessary to induce permanence of the SNARE complexes asymmetry. In animals advancing up to, but not beyond Stage 3, the asymmetry begins to develop; if they receive no further stimuli, by

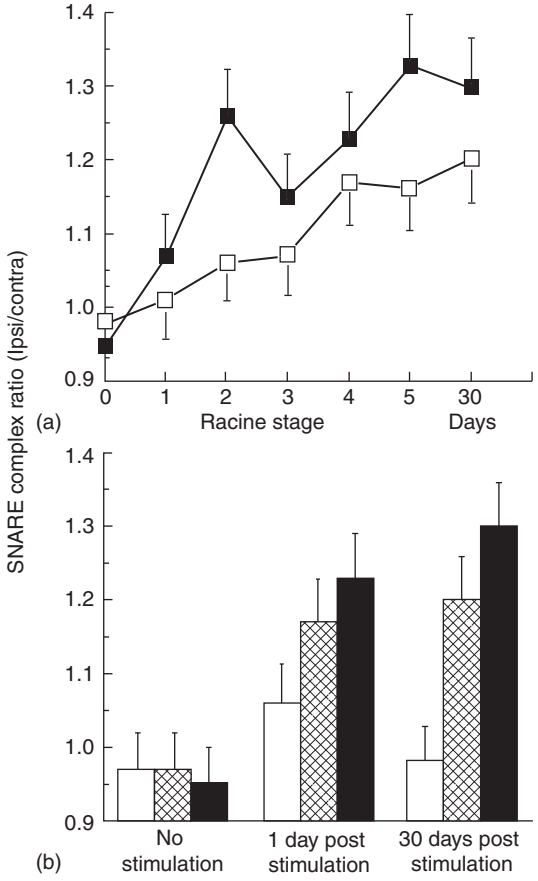

Figure 1 Asymmetric SNARE complex accumulation correlates with kindling stage. (a) Animals were electrically kindled by amygdalar (open squares) or entorhinal cortical (closed squares) stimulation until they exhibited behavior consistent with the indicated Racine stages. The next day, hippocampi were harvested from each animal and the ipsilateral/contralateral ratios of SNARE complexes were measured. One set of animals was fully kindled and hippocampi were harvested after 1 month (30 days). (b) Four cohorts of animals were held as naïve (no stimulation), kindled to stage 2 by amygdalar (open bars), or kindled to stage 4 by either amygdalar (hatched bars) or entorhinal cortical (solid bars) stimulation. Hippocampi were harvested from the animals either 1 day post stimulation or 1 month post stimulation and the ipsilateral/contralateral ratios of SNARE complexes were measured.

one month after the last stimulation hippocampal SNARE complexes symmetry is reestablished (**Figure 1(b)**).

Once attained, the asymmetric accumulation of SNARE complexes is the most stable biochemical marker of kindling-induced epileptogenesis that we have been able to find in the literature. It is not clear whether *trans*- or *cis*-SNARE complexes accumulate. If they are *trans*-SNARE complexes, it represents an increase in engagement of the membrane fusion machinery and our observations might be consistent with a focal enhancement of NT release. Accumulation of *cis*-SNARE complexes, in contrast,might signal defective recycling machinery – although this interpretation would not be entirely consistent with the observed increases in NT release, particularly glutamate, measured in hippocampi from patients undergoing epilepsy surgery and in several seizure models (including kindling).

At this stage of our investigations, it is also unclear whether the accumulation of SNARE complexes is associated with the cause of the kindled state or represents a *sequella* of the process. The control experiments described above demonstrate a tight correlation between kindling and asymmetric complex accumulation, but as discussed below, at least one anti-epilpetic drug can separate accumulation from kindling behavior. Further analysis of this association, for example, with transgenic mice expressing reduced SNARE levels or defective SNARE regulation, may prove to be a useful strategy to lower the availability of SNAREs and thus decrease the formation of SNARE complexes. Determining whether these conditions affect kindling progression might at least address whether complex accumulation is causative, responsive, or simply correlative. Either of the first two situations would indicate a locus for modification with agents useful to arrest epileptogenesis or quell epilepsy.

Effects on Other Elements of the Neuronal Secretory Machinery

Examination of several known elements of the neurosecretory machinery (α-SNAP, Munc18a, Munc13–1, complexin 1 and 2, and synaptotagmin 1) has generally shown that their protein levels do not undergo significant alteration during kindling epileptogenesis and upon attaining a fully kindled state. Three apparent exceptions are NSF, SV2, and tomosyn. NSF levels decrease with amygdala and septal kindling; the levels also appear to decline in entorhinally kindled animals (although that decrease was demonstrated only as a trend). A drop in NSF mRNA has also been reported in kainic acid-induced epilepsy. In our laboratory, the decrease of hippocampal NSF protein appears permanent and correlates with the altered asymmetry of SNARE complexes measured 1 year after amygdala kindling. Decreases in NSF could account for the accumulation of SNARE complexes, especially if such complexes are *cis* and thus represent postfusion events. In contrast to NSF, tomosyn and SV2 levels increase during amygdala kindling. In our studies, tomosyn increased early in the kindling process and then drifted back to normal levels as kindling progressed. The significance of this effect is not yet clear, although one could speculate that tomosyn might compete with v-SNAREs for t-SNARE binding; an increase in tomosyn could then lessen SNARE complexes assembly. SV2 levels began to rise early in the kindling process and subsequently remained elevated at 1 month following completion of kindling and cessation of further stimulation. The molecular ramifications of these increases are less clear than the changes for NSF, but given the role that these two proteins play in affecting secretion efficacy, one may propose that increased SV2 and tomosyn could affect either the formation of *trans*- or *cis*-SNARE complexes, generating several potentially testable scenarios. For example, if the kindling-induced increase of tomosyn is affecting formation of *trans* complexes at predominantly excitatory synapses in hippocampus, then the rise may represent a transient and unsuccessful compensatory response.

Effects of Levetiracetam

Levetiracetam (LEV) is an antiepileptic drug that specifically binds to SV2 (discussed above). Based on those data, it has been assumed that LEV's action is dependent on that interaction, although this assumption has not been definitively proved. Treatment of rats with LEV delays the progression of amygdala kindling, but does not prevent kindling if stimulations are continued. In our studies, LEV treatment dampens the asymmetric accumulation of SNARE complexes, even in animals taken to a fully kindled state. Thus, LEV treatment appears to separate the association of asymmetric SNARE complex accumulation and kindling progression. However, this effect is perhaps analogous to the results presented by Constantin *et al.*, who showed that intrahippocampal injection of botulinum toxin E (known to cleave the SNAP-25 t-SNARE) caused a delay in the development of hippocampal kindling. Such treatments would be expected to lower SNARE complex levels (not examined by Constatin *et al.*) as observed in LEV treated rats. However, both LEV and toxin treated animals did reach a fully kindled state with repeated stimulations.

LEV treatment also dampened the kindling-induced increase in SV2. Because the $SV2A^{-/-}$ mice show a decrease in global SNARE complex levels, perhaps LEV's effects are due to some alteration in SV2A function which directly affects complexes during kindling. Such an effect would only be relevant during epileptogenesis, as LEV appears to affect neither the normal function of neurons nor their SNARE complex levels.

Future Goals

At least three issues will require resolution before these data can be forged into a viable therapeutic approach to mollify epilepsy and to potentially protect against epileptogenesis. First, it will be necessary to determine in which cell types what aspects of the neurotransmitter release machinery become dysfunctional during epileptogenesis and persist with the epileptic state. Is the SNARE complex asymmetry distributed throughout the hippocampal formation, or is it confined to dentate gyrus, to a subdivision of the hippocampus proper (e.g., CA3), or is it seen in other structures? Is it confined to a certain cell type, specifically excitatory dentate granule or hippocampal pyramidal neurons, or inhibitory interneurons? If, for example, the SNARE complex accumulation localizes to glutamatergic neurons, then (based on the extensive literature of enhanced hippocampal glutamate release with kindling) one would propose testable mechanisms associated with accumulation of *trans* complexes. Do the regional and cellular localizations of altered NSF, SV2, and tomosyn comap with each other or with the SNARE complexes asymmetry? If they do not comap, are their changes consistent with a unified hypothesis consistent with epileptogenesis – that is, a synchronized hyperexcitable state?

Second, what molecular processes are functioning outside the bounds required for maintaining normal neuronal function? Certainly, resolution of the first issue will help in addressing this issue about mechanisms, by allowing more specific targeting. Do our observations reflect a pre or posttranslational process? One approach our laboratory has used to answer this question utilizes the hippocampal 'zipper' slice. This method allows for electrophysiologic characterization of individual excitatory neurons followed by single cell m-RNA RT-PCR analysis. Such a study will not only help determine if changes are occurring at the genetic level, but also whether such potential changes in NSF, SV2, and tomosyn are confined to a cell type or are dispersed (either regionally or by neuronal type). An additional approach to mechanism is the use of mutants that over- or underexpress various elements of the neurosecretory machinery. Our laboratory is currently evaluating amygdala-kindled viable heterozygotes that show a significant reduction in the levels of one or another of several proteins including synaptobrevin/VAMP-2, SNAP-25, and synaptotagmin I. Finally, our observation of altered protein levels may reflect our choice of antibody and whether posttranslational modification has merely altered detection ability. If there appears to be no evidence for pretranslational alterations, then further use of more refined, state-specific monoclonal antibodies may be used to explore this question. Again, determination of regional localization and cell type will make this quest more manageable.

The third issue for devising therapies directed toward the NT secretory machinery is the need to craft small molecule inhibitors or effectors which can affect the process. In this way, levetiracetam proves to be an interesting example because it has no adverse effect on normal neurons but dampens the process of epileptogenesis. Other newer anticonvulsants such as topirimate that have shown antiepileptogenicity in the kindling model are also potential probes. Methods for developing and using such probes, both to better understand basic mechanisms and for use as potential therapeutic agents, are discussed in more detail in another article of this Encyclopedia.

Role of Noradrenergic System in Seizure Regulation

R A Browning, Southern Illinois University School of Medicine, Carbondale, IL, USA

Introduction

There is a vast literature, extending over five decades, supporting an anticonvulsant role for norepinephrine (NE) in essentially all animal models of epilepsy. Despite the preponderance of evidence regarding a powerful NE anticonvulsant effect, there has been little effort to augment noradrenergic signaling as antiepileptic or seizure suppressing therapy. The reluctance to pursue adrenergic agents in this context is based partly on the perception (mistaken) that antidepressants that increase NE extracellular concentration have proconvulsant effects. In addition, the experimental data have been quite complex, with seemingly contradictory reports about pro- and anticonvulsant effects of various noradrenergic agents. Clarification of the specific receptor subtypes mediating antiepileptic (and potentially, antiepileptogenic) effects, and their localizations in different brain regions, would help to guide potential NE-based therapeutic strategies.

Our laboratories have a long standing goal to gain more complete understanding of the processes whereby central noradrenergic and serotonergic systems regulate seizure predisposition, including seizure susceptibility and severity. To achieve this objective, we have carried out numerous studies in rodent models of epilepsy. Most of these studies have been carried out using the Genetically Epilepsy-Prone Rat (GEPR), a unique seizure-prone rat that is innately deficient in CNS norepinephrine (NE) and serotonin (5-HT). *Why focus on these slower acting modulatory neurotransmitters* that signal through G-protein-coupled receptors (GCPRs) when we know that the faster acting amino acid neurotransmitters (GABA, glutamate) have profound regulatory effects on seizures (to the extent that they can start or stop a seizure even in a normal brain)? The answer to this question lies in the fact that the consequences of manipulating the synaptic effects of GABA or glutamate can be so dramatic, in terms of altering behavior, that the side effects/toxicity of drugs that alter these chemicals have – in some cases – turned out to be unacceptable. Nevertheless, we do have antiepileptic drugs on the market that enhance the inhibitory action of GABA (reducing the influences of glutamate has been more difficult to achieve without unacceptable side effects).

The monoamine neurotransmitters, however, have been shown to exert anticonvulsant effects in almost every animal model of seizures so far examined. Moreover, there is some evidence that NE may be more than seizure suppressant; it may also be antiepileptogenic. Despite a vast literature supporting NE's suppressive effect on convulsive seizures in many different models, there are many unanswered questions. For example, if the noradrenergic system in the brain is so effective at suppressing seizure activity, why do we not have more treatments of epilepsy that act primarily by augmenting this system? What is the cellular/molecular mechanism responsible for the seizure suppressant effects of NE? Does the pathophysiogical basis of some forms of epilepsy involve dysregulation of the noradrenergic system? While we cannot provide answers to all of these questions, we hope to provide the reader with some insight into what is known about them, and suggest some ways in which future research may reveal more answers.

Background and Recent Results

In this section, we examine the evidence for an anticonvulsant role of NE in experimental models of epilepsy where the seizures are restricted largely to a particular neuronal network. We have previously shown that convulsive behavior in rodents can be described as being driven by either the *forebrain circuitry* (limbic/cortical) or by a *brainstem seizure network*. The seizure behavior in a rodent experiencing a forebrain seizure is distinct from that of a rodent experiencing a brainstem driven seizure. The former is typically characterized and quantified by a scoring system described by Racine, while the latter is characterized and quantified by the scoring system described by Jobe and coworkers. While the behavioral components of forebrain and brainstem seizures have been best characterized in rodents, they can be seen in essentially all species, including humans. As we have indicated earlier, the noradrenergic system is a slower signaling system than the amino acids systems, but it has a widespread influence on brain function through two major projections that have been well mapped in brain: (1) the locus ceruleus (LC) system and (2) the lateral tegmental system. Both systems provide innervation to limbic forebrain as well as the brainstem, and the cell bodies of both systems are localized to the brainstem reticular formation. While both of these neuronal systems

seem to have effects on all types of seizures, the noradrenergic neurons of the LC have been more widely studied.

Forebrain Seizures

Seizures driven by forebrain circuitry that involves a limbic network serve as models of temporal lobe epilepsy in humans. Since rodents have been more extensively studied than any other species experimentally, we focus our remarks on studies involving rats or mice. Limbic structures such as the amygdala, hippocampus, and piriform cortex have a rich noradrenergic innervation.

Effect of a Noradrenergic Deficit

A reduction in the synaptic concentration of NE by lesions or pharmacological depletion has consistently resulted in a reduction in threshold for limbic seizures (e.g., decreased minimal electroshock threshold using corneal electrodes), or an increase in seizure severity (e.g., in response to low dose pentylenetetrazol (PTZ), pilocarpine, kainate). Moreover, lesions of ascending noradrenergic pathways with 6-hydroxydopamine (6-OHDA) facilitate the rate of electrically induced amygdala-kindling. Infusions of GABA antagonists or glutamate agonists into the deep prepiriform cortex ('area tempestas') of rats evoke limbic motor seizures lasting several minutes; the depletion of NE with DSP-4 (which damages LC neurons) converts these relatively short lived limbic seizures into status epilepticus.

Genetic studies in mice with mutations or deletions of key NE synthetic enzymes have also been shown to increase the susceptibility of such animals to PTZ or flurothyl-induced seizures. And genetic strains of rats deficient in brain NE, such as the GEPR, have a reduced threshold for minimal electroshock, chemically induced limbic motor seizures (e.g., flurothyl), and electrical kindling of amygdala or angular bundle. We discuss the GEPR in more detail in the following sections, in connection with the role of NE in brainstem seizures (see the later sections); it is worth noting, however, that it represents a unique model with enhanced predisposition for both forebrain and brainstem seizures. Our studies show that seizure predisposition in both forebrain and brainstem seizure networks is, in part, determined by the noradrenergic deficiency.

Effect of Noradrenergic Augmentation

The observations of the proconvulsant properties of deficiencies in noradrenergic transmission described earlier are reinforced by studies demonstrating anticonvulsant effects following treatments that increase signaling through noradrenergic receptors. For example, electrical stimulation of the LC retards amygdala kindling and reduces the severity of pentylenetetrazol (PTZ)-induced seizures, as well as seizures induced by injection of penicillin into the hippocampus. Grafting of fetal LC cells into the hippocampus of rats that have a reduced seizure threshold, following sustained damage to the LC, helps restore the seizure threshold to normal. Pharmacological treatments that elevate the synaptic concentration of NE or activate adrenoceptors produce anticonvulsant effects (see the later sections). A genetic mutation designed to increase the synaptic concentration of NE in mice, such as that seen in norepinephrine-transporter (NET) knock-out mice (NET-KO), has also been shown to provide protection against cocaine-, kainate-, and PTZ-induced seizures.

Interestingly, unconventional treatments known to suppress seizures in human patients and to protect various animal models from epileptic stimuli have recently been shown to require NE for their anticonvulsant effect. For example, we have found that vagus nerve stimulation fails to protect rats against PTZ and maximal electroshock seizures following lesions of the LC. Others have found that the ketogenic diet is no longer effective against flurothyl-induced seizures in mice that are lacking NE due to a genetic deletion of the dopamine-β-hydroxylase gene.

Receptor Subtypes Involved

Interpretation of the studies that have examined the role of various subtypes of adrenoceptors in the seizure suppressing effects of NE is not always easy. Variations in receptor subtype, distribution, and function – and the lack of complete specificity of the agonists and antagonists – make it difficult to interpret a literature that often has seemingly conflicting findings. Most of the conflict appears to arise from the lack of pharmacological specificity and the presence of autoreceptors on noradrenergic neurons. The most consistent finding regarding forebrain seizures is that the antiepileptic effects of NE on limbic seizures appear to be mediated through alpha-2 receptors. Certainly, the *development* of seizures kindled from the amygdala are inhibited by alpha-2 agonists and facilitated by alpha-2 antagonists. Further support for an anticonvulsant effect mediated by the alpha-2 receptor was obtained by making a point mutation in the alpha-2A receptor; such mice develop amygdala kindled seizures much faster than wildtype mice.

While both pro- and anticonvulsant effects of clonidine have been reported using chemoconvulsant-induced seizures in rodents, some of the conflicting findings appear to arise from the fact that alpha-2A receptors are found presynaptically (autoreceptors) and postsynaptically. Studies using receptor knockout and synthetic enzyme knockout mice have suggested that the *presynaptic* alpha-2A receptor is responsible for the proconvulsant effects of clonidine, while the *postsynaptic* receptors are

responsible for the anticonvulsant effects. Although there is some pharmacological evidence in favor of an anticonvulsant role for alpha-1 and beta adrenoceptors, more work will be needed before definitive conclusions are drawn.

Human Studies

Most seizures in humans with epilepsy are of forebrain origin (e.g., temporal lobe epilepsy). Can we suppress such seizures by enhancing noradrenergic signaling? The answer appears to be yes, but some of the evidence is indirect and must be deduced from effects of anticonvulsants or antidepressants on NE signaling. One of the more direct pieces of evidence comes from a study showing a deficit in alpha-1 adrenoceptor density in the temporal lobe taken from patients who were undergoing a temporal lobectomy. This finding is consistent with a recent study showing that alpha-1 adrenoceptor antagonists have proconvulsant effects in patients with medial temporal lobe epilepsy. Some antiepileptic drugs, such as valproate, are known to increase the activity of tyrosine hydroxylase and increase extracellular levels of NE in animals. However, the extent to which the effects of valproate and carbamazepine on NE signaling contribute to their other substantial anticonvulsant effects (e.g., blocking sodium channels) is not known. Nevertheless, a substantial number of animal studies have demonstrated that drugs which enhance NE signaling augment the antiseizure effects of standard anticonvulsant drugs used clinically. Thus, it is likely that enhancing noradrenergic signaling in treatment-resistant patients receiving other antiepileptic agents will be beneficial. Indeed, current data support the hypothesis that this mechanism is the basis for the beneficial effects of vagus nerve stimulation in patients with intractable epilepsy.

Additional evidence comes from the literature on tricyclic and other antidepressants that elevate extracellular levels of NE. While the tricyclic antidepressants are proconvulsant at supratherapeutic doses, they are universally anticonvulsant in both forebrain and brainstem seizure models. Several studies in humans have shown that antidepressant doses of antidepressants suppress seizures in humans. Indeed, the proconvulsant effect of these drugs appears to occur only at supratherapeutic doses and involve biological systems other than the monoamines.

Brainstem Seizures

Brainstem seizures manifest as generalized tonic–clonic seizures (GTCS) in humans and other mammalian species. All elements of GTCS in humans with epilepsy – including initiation, continuation and termination – are closely approximated by GTCS in GEPR-10s (rat model) and in the epileptic *Papio papio* (baboon model). In the GEPR-10 model, the brainstem seizure is reflected in tonic hindlimb and forelimb extension, but running-bouncing clonus alone or in combination with fore- and hindlimb extension is reflected in less severe brainstem seizures observed in GEPR-3s or GEPR-9s (see the later sections) as well as in other rodent brainstem seizure models.

Effect of Noradrenergic Deficits

Treatments that interfere with NE signaling clearly facilitate brainstem seizures. Indeed, loss of NE can convert forebrain seizures into brainstem seizures. The best animal models for studying brainstem seizures are the maximal electroshock seizure evoked by ear-clip electrodes and sound-induced seizures in genetically susceptible animals (e.g., in GEPRs). The GEPRs are innately deficient in NE and this deficiency has been shown to be a determinant of their seizure-prone state. Lesioning of the locus ceruleus with DSP4 clearly enhances the severity of maximal electroshock-induced seizures, as indicated by the increased extensor-to-flexor ratio. The loss of NE in GEPRs leads to an enhancement in seizure severity whether produced by reserpine, a nonselective drug, or by lesions that are more selective for the locus ceruleus (e.g., infusions of 6-OHDA or DSP-4). When exposed to a 100 db sound, the GEPR-3 displays a less severe form of brainstem seizure (i.e., no tonic extension), while the GEPR-9 displays a maximal tonic–clonic seizure. Impairment in NE signaling in the brain of a GEPR-3 can convert its seizure to that of a GEPR-9. Lesions of the LC also increased seizure severity in other strains of rat that are genetically susceptible to sound-induced brainstem seizures. A large number of pharmacological agents have been used (alone or in combination) to more specifically examine noradrenergic signaling in the GEPR; these studies have demonstrated that the loss of NE leads to a facilitation of the tonic (brainstem) seizure.

Effect of Noradrenergic Augmentation

Treatments that increase NE signaling have been shown to protect rats from the brainstem seizure phenotype. However, most pharmacological treatments designed to selectively increase NE neurotransmission (e.g., reuptake inhibitors of NE, amphetamine to increase release) are not entirely selective for NE, making conclusions more tentative. The administration of NE and several noradrenergic agonists directly into the brain of GEPRs has further demonstrated the seizure inhibitory role of NE. Studies designed to identify the noradrenergic terminal field(s) responsible for the anticonvulsant effects of NE on brainstem seizures in GEPR-3s showed that the critical regions are contained in the midbrain exclusive of the

inferior colliculus. Even stronger evidence for the seizure suppressing effects of NE on brainstem seizures was obtained by showing that desipramine (a selective NE uptake blocker) and yohimbine (an alpha-2 adrenergic antagonist) are anticonvulsant in GEPR-9s. Moreover, the time-course for their anticonvulsant effects was highly correlated with the increase in extracellular brain NE (measured by microdialysis) produced by these drugs. The depletion of norepinephrine stores negates the anticonvulsive effects of desipramine.

More recently, Jobe and colleagues have shown that microinfusion of selective NE reuptake blockers into the superior colliculus (a midbrain site) of GEPRs suppresses (does-dependently) brainstem-driven tonic–clonic seizures. Moreover, the alpha-1 agonists phenylephrine and methoxamine infused into the superior colliculus produced similar effects, and these effects were blocked by the alpha-1 antagonist prazosin. Such findings are in agreement with NE pathway lesion studies and support the concept that the superior colliculus is the midbrain site where NE exerts its seizure suppressing effect on tonic seizures. These studies also show that this effect is mediated, at least in part, by the alpha-1 adrenoceptor. The importance of the superior colliculus as the site of action of NE on brainstem seizures has also been reported by another group.

Receptor Subtypes Involved

Studies designed to identify which adrenergic receptor subtype is responsible for the brainstem seizure inhibitory effects of NE have suggested that more than one subtype is involved. Intracerebroventricular injections of alpha (phenylephrine), beta-1 (dobutamine), and beta-2 (terbutaline) agonists can suppress sound-induced seizures in GEPRs, while an alpha-2 agonist cannot. More recent studies in GEPR-9s show that the seizure suppressing effects of alpha-1 receptors is produced in the superior colliculus (as indicated earlier). Whether the other adrenoceptors produce their effects in this same brain region has not yet been examined.

Human Studies

Generalized tonic–clonic seizures (grand mal) are essentially brainstem-driven convulsive seizures in humans. Antidepressants that inhibit NE reuptake are anticonvulsant against tonic–clonic seizures in humans. This effect is expected, given the data showing that NE is so dramatically effective against tonic extension in both the maximal electroshock and in tonic–clonic seizures in GEPRs. Since many of these tonic–clonic seizures are secondarily generalized, it is expected that the effects of NE on forebrain seizures (e.g., temporal lobe seizures), as described earlier, would also suppress the transition from limbic/cortical to brainstem seizures and be beneficial in suppressing tonic–clonic seizures. In fact, there is evidence that monoamine enhancing antidepressants can suppress seizures in patients with secondarily generalized convulsive seizures.

Methods

Whole Animal Integrative Studies

We have employed an integrative system approach, which we feel is best suited for translational research. In our laboratory we use genetically epilepsy-prone rats (GEPRs) because they provide an ideal animal model for studying epilepsy and its comorbidities. Our rationale is based on multiple factors:

1. GEPRs have an innate predisposition for forebrain and brainstem seizures, and therefore are able to model the major convulsive epileptic disorders seen in human patients.
2. Details of brain function can be determined through the use of excellent stereotaxic atlases of the rat brain. When used with the GEPRs, these atlases provide opportunities for targeting discrete brain regions for functional and anatomical analyses.
3. The extensive and detailed neuroanatomy of the noradrenergic and serotonergic systems are well known in the rat brain and are readily adaptable to GEPR studies.
4. We have developed methods whereby the behavioral (convulsive) and electrographic characteristics of the seizures and comorbid disorders can be studied with the GEPR.
5. As a tool for the identification of antiepileptic drugs, GEPR paradigms clearly separated clinically useful antiepileptic drugs based on their effectiveness in absence versus GTCS indicating that it is a model with predictive value.
6. The GEPR model has proved useful in correcting longstanding mistaken conclusions regarding the convulsant liabilities of antidepressant drugs, drugs that are otherwise essential to the treatment of affective disorders and other psychiatric illnesses.

Localization of Noradrenergic Anticonvulsant Effect

We have used the systemic administration of DSP-4 to lesion selectively the locus ceruleus noradrenergic system; we have shown that activation of these neurons suppress both forebrain and brainstem seizures in Sprague–Dawley rats subjected to corneal electroshock (forebrain seizures) or maximal electroshock (ear-clip electrodes).

Discrete microinjections of the catecholamine neurotoxin 6-OHDA into specific ascending or descending noradrenergic pathways have been used to assess the influence of the forebrain, brainstem, cerebellum, and spinal cord norepinephrine on brainstem seizures in GEPR-3s. In a typical experiment, animals are anesthetized with chloral hydrate 400 mg kg^{-1}, placed in a stereotaxic apparatus; after exposing the skull and drilling a small hole, animals are infused with 4 μg per 2 μl of 6-OHDA. Two weeks later they are subjected to sound-induced seizures and their behavior is assessed for evidence of changes in severity. EEG electrodes can also be implanted, at the time neurotoxin lesions are made, for electrographic assessment of seizure severity. Similar studies, using the serotonin neurotoxin 5,7-dihydrotryptamine, have been performed by our laboratories to determine the site of action of 5-HT in GEPRs. The superior colliculus has also been identified as an important site for mediating the anticonvulsant effect of 5-HT on brainstem-driven (tonic–clonic) seizures.

Microinjection Studies

Stereotaxic implantation of guide cannulae (Plastics One Inc.), followed one week later by infusion of adrenergic drugs (agonist or antagonist), provide another approach to localize the site of anticonvulsant action of NE. In microinjection studies it is important to test nearby (1–2 mm away) drug infusions to determine that an effect is specific for a particular structure. Recent studies in our lab have revealed that infusion of NE into brainstem nucleus pontis oralis (RPO), a nucleus that is important in the brainstem seizure network, does reduce the duration of tonic hindlimb extension in the maximal electroshock test, but does not abolish this response. Microinjection of NE alone, as well as injections of alpha and beta agonists into this region of the brainstem reticular formation, failed to alter the tonic seizure in GEPRs. Such findings are consistent with the superior colliculus as a site of action of NE in brainstem seizures (see earlier). Infusions of NE or other adrenoceptor agonists selective for alpha or beta receptors into the inferior colliculus also failed to attenuate tonic seizures in GEPRs. Such findings are consistent also with the studies mentioned earlier showing that the superior colliculus is the site at which the noradrenergic system exerts seizure attenuating effects on brainstem seizures.

Microdialysis Studies

We have extensively employed microdialysis to measure extracellular levels of norepinephrine and serotonin in GEPRs receiving anticonvulsant drug treatment, and also as a way of administering drugs site specifically within the brain (e.g., to superior colliculus). Animals are implanted with guide cannulae stereotaxically, and allowed to recover. Prior to sample collection, the microdialysis probe is inserted into the guide and baseline levels of extracellular NE are measured for several hours. Animals are then subjected to drug treatment and seizure initiation by a 100 db sound stimulus.

Fos Immunohistochemistry

We have employed fos immunohistochemistry to map seizure circuitry in rats subjected to various types of seizures (both forebrain and brainstem). Rats were subjected to seizure testing and two hours later were perfused with PBS and paraformaldehyde, followed by sectioning of brain and exposure to antibodies directed at fos. Fos is a marker for increased neuronal activation, and cells that are activated by the seizure display enhanced fos staining. Of interest to the noradrenergic hypothesis of seizure suppression is that irrespective of the model examined (PTZ, electroshock, audiogenic) or the rat strain (Sprague–Dawley or GEPR), the locus ceruleus was activated in all seizure models. Other laboratories have also reported LC activation using fos following other types of seizures, including secondarily generalized limbic motor seizures initiated from the deep prepiriform cortex.

Vagus Nerve

Vagus nerve stimulation (VNS) has been used since the late 1990s to treat intractable seizures in patients with epilepsy. As indicated earlier, we have previously found that the anticonvulsant effects of VNS are essentially abolished following 6-OHDA lesions or lidocaine inactivation of the locus ceruleus. More recently, we have shown, using microdialysis, that VNS (0.5 and 1.0 mA) increases extracellular NE in the hippocampus, and that 1.0 mA stimulation increases NE in the cerebral cortex of awake freely moving rats. Two other laboratories have made similar findings. Thus, it seems possible that VNS provides a means of producing locus ceruleus activation without producing peripheral side effects seen with the numerous drugs that are available to enhance noradrenergic signaling. There is also electrophysiological evidence that VNS increases the firing rate of LC as well as raphe neurons, suggesting that the VNS increases the extracellular concentration of both NE and 5-HT. Such findings appear to explain the effectiveness of VNS in the treatment of intractable depression. There is now substantial evidence that depression and epilepsy are comorbid diseases, with perhaps a common pathophysiology (i.e., deficits in NE and/or 5-HT).

Future Directions

Despite the fact that the seizure suppressing effects of NE have been repeatedly demonstrated in animal models of epilepsy, the cellular/molecular mechanism by which NE produces this effect remains unknown. However, new evidence has shown that NE can reduce electrical coupling between GABAergic interneurons in the hippocampal slice, via a beta adrenergic receptor coupled to PKA phosphorylation. This mechanism provides a means for preventing the hypersynchronous activity that is essential for seizures. Whether this intriguing mechanism is responsible for the seizure suppressing effects of NE remains to be determined. However, it would seem unlikely that this is the only mechanism, since NE has been shown to also act through alpha adrenoceptors to suppress seizures. Perhaps there are different mechanisms in different parts of the brain.

Genetic studies should be carried out to identify the gene(s) responsible for the NE deficit in GEPRs, and studies should be carried out in humans afflicted with both depression and epilepsy to determine if there are abnormalities in genes involved in development or functional maintenance of the noradrenergic neurons.

More effort should be directed at clinically augmenting central noradrenergic signaling, without a concomitant increase in peripheral sympathetic autonomic signaling, such as seems possible via vagus nerve stimulation. Other approaches besides VNS should be examined – for example, via transcranial magnetic stimulation or deep brain stimulation. There is one report of locus ceruleus stimulation producing antiepileptic effects in humans. Could adrenoceptor agonists be infused into the lateral ventricles to maximize central and reduce peripheral effects? Would the benefits of deep brain stimulation of noradrenergic pathways outweigh the risks in patients with intractable epilepsy?

Another area that should be carefully assessed in future studies is the role of NE in epileptogenesis. Do the noradrenergic neurons of the locus ceruleus have the ability to retard the development of epilepsy? In this regard, could activation of the locus coeruleus system prevent the development of seizures associated with traumatic brain injury? Clearly, this is an area of great importance that should receive attention in future studies.

Synaptic Activities and Transmitter Function: Receptor Trafficking

D E Naylor, UCLA School of Medicine, Los Angeles, CA,USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Receptor trafficking is a well-established process affecting synaptic plasticity as part of normal function and development in the central nervous system. It plays an important role in such normal processes as experience, activity-dependent plasticity, and LTP, and can occur rapidly – on the order of minutes or hours. As a part of the dynamic regulation of synaptic strength, receptor trafficking also may mediate a homeostatic process of 'synaptic scaling', important in maintaining balanced inputs to neurons in a circuit.

Although the importance of NMDA and AMPA receptor trafficking is well-established in the nervous system, much less is known regarding trafficking at inhibitory synapses. Even less is known regarding the role of trafficking associated with neurological disorders such as epilepsy and status epilepticus (SE).

When seizure activity continues for prolonged periods, we refer to that condition as 'status epilepticus.' By 30 min of such activity, rapid changes at both inhibitory and excitatory synapses occur, and seizures become self-sustaining and pharmacoresistant. Postsynaptic receptor trafficking during SE contributes to this pathophysiology and provides a mechanism for the initiation, as well as the maintenance, of SE.

Study of receptor trafficking, at both inhibitory and excitatory synapses, can provide insights into the mechanisms underlying alterations of synaptic strengths, and the subsequent imbalance between excitation and inhibition. In the hippocampus, that imbalance is thought to lead to circuit pathology that gives rise to seizures and SE. Thus, it is important to determine if aberrant plasticity at synapses contributes to the disease process – and if so, what mechanisms regulate this process?

As mentioned earlier, most studies of receptor trafficking have assessed the upregulation of AMPA receptors at synapses (within the context of LTP). Since seizure activity rapidly propagates through circuits to affect both excitatory and inhibitory pathways, SE provides a useful model to study simultaneous changes at inhibitory and excitatory synapses, and a context for exploring how opposed inhibitory and excitatory pathways interact and regulate each other. For example, activation of NMDA receptors can lead to internalization of $GABA_A$ receptors through LTD, and blockade of NMDA receptors preserves the efficacy of benzodiazepines during SE.

Regulation between inhibitory and excitatory pathways that is important for normal hippocampal function may go awry with pathological states such as SE. During SE, there is a dramatic loss of inhibition, offering investigators an opportunity to evaluate various mechanisms involved in downregulation of inhibition at GABAergic synapses – including the possibility of $GABA_A$ receptor trafficking. $GABA_A$ receptor internalization has been shown to be a consequence of agonist/ligand exposure in several studies; similarly, excessive GABA release – with receptor exposure and desensitization – may precede $GABA_A$ receptor internalization during SE and contribute to a loss of inhibition.

Another important consequence of synaptic plasticity during SE involves the development of a chronic epileptic state. Approximately 60% of animals develop chronic recurrent seizures after SE. The acute changes observed at synapses during SE may help to reveal the mechanisms that contribute to the development of this chronic epileptogenicity, and thus to epilepsy in general. In particular, trafficking of NMDA receptors towards the cell surface during SE may initiate epileptogenic plasticity and/or excitotoxicity, with alterations of circuit architecture and selective cell loss.

Background

A proper balance between excitation and inhibition is necessary for normal functioning in the brain, and pathophysiological states, such as SE, likely result from a disruption of that balance. As the primary inhibitory and excitatory transmitters in the brain are GABA and glutamate, respectively, many animal models of SE use pharmacological agents that act on GABA or glutamate systems in order to upset that balance. For example, SE is elicited by either blockade of ionotropic $GABA_A$ receptors (e.g., bicucculline, picrotoxin, penicillin, pentylenetetrazol) or activation of ionotropic glutamatergic receptors (e.g., kainic acid, domoic acid).

Failure of inhibition occurs early during SE. Even brief periods (1–5 min) of convulsion-mimicking electrical stimulation of perforant path inputs to the hippocampus cause loss of paired-pulse inhibition; this loss may last 45 min or more, in both in vivo and in vitro models. As a result of this loss of inhibition, there is a further lowering of seizure threshold, thus establishing a self-perpetuating

feedback cycle during which seizures become self-sustaining and SE is established. That is, removal of the initial trigger for seizure activity will not arrest SE, and seizures will continue unabated. In parallel with the transition to self-sustaining SE, there is a loss of responsiveness to GABAergic drugs. While benzodiazepine treatment within 10 min of SE onset can arrest seizure activity, treatment after 45 min has little or no effect in animal models – or in studies of patients.

Alterations in the composition and characteristics of postsynaptic $GABA_A$ receptors contribute to this failure of synaptic inhibition during SE. $GABA_A$ receptors are pentomeric structures, generally consisting of two α subunits, two β subunits, and either a γ or δ subunit. At synapses, $GABA_A$ receptors predominantly contain $\gamma 2$ subunits; δ-subunit containing receptors are found at extrasynaptic/perisynaptic sites. Receptors containing $\gamma 2$ subunits have attributes that include pronounced desensitization, sensitivity to benzodiazepines, and the ability to directly interact with the AP-2 proteins involved with clathrin-dependent endocytosis. In contrast, receptors containing δ subunits show little desensitization, are benzodiazepine insensitive, and do not have consensus sequences for interaction with AP-2 proteins/clathrin. As a result of the properties of synaptic $GABA_A$ receptors, GABA exposure can cause $GABA_A$ receptor desensitization and internalization. Our results suggest that trafficking of extrasynaptic δ-subunit containing receptors does not occur during SE. However, ovarian cycle-dependent decreases in cell surface expression of these extrasynaptic $GABA_A$ receptors are associated with an increase in seizure susceptibility, and may be relevant to catamennhial epilepsy.

Postsynaptic glutamatergic receptors consist of NMDA and non-NMDA (AMPA, KA) types. The NMDA receptors have slower kinetics and greater Ca^{2+} permeability than the non-NMDA receptors. Both types coexist at the same synapses. Trafficking of non-NMDA receptors, AMPA receptors in particular, has been well characterized in the context of LTP, where activation of NMDA receptors leads to a rapid delivery of AMPA receptors to synaptic sites.

Unlike synaptic inhibition, where rapid degradation of the synaptic $GABA_A$ receptors renders SE resistant to GABA-enhancing agents, synaptic excitation mediated by NMDA receptors remains susceptible to pharmacological blockade; NMDA antagonists can arrest seizures hours after the onset of SE. This observation suggests that a rapid loss of GABAergic inhibition is important in the initiation of SE, while the persistence of robust glutamatergic excitation is responsible for the maintenance of SE. In addition, glutamatergic excitation/NMDA activation may have important effects on the later sequelae of SE, since NMDA blockade is able to prevent the development of spontaneous recurrent seizures. Interestingly, trafficking of NMDA receptors initially appears to involve their delivery to extrasynaptic sites (i.e., prior to their movement into synapses); as extrasynaptic receptors are implicated in excitotoxic cell death, NMDA blockade during SE may provide neuroprotection.

Methods

Electrophysiological Recordings

Wistar rats, 4-7 weeks old received lithium (3 mEq kg^{-1} intraperitoneal; night before) and methylscopolamine (1 mg kg^{-1} subcutaneous) 30 min before either pilocarpine (40 mg kg^{-1} intraperitoneal) or normal saline. After $\sim$1 h from the onset of stage 5 seizures, rats are anesthetized with halothane, decapitated, and the brains placed in ice-cold artificial cerebrospinal fluid (ACSF). Brain slices are cut (350 μm coronal sections) and perfused at 1.5 ml min^{-1} with 33–35 °C ACSF. Whole cell patch clamp recordings from somata of visualized neurons are made using borosilicate microelectrodes. Inhibitiory postsynaptic currents (IPSCs) are isolated using selective pharmacological blockade of both NMDA and non-NMDA excitatory currents with kynurenic acid (2 mM). Alternatively, picrotoxin (30 μM) is used to block $GABA_A$ inhibitory currents, either with DNQX (10 μM) with 0 Mg^{2+} in the ACSF or with APV (50 μM) to isolate NMDA and non-NMDA EPSCs, respectively.

Immunocytochemistry

Serial formaldehyde-fixed 40 μm coronal sections are incubated overnight in mouse antibody to either the $GABA_A$ receptor $\gamma 2$ or the NMDA receptor NR1 subunits and rabbit antisynaptophysin antiserum. The sections are then incubated for 1 h in FITC-labeled goat antirabbit IgG and Cy^3-labeled donkey antimouse IgG diluted in PBS containing 1% goat serum, horse serum, and 0.3% Triton X-100. Quantification of immunofluorescent receptors is acquired at 100× with a confocal microscope. Colocalization is determined by examination of the overlaid synaptophysin and receptor-stained images.

Computer Analysis

The synapse is an elaborate structure with presynaptic and postsynaptic components that add complexity that is difficult to resolve and interpret without computer and mathematical analysis. Such analysis can help identify receptor desensitization/trafficking at synapses. Mean and variance traces generated from superimposed postsynaptic currents recorded from a dentate gyrus granule cell are analyzed using computer optimization programs

that estimate the number of postsynaptic NMDA receptors (N), the single channel conductance (i), and the channel open probability (P_{open}). For channels with open probability P_{open}, the binomial distribution for the population of channels at a synapse generating postsynaptic currents has a mean current (I)

$$I = NP_{open}i \quad [1]$$

and variance (σ^2)

$$\sigma^2 = NP_{open}(1 - P_{open})i^2 \quad [2]$$

P_{open} will depend on several factors, including the concentration of GABA or glutamate in the synaptic cleft and the kinetics of the individual postsynaptic receptors. Substituting eqn. [1] in eqn. [2] determines the parabolic equation,

$$\sigma^2 = iI - I^2/N \quad [3]$$

and eliminates P_{open} as a variable, allowing N and i determination from optimized fits of variance versus mean plots.

The basic assumptions of a more elaborate synaptic model are: (1) individual $GABA_A$ (or NMDA) receptors open and close randomly, with an open probability determined by the synaptic cleft [GABA] (or [glutamate]); (2) an m-state receptor kinetic model (including closed, ligand-binding, open, and desensitized states) can characterize the relation between [GABA] (or [glutamate]) and the receptor channel open probabilities; (3) vesicle release of transmitter into the cleft can be modeled as a pulse with exponential decay; and (4) postsynaptic currents represent the linear sum of the individual postsynaptic receptor current responses.

A computer model of postsynaptic currents is generated by matrix multiplication of $\mathbf{A}$ (where $\mathbf{A}$ is $m \times m$ for the m number of receptor states; the particular value of the matrix indexed by j and k, $\mathbf{A}_{jk}$, is the probability that a receptor in state k will transition to state j during a specified time increment of iteration $\sim$ 0.01 ms) by $\mathbf{x}_n$ (m $\times$ 1; containing the probability of each state at the current time), thereby generating the time-updated probability vector, $\mathbf{x}_{n+1}$, to be substituted for $\mathbf{x}_n$ in subsequent iterations ($\mathbf{A} \times \mathbf{x}_n = \mathbf{x}_{n+1}$) across time. P_{open} is the sum of the probabilities from the open states of $\mathbf{x}_n$, and P_{desens} the sum of the probabilities for desensitized states of $\mathbf{x}_n$.

Results

After 1 h of SE, there is a 27% reduction in the mean mIPSC absolute amplitude (from 53 pA for control animals to 39 pA for SE animals). Similar results have been obtained for in vitro models of SE using 0 Mg^{2+}. We suspected that the reduction in amplitude is related to a decrease in the number of functional postsynaptic $GABA_A$ receptors. To analyze the results, mean-variance analysis (see the Methods section) of mIPSCs was performed with the basic assumptions that individual $GABA_A$ receptors open and close randomly, with an open probability depending on cleft [GABA]; mIPSCs represent the sum of the individual $GABA_A$ postsynaptic receptor current responses. The results of this analysis (in conjunction with receptor kinetic modeling) suggest that the number of postsynaptic $GABA_A$ receptors decreases 50%, from 36 $\pm$ 11 per synapse in controls to 18 $\pm$ 4 per synapse in slices obtained after 1 h of SE.

To confirm that the reduction in the number of functional $GABA_A$ receptors was from internal relocation of receptors towards the cell interior (away from synapses), immunocytochemical labeling of $GABA_A$ receptors was performed. In granule and pyramidal cells from control (left column) hippocampi, immunoreactivity against the $\beta2/\beta3$ (top row) or $\gamma2$ (bottom row) subunits of $GABA_A$ receptors outlines the cell membrane (red fluorescence), and frequently colocalizes with the presynaptic marker for synaptophysin (green); overlay of subunit and synaptophysin markers appears as yellow dots. After 1 h of SE in vivo, much of this $\beta2/\beta3$ and $\gamma2$ subunit immunoreactivity is in the interior of the cell (right column), surrounded by synaptophysin immunoreactivity outlining the cell membrane. The colocalization of $GABA_A$ receptor $\beta2/\beta3$ subunits with synaptophysin decreases from 43% (controls) to 13% (with SE in vivo). Similar results have been found in vitro, using 0 Mg^{2+} to produce an SE-like discharge pattern in hippocampal cultures. Recently, a $\gamma2$ subunit mutation that shifts trafficking of $GABA_A$ receptors away from the cell surface in a temperature-dependent manner has been associated with febrile seizures, suggesting a causal relation between the surface location of $\gamma2$ subunit-containing receptors and seizure susceptibility. Using inhibitors of dynein in recording electrodes, these in vitro studies showed that the internalization of $GABA_A$ receptors was clathrin-dependent.

Our results also indicate an increase in extracellular GABA during SE, likely from presynaptic release during seizure activity. To determine if an increase in extracellular GABA could mimic the effects of SE, hippocampal slices were perfused with aCSF containing 3 μM of GABA. A reduction of mIPSC amplitude similar to that seen with SE occurs under these conditions, suggesting that increased ligand exposure may contribute to desensitization and downregulation of $GABA_A$ receptors (**Figure 1**).

Unlike mIPSCs, the absolute amplitude of NMDA-mEPSCs increases 25% after SE (from 16 to 20 pA). Mean-variance analysis suggests that an increase from 8 to 11 NMDA receptors per synapse is responsible for the physiological changes. This shift is confirmed by immunocytochemistry, using antibodies to the NR1 subunit of NMDA receptors; these studies show a relocation

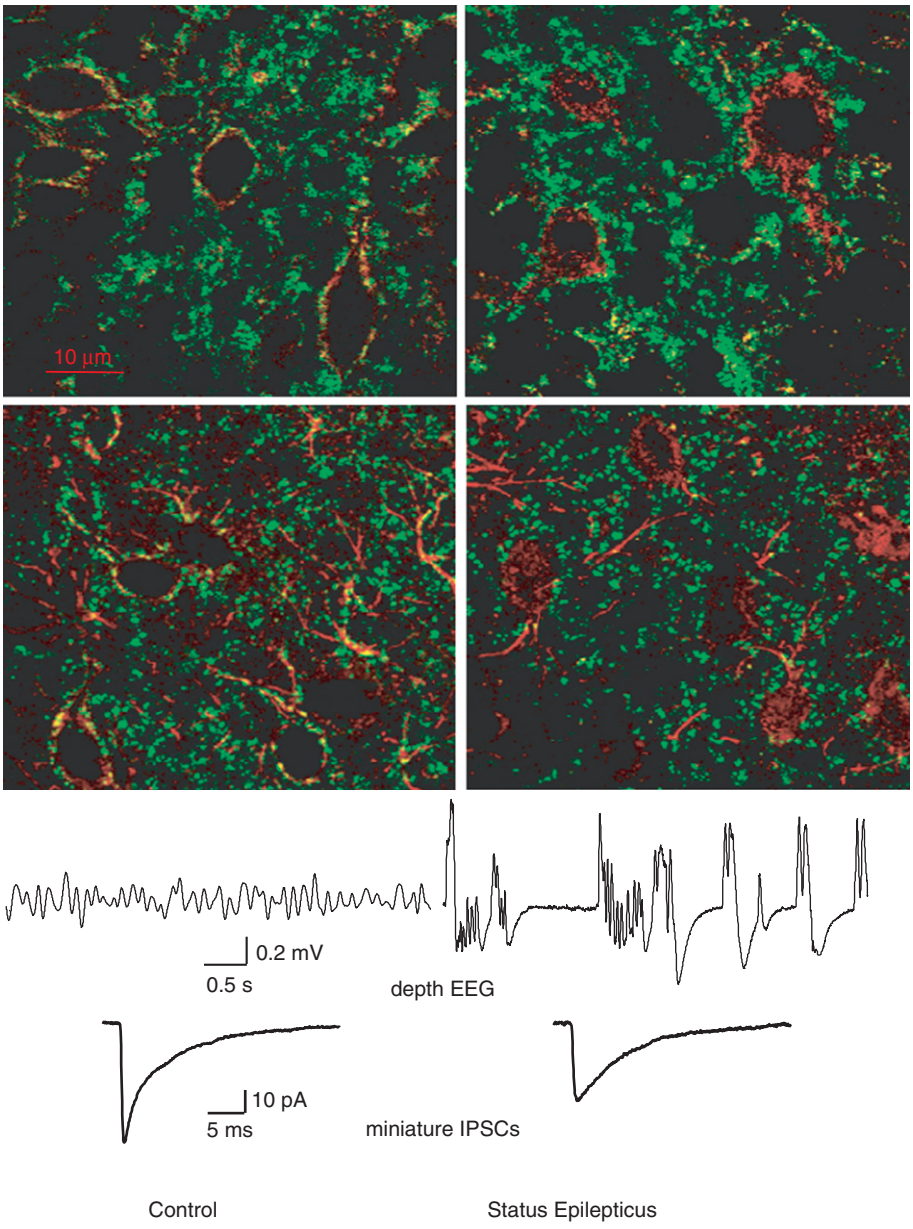

Figure 1 Subcellular redistribution of hippocampal $GABA_A$ receptor subunits reflects physiological changes in EEG and miniature inhibitory postsynaptic currents (mIPSCs) during status epilepticus (SE). $GABA_A$ β2/β3 (red, first row) and γ2 (red, second row) subunits relocate to the cell interior during SE, with decreased yellow colocalization of subunits with the presynaptic marker synaptophysin (green). Stereotaxic EEG recorded in the hippocampal dentate gyrus demonstrates polyspike and wave discharges during SE (third row), with a decrease in the amplitude of mIPSCs recorded from dentate gyrus granule cells (fourth row). The functional loss of synaptic inhibition associated with the internal aggregation of $GABA_A$ receptor subunits may help sustain SE. Adapted from Naylor DE, Liu H, and Wasterlain CG (2005) Trafficking of GABAA receptors, loss of inhibition, and a mechanism for pharmacoresistance in status epilepticus. *Journal of Neuroscience* 25(34): 7724–7733, with permission from Society of Neuroscience.

of subunits to the surface of granule and pyramidal cells in the hippocampus, with increased colocalization with synaptophysin at synapses. An increase in the amplitude of non-NMDA mEPSCs also occurs during SE, and is predicted to represent an increase (from 36 to 40) of non-NMDA glutamate receptors per synapse.

The direction of trafficking of receptors during SE appears to be specific to receptor type, with a downregulation in the number of $GABA_A$ receptors at inhibitory synapses and an increase in the number of NMDA and non-NMDA glutamate receptors at excitatory synapses. This shift should cause an imbalance between inhibition and excitation, and contribute to the initiation and maintenance of self-sustaining SE. The dramatic reduction (20-fold) in potency of benzodiazepines within minutes of the onset of SE can be explained

by the rapid loss of available $GABA_A$ receptors at postsynaptic sites. Similarly, the ability of NMDA antagonists such as ketamine or MK801 to abort SE, after more than an hour of seizure activity, can be attributed to the persistent availability and upregulation of NMDA receptors at postsynaptic sites. The rapid loss of inhibition is likely important in the initiation phase of SE (i.e., the transition from single seizures to self-sustaining SE), while NMDA receptor upregulation helps maintain SE.

Since seizure activity increases the level of extracellular GABA, and $GABA_A$ receptors at postsynaptic sites downregulate with GABA exposure, increases in firing/release should result in a loss of inhibition. This loss will then increase excitability/firing and lead to further GABA release and downregulation of synaptic inhibition mediated by $GABA_A$ receptors, establishing a pathophysiological cycle. At a critical threshold for the loss of synaptic inhibition, the resultant excitability will become self-sustaining. The increase in NMDA and non-NMDA receptors at excitatory synapses not only should accentuate excitation, but also can contribute to $GABA_A$ receptor downregulation/internalization, with chronic effects on $GABA_A$ receptor function.

Future Directions

Future research will explore the relation between NMDA activation and $GABA_A$ receptor trafficking and determine whether blockade of NMDA activity can reduce $GABA_A$ internalization. In addition, a time-course study of SE will help determine if $GABA_A$ receptor desensitization (reflected physiologically by a decrease in mIPSC amplitude) precedes internalization (as revealed by immunocytochemistry). Similarly, studies that prevent receptor internalization will show if mIPSC amplitude reduction can occur despite blockade of clathrin-dependent endocytosis; results from such an experiment also can elucidate whether receptor desensitization precedes internalization.

Many new potential therapies for SE may emerge from these studies. In particular, treatments that disrupt clathrin-dependent endocytosis, including treatment with osmotic agents, may prevent the internal relocation of postsynaptic $GABA_A$ receptors and help restore/maintain synaptic inhibition. Since extrasynaptic $GABA_A$ receptors are not down-regulated in the same way that synaptic $GABA_A$ receptors are down-regulated, potentiation of tonic (i.e., extrasynaptic) $GABA_A$ currents could provide a route towards restoration of inhibition. Therefore, pharmacological agents that enhance these currents, such as neurosteroids, may counterbalance losses of inhibition at synapses. Finally, since NMDA and non-NMDA glutamate receptors are upregulated at excitatory synapses and remain accessible as targets for pharmacological blockade, therapies that use antagonists directed at these receptors should improve the efficacy of pharmacotherapy, especially after the initiation of SE, over agents directed towards enhancing synaptic inhibition alone.

Introduction

Some of the first evidence that neuronal gene expression in brain is influenced by physiological activity came from studies of the effects of seizures. Work in the early 1980s found that in rodents, seizures increase levels of the neuropeptide enkephalin throughout the limbic telencephalon. These results were quickly followed by reports that seizures increase mRNA levels for several transcription factors that, in turn, regulate genes encoding families of proteins; the breadth of this second order response was largely unknown. Findings of these types prompted efforts in many laboratories to test whether, *in the adult brain*, increases in neuronal activity during seizures initiate the expression of genes associated with growth and plasticity. That such was the case was first demonstrated for nerve growth factor (NGF), and soon thereafter for the structurally related neurotrophin, brain derived neurotrophic factor (BDNF). Both NGF and BDNF mRNA levels are increased over 10-fold within 3 h of seizure onset in rat hippocampus, and at somewhat greater latencies in the neocortex (**Figure 1(a)** and **1(b)**). It soon became clear that these alterations in neurotrophin gene expression were occurring within a context of myriad, seizure-induced changes in the expression of neuroactive peptides, transcription factors, adhesion proteins, structural proteins, and more. The trophic factors alone exhibited a staggering array of responses, including: increases in the expression of transforming growth factor (TGF) superfamily members such as the potent survival factor for basal ganglia neurons, glial cell-derived neurotrophic factor (GDNF), the fibroblast growth factors (FGF1 and FGF2), and vascular endothelial growth factor (VEGF); and decreases in neuronal expression of others mRNAs (e.g., neurotrophin-3). Surprisingly, several trophic factors that are predominantly expressed by glial cells and are induced during deafferentation (e.g., ciliary neurotrophic factor, insulin-like growth factor-1) respond little, if at all, to seizures (or to other increases in neuronal activity).

Background – BDNF Facilitates Synaptic Plasticity in Adult Brain

Among the trophic factors induced by seizures and considered likely to contribute to lasting changes in brain, BDNF stands out as being of particular interest. BDNF expression responds rapidly and with very low threshold to increases in neuronal activity and, along with its high affinity receptor TrkB, is expressed throughout the brain and spinal cord. As a consequence, even brief or localized increases in neuronal activity (e.g., epileptiform bursts in the absence of a frank seizure) increase BDNF production and, most probably, signaling. It is also the case that BDNF produces an impressive and diverse array of neuronal responses. Along with other members of the neurotrophin family (e.g., NGF, NT3, NT4/5), BDNF influences the differentiation, process outgrowth, gene expression, and survival of responsive neurons. Importantly, it is largely anterogradely transported, released from synapses in an activity-dependent fashion, and has acute effects on neuronal function that departs from classic actions on the trophic center of the cell. Through local signaling, including that occurring in the vicinity of the synapse, BDNF regulates properties of various ion channels, calcium influx, cytoskeletal remodeling, local protein translation, neurotransmitter release, and neurotransmitter receptor function. Moreover, and not

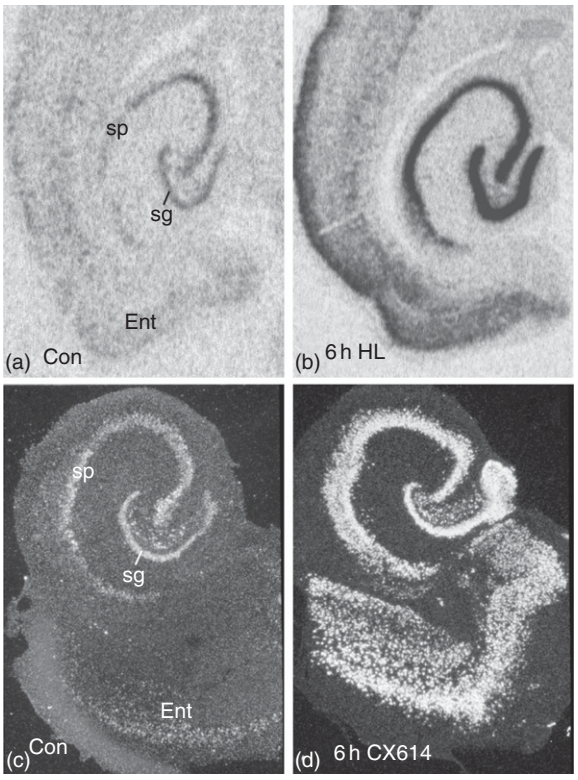

Figure 1 BDNF expression is positively regulated by neuronal activity. Photomicrographs show ^{35}S-cRNA in situ hybridization labeling of BDNF mRNA in sections through rat hippocampus (a, b) and cultured hippocampal slices (c, d). (a, b) Bright field photographs of film autoradiograms show labeling in hippocampus and adjacent entorhinal cortex (Ent) of a control rat (a) and an experimental seizure rat killed 6 h after limbic seizure onset (b): as shown, seizures increased BDNF mRNA in the granule and pyramidal layers of hippocampus (sg and sp, respectively) and in surrounding cortical fields. (c, d) Dark field photographs show labeling of BDNF mRNA in cultured hippocampal slices harvested without treatment (c) and after 6 h CX614 exposure (cRNA labeling appears white). Like seizure activity, ampakine treatment increased BDNF mRNA in granule and pyramidal layers of hippocampus and in adjacent cortical fields.

surprisingly considering this list of functions, BDNF also facilitates and enhances the magnitude of activity-dependent synaptic plasticity.

Long-term potentiation (LTP) is a principal form of synaptic plasticity in the mammalian brain, thought to underlie learning and memory and, more generally stated, enduring experience-dependent enhancement of synaptic transmission. In experimental settings LTP is typically induced by high-frequency (100–200 Hz) afferent stimulation, but studies have shown that it is more efficiently induced with patterns of afferent activity that simulate the natural, 5 to 8 Hz 'theta' rhythm of cell firing that can be recorded from hippocampus and limbic cortical regions during behavior. As neurons are known to discharge at high frequencies and in synchronous bursts during seizures, it has long been speculated that synaptic potentiation and, specifically LTP, contribute to the enhancement of circuit activity, reductions in seizure threshold with kindling in experimental models, and epileptogenesis in man.

The first evidence that BDNF may be involved in LTP came from the demonstration that infusion of this neurotrophin into rat hippocampus leads to an LTP-like enhancement of synaptic transmission. Although this response has proved to be variably obtained and is likely to be region-specific (i.e., it is reliably observed in the dentate gyrus but not hippocampal field CA1), the basic conclusion that BDNF facilitates potentiation when applied in combination with afferent stimulation has held. Studies in many laboratories have shown that infusion of exogenous BDNF both lowers the activity-dependent threshold and increases the magnitude of LTP induced by theta burst afferent stimulation, whereas reductions in BDNF availability or signaling (through genetic manipulation in mice or treatment of experimental tissue with reagents that impede BDNF delivery or receptor function) prevents LTP induction by theta stimulation.

While these findings show that BDNF is important for LTP, and therefore is likely to contribute to changes in circuit function with seizures, there are still questions as to the cellular mechanisms through which BDNF enhances synaptic transmission; it is also still unclear whether activity-regulated increases in the endogenous neurotrophin influence neuronal survival in response to insult in the developing and adult brain. The latter question is of particular importance in the instance of seizures and epilepsy, because experiments using in vitro preparations have shown that BDNF can reduce cell death in response to excitotoxic insult and ischemia, events thought to contribute to neuropathology as well as the likelihood of future seizure in man.

To address these issues, recent studies have made use of hippocampal slice preparations to elucidate mechanisms through which exogenous BDNF facilitates LTP, and to test if increases in the endogenous protein similarly facilitate LTP and reduce neuronal vulnerability to insult. Results of these studies indicate that activity-induced increases in BDNF expression in the adult brain both (i) enhance a form of synaptic plasticity that is likely to contribute to epileptogenesis (i.e., LTP) and (ii) give rise to secondary changes in gene expression that counteract epileptogenic influences and reduce vulnerability to ischemic insult.

Methods

Studies in our laboratory have made use of both acute and cultured hippocampal slices to test BDNF effects on synaptic transmission and neuronal survival. The acute hippocampal slice preparation has many advantages for studies of synaptic plasticity in adult brain. Hippocampal

slices, cut 400 μm thick perpendicular to the long axis of the structure, can be maintained for hours in a constantly perfusing, heated and oxygenated artificial cerebrospinal fluid (aCSF) bath, and drugs can be applied via the aCSF input line without disturbing the slice. A large proportion of the hippocampal circuitry lies within the cross sectional plane of the slice, and due to differences in lipid content, the cell layers and afferent lamina are clearly visible; thus, electrodes can be placed within specific hippocampal laminae to stimulate and record synaptic responses from known axonal systems. Our studies have focused on synaptic responses to the Schaffer collateral afferents to hippocampal field CA1. These axons arise from hippocampal CA3 pyramidal cells and innervate the apical and basal dendrites of CA1 pyramidal cells in a highly laminated fashion. Potentiation of CA3-to-CA1 synaptic transmission can be elicited by activation of the Schaffer collaterals with theta burst stimulation (TBS; i.e., four pulses at 100 Hz spaced by a 200 ms interburst interval). Hippocampal CA3 pyramidal cells fire in short trains of 3–5 bursts at theta frequency in vivo. Thus, TBS replicates the natural cellular firing pattern that occurs in hippocampus during behavior. Stimulation with 5 theta bursts is generally sufficient to induce stable LTP; a modestly suprathreshold train of 10 theta bursts is typically used.

The objective of testing the influence of activity-regulated changes in BDNF expression on synaptic function has been addressed using two experimental preparations. First, exogenous BDNF was added to the acute hippocampal slice aCSF bath during electrophysiological recordings; control preparations are bathed in aCSF alone or containing heat inactivated BDNF. Second, to evaluate the consequence of increases in endogenous BDNF levels, positive modulators of AMPA-class glutamate receptors (also known as ampakines) were employed. We have shown that spaced ampakine treatments increase BDNF gene expression and sustain increases in hippocampal BDNF protein content in vitro (**Figure 1(c)** and **1(d)**) and in vivo.

Finally, to test if increases in endogenous BDNF reduce neuronal vulnerability to insult, an in vitro model of oxygen–glucose deprivation (OGD) was used. Hippocampal slices were prepared from postnatal day 10 rat pups and explanted to interface culture 10 days before use. Over this time, the cultured slices exhibit maturational changes that parallel those in same-aged tissue in vivo. Slices were treated with the ampakine CX614 (3 h day^{-1} for 2 days), which causes a modest increase in neuronal firing during the CX614-on period, and both induces and sustains robust increases in endogenous BDNF protein content. One day after ampakine pretreatment, slices were exposed to 45 min OGD by submersion in oxygen- and glucose-depleted aCSF, and then returned to normal culture conditions until harvest 24 h later. Levels of cell death were assessed using FluoroJade staining and propidium iodide uptake.

Results

BDNF Facilitates Synaptic Responses through Effects on SK2 Channels

Although there is considerable evidence that BDNF facilitates activity-induced synaptic potentiation in hippocampus, the components of the BDNF-response profile contributing to this facilitation are not fully appreciated. In reexamining this issue, we evaluated effects of infusing BDNF on Schaffer collateral synaptic responses in field CA1. In agreement with results from many laboratories, BDNF infusion had negligible effect on field excitatory evoked potentials (fEPSPs), but did lower the stimulation threshold and increase the magnitude of LTP. In the presence of 2 nM BDNF, two theta bursts elicited modest LTP; this level of stimulation is not sufficient to potentiate transmission in control preparations. Moreover, the magnitude of maximal potentiation was elevated nearly twofold in the presence of added BDNF.

Examination of fEPSP responses to single theta bursts provided clues as to the locus of these BDNF effects. There is normally a modest facilitation of postsynaptic responses within a train of theta-bursts; in the presence of excess exogenous BDNF, this within-train facilitation is enhanced 60 to 100% – but effects are evident only after the first burst. This observation suggests that BDNF may attenuate the magnitude of the afterhyperpolarization (AHP) that follows a single burst response. Tests of this possibility proved positive: BDNF infusion reduced the postburst AHP as determined by whole cell recordings. The AHP reflects calcium-activated potassium currents and, at the latency of the BDNF-associated AHP change, the small-conductance calcium activated potassium (SK2) channels are thought to play a role. Indeed, treatment with SK2 inhibitors had the same effect as BDNF on within-train facilitation of burst responses and on the magnitude of maximal LTP. The effects of cotreatment with SK2 inhibitors and BDNF were not additive, suggesting that they act on the same pathway to influence LTP. These results indicate that BDNF facilitates LTP, at least in part, by reducing AHP potassium currents, thereby enhancing synaptic responses during a high-frequency train. Moreover, these findings suggest that endogenous BDNF will enhance synaptic responses to high-frequency burst activity such as seen in the epileptic brain.

BDNF Supports Cytoskeletal Changes that Stabilize Synaptic Potentiation

Recent studies indicate that LTP is associated with changes in synapse and spine morphology, and that both morphological changes and potentiation depend upon remodeling of the actin cytoskeleton. Knowing that BDNF influences actin polymerization in immature

systems, we tested the hypothesis that BDNF plays an instructive role in the activity-induced remodeling of the spine cytoskeleton involved in LTP. Using in situ infusion of rhodamine-phalloidin to label and quantify F-actin, we found that TBS induces large increases in spine F-actin that are restricted to laminae of afferent activation. This increase is blocked by latrunculin-A, which prevents the conversion of soluble monomeric- to filamentous-actin; this effect demonstrates that stimulation increases *new* actin filament assembly. With this result in hand, the effects of BDNF on stimulation-induced increases in spine F-actin were tested. BDNF decreased the stimulation threshold for eliciting both LTP and actin polymerization, although BDNF infusion alone (without stimulation) had no effect on spine F-actin content.

This study demonstrates that excess exogenous BDNF facilitates activity-induced increases in spine F-actin. To determine if endogenous neurotrophin is present and released at sufficient levels to have similar effects, slices were treated with BDNF antagonists and TBS was applied. TrkB-Fc is a chimeric protein containing the extracellular domain of the TrkB receptor that effectively scavenges released BDNF; K252a is a kinase antagonist that blocks TrkB autophosphorylation and signaling. TrkB-Fc and K252a block BDNF signaling through the high-affinity TrkB receptor. Both reagents, applied to hippocampal slices during or immediately after TBS, blocked LTP and increases in spine F-actin otherwise elicited by this level of stimulation.

These results demonstrate that BDNF facilitates the activity-induced increases in spine F-actin that are considered critical for the stabilization of synaptic potentiation, and that signaling by endogenous, synaptically released BDNF is needed for LTP stabilization and actin polymerization in the minutes immediately following theta pattern synaptic activity.

Ampakine Regulation of BDNF Expression in vitro and in vivo

Studies described above identified specific mechanisms through which (i) endogenous BDNF contributes to synaptic plasticity, and (ii) increases in BDNF availability might facilitate activity-dependent changes in circuit function in association with patterned neuronal activity and seizures. However, up to this point we had not shown that increases in endogenous BDNF protein content replicate the effects of adding excess BDNF on synaptic plasticity. This 'replication' cannot be assumed, since BDNF trafficking and release might be regulated to maintain, or set limits upon, trophic signaling. Further, BDNF arising from natural sources is not expected to be present throughout the tissue as is the case with added exogenous protein. BDNF is largely anterogradely transported, from perikarya to axon terminals, and released in an activity- and frequency-dependent fashion. As a consequence, secretion and signaling by the native neurotrophin is likely to occur preferentially in the region of the synapse and in association with high-frequency synaptic discharges. To better replicate this pattern of exposure and assess the functional consequences of fluctuations in endogenous BDNF content, we needed a method for manipulating the production of the neurotrophin in situ.

To this end, we have devised paradigms using positive allosteric modulators of AMPA class glutamate receptors (also known as ampakines) to increase BDNF expression. Early studies showed that BDNF gene expression and protein levels are positively regulated by AMPA receptor-mediated activity. The ampakines slow AMPA receptor desensitization and ligand-induced deactivation without direct agonist or antagonist activities, and without interfering with the native ligand binding site. As a consequence, they modestly enhance monosynaptic glutamatergic synaptic responses and more greatly enhance responses across the polysynaptic glutamatergic networks within hippocampus and neocortex. Ampakines cross the blood–brain barrier; hence, effects of ampakine treatment can be evaluated either in vitro or in vivo following systemic injection. Initial studies showed that in cultured hippocampal slices, prolonged ampakine exposure increased BDNF expression but also downregulated the AMPA receptors themselves. However, with shorter (<3 h), spaced ampakine treatments that simulate patterns of ampakine exposure likely to be obtained with intermittent dosing in vivo, BDNF protein levels are increased and can be sustained at elevated levels for days without effects on the AMPA receptor system.

BDNF is generated as a precursor protein (referred to as proBDNF) that is cleaved by intracellular and extracellular proteases to form the mature (m), 14–15 kDa BDNF. Both pro- and mature-forms are released and biologically active. There is evidence that pro- and mBDNF preferentially interact with the p75 low-affinity neurotrophin receptor ($p75^{NTR}$) and TrkB, respectively, and through these receptors facilitate potentiation (via TrkB) and depression (via $p75^{NTR}$) of synaptic responses. These findings raised concern as to whether the ampakines influence levels of proBDNF, mBDNF, or both. Using western blots to evaluate BDNF forms induced by ampakine treatment of cultured hippocampal slices, we found that 3 hr pulse ampakine treatments induced modest (20–50%) increases in 25–35 kDa proBDNF that dissipated within about 12 h, and both larger and more enduring increases in mBDNF (+100 to 200%) that lasted for days. Thus, the predominant effect of ampakine treatment is a lasting increase in the mature BDNF protein expected to facilitate LTP.

The next goal was to test if pulse ampakine treatments sustain increases in mBDNF protein content in vivo. Studies in rats and mice have examined effects of twice daily injections of a short acting ampakine (CX929, half

life of 15–20 min in rat). In one study, socially housed rats were handled daily for several days to reduce the stress of the injection procedure. Rats then received twice daily (morning, afternoon) intraperitoneal ampakine injections and were allowed to socially play for 20 min after each injection; within-group control rats received vehicle injections. The ampakine had no significant effect on locomotor activity, and experimental rats generally appeared indistinguishable from controls. Effects on BDNF protein levels were assessed by ELISA and western blot analyses of brain tissue samples from animals killed 1 day after the last injection. Both measures showed that ampakine treatment increased mBDNF protein concentrations by 50–100% in hippocampus and neocortex. Increases in BDNF content were dose-dependent, evident after the first day of ampakine treatment, and still in place after injection day 4. These and modest variations of these paradigms have been used in subsequent analyses of the consequence of activity-regulated increases in endogenous BDNF on properties of synaptic plasticity (i) in several animal models of cognitive dysfunction and (ii) in an in vitro model of ischemic insult, as described below.

Ampakine Treatment Increase BDNF and can Restore LTP in Models of Cognitive Impairment

As described above, BDNF facilitates LTP, and increases in BDNF availability from exogenous sources can compensate for deficiencies in induction or stabilization of potentiation, including otherwise subthreshold levels of synaptic stimulation. These findings have encouraged speculation that BDNF might be used to restore LTP, and cognitive processes deriving from it, in human syndromes involving cognitive impairment. Deficits in LTP have been described in association with normal aging and in animal models of Alzheimers disease, Fragile-X syndrome, and Huntingtons disease. In the latter two instances, electrophysiological studies of acute hippocampal and neocortical slices have shown that rhythmic or high-frequency activity induces short-lived potentiation that decays with time – i.e., the potentiation fails to stabilize. Nevertheless, infusion of exogenous BDNF fully restores stable LTP in both Fragile-X (**Figure 2(a)**) and Huntingtons disease mutant mice.

The most complete demonstration of the therapeutic potential of manipulating *endogenous* BDNF availability to offset deficits in synaptic plasticity has been obtained in studies targeting impairments in LTP with normal aging. In rats, learning and memory deficits first appear in 'middle age' (~12 months) and worsen with further aging. Prior studies of hippocampal LTP had not identified corresponding deficits in synaptic plasticity in middle-aged animals. However, these previous analyses focused on the dentate gyrus or the apical CA1 dendritic field. We reexamined the effects of aging on LTP of Schaffer collateral innervation of the CA1 basal dendritic field, known to exhibit some differences in the threshold and magnitude of potentiation. In the CA1 basal dendrites, TBS initially induced robust potentiation in slices from both young adult (2–3 months old) and middle-aged (8–12 months old) rats. In tissue from the young adults, potentiation stabilized at nearly twofold prestimulation values as measured 60 min post-TBS; in contrast, in the middle-aged hippocampus, basal dendritic potentiation failed to stabilize and decayed to baseline levels by this time point. Infusion of exogenous BDNF, initiated minutes before stimulation, rescued LTP in the basal dendrites of middle-aged rats.

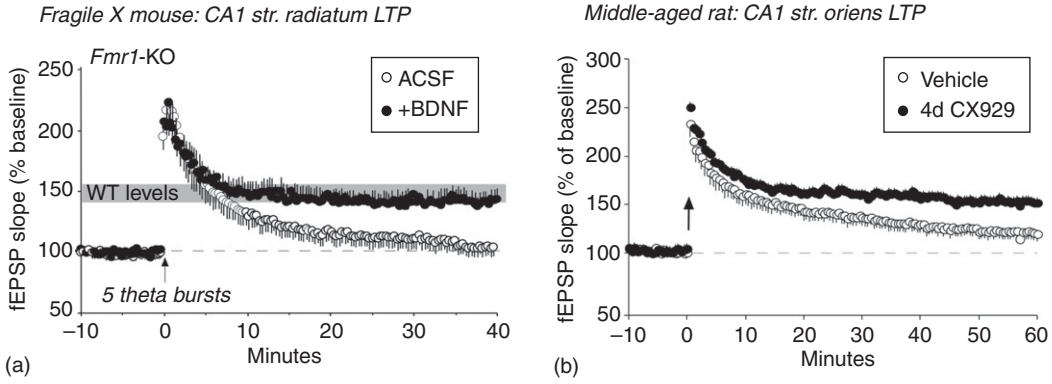

Figure 2 BDNF rescues LTP in rodent models of cognitive impairment. Plots of Schaffer collateral fEPSPs elicited by single test stimulation pulses applied before and after TBS (at arrow). (a) Plots of responses obtained in slices from Fmr1-KO mice (the murine model of Fragile X syndrome) show that in normal ACSF bath five bursts of TBS elicits an initial increase in the fEPSP that decays to prestimulation levels over about 30 min (i.e., potentiation fails to stabilize). In contrast, with 2 nM BDNF in the tissue bath the synaptic response is enhanced and potentiation stabilizes at about 150% baseline values. Grey bar shows the level of potentiation obtained in slices from wild-type mice. (b) Plots of Schaffer collateral fEPSP responses recorded from CA1 str. oriens in slices from vehicle-treated (open symbols) and CX929-treated (closed circles) middle-aged rats. As shown, TBS induced stable potentiation of the fEPSP (150% baseline values) in tissue from ampakine-but not vehicle-pretreated rats.

These results encouraged the thought that increases in endogenous BDNF levels might similarly rescue LTP in middle-aged animals. Using the spaced, systemic ampakine treatment strategy described above (i.e., twice daily injections of CX929 and sacrifice 1 day after the last injection) hippocampal and cortical BDNF protein levels were increased by about 60% in middle-aged rats. Electrophysiological analyses of hippocampi from ampakine-treated rats and age-matched vehicle-treated controls demonstrated that ampakine pretreatment fully rescued stable LTP to the basal dendritic field (**Figure 2(b)**) without changes to potentiation in the apical dendritic field (where age-related deficits were not observed). Moreover, in slices from ampakine pretreated rats, the restored LTP was eliminated by infusion of the BDNF scavenger TrkB-Fc, thereby demonstrating that endogenous BDNF was critical to the reestablishment of synaptic potentiation.

These findings demonstrate that increases in BDNF expression facilitate activity-dependent synaptic plasticity and can restore LTP in at least one condition (aging) involving deficits in both LTP and learning. Moreover, these results encourage the expectation that the more robust increases in BDNF expression and protein content induced by seizures will facilitate enduring synaptic plasticity.

Increases in Endogenous BDNF Reduce Vulnerability to Ischemia through Secondary Effects on NPY Gene Expression

BDNF and related neurotrophins are well known to reduce neuronal vulnerability to insult in a variety of model systems. These findings suggest that activity- and seizure-induced increases in endogenous BDNF protein might also be neuroprotective. However, other work has shown that in some instances (e.g., excitotoxic insults leading to necrotic cell death), applied BDNF can actually exacerbate toxicity. To test if increases in endogenous BDNF expression reduce vulnerability of hippocampal neurons to insult, we employed cultured hippocampal slices and a well-characterized oxygen–glucose deprivation (OGD) model of ischemia.

To increase endogenous BDNF content, the ampakine CX614 was applied to cultured slices for 3 h day^{-1} for 2 days. Such treatments increase mBDNF protein content over twofold. On day 3 (21 h after ampakine removal) the slices were exposed to OGD for 45 min and then returned to normal culture conditions until harvest 24 h later. As demonstrated using FluoroJade staining to label dying neurons, OGD alone caused robust neuronal cell death in hippocampal field CA1 pyramidal cells (**Figure 3(a)**). In contrast, there was little to no cell death in response to OGD in ampakine-pretreated slices. Thus, ampakine pretreatment markedly reduced neuronal vulnerability to ischemia. Cotreatment of cultures with the ampakine and a BDNF antagonist (either TrkB-Fc or K252a) during the 2 days prior to insult totally eliminated the protective effects of ampakine pretreatment, thereby demonstrating that protection was indeed BDNF-dependent.

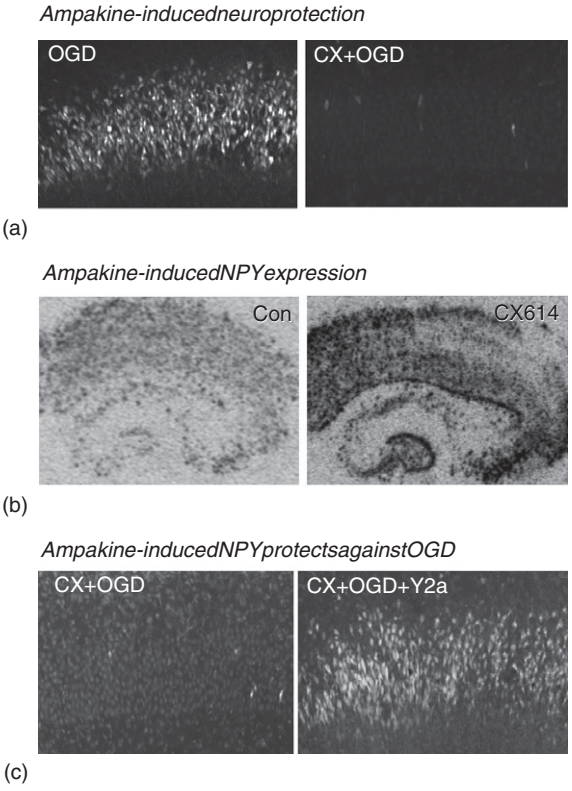

Figure 3 Neuroprotective effects of ampakine treatment are mediated by BDNF and NPY. Cultured hippocampal slices were pretreated with the ampakine CX614 (CX) (3 h day^{-1}, 2 days) then exposed to OGD. (a) Photographs of FluoroJade labeling in the CA1 pyramidal cell layer show that OGD elicits robust cell death in otherwise untreated slices (a, left; dying neurons appear white) but not in ampakine pretreated tissue (a, right). (b) In situ hybridization to NPY mRNA in an untreated cultured hippocampal slice (Con, left) and a slice treated with CX614 (3 h day^{-1}, 2 days) (right) shows that the ampakine increased NPY expression in hippocampal and cortical fields. (c) Photomicrographs of field CA1 showing FluoroJade labeling of dying neurons in slices exposed to OGD after CX614 pretreatment alone (left), or with Y2 receptor antagonist cotreatment (right): results show that ampakine-mediated neuroprotection depends upon the actions of NPY.

BDNF influences the expression of a battery of genes in target neurons, suggesting the possibility that secondary changes in gene expression might contribute to protective effects of ampakine pretreatment. In particular, BDNF stimulates the expression of neuropeptide Y (NPY), a neuroactive peptide that is reported to influence neuronal vulnerability to a variety of insults. To test if regulated changes in NPY expression contribute to changes in neuronal vulnerability with ampakine treatment, experiments were first conducted to determine

if the ampakines increase NPY expression in cultured hippocampal slices. Using in situ hybridization analysis, we found that spaced ampakine treatments elicited broadly distributed increases in NPY mRNA in hippocampus (pyramidal cells, granule cells, and interneurons) and by neurons distributed across all layers of neocortex (Figure 3(b)). NPY expression was elevated within 24 h of treatment onset and persisted through 4 days. Cotreatment with the ampakine ($3\,h\,day^{-1}$) and BDNF antagonists (continuous) completely blocked increases in NPY expression, demonstrating that this response is BDNF-mediated.

These results show that the ampakine treatments that reduced vulnerability to OGD, increased hippocampal NPY content well before the OGD insult. This result raises the possibility that BDNF-induced increases in NPY expression contribute to protection at the time of ischemia. To assess this hypothesis, and determine the relative contributions of BDNF and NPY to neuronal survival, we examined the effects of adding the BDNF scavenger TrkB-Fc or an NPY receptor antagonist to the culture media either throughout the 2 day period of ampakine pretreatment or just 2 h before and during the OGD insult. As shown in Figure 3c, ampakine (CX614) pretreatment alone eliminated OGD-induced cell death. This protection was reversed if either a BDNF signaling or an NPY Y2 receptor antagonist was present during the full pretreatment period, thereby indicating that, in the largest sense, protection was both BDNF- and NPY-mediated. In contrast, with the addition of the same antagonists 2 h before and during OGD, the NPY Y2 antagonist eliminated neuroprotection whereas TrkB-Fc had no significant effect.

These results support the somewhat surprising conclusion that, at the time of insult, protection is mediated by NPY acting through its Y2 receptor, and not by BDNF per se. NPY is localized to presynaptic elements forming axo-axonic contacts in hippocampus; through these contacts and Y2 receptor signaling, NPY is thought to attenuate presynaptic glutamate release. The reduction in glutamate release, in turn, mediates anticonvulsant and, presumably, neuroprotective effects of NPY. Our results indicate that activity-, and therefore seizure-, induced increases in BDNF expression likely go hand-in-hand with increases in the availability and action of NPY in hippocampal and cortical fields. Thus, although seizure-induced increases in BDNF might enhance regional excitability through potentiation of circuit relays, associated increases in NPY would be expected to offset some of these effects on circuit excitability through attenuation of transmitter release, and thus to protect cells from excitotoxic insult.

Future Goals

Evidence that BDNF is positively regulated by neuronal activity, and massively induced by epileptiform-like discharges, raised questions about its roles in plasticity and the network level changes that follow seizures. Studies from several groups established that BDNF lowers the threshold and increases the magnitude of LTP, but left unsettled the issue of how such effects might be achieved. The results described above provide a partial answer: BDNF (i) attenuates after-hyperpolarizing currents and thereby augments the repetitive EPSPs used to induce LTP, and (ii) via a quite different mechanism, potently facilitates activity-induced remodeling of the spine cytoskeleton and thus the stabilization of synaptic changes. The neurotrophin also affects other LTP-related events such as calcium influx and local protein synthesis. A critical objective for future research is to determine if these seemingly diverse effects are in fact interrelated and perhaps even sequential. There is good evidence, for example, that calcium contributes to cytoskeletal reorganization, which in turn has been linked to the initiation of dendritic protein synthesis. It is thus possible that released BDNF causes a relatively discrete set of early changes that, acting in concert with other signaling cascades set in motion by patterned afferent activity, modify the immensely complex apparatus that governs spine actin networks and local translation. Better understanding of these points is a likely prerequisite for formal hypotheses about BDNF's contributions to the long-lasting changes produced by seizure episodes.

The above observations have also prompted efforts to exploit the activity-dependent regulation of BDNF for the development of novel therapeutic strategies. Our work in this area showed that increasing endogenous BDNF, even by relatively modest amounts (+40 to 60%) rescues LTP in animal models of cognitive impairment. Increases in BDNF expression are far greater with seizures, and such changes could promote synaptic plasticity for days after a seizure. An effect of this kind might serve to partially offset the numerous postepileptiform events that depress LTP-like changes. Alternatively, there is the possibility that excessive levels of neurotrophin have effects on the spine cytoskeleton and dendritic protein synthesis that interfere with the production of long-lasting increases in synaptic strength. An important objective for future work is to test how partial blockade or sequestration of BDNF affects the threshold and magnitude of LTP in slices prepared from rats with recent limbic seizure activity.

Finally, studies showing that increased levels of endogenous BDNF reduce vulnerability to ischemic insult, via secondary increases in the expression of NPY, have important implications for epilepsy research. As suggested by a number of investigators, BDNF could potentially promote epileptogenesis because of its positive influence on LTP; the established anticonvulsant actions of NPY have the potential to offset such effects. A prominent goal for future research is to determine if pharmacologically induced increases in BDNF are reliably linked

to elevated levels of NPY, and then to test the significance of this link for seizure proneness. Given that we have been able to chronically increase BDNF levels using short half-life ampakines, it would be possible to carry out such tests under conditions in which the neurotrophin (and NPY) are present at high levels, but the inducing drug has long been cleared from the brain. Ampakine drugs are under development by several pharmaceutical companies and have been successfully used in clinical trials without evident side effects. Work on the above noted goals could thus have significant therapeutic implications with regard to the treatment of epilepsy.

Introduction

Seizures can induce acute and delayed cellular alterations that may favor development and/or progression of epilepsy, including neuronal loss, neurogenesis, axonal and dentritic sprouting, gliosis and, ultimately, circuit remodeling. Neurotrophic factors are well-known physiological mediators in each of these cellular events, and thus they have been hypothesized to be involved in the pathogenesis of some types of epilepsy. Consistent with this idea, the expression of many neurotrophic factors has been reported to be altered in diverse, broadly distributed neuronal populations during epileptogenesis and following seizures.

Together with other neurotrophic factors, FGF-2 seems a good candidate for a role in the plastic changes associated with epilepsy. As described earlier, it regulates neurogenesis, cell survival, axonal sprouting, and synaptogenesis. Furthermore, as detailed in the following sections, (1) seizures increase FGF-2 mRNA and protein levels in specific brain areas and upregulate the expression of FGFR-1 receptors; (2) acute intrahippocampal injection of FGF-2 causes seizures, while chronic i.c.v. infusion of low dose FGF-2 does not affect kainate-induced seizures, but does promote behavioral recovery and reduces hippocampal damage; (3) seizure severity (in response to kainate) is not altered in FGF-2 knockout mice, but is increased in FGF-2 over-expressing mice; and (4) seizure-induced neuronal damage is attenuated in FGF-2 over-expressing mice.

Background

Fibroblast Growth Factor-2

The fibroblast growth factor-2 (FGF-2, previously named basic fibroblast growth factor, bFGF) belongs to a family of structurally related proteins, the FGFs. It is a single-chain

to elevated levels of NPY, and then to test the significance of this link for seizure proneness. Introduction

Seizures can induce acute and delayed cellular alterations that may favor development and/or progression of epilepsy, including neuronal loss, neurogenesis, axonal and dentritic sprouting, gliosis and, ultimately, circuit remodeling. Neurotrophic factors are well-known physiological mediators in each of these cellular events, and thus they have been hypothesized to be involved in the pathogenesis of some types of epilepsy. Consistent with this idea, the expression of many neurotrophic factors has been reported to be altered in diverse, broadly distributed neuronal populations during epileptogenesis and following seizures.

Together with other neurotrophic factors, FGF-2 seems a good candidate for a role in the plastic changes associated with epilepsy. As described earlier, it regulates neurogenesis, cell survival, axonal sprouting, and synaptogenesis. Furthermore, as detailed in the following sections, (1) seizures increase FGF-2 mRNA and protein levels in specific brain areas and upregulate the expression of FGFR-1 receptors; (2) acute intrahippocampal injection of FGF-2 causes seizures, while chronic i.c.v. infusion of low dose FGF-2 does not affect kainate-induced seizures, but does promote behavioral recovery and reduces hippocampal damage; (3) seizure severity (in response to kainate) is not altered in FGF-2 knockout mice, but is increased in FGF-2 over-expressing mice; and (4) seizure-induced neuronal damage is attenuated in FGF-2 over-expressing mice.

Background

Fibroblast Growth Factor-2

The fibroblast growth factor-2 (FGF-2, previously named basic fibroblast growth factor, bFGF) belongs to a family of structurally related proteins, the FGFs. It is a single-chain

polypeptide composed of 146 amino acids. In humans and rodents, FGF-2 exists in multiple isoforms generated from a single mRNA by alternative translation. In the rodent brain, three high molecular weight (HMW; 22, 22.5, 24 kDa) and one low molecular weight (LMW; 18 kDa) form have been identified. The HMW forms contain a nuclear targeting signal and are predominantly localized in the nucleus, where they are thought to serve intracrine functions, to regulate gene transcription and activate programs for plasticity and proliferation. The LMW form is cytosolic, secreted, and capable of activating cell surface FGF receptors (FGFRs) – functioning in an autocrine and/or paracrine manner. Thus, different molecular weight proteins have different subcellular localizations and appear to serve different biological functions.

FGF-2 Receptors

FGFRs can be subdivided in four high- and one low-affinity receptor. The low-affinity receptor is a heparan sulfate proteoglycan. It seems to be critical for FGF signaling, because enzymatic removal of heparin/heparan sulfate from the cell surface or inhibition of sulfation abolishes the biological activity of FGFs. It has been proposed that heparan sulfate may facilitate activation of the high-affinity receptors.

The high-affinity FGFRs (FGFR-1 through FGFR-4) show substantial sequence homology and are similar in their general structure: they all are tyrosine kinase receptors, with one membrane spanning domain and two or three extracellular immunoglobulin-like domains. Alternative RNA splicing produces several different splice variants for each receptor mRNA. Binding of FGFs to these receptors leads to dimerization of receptor monomers, to activation of intracellular kinase domains, and to receptor transphosphorylation at multiple tyrosine sites. A number of Src-homology 2 (SH2) domain-containing signal transduction molecules can bind to these phosphotyrosine sites, potentially activating several signaling pathways, including the Ras/mitogen-activited protein kinase (MAPK) and the phospholipase Cγ (PLCγ). Depending on the activated receptor subtype and signaling pathway, different cellular responses may be produced. Apart from initiating tyrosine kinase signal transduction pathways, FGF-2 and FGFRs may internalize and translocate to the nucleus, influencing the cell cycle machinery. FGF-2 binds FGFR-1 with the highest affinity among high-affinity FGFRs.

Localization

FGF-2 has been found throughout the central nervous system, including the spinal cord, brainstem, midbrain, and forebrain (both subcortical and cortical regions). In the adult, FGF-2 mRNA and protein are present in the astrocytes of all these brain regions, and also in selected neuronal populations, most prominently in the pyramidal neurons of the CA2 hippocampal region and in neurons of the retrosplenial cortex.

Cellular Effects of FGF-2

FGF-2 is a pleiotropic factor that exerts its effects in different cells and organs. For example, it is a potent chemotactic factor for fibroblast and endothelial cells, and is a potent angiogenic molecule that stimulates wound healing and tissue repair via direct actions on endothelial and smooth muscle cells.

With reference to epilepsy, however, the most interesting effects of FGF-2 are neurotrophic. FGF-2 can regulate the proliferation and differentiation of neural stem cells and progenitors. Furthermore, it enhances the resistance to damage, survival, axonal branching, and synaptogenesis of mature neurons. FGF-2 acts as a neurotrophic factor both in the developing and in the adult nervous system. During development, it is thought to play a critical role in neurogenesis as well as in cell–cell signaling between neurons, astrocytes, and microglia. In the adult brain, it is involved in the regulation of plasticity and in the maintenance of structural integrity.

Proliferation and differentiation

FGF-2 is a potent mitogen, not only (as originally discovered) for fibroblasts, but also for a variety of cells of mesodermal and neuroectodermal origin. In vitro, exogenously administered FGF-2 exerts mitogenic and differentiative effects on embryonic hippocampal neurons in culture, stimulates proliferation of cortical precursor cells, and (with other growth factors) regulates the generation of neurons and astrocytes from progenitor cells. FGF-2 also favors the differentiation of cultured neonatal dentate granule cells. Different concentrations of FGF-2 may influence the fate of early cortical stem cells: low FGF-2 levels predominantly lead to development into neurons, whereas higher levels lead to generation into glia as well as neurons.

Similar effects have been observed in vivo. Injection of an antibody against FGF-2 in the neonatal rat brain inhibits neurogenesis; conversely, a single subcutaneous FGF-2 injection in neonatal rats elicits a significant increase in hippocampal cell number. The mitotic effects of exogenous FGF-2 persist in the adult brain in the regions (subgranular zone of the dentate gyrus and subventricolar zone) where neurogenesis persists during adulthood.

The mitogenic and differentiating effects of FGF-2 appear to vary depending on the specific developmental stage and on the cell type. It seems likely that different FGF-2 isoforms and/or receptor subtypes, as well as site- and time-specific synergies with other neurotrophic factors, account for this complexity of action.

Neuroprotection

A protective effect of FGF-2 has been documented in vitro. FGF-2 has been found to attenuate glutamate-induced death in cultures of neurons derived from many different brain regions. Since many of these preparations are essentially glia-free, these data suggest that at least part of the neuroprotective effect is exerted directly on neurons.

FGF-2 promotes neuronal survival and recovery against a remarkably wide variety of insults, reducing brain cellular damage and improving functional recovery in experimental models of stroke, of chemical, mechanical, and traumatic brain and spinal cord injury, and of epilepsy. In rats subjected to focal ischemia, for example, intravenous FGF-2 produces a significant reduction in cortical infarct volume and a marked improvement in rotarod performance. FGF-2 also increases long-term survival of spinal motor neurons and improves respiratory function after experimental spinal cord injury. More interestingly in the context of the present volume, chronic i.c.v. administration of FGF-2 protects against seizure-induced cell loss and reduces long-term behavioral deficits. Conversely, recovery from injury is impaired when neutralizing antibodies were used to prevent FGF-2 from activating its receptors during the postinjury period.

Neurite outgrowth and synaptogenesis

FGF-2 also produces morphogenic effects in mature neurons. It accelerates bifurcation and growth of axonal branches without affecting the elongation rate of primary axons in cultured rat hippocampal neurons, and it enhances neurite growth in hippocampal and cortical neurons. A greater number of axon branches is expected to produce a greater number of synaptic contacts, and indeed, local application of FGF-2 has been found to increase (in a concentration-dependent manner) the number of excitatory synapses between hippocampal neurons; these synapses are morphologically mature and functionally active.

Methods: Experimental Analyses

Gene Expression Studies

FGF-2 gene expression is induced with similar patterns in different acute seizure models: increased FGF-2 mRNA levels have been observed after application of bicuculline, lesion of the dentate gyrus hilus, kainate, and electroconvulsive shock. This phenomenon is marked and transient, peaking at 6–24 h in different hippocampal subfields and in the cortex. Increased levels of FGF-2 mRNA are observed in different regions (including neocortex, amygdala, and septum), but most prominently in the hippocampus. As described earlier, FGF-2 is expressed diffusely in astrocytes, and also in CA2 pyramidal neurons in the hippocampus of naive rodents. Following seizures induced by kainate or hilar lesion, increased FGF-2 mRNA levels have been observed in these cell populations, as well as new expression in CA1 pyramidal neurons and in dentate gyrus granule cells.

In the kindling model, induction of FGF-2 mRNA expression is observed in the hippocampus, neocortex, and hypothalamus; curiously, this expression is more pronounced after a single afterdischarge (not accompanied by behavioral seizures) than after a fully kindled, generalized tonic–clonic seizure lasting more than a minute. A higher responsiveness to low-level, compared with maximally-effective, stimulations has also been observed in the hippocampus after minimal, as compared with maximal electroshock, suggesting that the duration and intensity of seizures within a specific area does not necessarily correlate with the magnitude of FGF-2 mRNA level increase.

The induction of FGF-2 mRNA is followed by an increase in the protein levels. In the kainate model, FGF-2-like immunoreactivity is detectable 6 h after injection of the convulsant agent and peaks at 24 h, being mainly localized in the nuclei of astrocytes. After electroconvulsive shock, FGF-2 protein expression increases in the frontal and rhinal cortex, peaking at 20 h, and still elevated at 72 h. The HMW isoforms of FGF-2 appear to be produced more than the LMW isoform. In one study, FGF-2 protein levels were found to remain elevated in astrocytes up to 30 days following kainate-induced seizures, suggesting that the transient pattern of FGF-2 mRNA elevation has prolonged translational effects that may be capable of influencing long-term plasticity changes.

Seizure-induced changes in the expression of only two (FGFR-1 and FGFR-3) of the four high-affinity tyrosine kinase FGFRs have been studied in the kainate model. Seizure activity modulates FGFR-1 mRNA expression: in situ hybridization reveals increased FGFR-1 mRNA levels in the cell body of granular and pyramidal neurons, up to 24 h after kainate injection. At the protein level, FGFR-1 positive cells appear first in the molecular layer of the dentate gyrus after kainate seizures, then in other hippocampal subfields, and finally (by 24 h) very diffusely throughout the hippocampus and the cerebral cortex. Thirty days after kainate injection, strong FGFR-3 immunopositivity has been found in OX-42-positive reactive microglia in several brain areas, including hippocampus, amygdala, piriform, and entorhinal cortex.

In spite of some minor discrepancies between different models, these observations lead to the notion that seizures coordinately increase the expression of FGF-2 and its receptor(s), potentiating it signally potential in several brain regions. Interestingly, the ability of experimental seizures to produce damage is not essential for induction of FGF-2 expression; activation of the FGF-2 system can be also observed after relatively mild, noninjurious seizures. In other words, not only the actual production

of injury, but even the simple threat or anticipation of injury, may be sufficient for potentiating the endogenous FGF-2 system.

The conditions that have been found to trigger FGF-2 expression encompass a wide spectrum, ranging from physiological to pathological. At one end of this spectrum is sustained neuronal activity and at the other end is injury and cell death; in between, there are a number of other conditions, like stress and noninjurious seizures, that induce FGF-2 expression. Accordingly, the roles that newly-produced FGF-2 may exert appear to span in a wide range, from activity-dependent plasticity to resistance to damage to rescue, repair, and regeneration.

In the frame of epileptic conditions, potentiation of the FGF-2 system is likely to occur as part of an adaptive response to excessive activation of specific neuronal circuitries as well as a response to seizure-induced damage. The hypothesis that FGF-2 takes part in the plastic changes associated with epilepsy has been investigated using pharmacological and genetic tools.

Pharmacological Studies

Injection of FGF-2 into the dentate region of the ventral hippocampus causes an excitatory effect culminating in electrographic and behavioral seizures. This acute effect appears to be dose-dependent, with the percentage of seizing animals and the duration of seizures greater after injections of 50 than of 25 ng FGF-2. These acute electrical alterations of hippocampal activity cannot be ascribed to trophic effects, and have been proposed to result from a fast signal transduction mechanism leading to changes in excitability.

In contrast with the effects of acute administration, the chronic infusion of relatively low FGF-2 doses ($2.5\,\mathrm{ng\,h^{-1}}$) into the cerebral ventricle does not modify latency and duration of kainate seizures; however, it effectively prevents seizure-induced hippocampal cell loss and improves long-term behavioral recovery. This neuroprotective action of FGF-2 may depend on potentiation of Ca^{2+}-dependent inactivation of *N*-methyl-D-aspartate (NMDA) currents in hippocampal neurons, an effect produced by chronic (hours), but not by acute, treatment with FGF-2. Another possible mechanism of this effect may be the induction of activin A (ActA), a cytokine belonging to the transforming growth factor-beta superfamily. When coinjected with kainate in the hippocampus, FGF-2 prevents the loss of CA3 neurons in mice. In mice treated with kainate and FGF-2, but not in those treated with kainate alone, ActA-immunoreactivity was found to be high in CA3 as well as in CA1 and CA2 neurons. Critically, FGF-2 fails to protect CA3 neurons against kainate-induced death in presence of the ActA-neutralizing protein, follistatin.

A neuroprotective effect of FGF-2 has also been demonstrated in a quite different experimental situation – the grafting of fetal cells in the sclerotic hippocampus. Cell transplantation may offer a new therapeutic approach to reduce hippocampal cell loss, to prevent acute or delayed plastic brain alterations, and to restore the disrupted circuitries in the seizure-injured or epileptic hippocampus. Pretreatment of CA3 fetal hippocampal cells with FGF-2, alone or together with other trophic factors, is associated with a robust increase in long-term cell survival and enhanced graft neuronal integration in the injured hippocampal region. The efficacy of this cell grafting strategy appears to depend on the trophic action of FGF-2.

Genetic Studies

The generation of mice with homozygous deletion of the FGF-2 gene (FGF-2 knockout mice), and with a species-specific transgene inserted in the genome (human FGF-2 transgenic mice), has provided new tools to study the molecular, physiological, and pathological roles of FGF-2 in vivo. The FGF-2 knockout mice are viable, fertile, and without any obvious phenotypical difference from their wild-type (WT) littermates. However, these mice exhibit a significant reduction in the number of neurons in the neocortex, in particular in the motor areas. Furthermore, they display delayed wound healing. The susceptibility to seizures of FGF-2 knockout mice has been studied in the kainate model. The severity of kainate seizures is not different between knockout and WT mice. Under resting conditions, neurogenesis in the dentate gyrus is not significantly different between FGF-2 knockout and WT mice. In response to kainate seizures, however, an increase in FGF-2 protein levels and neuroproliferation were observed in the hippocampus of WT mice, while very low levels of neurogenesis were observed in the knockouts. Using a viral gene delivery system, high FGF-2 levels can be restored in the mutant mice, also restoring levels of neurogenesis comparable to those of WT littermates. These data suggest that seizure-induced FGF-2 expression is necessary to prime proliferation and differentiation of progenitor cells in the adult hippocampus.

Recent Results

In an attempt to further elucidate the effect of FGF-2 in epilepsy, we studied transgenic mice expressing the human FGF-2 (TgFGF2 mice). These mice have been previously characterized molecularly and phenotypically. Western blot analysis has shown that the murine and human FGF-2 isoforms are tissue-specifically expressed and translationally regulated. In gross examination, these transgenic mice are often affected by skeletal malformations (such as shortening and flattening of long bones) and moderate macrocephaly. In addition, without having any spontaneous or inherent vascular defect, they exhibit a

predisposition to angiogenic reactions with subsequent amplified angiogenesis.

The human FGF-2 transgene is highly expressed in the brain of these mice. Based on in situ hybridization and immunohystochemistry, we found that TgFGF2 mice express FGF-2 mRNA and protein in all hippocampal principal neurons (pyramidal and granule cells), not only in CA2 pyramidal neurons as in WT animals. This pattern of overexpression is remarkably similar to the one caused by seizures in WT animals (above).

These mice that 'overexpress' FGF-2 at baseline have a latent epileptic phenotype (**Figure 1(a)**), in that latency to generalized seizure onset is reduced, and behavioral seizure scores and lethality are increased. Some of the pathological sequelae of seizures (namely increased neurogenesis, cell damage, and sprouting of the mossy fibers) were also examined. First, in spite of the fact that FGF-2 is one of the most potent mitogenic factors for hippocampal neural stem cells, its over-expression in FGF-2 transgenic mice did not lead to increased neurogenesis under basal conditions or after kainate-evoked seizures. Under basal conditions, the number of BrdU immunoreactive cells in the dentate gyrus (an index of neuroregeneration) did not differ between FGF-2 transgenic and WT mice. Seizures increased cellular proliferation in a seizure severity-dependent manner (that is, the number of BrdU-positive cells increases as a function of seizure severity). However, seizures of similar grade increased the number of BrdU-positive cells in a similar manner in the two experimental groups. Together with the earlier-described data showing that seizure-induced neurogenesis is abolished in FGF-2 knockout mice, the data suggest that FGF-2 is necessary, but not alone sufficient, for seizure-induced neurogenesis.

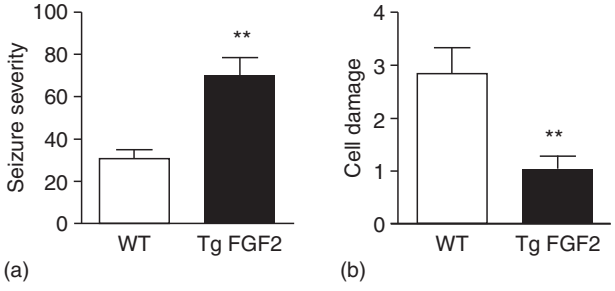

Figure 1 (a) Kainate seizure severity in wild-type (WT) and FGF-2 transgenic mice (TgFGF2). Seizure severity was scored according to a published scale (cumulative seizure score) and refers to the 2 h of behavioral observation following kainate injection. Data are the mean ± SE of 20 animals per group. $^{**}P < 0.01$ versus WT; Mann–Whitney *U* test. (b) Quantification of kainate-induced neurodegeneration in the hippocampus of WT and FGF-2 transgenic mice (TgFGF2) following seizures of similar grade (cumulative seizure score of 50). The degree of neurodegeneration was scored according to a published scale (degeneration index). Data are the mean ± SE of six animals per group. $^{**}P < 0.01$ versus WT; Mann–Whitney *U* test.

Second, neuroprotection was explored using several markers of cell death and apoptosis: Fluoro-Jade B labeling, silver impregnation, active caspase 3 immunohistochemistry. Following kainate-induced seizures of similar severity, we observed greater cell damage in WT than in FGF-2 transgenic mice (**Figure 1(b)**). In WT animals, Fluoro-Jade B labeling displayed the typical pattern of neurodegeneration associated with kainate seizures, involving different hippocampal subfields (CA1, CA3, CA4) and extrahippocampal regions like thalamus and cortex. In contrast, in transgenic mice that underwent severe kainate seizures, Fluoro-jade B-positive neurons were observed only in the hilar dentate gyrus region. These data are in good agreement with the neuroprotective action of FGF-2 in injury models. We hypothesize (see above) that seizures prompt the overproduction of FGF-2 in astrocytes and neurons; in turn, this newly produced FGF-2 enhances the production of ActA in selected neurons. In the hippocampus, ActA may reach high levels in CA1 and CA3 neurons, protecting these cell types from injury. Accordingly, we observed in TgFGF-2 mice the preservation from degeneration of CA1 and CA3 neurons, but not of neurons in the hilus of the dentate gyrus. Further experiments are in progress to challenge this hypothesis.

Third, we examined a long-term seizure-induced synaptic rearrangement, the sprouting of mossy fiber axons. Under control condition, neither control nor FGF-2 overexpressing mice display sprouting of the mossy fibers (as detected using the Timm staining). Thirty days after kainate seizures of similar grade, a similar degree of sprouting was observed in transgenic and in control mice. Thus, the overexpression of human FGF-2 does not seem to be sufficient to influence seizure-induced morphological reorganization.

Therefore, the latent epileptic phenotype of FGF-2 overexpressing mice cannot be explained on the basis of effects on neurogenesis (not altered in the mutant mice), cell death (not altered under basal conditions, and actually reduced after kainate seizures), or sprouting of the mossy fibers (not altered). Another hypothesis to explain the latent epileptic phenotype focuses on the ability of FGF-2 to increase the number of excitatory synapses. To explore this possibility, we have investigated the effect of FGF-2 overexpression on excitatory synaptic transmission. To estimate the density of excitatory terminals, we evaluated the expression of the glutamatergic vesicular transporter VGLUT1. A clear enhancement of VGLUT1 immunoreactivity was observed in the hippocampus of FGF-2 transgenic compared with WT mice. In contrast, no differences were observed in the density and distribution of VGAT, the vesicular transporter of GABA and a marker of GABAergic terminals.

To explore the functional correlates of these observations, we compared the basal properties of the Schaffer collateral-CA1 synapse in hippocampal slices. Extracellular field potential recordings in the area CA1 have been

performed to generate input/output (I/O) curves for each mouse strain. We found that the I/O curve was shifted leftwards in FGF-2 transgenic compared with WT mice, indicating increased excitability in the former.

Furthermore, in an attempt to trigger release from only one axon connected to the neuron under recording, and to measure changes in neurotransmitter release due to alterations in the quantal content, we used paired-pulse minimal stimulation of Shaffer collaterals to evoke EPSCs in CA1 pyramidal neurons. When pairs of EPSCs were elicited every 60 s, at intervals of 50 ms, the mean amplitude of the second EPSC (EPSC2) was larger than EPSC1, an effect known as paired-pulse facilitation (PPF). If the fluctuation in the amplitude of EPSC1 results from changes in its quantal content, then the amplitude of the second response is inversely related to the quantal content of the first response; that is, increased probability of glutamate release results in a decrease of PPF. In slices prepared from FGF-2 transgenic mice, the mean amplitude of EPSC1 was larger and EPSC2 was smaller than in WT. These results suggest an increase in the amount of neurotransmitter released in TgFGF-2 mice due to an increase of the quantal content in the Schaffer collaterals. Thus, FGF-2 transgenesis either increases the number of vesicles per glutamatergic terminal or the number of terminals per axon. Although our data do not allow distinction between these two hypotheses, the evidence (see above) that FGF-2 has synaptogenetic effects strongly supports the latter. Together, these data suggest that an anomalously increased excitatory synaptic input may cause an increased propensity to seizures in TgFGF2 mice.

Future Goals

In conclusion, the experimental evidence presented in this article suggests the following: (1) seizures (most notably epileptogenic seizures) induce the synthesis of FGF-2 in astrocytes and neurons constitutively expressing its gene, and ectopically in neurons that do not normally produce this neurotrophic factor; (2) pharmacological and genetic data suggest that increased availability of FGF-2 increases seizure susceptibility, but reduces seizure-induced cell death.

The multiple effects of FGF-2 (increased hippocampal excitability and reduced cell death) have apparently contrasting physiopathological implications, like increased susceptibility to seizures but decreased seizure-induced cell death and, thus, may depend on different mechanisms (for example, on different isoforms or different receptor subtypes). Identifying these mechanisms will be critical in pursuing therapeutic goals (controlling seizures and their deleterious consequences) through modulation of the FGF-2 system.

GDNF: A Neurotrophic Factor Against Epilepsy

M Kokaia, University of Lund, Lund, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The glial cell line-derived neurotrophic factor (GDNF) is a member of the transforming growth factor-beta superfamily. Initially GDNF was discovered as a survival factor for dopaminergic neurons. Subsequently, motoneurons and noradrenergic neurons were found to be sensitive to GDNF for their survival. Parkinson's disease is a primary candidate for GDNF-based treatment, but stroke and motoneuron injury are also being considered. Members of the GDNF family include neurturin, artemin, and persephin. All these proteins have their selective receptors (i.e., GFRa1, 2, and 3), which as a complex bind to a common transmembrane receptor tyrosine kinase (RET) to induce signaling.

Wide distribution of GDNF and its receptors in the rat and human central nervous system and their regulation by seizures suggested a role for GDNF in seizure activity. It has also been demonstrated that intraventricular infusion, as well as adenoviral vector-mediated overexpression of GDNF in the hippocampus, suppresses generalized seizures and kindling epileptogenesis. Most recently, we have shown that hippocampal GDNF overexpression, mediated by an adeno-associated viral vector, could suppress seizure activity in various electrically induced animal models of epilepsy.

Background

Gene transfer has developed into one of the main experimental tools in neuroscience to explore and to understand the functions of various proteins. This technology is designed to manipulate gene expression in large populations of neural cells, in dissociated and organotypic slice cultures, and in vivo. Moreover, gene transfer is beginning to be used for therapeutic purposes. Recombinant viral vectors provide one of the most efficient methods of gene transfer in the CNS.

The two main routes to transfer genes to the CNS, the indirect (ex vivo) and direct (in vivo), have their advantages and disadvantages. The direct in vivo gene transfer, by recombinant viral vectors such as adenoviral vectors, adeno-associated viral vectors, and lentiviral vectors, entails transduction of nondividing resident host cells and modifying them genetically, with long-lasting and nonreversible expression of the transgene. In ex vivo gene transfer, the vector is first delivered to a cell line in vitro, and these cells are then transplanted into the brain. In this case, there is no integration of foreign DNA causing a genome dysregulation of the host cells. Further, the special case of encapsulated cell biodelivery (ECB) provides an additional safety aspect to the procedure, as it is possible to remove the cell-containing capsules in case of unwanted side effects. Both direct (in vivo) and indirect (ex vivo) gene transfers have been used to control epileptic seizures in animal models with variable success, depending on the targeted genes and cells.

Methods

In our laboratory, we use recombinant adeno-associated viral (rAAV) vectors to transfer GNDF gene into the rat brain, particularly into the hippocampus. rAAV is produced according to the standard procedures, and is obtained through a collaboration with Dr. Deniz Kirik from Wallenberg Neuroscience Center, Lund. In brief, a chicken β-actin promoter, a hybrid between a cytomegalovirus enhancer element and a chicken β-action promoter, was driving the expression of the GDNF or the GFP gene. Vectors further contained a woodchuck hepatitis virus post-transcriptional regularity element downstream of the transgene. The injection procedure is as follows: The animals are anaesthetized and placed in a stereotactic frame; a hole is drilled in the skull according to the preselected coordinates, and the glass pipette filled with viral vector solution is inserted into the brain through the skull hole. Injection of 1 μl solution is performed over several minutes, and the pipette is left in position after the injection for another few minutes to prevent back-flow of the injected viral vector into the pipette tract.

To test the seizure-suppressant effect of such gene transfer, we use various models of epilepsy, such as electrical kindling and electrical status epilepticus. In kindling, initially focal seizures, induced by daily stimulations, gradually generalize and can be scored by behavioral seizure manifestations. Once animals reach a generalized seizure stage, stimulations that initially induced only focal seizures induce generalized convulsion, and animals are said to be kindled. This process of gradual generalization of seizures is considered as a model of epileptogenesis, which can be studied experimentally. In our status epilepticus model, we use 10 s trains of 1-ms duration square-wave pulses (at 50 Hz) over the course of 1 h, interrupted every 10 min by 1-min EEG recording. Such

stimulation leads to self-sustained status epilepticus-like activity, and after a few weeks, results in the development of spontaneous generalized seizures in these animals.

Characterization of the tissue is performed at the end of these experiments using conventional immunocytochemistry and general tissue staining methods. The role of neurogenesis in the effects of GDNF is evaluated by intraperitoneal injections of BrdU and other conventional immunostaining methods (e.g., immunostaining for DCX).

Another approach for ex vivo gene therapy is to implant an encapsulated GDNF-producing cell line. For this purpose, we use Encapsulated Cell Biodelivery (ECB) devices from NsGene A/S, Denmark. These devices consist of a semipermeable membrane, which allows exchange of extracellular fluids across the mebrane, and delivery of the cell secretion products into the surrounding host tissue. The insertion of the ECB devices into the brain is performed via preimplanted canulas.

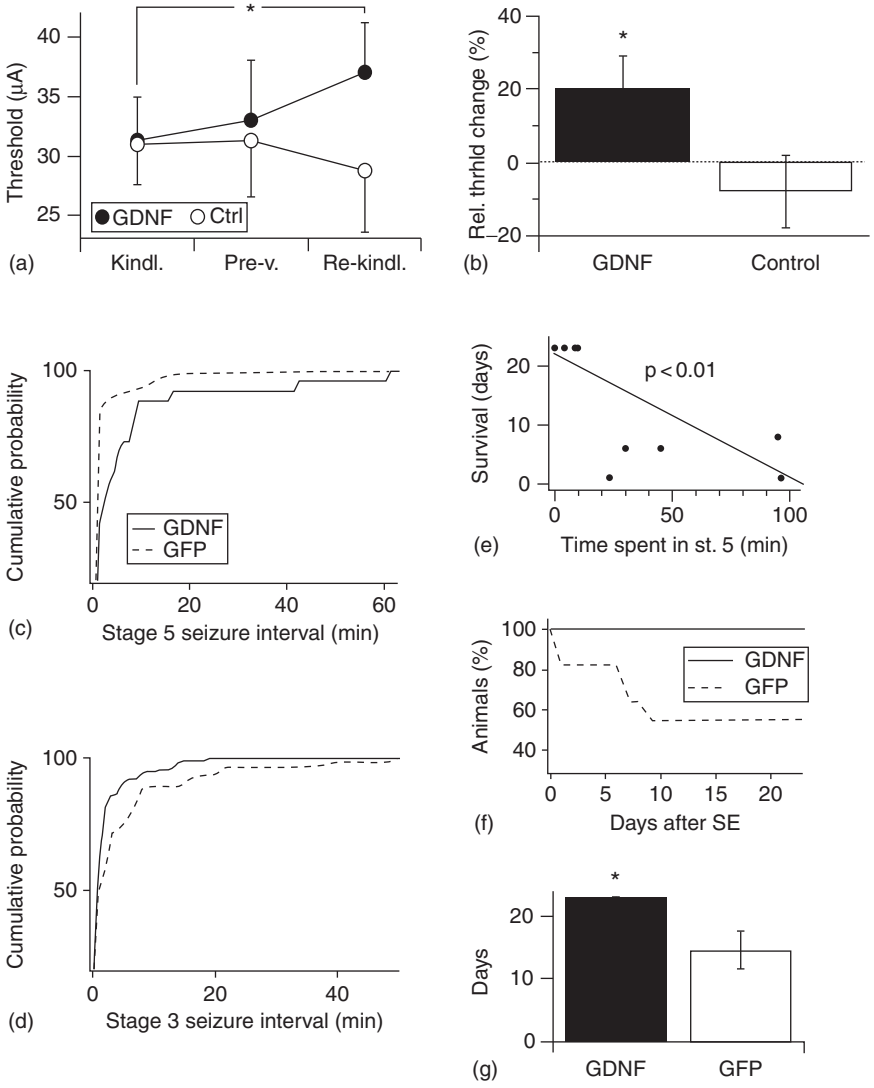

Figure 1 Transgene GDNF increases the seizure-induction threshold in kindled animals, and decreases severity of SE seizures and survival rate of animals. (a) Relative change of the threshold from kindling to 3 weeks post-virus (Post-v.), i.e., injection of rAAV–GDNF (* indicates $p < 0.05$ for the absolute threshold change, Student's paired *t*-test). (b) Similar to (a) in rAAV–GFP and vehicle treated controls. Dashed lines represent values of individual animals, thick lines show group averages. rAAV–GDNF, $n = 10$ and control, $n = 8$ (rAAV–GFP, $n = 5$ and vehicle $n = 3$). (c) The cumulative probabilities of generalized stage 5 and (d) focal stage 3 seizures during the self-sustained phase of SE. (e) The number of animals (as percentage of the initial group size) surviving at the days following SE. (f) The correlation between the number of stage 5 seizures during SE and the survival time of GFP expressing animals (corr. coefficient $r = -0.7$, $p < 0.01$). (j) The survival time (in days) following SE (*$p < 0.05$, Student's unpaired *t*-test). rAAV–GDNF, $n = 10$ and rAAV–GFP, $n = 11$. Error bar is mean ± SEM. Recent Results

The main findings of our studies demonstrate that the rAAV–GDNF vector does transduce hippocampal cells, GDNF is produced and released in the whole hippocampus, and has inhibitory effect primarily on generalized seizures. Moreover, seizure induction threshold and mortality after status epilepticus are decreased in treated animals. These results are summarized in Figure 1.

To apply these findings in more clinically safe and relevant delivery systems, we have used GNDF-producing encapsulated cells transplanted into the hippocampus

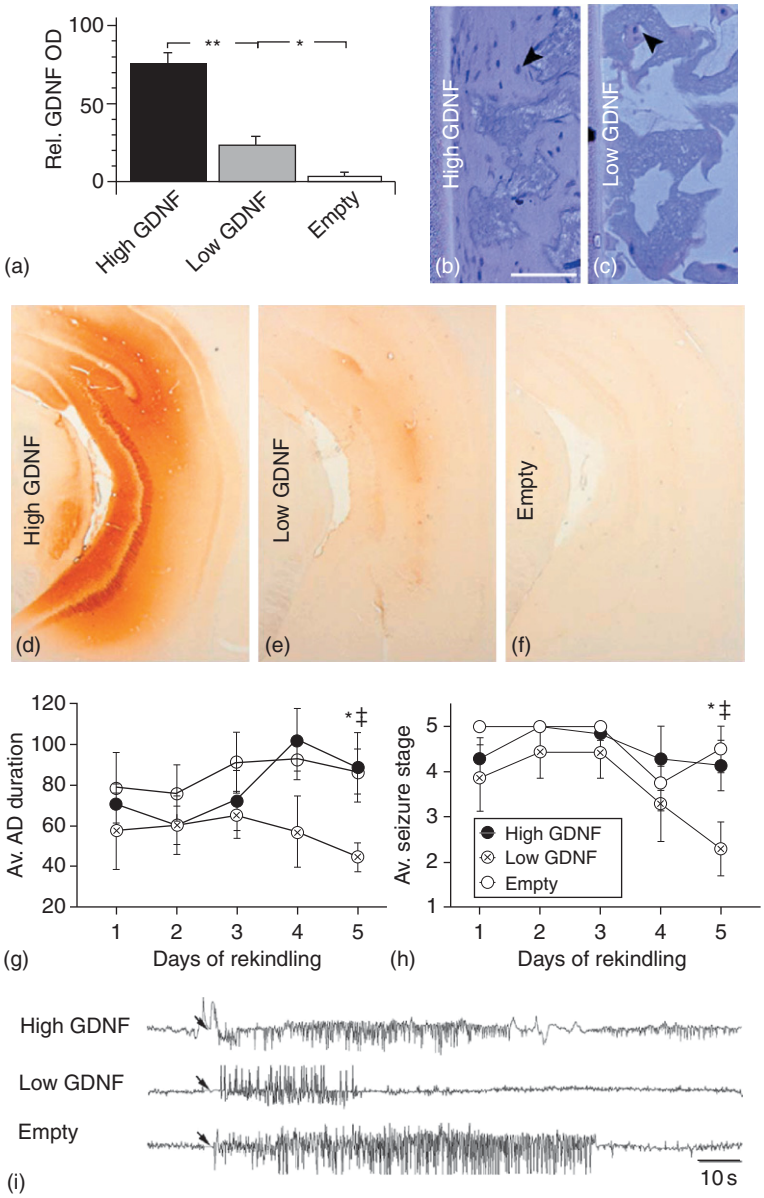

Figure 2 GDNF release from ECB devices in vitro and in vivo, and its seizure-suppresses activity in rekindling. (a) Relative optical density (OD) of GDNF-IR in the hippocampus of animals assigned to the three experimental groups. OD was measured adjacent to the device implantation site, and values are averaged for left and right portion of the hippocampus ($n = 7$ for high and low GDNF, and 4 for empty, respectively, $^{**}p < 0.01$, $^{*}p < 0.05$). (b) Example of an ECB device of the high GDNF group containing some living cells. (c) Example of an ECB device of the low GDNF group containing hardly any living cells. Arrowheads in (d) and (e) indicate viable cells. GDNF-IR in the hippocampus of an animal with high (d) or low (e) GDNF release from ECB devices, and in the hippocampus of an animal implanted an empty ECB device (f). Scale bar are 100 μm in (b, c) and 1 mm in (d, e). (g) The average duration of afterdischarges (ADs) on the five days of rekindling. (h) The average seizure stage on the 5 days of rekindling. Stars indicate $p < 0.05$ for low GDNF compared to high GDNF, and ‡indicates $p < 0.05$ for low GDNF compared to empty, respectively. Representative EEG traces of ADs are shown in (i). Arrows indicate the electrical stimulation and the beginning of epileptiform EEG activity. Reproduced from Kanter-Schlifke I, Fjard-Larsen L, Kusk P, Angehagen M, Wahlberg L and Kokaia M (2009) GDNF released from encapsulated cells suppresses seizure activity in the epileptic hippocampus. *Experimental Neurology* 216: 413–419.

(ECB devices provided by NsGene A/S, Denmark). These experiments showed that such an approach is also effective in decreasing seizure severity and duration in kindled animals, and that the effect is dependent on the relative amount of GDNF released from these capsules. Unexpectedly, lower levels of released transgene GDNF seemed to be more effective rather than higher levels, as assessed by the relative intensity of GNDF immunoreactivity in the host hippocampal tissue surrounding the transplants (**Figure 2**).

We then explored some possible mechanisms that could underlie the seizure-suppressant effect of transgene GDNF. Among others, increased expression of neuropeptide Y (which has been shown to be induced, e.g., by BDNF exposure), decreased GFRalpha-1 receptor, and altered neurogenesis have been explored. However, none of these mechanisms seems to be critically responsible for transgene GDNF effects.

Future Goals

What remains to be explored is whether transgene GDNF can alter synaptic transmission in the hippocampus (directly or indirectly). It has been shown to upregulate glutamate transporters, in particular GLAST and GLT-1, which would result in more effective removal of elevated extracellular glutamate in chronic models of epilepsy. More directly, GDNF could modulate excitatory or inhibitory synaptic transmission in the brain, as shown in studies of GDNF effects on myocytes or cultured midbrain neurons. To achieve these goals, specific immonstainings and whole-cell patch clamp techniques will be used. Such experiments will reveal the mechanisms behind GDNF antiepileptic activity and will open possible novel research perspectives in using GDNF as a potential target molecule in gene therapy for epilepsy.

The Influence of Neurotrophins on Excitability in Hippocampus and its Potential Relevance to Epilepsy

H E Scharfman, The Nathan Kline Institute for Psychiatric Research, Orangeburg, NY, USA, and Child & Adolescent Psychiatry and Physiology & Neuroscience, New York University School of Medicine, New York, NY, USA

Introduction

The idea that the hippocampus is related to epilepsy, specifically temporal lobe epilepsy, has a long history of support from basic and clinical studies. One of the seminal questions is why the hippocampus appears to be 'seizure-susceptible' – in other words, why epileptiform discharges are readily evoked, and seizures often begin, within this structure. One hypothesis is that the hippocampus is designed to support diverse types of structural and functional plasticity under normal conditions, which is important to hippocampal-dependent functions, such as learning and memory. However, the mechanisms that support plasticity, especially mechanisms that increase glutamatergic transmission and synchronization, may lead to a greater risk of seizures.

Here we examine one of the neurotrophins that is expressed in hippocampus, BDNF. BDNF is one example of a modulator of hippocampal function that needs to 'balanced,' because it can induce plasticity that enhances normal hippocampal function, and it can induce seizures. It may contribute to plastic changes in the brain that are

Neuroprotective Strategies in Epilepsy

S D Croll, Queens College of the City University of New York, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

From the earliest attempts to develop treatments for epilepsy, the primary goal of epilepsy therapeutics has been seizure control. Since seizures are not only pathognomonic for epilepsy, but also represent a significant problem for patients, this strategy has been both rational and fruitful. However, in spite of the development of a wide array of anticonvulsant drugs, some patients have poorly controlled seizures while many more report breakthrough seizures. Efforts to seek better anticonvulsant treatments are ongoing, and these efforts have been accompanied by a concurrent effort to protect the brain from the damaging effects of seizures.

Using animal models, epilepsy researchers have discovered that seizures lead to permanent changes in the brain circuitry. Some of these changes, such as mossy fiber sprouting, could potentially be associated with seizure progression. In addition, uncontrolled seizures may cause a loss of brain cells. Humans with chronic temporal lobe epilepsy (TLE) show neuronal loss, sclerosis, and atrophy, especially in the hippocampus. In animal models, the occurrence of severe seizures leads to cell loss in various regions of the brain, especially the limbic system. As illustrated in **Figure 1**, the hippocampus of rodents has proved to be exquisitely sensitive to the excitotoxic cell death induced by seizures, and this cell loss in the animal model reflects the damage profile seen in human TLE. Behavioral studies in animals have also shown that seizure-related cell loss is associated with functional impairments, such as memory decline and emotional deficits, similar to findings in humans where epilepsy has been associated with functional impairments ranging from memory loss to alterations in mood. Protecting neurons in the human epileptic brain may protect against functional impairments.

As a consequence of the realization that seizures beget neuronal loss and behavioral impairment, epilepsy researchers are increasingly interested in pursuing neuroprotective strategies in epilepsy. Protecting neurons from death or functional compromise after seizures would, in the short term, prevent some of the far-reaching consequences of breakthrough seizures. In the longer term, the optimal treatment for epilepsy would simultaneously prevent seizures and protect neurons from the damaging consequences of seizure activity.

Background

Neurotrophic Factors and Neuroprotection

The past two decades have seen a surge in interest in the potential of protein growth factors to protect cells throughout the body. From the perspective of an epilepsy researcher, those protein factors capable of protecting cells in the nervous system, termed neurotrophic factors,

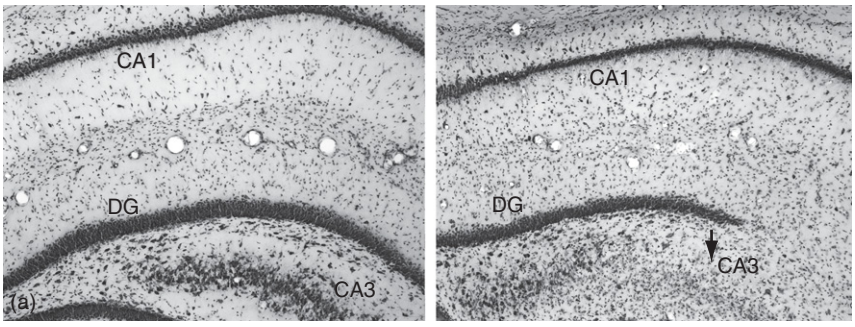

Figure 1 Neuronal loss induced by status epilepticus in rat hippocampus. (a) Photomicrograph of a normal cresyl violet-stained rat hippocampus showing CA1, CA3, and the dentate gyrus granule cell layer (DG). (b) A similar photomicrograph from a hippocampal section taken 24 h after the animal experienced pilocarpine-induced status epilepticus showing severe neuronal loss in CA3 (arrow) and thinning of the cell layer in CA1.

represent promising therapeutic candidates. These proteins – which protect neurons from insults ranging from oxygen deprivation and serum starvation to excitotoxic damage – have moved from the Petri dish into animal models. A number of these factors have been tested in animal models of seizure disorders, with varying degrees of success.

A Tale of Two Factors

Our laboratory has a long-standing interest in the potential of growth factors to protect neurons, and has focused on the potential of two growth factors – brain-derived neurotrophic factor (BDNF) and vascular endothelial growth factor (VEGF) – as treatments for epilepsy.

BDNF

BDNF is a member of the neurotrophin family of growth factors. Receptors for the neurotrophins include the p75 neurotrophin receptor, which binds to neurotrophins with low affinity, and the Trk (tropomyosin-related kinase) family of receptors, which bind preferentially to certain neurotrophins with high affinity. Of the three Trk receptors, only TrkB binds BDNF. While both BDNF and its relative, nerve growth factor (NGF), are upregulated after seizures, BDNF and TrkB are more widely distributed in limbic structures, making BDNF the more promising candidate for seizure neuroprotection. Before being tested as a protective factor in the context of epilepsy, BDNF proved to be protective in a variety of other situations, ranging from developing cells in vitro through in vivo models of various disorders. BDNF was first tested for neuroprotective potential after seizures using the kainic acid model of status epilepticus. In this model, animals are administered kainic acid intraperitoneally and develop status epilepticus (SE) within about an hour. Starting 24 h after SE, significant neuronal loss can be detected in the CA1 and CA3 pyramidal neurons as well as in the hilar neurons of the hippocampus. When exogenous recombinant BDNF was delivered in this model, it failed to significantly protect against neuronal death in CA1, and actually significantly worsened damage in CA3. Since BDNF had previously been considered a well-established neurotrophic factor, this result was unanticipated.

VEGF

In contrast to BDNF, VEGF was first described as a vascular factor. It was only a decade later that its potential as a neurotrophic factor began to be appreciated. Perhaps most relevant for seizure researchers, VEGF was shown to protect against excitotoxic damage in hippocampal cultures. However, because VEGF's primary signal-transducing receptors, VEGFR1 (Flt-1) and VEGFR2 (Flk-1, KDR), were not constitutively expressed on adult neurons, it was unclear whether VEGF would work as a protective factor in adult epilepsy. The discovery that VEGF receptors were upregulated after brain insult – e.g., after stroke or after status epilepticus – made this possibility more likely. Using pilocarpine-induced status epilepticus in rats (a chemoconvulsant model resembling the kainic acid model), we discovered that VEGF significantly protected hippocampal neurons from damage (see **Figure 2**).

Physiological Effects of Neurotrophic Factors

The interpretation of the protective effects of various neurotrophic factors has been complicated by the initially unexpected finding that many of these factors have acute physiological effects on neurons. Traditionally, these protein factors were thought to mediate only longer-term effects on cell survival, function, and morphology. As physiologists became more interested in studying growth factors, the initially heretical idea that these protein modulators could cause relatively rapid alterations in cell firing became a well-established fact. Because excitability is an important contributor to excitotoxicity, enhancement or suppression of neuron excitability has the potential to complicate both the interpretation of and the efficacy of neuroprotective effects of growth factors, including BDNF and VEGF.

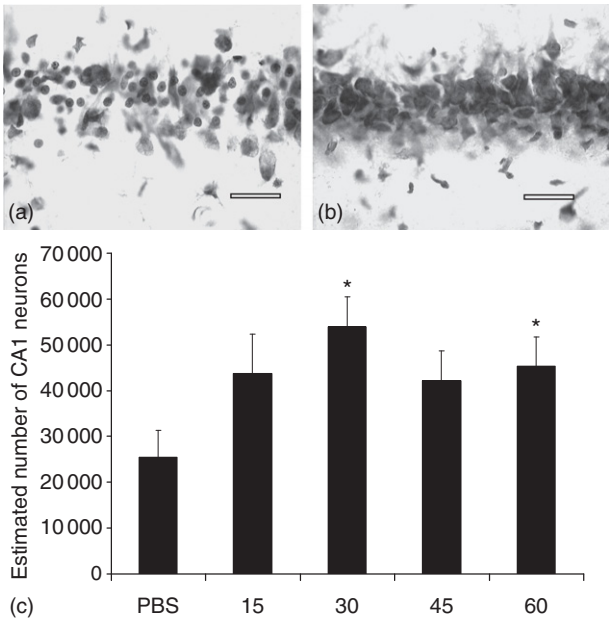

Figure 2 Rescue of hippocampal CA1 neurons by treatment with VEGF. (a) Rats treated only with vehicle (phosphate-buffered saline, PBS) show a normal loss of CA1 neurons 24 h after pilocarpine-induced status epilepticus. (b) CA1 neurons appear to be protected from status-epilepticus-induced cell death in the presence of VEGF. (c) This protection is statistically significant, as determined by stereological counting of CA1 neuronal profiles, *significantly more cells than PBS vehicle, $p < .05$, scale bars in (a, d) = 50 μm. Reproduced from Nicoletti JN, Shah SK, Goodman JH *et al.* (2008) Vascular endothelial growth factor (VEGF) is upregulated after status epilepticus and serves a neuroprotective role. *Neuroscience* 151(1): 232–241, with permission.

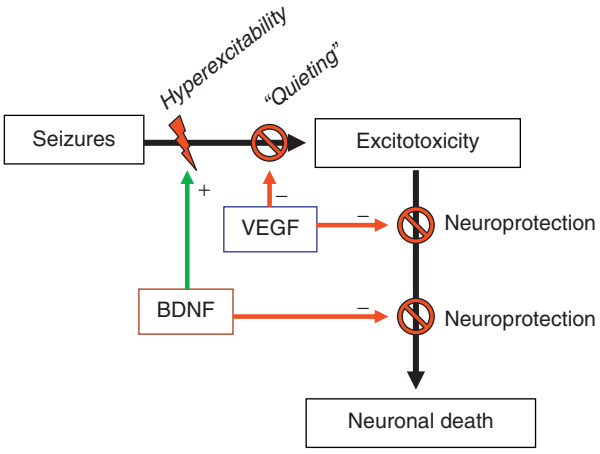

Figure 3 Dual actions of neurotrophic factors. Protein growth factors can prevent neuronal death either by signaling through cell survival pathways in neurons, thereby inducing direct neuroprotection, or by reducing neuronal excitability, thereby reducing excitotoxicity. Examples of two neurotrophic factors which can induce direct neuroprotection are BDNF and VEGF. However, one of these factors, VEGF, also has the potential to decrease excitotoxicity by reducing cell excitability while the other, BDNF, has the opposite effect.

Based on its established protective effects, BDNF was predicted to protect neurons from seizure-induced cell death. It was therefore surprising when BDNF increased neuronal loss in CA3, as indicated earlier. However, BDNF had also been shown to enhance synaptic transmission in hippocampal slices and to induce hyperexcitability – resembling epileptiform activity – in entorhinal/hippocampal slices. In vivo, mice transgenically overexpressing BDNF seized more readily while those deficient in BDNF were more resistant to seizure activation. Further, administration of BDNF protein to normal rats induced seizures in the absence of other convulsant stimuli. Some laboratories, however, have reported beneficial effects of BDNF against epileptogenesis, perhaps as a consequence of TrkB downregulation during certain administration paradigms. Given these results, BDNF's ability to increase excitability, potentially leading to increased excitotoxicity, could outweigh its ability to directly protect neurons (see **Figure 3**). It is for this reason that it is crucial for all potential neuroprotective agents to be evaluated for effects on neuronal excitability.

In contrast to the proexcitability effects of BDNF, the neurotrophic factor VEGF appears to 'quiet' neurons, making them less excitable. Like BDNF, this factor showed promising neuroprotective effects in other situations before being tested for efficacy against status epilepticus-induced neuronal loss. But unlike BDNF, VEGF showed significant efficacy in protecting hippocampal neurons from death after status epilepticus. While it is tempting to attribute this effect solely to VEGF's demonstrated protective effects, the interpretation of the mechanism of its efficacy is complicated by its physiological effects (see **Figure 3**). Specifically, since VEGF decreases the excitability of neurons in hippocampal slices, its protective effects could be mediated through reduced excitability rather than direct neuroprotection. The frustrations involved in interpreting the nature of VEGF's protective effects are, however, more than compensated for by the exciting possibility that VEGF may represent a therapeutic approach which both protects neurons from excitotoxic damage and reduces the likelihood that the patient will have seizures.

Methods

While there are many animal models of epilepsy and epilepsy-induced neuronal loss available, our laboratory has chosen to use the pilocarpine and kainic acid models of acute SE. Both models induce severe SE in the majority of animals injected, and both produce replicable damage to the brain, most striking in the pyramidal cells of the hippocampal CA1 and CA3 subfields, as well as hilar neurons. Damage continues to progress for several days

to a week after SE, which allows us the flexibility to study the brain either several days after SE to determine the full extent of damage, or 24 h after SE to study the process of cell death.

In either model, we introduce growth factors directly into the brain via implanted cannulae, because these large growth factors do not cross the blood–brain barrier. Growth factors can be administered acutely via injection through the cannula, chronically via infusion into the cannula by means of a pump, or genetically by introducing a virus delivering DNA or RNA for the growth factor into brain cells. This latter approach results in longer-term delivery of physiologically relevant levels of growth factors since the brain cells will then make increased levels of growth factor protein using the extra genetic material. In our laboratory, we deliver growth factors into the hippocampus, both because the cell loss after SE is striking in that structure, and also because hippocampal damage has been associated with well-defined behavioral impairments.

In our laboratory we use two approaches to quantifying the neuroprotective effect of growth factors – measuring neuronal density and evaluating behavioral outcome. Neuronal density is determined using stereological software which allows for unbiased estimates of cell density. Behavioral outcome is determined using the Morris water maze for learning and memory ability and the light-dark exploration task for anxiety levels, a measure of emotional tone. It has been well-established that hippocampal damage leads to impairment in both of these behavioral tests.

Results

Functional Preservation

While some work has been done looking at the potential of growth factors to protect against the neuronal loss caused by severe seizures, less work has been carried out to determine if this protection translates into behavioral rescue. Should neuroprotective factors rescue neurons from death, but fail to preserve their ability to function normally, these treatments would ultimately be of little clinical value.

Memory impairment stands out as the most carefully validated impairment in epileptic patients, especially those showing hippocampal sclerosis. While memory and emotional disturbances have been reported repeatedly in animal models of epilepsy, we have found that neuronal rescue and functional rescue after status epilepticus are not always linearly related. With VEGF, for example, we have documented approximately 50% rescue of neurons after status epilepticus. Two weeks after SE, VEGF-treated animals show full rescue from impairments in anxiety, but only partial rescue from learning and memory impairments in the Morris water maze. This 'discrepancy' points to the likelihood that the relation between neuronal and behavioral rescue will be complex, and that the ultimate functional outcome of neuronal rescue may depend on the type and location of rescued neurons, on the nature of the behavior measured, and on the functional status of the hippocampal circuitry that remains intact. Behavioral impairments can be induced in animals, for instance, simply by causing abnormal electrical spiking in the intact hippocampal circuit. In addition, abnormal brain chemistry has been found to be correlated with cognitive deficits in human epileptic patients, independent of gross anatomical lesions. Given the importance of functional preservation, it seems appropriate to eventually expand our definition of 'neuroprotection' to cover not just prevention of neuronal loss, but also protection of normal neuronal functioning. Indeed, researchers increasingly include preservation of normal neuronal physiology and circuitry in their definition of neuroprotection.

Directions for Future Research

While work in the area of neuroprotection in epilepsy is progressing, challenges remain. In addition to our work with BDNF and VEGF, promising data have been obtained by others with protein factors such as glial-derived neurotrophic factor (GDNF) and fibroblast growth factor-alpha (FGFα). Perhaps the biggest impediment to using any of these growth factors in human epilepsy is that the factors are too large to cross the blood–brain barrier. Therefore, chronic administration of these factors requires the introduction of an indwelling cannula into the brain, an approach which would not only be invasive, but would expose human epileptics to the risk of infection.

In an attempt to minimize the invasive nature of growth factor treatment, more research is currently being conducted using acute administration of viral vectors containing DNA or RNA (i.e., gene therapy) for growth factors. While this approach is invasive, it requires only one surgery, after which the brain can be left to heal. Preliminary data from our laboratory has suggested that gene therapy introducing extra copies of the VEGF gene is at least as effective as protein infusions in preventing neuronal death after status epilepticus. Gene therapy using other protective agents (e.g., GDNF) has already shown therapeutic potential in animal models of epilepsy. Once gene therapy is optimized in animal models, it may become possible to move this treatment strategy into humans. However, this approach is only likely to be undertaken in severe cases because it requires brain surgery. Treatment with growth factors for less severe cases may need to await the development of small molecules targeting growth factor receptors and signaling pathways.

In order to minimize the need for invasive therapies, our work is increasingly focusing on identifying the receptors and signaling pathways involved in growth factor-induced neuroprotection. Once these pathways are established, small molecule reagents could be sought which would emulate the beneficial effects of large protein factors without the need for brain surgery. The development of a neuroprotective small molecule would pave the way for a systemically administered drug (such as a pill) which could combat the brain damage and resultant behavioral impairments suffered by some epileptics.

Another advantage of identifying the particular receptors involved in the protective effects of factors such as VEGF is that most growth factors bind at multiple receptors which mediate multiple effects within the brain (e.g., VEGF signals through both VEGFR1 and VEGFR2 which have been proposed to modulate inflammation and vascular plasticity as well as protection). Selective targeting of the receptor which mediates neuroprotection would reduce side effects that could result from binding at those receptors not involved in the protective effects. Our laboratory is currently using reagents which preferentially block one VEGF receptor at a time in an attempt to discover which receptor mediates VEGF's protective effects in epilepsy.

While the search for therapeutic reagents emulating protein growth factors is ongoing, other laboratories are targeting the pathways which lead to neuronal death. All cells, for instance, share common biochemical cascades which mediate apoptosis, or programmed cell death. Protein growth factors are known to act via these pathways, with phosphorylation of their receptors leading to activation of the mitogen-activated protein kinase (MEK), extracellular signal-regulated protein kinase (Erk1/2), and/or phosphatidylinositol-3-kinase (PI3K)-Akt survival pathways (see **Figure 4**). Indeed, much of VEGF's neuroprotective effect in other systems appears to be mediated via the Akt pathway, but it also has the potential to mediate survival via the Erk pathway. Both of these pathways, as well as other trophic signaling pathways, lead to effects on components of cell death and survival pathways such as caspases, BAD, Bcl-2, Bax, Bim, and Bcl-w – all of which could impact on neuronal survival during seizures (**Figure 4**). For instance, animals deficient in Bcl-w and animals treated with a caspase-3 inhibitor both show enhanced cell protection after status epilepticus, validating the idea that neurons could be protected from SE-induced neuronal death by blocking the biochemical pathways leading to cell death.

While it is challenging to identify small molecule reagents that cross the blood–brain barrier, are soluble in water-based solutions, and selectively activate prosurvival signaling pathways, aggressive research in this area should lead us ever-closer to viable therapeutics. Inhibitors of programmed cell death would have to be used with care in young children with epilepsy, as programmed cell death is an important component of normal development. In older children and adults, however, this 'downstream' strategy for neuroprotection may one day be possible.

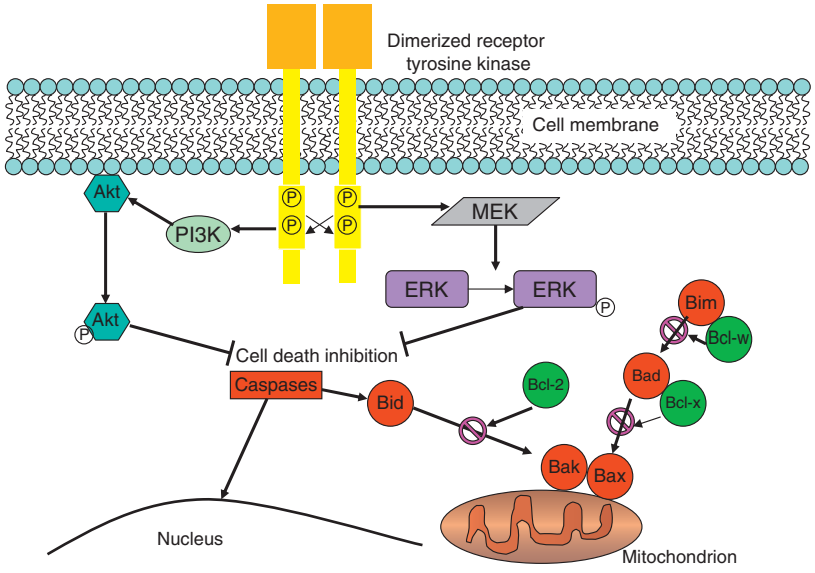

Figure 4 Signaling cell survival. Most protein growth factors transduce signals through biochemical pathways which can inhibit cell death. Two common prosurvival pathways are the PI3K/Akt pathway and the MEK/Erk pathway, both of which can be induced by transphosphorylation of dimerized receptor tyrosine kinases. This simplified cartoon illustrates some of the key players in these pathways, including the procell death mediators Bim, Bad, Bax, Bid, Bak, and cleaved caspases in red and the prosurvival mediators Bcl-2, Bcl-w, Bcl-x, in green. These substances could, themselves, become potential targets for neuroprotective therapeutics.

Whatever the eventual neuroprotective approach taken in humans, be it growth factor-related or not, preserving the brain of the epileptic patient is a promising strategy for maintaining normal functioning. The success of neuroprotective approaches could lead to a substantial enhancement in the quality of life of epileptic patients.

Introduction

Elucidating the cellular and molecular mechanisms of epileptogenesis could lead to novel therapeutic approaches aimed at the prevention or management of the disease. The discovery that limbic seizures increase nerve growth factor (NGF) mRNA levels led to the idea that seizure-induced expression of neurotrophic factors might contribute to the lasting structural and functional changes underlying epileptogenesis. Similarly, increases in neurotrophin expression that follow other insults (e.g., ischemia and traumatic brain injury) could also contribute to epileptogenesis. In the past decade, there has been an exciting confluence of in vitro and in vivo findings that strongly implicate the neurotrophin, brain-derived neurotrophic factor (BDNF), in particular, limbic circuits involved in the cascade of electrophysiological and behavioral changes underlying the development of the epileptic state.

Whatever the eventual neuroprotective approach taken in humans, be it growth factor-related or not, preserving the brain of the epileptic patient is a promising strategy for maintaining normal functioning. The success of neuroprotective approaches could lead to a substantial enhancement in the quality of life of epileptic patients.

Introduction

Elucidating the cellular and molecular mechanisms of epileptogenesis could lead to novel therapeutic approaches aimed at the prevention or management of the disease. The discovery that limbic seizures increase nerve growth factor (NGF) mRNA levels led to the idea that seizure-induced expression of neurotrophic factors might contribute to the lasting structural and functional changes underlying epileptogenesis. Similarly, increases in neurotrophin expression that follow other insults (e.g., ischemia and traumatic brain injury) could also contribute to epileptogenesis. In the past decade, there has been an exciting confluence of in vitro and in vivo findings that strongly implicate the neurotrophin, brain-derived neurotrophic factor (BDNF), in particular, limbic circuits involved in the cascade of electrophysiological and behavioral changes underlying the development of the epileptic state.

In particular, seizure activity increases the expression of BDNF mRNA and protein, and interfering with BDNF signal transduction inhibits the development of the epileptic state in vivo. The purpose of this article is to summarize the evidence regarding a role of BDNF in epileptogenesis, and to examine the implications of BDNF's involvement in epileptogenesis for new therapeutic targets.

Background

Historical Background

In 1982, BDNF, the second member of the 'neurotrophin' family of neurotrophic factors, was shown to promote survival of a subpopulation of dorsal root ganglion neurons, and subsequently purified from pig brain. The amino acid sequence of BDNF has a strong homology with NGF, the neurotrophin first described because of its trophic (survival and growth-promoting) effects on sensory and sympathetic neurons. Since the discovery of NGF in the early 1950s by Rita Levi-Montalcini and Viktor Hamburger, and the discovery of BDNF by Yves Barde and colleagues in 1982, other members of the 'neurotrophin' family such as neurotrophin-3 (NT-3) and neurotrophin-4/5 (NT-4/5) have been described. Each appears to have a distinct profile of trophic effects on distinct subpopulations of peripheral nervous system (PNS) and central nervous system (CNS) neurons.

BDNF Structure

The gene for the mature form of human BDNF has been mapped to chromosome 11p. The protein shares about 50% amino acid identity with human NGF, NT-3, and NT-4/5. The structure of each neurotrophin protein molecule contains: (1) a signal peptide important for intracellular sorting of the protein; (2) a pro-region containing an N-linked glycosylation site and a proteolytic cleavage site for furin-like pro-protein convertases; (3) the mature BDNF protein sequence; and (4) a distinctive three-dimensional structure containing two pairs of antiparallel β-strands and cysteine residues in a cystine knot motif. Neurotrophins are initially produced as proneurotrophins; prohormone convertases, such as furin, cleave the proneurotrophins (MW ~30 kDa) to the mature neurotrophin protein. Proneurotrophins have altered binding characteristics and distinct biologic activity in comparison with mature neurotrophins. Mature neurotrophin molecules are noncovalently-linked homodimers, with molecular weight about 28 kDa. The BDNF gene has four 5′ exons (exons I–IV) that are associated with distinct promoters, and one 3′ exon (exon V) that encodes the mature BDNF protein. Eight distinct mRNAs are transcribed, with transcripts containing exons I–III expressed predominantly in brain and exon IV found in lung and heart.

BDNF Signal Transduction

Each neurotrophin binds one or more of the trk (tropomyosin-related kinase) receptors, members of the family of receptor tyrosine kinases (RTKs). Trk proteins are transmembrane RTKs homologous to other RTKs, such as the epidermal growth factor (EGF) receptor and insulin receptor family. Ligand-induced receptor dimerization results in kinase activation; subsequent receptor autophosphorylation on multiple tyrosine residues creates specific binding sites for intracellular target proteins, which bind to the activated receptor via SH2 domains. The intracellular proteins that bind to the activated receptor include PLCγ1 (phospholipase C), p85 (the noncatalytic subunit of PI-3 kinase), and Shc (SH2-containing sequence); activation of these target proteins can then lead to a variety of intracellular signaling cascades, such as the Ras-MAP (mitogen-activated protein) kinase cascade and phosphorylation of CREB (cyclic AMP-response element binding protein).

Binding specificity is conferred via the juxtamembrane Ig-like domain of the extracellular portion of the receptor in the following pattern: trkA binds NGF (with low-affinity binding by NT-3 in some systems); trkB binds BDNF and NT-4/5 (with lower-affinity binding by NT-3); and trkC binds NT-3. Trk receptors exist in both a full-length (trkB.FL) form as well as truncated (trkB.T1, trkB.T2) forms lacking the kinase domain. Although most functions attributed to BDNF are associated with trkB.FL, several roles have been suggested for truncated receptors, including growth and development and negative modulation of trkB receptor expression and function. Expression of truncated trk receptors on astrocytes is upregulated following injury, and may modulate neuronal vulnerability and sequestration of BDNF in astrocytes. Recent studies have shown that BDNF activates glial calcium signaling by truncated trk receptors.

In addition, all of the neurotrophins bind to the p75 receptor, designated $p75^{NTR}$. $p75^{NTR}$, related to proteins of the tumor necrosis factor (TNFR) superfamily, has a glycosylated extracellular region involved in ligand binding, a transmembrane region, and a short cytoplasmic sequence lacking intrinsic catalytic activity. Neurotrophin binding to $p75^{NTR}$ is linked to several intracellular signal transduction pathways, including nuclear factor-κB (NF-κB), Jun kinase, and sphingomyelin hydrolysis. $p75^{NTR}$ signaling mediates biologic actions distinct from those of the trk receptors, notably the initiation of programmed cell death (apoptosis). It has also been suggested that p75 may serve to determine neurotrophin binding specificity.

Localization, Transport, and Release of BDNF

BDNF mRNA has a widespread distribution in the central nervous system, including limbic forebrain and

neocortex, and is abundant in all principal neurons of the hippocampus. Like BDNF mRNA, constitutive BDNF protein expression is widespread, localized on neuronal cell bodies, axons, and dendrites. The mossy fiber axons of hippocampal dentate granule cells display especially intense BDNF immunoreactivity. TrkB mRNA and protein are widespread in hippocampus. Truncated trkB is also found in the ependymal cells lining the ventricular cavities, effectively limiting diffusion of intraventricularly administered BDNF.

Unlike the classical target-derived trophic factor model in which neurotrophins (such as NGF) are retrogradely transported, there is now abundant evidence that BDNF is also anterogradely transported in brain. First, BDNF protein is localized to nerve terminals, and pathway transection or axonal transport inhibition eliminates this terminal expression. Second, high-resolution microscopic studies have shown that BDNF is associated with dense-core vesicles, which are the primary site for neuropeptide storage and release from nerve terminals. Third, functional studies have supported the anterograde transport hypothesis. Fourth, pro-BDNF is shuttled from the trans-Golgi network into secretory granules, where it is cleaved by prohormone convertase 1 (PC1).

In addition, emerging evidence suggests that both BDNF and trk receptors may undergo regulated intracellular transport. For example, seizures lead to redistribution of BDNF mRNA from hippocampal CA3 cell bodies to their apical dendrites. Trk signaling is now thought to include retrograde transport of intact neurotrophin–trk complexes to the neuronal cell body.

Evidence also indicates that neurotrophins are released acutely following neuronal depolarization. In fact, direct activity-dependent pre- to postsynaptic transneuronal transfer of BDNF has been demonstrated using fluorescently-labeled BDNF. The released form of BDNF is thought to be pro-BDNF, raising the possibility of postsecretory proteolytic processing by membrane-associated or extracellular proteases in the modulation of BDNF action.

BDNF Gene Regulation

A multitude of stimuli have been described that alter BDNF gene expression in both physiologic and pathologic states. Physiologic stimuli are known to increase BDNF mRNA content. For example, light stimulation increases BDNF mRNA in visual cortex, osmotic stimulation increases BDNF mRNA in the hypothalamus, and whisker stimulation increases BDNF mRNA expression in somatosensory barrel cortex. Electrical stimuli that induce long-term potentiation (LTP) in the hippocampus (a cellular model of learning and memory) increase BDNF and NGF expression. Even physical exercise has been shown to increase NGF and BDNF expression in hippocampus. Interestingly, BDNF levels vary across the estrus cycle, with BDNF levels correlated with changes in neural excitability.

Distinct BDNF 5′ exons are differentially regulated by different stimuli (such as neural activity). For example, exons I–III, but not exon IV, increase after kainic acid-induced seizures or other stimuli that increase activity. Protein synthesis is required for the effects of activity on exon I and II, but not on III and IV, raising the possibility that the latter act as immediate-early genes. The transcription factor CaRF activates transcription of exon III under the control of a calcium-response element, CaRE1. CREB, which can be stimulated by diverse stimuli ranging from activity to chronic antidepressant treatment, also modulates exon III transcription. Recent evidence also indicates that neural activity triggers calcium-dependent phosphorylation and release of MeCP2 (methyl-CpG binding protein 2) from BDNF promoter III to de-repress transcription.

Effects of BDNF on Synaptic Transmission

BDNF has an enormous range of physiologic actions at both developing and mature synapses, overall enhancing synaptic transmission by both pre- and postsynaptic mechanisms. The first studies of BDNF effects on synaptic transmission showed that BDNF increased the frequency of miniature excitatory postsynaptic currents (mEPSCs) at neuromuscular synapses in *Xenopus*. Since then, numerous studies have examined the actions of BDNF. Overall, BDNF appears to strengthen excitatory (glutamatergic) synapses and weaken inhibitory (GABAergic) synapses. Exposure of adult rat hippocampal slices to BDNF leads to a long-lasting potentiation of synaptic strength at Schaffer collateral-CA1 synapses. Subsequent studies have supported a role of BDNF in long-term potentiation (LTP). For example, incubation of hippocampal or visual cortical slices with trkB inhibitors inhibits LTP, and hippocampal slices from $BDNF^{-/-}$ mice exhibit impaired LTP induction – which is restored by reintroduction of BDNF.

Whether BDNF-induced synaptic potentiation occurs primarily by a presynaptic action (e.g., through enhancement of glutamate release) or postsynaptically (e.g., via phosphorylation of neurotransmitter receptors) is intensely debated. A number of studies have provided evidence for a presynaptic locus, but evidence for postsynaptic actions has also been obtained. Both pre- and postsynaptic trkB receptors in the hippocampus may be important.

A role for BDNF in GABAergic synapses was first raised by studies showing that BDNF influences GABAergic neuronal phenotype. Subsequently, BDNF was shown to decrease inhibitory (GABAergic) synaptic transmission. Recent evidence shows that BDNF can modulate the

function of $GABA_A$ receptors via modulation of phosphorylation state. Interestingly, BDNF may also regulate the efficacy of GABAergic synapses by direct downregulation of the neuronal K^+–Cl^- cotransporter, which would impair neuronal Cl^- extrusion and weaken GABAergic inhibition. Indeed, BDNF selectively decreases the efficacy of inhibitory neurotransmission by downregulation of Cl^- transport.

Methods

BDNF gene regulation by seizure activity has been studied at both the mRNA and protein levels. Changes in mRNA induced by seizure activity have been studied by Northern blot and in situ hybridization analysis. In Northern blot analysis, total RNA is extracted from a tissue sample, run on an RNA gel, and a specific labeled antisense oligonucleotide probe is used to detect the RNA of interest. Similarly, in situ hybridization utilizes a specific radiolabeled or chemically labeled antisense RNA strand to detect specific genes (in this case BDNF) in ex vivo tissue sections. While it is less quantitative than Northern blot analysis, the advantage of in situ hybridization is that not only the level but the anatomic site(s) of BDNF mRNA regulation can be determined. Immunohistochemistry, Western blot analysis, and ELISA (enzyme-linked immunosorbent assay) have been used to examine BDNF protein regulation following seizures. Immunohistochemistry, using a specific antibody to BDNF, has shown levels and anatomic sites of BDNF protein upregulation by seizure activity. ELISA and Western blot can be used to evaluate, in a more quantitative manner, BDNF protein levels in tissue extracts.

Studies of the function of BDNF on synaptic transmission and epilepsy have used both in vitro and in vivo techniques. Potentiation of synaptic strength by BDNF has been most commonly studied in ex vivo slices of hippocampus. In these studies, specific hippocampal synaptic pathways (e.g., Schaffer collateral-CA1 synapses) are stimulated electrically and the responses recorded in the presence and absence of bath-applied BDNF. Likewise, inhibitors of BDNF transmission (such as trkB inhibitors) or studies of hippocampal slices from $BDNF^{-/-}$ mice have shown impaired induction of long-term potentiation, a common model of synaptic plasticity and learning and memory.

In vivo studies of the role of BDNF in epilepsy have used animal models of epilepsy, such as the pentylenetetrazol (PTZ) model, kainic acid (KA) model, and kindling model. In these studies, BDNF or BDNF inhibitors are given in the attempt to affect epileptogenesis. For example, trkB receptor bodies (which sequester endogenous BDNF) have been injected chronically via an intracerebroventricular route and have been shown to inhibit epileptogenesis in the kindling model.

Epilepsy-Relevant Results

Role of BDNF in Animal Models of Epilepsy

The discovery that limbic seizures increase NGF mRNA levels led to the idea that seizure-induced expression of neurotrophic factors may contribute to the lasting structural and functional changes underlying epileptogenesis. It is now clear that BDNF and trkB are markedly upregulated by seizures. A wide variety of seizure paradigms (kindling, kainic acid, pilocarpine, PTZ, electroconvulsive shock (ECS)) rapidly and markedly increase expression of BDNF mRNA in dentate gyrus as well as in other areas of the hippocampus and cortex. This mRNA increase is associated with a transient upregulation of BDNF protein. TrkB mRNA and protein in the dentate gyrus are also upregulated following various seizure protocols. TrkB mRNA expression is increased in dentate granule cells 2–6 hours after rapid electrical kindling, hippocampal afterdischarge, PTZ kindling, ECS, or pilocarpine status epilepticus. Subcellular studies have demonstrated targeting of BDNF and trkB mRNAs to dendrites in CA3 neurons following kindled seizures.

Studies using the kindling model of epilepsy have functionally implicated BDNF in epileptogenesis. In the kindling model, repeated, focal application of initially subconvulsive electrical stimuli eventually results in intense focal and tonic–clonic seizures. Once established, this enhanced sensitivity to electrical stimulation persists for the life of the animal. The kindling model has been an important tool, since it allows experimental control over seizures and precise quantitation of effects of experimental manipulation on epileptogenesis in vivo.

The development of kindling is partially inhibited in heterozygote knockout BDNF mice or mice with conditional BDNF gene deletion. Intraventricular infusion of trkB-Fc, a chimera of human IgG-Fc domain and the extracellular domain of the trkB receptor that would sequester and limit the activity of endogenous BDNF, inhibits kindling development. Mice overexpressing a truncated trkB display reduced seizure susceptibility. Interestingly, conditional homozygous deletion of trkB appears to prevent kindling. These results are consistent with studies demonstrating that increasing BDNF promotes excitability. For example, direct application of BDNF to hippocampal slices induces hyperexcitability in vitro; overexpression of BDNF in transgenic mice leads to spontaneous seizures; and intrahippocampal infusion of BDNF is sufficient to induce seizure activity in vivo.

A separate group of experiments has demonstrated that chronic BDNF infusion can inhibit kindling. These inhibitory effects appear to be due to trkB receptor downregulation following chronic BDNF administration, and hence are still consistent with the 'proepileptogenic BDNF' hypothesis. This interpretation is supported by

the observation that chronic exposure to BDNF in vitro leads to downregulation of trkB mRNA and protein. Similarly, continuous in vivo intrahippocampal BDNF infusion results in downregulation of trkB protein by as much as 80%. Thus, whereas chronic BDNF infusion inhibits kindling progression, acute microinjections of BDNF enhance epileptogenesis in the absence of effect on trkB expression. Furthermore, chronic infusions of BDNF may upregulate the inhibitory neuropeptide Y.

Whether BDNF has a significant effect on seizure-associated mossy fiber sprouting is not clear. Although mossy fiber sprouting has been reported in $BDNF^{+/-}$ mice and following BDNF infusion, there is no effect on mossy fiber sprouting in BDNF-overexpressing mice or following chronic infusion or bolus injection of BDNF in other studies. However, BDNF overexpression does increase dendritic length and complexity in the hippocampus. The relative role of BDNF in synaptic changes vs. larger-scale morphological changes during epileptogenesis remains to be clarified.

Trk Receptor Activation Following Seizure Activity

The ability to monitor trk receptor activation following seizures using phospho-specific trk antibodies has enabled investigators to identify the anatomical, time course, and threshold characteristics of trk receptor activation in the hippocampus following seizure activity. Following seizure activity, phospho-trk immunoreactivity is selectively increased in dentate hilus and CA3 stratum lucidum of hippocampus. This distribution precisely coincides with the 'mossy fiber' pathway of dentate granule cell axon terminals. In addition, this anatomic pattern coincides with the distribution of both basal and seizure-induced BDNF protein. Basal BDNF protein is also localized in hilus and CA3 stratum lucidum, and seizures increase levels of BDNF protein in dentate gyrus and CA3 (and BDNF immunoreactivity in hilus and CA3 stratum lucidum). This precise anatomic colocalization of increased phospho-trk immunoreactivity and increases in BDNF protein suggests that the phospho-trk immunoreactivity is caused by seizure-induced increases in BDNF. However, interesting recent evidence also demonstrates transactivation of trkB in the mossy fiber pathway by the divalent cation zinc, in a neurotrophin-independent manner.

Perspective and Goals for Future Research

Since the discovery of BDNF in the 1980s, a great deal of evidence has mounted for roles of BDNF in development, physiology, and pathology. BDNF appears essential to molecular mechanisms of synaptic plasticity and larger-scale structural rearrangements of axons and dendrites. Basic activity-related changes in the central nervous system are thought to depend on BDNF modulation of synaptic transmission. However, pathologic levels of BDNF-dependent synaptic plasticity appear to contribute to epileptogenesis in a variety of animal models. On the basis of distribution, regulation, and localization studies, the hippocampus and closely associated limbic structures are thought to be particularly important in the proepileptogenic effects of BDNF. Specimens from patients with temporal lobe epilepsy have also demonstrated BDNF upregulation. It is hoped that understanding of the hyperexcitability associated with BDNF in epilepsy animal models may lead to novel anticonvulsant or antiepileptic therapies.

New methods of regulation of neurotrophins have been developed to achieve therapeutic efficacy in diseases of neurotrophin deficiency. For example, 'ampakines' represent a new class of compounds that have been shown to upregulate BDNF over a long period of time. Determination of proper dosing protocols, so as not to trigger downregulation of important neurotrophin signaling pathways, will be critical to avoiding deleterious side effects of these potential new therapies. Nevertheless, these and similar compounds are under active clinical investigation as cognitive and memory-enhancing drugs.

Manipulating neurotrophin action by simple up- or downregulation may lead to many nonspecific effects. For ultimate clinical application in specific conditions such as epilepsy, it will be very helpful to elucidate downstream neurotrophin signaling pathways responsible for specific phenotypic effects. For example, BDNF activation of trkB downregulates hippocampal KCC2, a K^+–Cl^- cotransporter; this suppresses chloride-dependent fast GABAergic inhibition and may partially account for BDNF modulation of GABAergic synapses. In addition, BDNF phosphorylates specific subunits of both the NMDA receptor and the $GABA_A$ receptor, altering their function. Longer-term effects of BDNF must take into account the fact that it upregulates many other plasticity-related genes, such as neuropeptide Y. NPY, for example, may not only modulate excitability but also other phenomena such as neurogenesis. Targeting the downstream pathways specifically associated with epileptic hyperexcitability, in an anatomically and temporally restricted manner, will be necessary for optimal therapeutic effect.

Introduction

All neurons and glia maintain an electrical potential across the cell membrane, which is negative relative to the extracellular environment. This negative potential provides a driving force for charged particles to move across the membrane. Every nerve impulse is dependent on this movement of ions. Most of these ions move through ion channels, along concentration gradients generated by electrogenic pumps, but some ions move across membranes on transporters. Abnormalities in the control of ionic movement across membranes can result in abnormalities in neuronal excitability.

With neuronal activity, action potential firing results in movement of potassium out of the cell and sodium into it. A single action potential will result in little change in the ion concentrations in the extracellular space. During seizures (i.e., intense neuronal activity), however, the amount of potassium moving out of neurons exceeds the ability of the brain to regulate precisely the ion concentrations, and the extracellular potassium will increase from a resting level of around 3 to 10–12 mM.

(ECB devices provided by NsGene A/S, Denmark). These experiments showed that such an approach is also effective in decreasing seizure severity and duration in kindled animals, and that the effect is dependent on the relative amount of GDNF released from these capsules. Unexpectedly, lower levels of released transgene GDNF seemed to be more effective rather than higher levels, as assessed by the relative intensity of GNDF immunoreactivity in the host hippocampal tissue surrounding the transplants (**Figure 2**).

We then explored some possible mechanisms that could underlie the seizure-suppressant effect of transgene GDNF. Among others, increased expression of neuropeptide Y (which has been shown to be induced, e.g., by BDNF exposure), decreased GFRalpha-1 receptor, and altered neurogenesis have been explored. However, none of these mechanisms seems to be critically responsible for transgene GDNF effects.

Future Goals

What remains to be explored is whether transgene GDNF can alter synaptic transmission in the hippocampus (directly or indirectly). It has been shown to upregulate glutamate transporters, in particular GLAST and GLT-1, which would result in more effective removal of elevated extracellular glutamate in chronic models of epilepsy. More directly, GDNF could modulate excitatory or inhibitory synaptic transmission in the brain, as shown in studies of GDNF effects on myocytes or cultured midbrain neurons. To achieve these goals, specific immonstainings and whole-cell patch clamp techniques will be used. Such experiments will reveal the mechanisms behind GDNF antiepileptic activity and will open possible novel research perspectives in using GDNF as a potential target molecule in gene therapy for epilepsy.

Introduction

The idea that the hippocampus is related to epilepsy, specifically temporal lobe epilepsy, has a long history of support from basic and clinical studies. One of the seminal questions is why the hippocampus appears to be 'seizure-susceptible' – in other words, why epileptiform discharges are readily evoked, and seizures often begin, within this structure. One hypothesis is that the hippocampus is designed to support diverse types of structural and functional plasticity under normal conditions, which is important to hippocampal-dependent functions, such as learning and memory. However, the mechanisms that support plasticity, especially mechanisms that increase glutamatergic transmission and synchronization, may lead to a greater risk of seizures.

Here we examine one of the neurotrophins that is expressed in hippocampus, BDNF. BDNF is one example of a modulator of hippocampal function that needs to 'balanced,' because it can induce plasticity that enhances normal hippocampal function, and it can induce seizures. It may contribute to plastic changes in the brain that are

associated with epileptogenesis, and hence 'pathological plasticity.' The paragraphs below provide an overview of the evidence that hippocampal BDNF may be one of reasons why the hippocampus is predisposed to seizures.

Background

Neurotrophins, their Receptors, and Distribution within Hippocampus

The neurotrophin family is composed of nerve growth factor (NGF), BDNF, neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). There are two receptors for neurotrophins: p75 and trk. All neurotrophins bind p75, which mediates important actions in development to prune excess neurons. In adult brain, and hippocampus specifically, the role of p75 is not yet clear. Effects of neurotrophins at trk receptors are better understood. Neurotrophins bind to selected trk receptors, as follows: NGF binds trkA, BDNF and NT-4/5 bind to trkB, and NT-3 binds to trkC. Compared to BDNF expression, the expression of NT-4/5 in hippocampus is weak, and the hippocampal effects of NT-4/5 are poorly characterized. Therefore, most consider BDNF the primary ligand for trkB in hippocampus.

Receptor dimerization after ligand binding is followed by receptor autophosphorylation and its participation in a variety of signaling pathways, such as the MAP kinase pathway, and many others. Trk activation ultimately leads to synthesis of transcription factors such as cyclic-AMP response element binding (CREB) proteins, which exert effects such as stabilization of LTP. Truncated trk receptors, which lack the internal kinase domain, appear to be expressed primarily on glia, and it has been suggested that the function of truncated receptors is to limit the effects of neurotrophins. However, truncated receptors exert specific effects besides simply binding the ligand even though they lack the kinase domain. However, the effects of truncate trkB in hippocampus are not clear at present time.

BDNF is synthesized from a precursor, proBDNF, which is thought to act primarily at p75 rather than at trkB receptors. Under normal conditions, proBDNF has actions that are limited by extracellular proteases such as furin, plasmin, or matrix metalloproteases that normally cleave proBDNF. Nonetheless, it is thought to play an important role in long-term depression (LTD) since proBDNF increases LTD in CA1.

BDNF mRNA is present in all principal cells of hippocampus, but normally protein expression appears to be primarily in granule cells, where BDNF is anterogradely transported to the mossy fiber axons. Interestingly, some antibodies detect BDNF preferentially in somatic locations, possibly because BDNF has different conformations in the soma versus axon.

After seizures, there are many changes in the expression of BDNF and its associated receptors. To date, evidence for the upregulation of proBDNF by seizures is weak, but there is robust evidence for a rapid increase in BDNF and trkB in granule cells. These changes appear to occur after a variety of types of seizures. The increase in BDNF and trkB may initiate changes associated with seizures, such as increased neuropeptide Y; BDNF induces NPY by trkB activation. p75 also increases after seizures, and may contribute to seizure-induced apoptosis.

BDNF may have widespread actions after seizures, beyond those that occur normally, because its expression increases in cells that normally translate message only at a low level, such as hippocampal pyramidal cells. BDNF may also change its subcellular location (somatic to dendritic). Therefore, after seizures, BDNF may have a more widespread role than its normal expression pattern would suggest.

The changes in BDNF and its receptors after status epilepticus (SE) in the adult rodent is especially interesting because chronic seizures develop in the subsequent weeks. It has been proposed that the upregulation of BDNF by the prolonged seizures that characterize status epilepticus may initiate epileptogenesis. It is possible that upregulation of BDNF after intermittent seizures also contributes to epileptogenesis, because deleting trkB in forebrain impairs epileptogenesis in the kindling model.

BDNF and Synaptic Plasticity in Hippocampus

Evidence that BDNF influences hippocampal synaptic transmission began with studies of Kang and Schuman, who showed that Schaffer collateral-evoked transmission was potentiated by perfusion of the slice ('bath-application') with recombinant BDNF. This effect was long-lasting, and it was suggested that BDNF induced a unique form of LTP. Subsequent studies extended these findings by showing that LTP was impaired in mice that lacked BDNF, as was learning and memory. Interestingly, many laboratories had difficulty replicating the BDNF-induced LTP in slices, and the reasons have never been completely clarified. Current ideas to explain discrepancies across laboratories include differences in the source of BDNF, its concentration, the flow rate, slice procedure, constituents of the buffer, and animal age. Age is a particularly interesting variable in the context of epilepsy, because there appears to be a decrease in epileptogenesis in aged animals; this decrease could be due to the decline in BDNF that occurs with aging.

Although there are discrepancies concerning BDNF-induced potentiation in slices, there currently is agreement that BDNF plays a critical role in the late phase of tetanus-evoked LTP in area CA1 and the dentate gyrus. It has been suggested that BDNF exerts its effect by influencing the factors that stabilize LTP. These are likely to involve ERK1/2 and the MAP kinase pathway in the dentate gyrus. The phospholipase Cγ (PLCγ) pathway could be

critical in CA1; disrupting trkB activation of the PLCγ pathway appears to block CA1 LTP. These, and other studies, suggest that both pre- and postsynaptic mechanisms contribute to the effects of BDNF on LTP, and mechanisms in dentate gyrus may be different from CA1.

BDNF has many other actions besides the potentiation of glutamatergic transmission on principal cells of hippocampus. Dentate gyrus neurogenesis is increased by BDNF by actions at trkB receptors on progenitors in the subgranular zone. The density and complexity of dendritic spines are increased by BDNF. Interneuron expression of neuropeptides is induced by BDNF, and BDNF downregulates KCC2, a potassium-chloride cotransporter that controls the transmembrane chloride gradient. $GABA_A$ receptor distribution is altered by BDNF. BDNF also influences specific sodium channels (NaV1.9), leading to depolarization. These actions, and others, make it highly likely that BDNF could influence multiple mechanisms involved in seizures, epileptogenesis, and epilepsy (Figure 1).

Methods

To address an issue such as the role of hippocampal BDNF in seizures and epilepsy, it is important to use methods that can examine the hippocampus at relatively high resolution, typically in vitro. It also is important to validate in vitro findings using an intact system, i.e., an in vivo approach. In vitro methods discussed below include electrophysiology in hippocampal slices, or morphological/structural studies in sections from perfusion-fixed brain. In vivo methods include recordings from animals that have chronic electrodes in hippocampus. Pharmacological analysis is challenging when neurotrophins are used, because there are few antagonists, and agonists are large molecules that do not diffuse well. Therefore, peripheral systemic injection – or even i.c.v. infusion – is not ideal. Direct application of drugs into hippocampus is one resolution to this problem, but controls are essential, because insertion of a cannula or needle into hippocampus can upregulate BDNF locally, and subsequently induce neuromodulators such as NPY. Obtaining proper controls is not trivial, however, because saline or buffer injection is inadequate to control for the effects of a large protein such as BDNF. Using cytochrome C as a control for BDNF is useful, because it has similar physical chemistry to BDNF but lacks activity at trkB. Another important consideration in these experiments is stress to the animal prior to use; stress has profound and complex time-dependent effects on BDNF levels, and

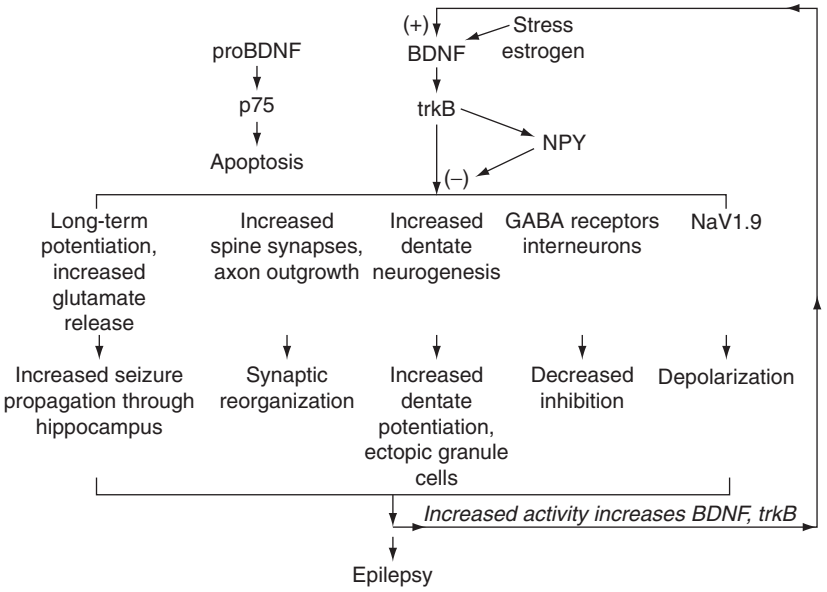

Figure 1 BDNF and epileptogenesis. A schematic illustrates the actions of proBDNF and BDNF that may contribute to epileptogenesis. ProBDNF via p75 could lead to seizure-induced apoptosis. BDNF via trkB has many potential actions, and most would be likely to facilitate seizures. For example, BDNF stabilizes LTP, and increases glutamate release in hippocampus, which could facilitate seizure propagation through hippocampus. Also, BDNF may contribute to synaptic reorganization because it promotes spine synapse formation and axonal outgrowth, although evidence for a role in mossy fiber sprouting, a striking example of synaptic reorganization that is thought to be relevant to epileptogenesis by many investigators, is unclear. BDNF increases neurogenesis of granule cells and ectopic granule cells in the hilar region, which could increase excitability of the dentate gyrus by increasing perforant path – evoked LTP, or by increased synchronization between granule cells and pyramidal cells. BDNF has many actions on GABA receptors and interneurons, and some of these effects would lead to disinhibition. Actions at NaV1.9 may depolarize hippocampal neurons. An important consideration is the fact that activity increases BDNF and trkB, which would potentially create a positive feedback loop in this schematic, and ultimately could underlie the development of chronic seizures (epilepsy).

glucocorticoids have effects on the target neurons of BDNF-expressing axons (e.g., CA3 pyramidal cells). Social housing and regular handling are important methods for reducing stress in experimental subjects.

Results

Initial Studies

Our initial experiments addressed the role of BDNF in mossy fibers. Mossy fibers appear to contain the most BDNF protein of all neurons in hippocampus, but most studies focused on area CA1 rather than mossy fibers. The high BDNF protein content of mossy fibers suggested retrograde effects on granule cells or anterograde effects on mossy fiber targets. To address potential effects on granule cells and mossy fiber transmission, the slice preparation was used with recording electrodes in multiple sites to detect potential effects. We found that application of recombinant BDNF potentiated mossy fiber transmission, with little detectable effect on granule cell physiology. The effect on mossy fiber transmission appeared to be selective for the excitatory input to pyramidal cells; inhibition was unaffected when IPSPs were recorded in pyramidal cells. In addition, even low doses of convulsants and GABA receptor antagonists could not reproduce the BDNF effect. Inputs to CA3 pyramidal cells from the fimbria and recurrent collaterals did not appear to be influenced by exposure to BDNF. Subsequent studies have shown high levels of BDNF in the large boutons of mossy fibers that innervate pyramidal cells, but not in the smaller boutons that innervate interneurons, explaining the preferential increase in glutamatergic mossy fiber transmission to CA3 pyramidal cells.

Mossy fiber stimuli (at 1–2 Hz) led to repetitive population spikes in area CA3 in the presence of BDNF; after three pairs of stimuli at 1 Hz, each stimulus evoked more than one population spike rather than a single population spike. This stimulation frequency is very low compared to that traditionally used to induce LTP, and stimulation was much shorter in duration compared to the stimuli required to induce LTD. The trains of population spikes occurred approximately in the range of gamma frequency, suggesting a novel mechanism to induce gamma oscillations in CA3. In some cases, the repetitive discharge was followed by spreading depression episodes, suggesting hyperexcitability. Indeed, gamma oscillations have been observed to precede epileptiform discharges. These data suggested a potential role of BDNF in seizure susceptibility of hippocampus.

Recombinant BDNF was perfused onto the slice at concentrations (50–250 ng ml^{-1}) that were in the range used by others, and thought to be physiologically relevant. However, the physiological in situ concentration of BDNF remains unclear. It is also unclear how much BDNF is retained in tissue slices (i.e., when tissue is prepared for in vitro studies), and some have suggested it actually is increased by the slice procedure. Therefore, alternate methods are necessary to confirm that the results seen in slices were not a pharmacological phenomenon. One approach to this problem involved using slices from a BDNF-overexpressing mouse line that had elevated BDNF in mossy fibers. BDNF was not added to the slice at all, but the same type of responses to mossy fiber stimuli were observed as those that were recorded from normal male rat slices after exposure to BDNF. Pairs of mossy fiber stimuli at 1 Hz led to repetitive population spikes and spreading depression. An in vivo approach was then used to examine the question of in vivo versus in vitro effects. BDNF was infused into hippocampus directly, and results were compared to the effects of cytochrome C or another large protein, albumin. Infusion of BDNF into the adult rat brain led to seizures in many of the rats, but no seizures were detected in controls.

Surprisingly, after BDNF was infused in vivo and seizures were observed, seizures did not continue, despite the fact that BDNF continued to be perfused for 2 weeks or more. In addition, some rats that were infused with BDNF did not exhibit seizures (although seizures were not monitored continuously, so some seizures could have been missed). One possible explanation for this loss of effect is that membrane trkB receptors are internalized when high doses of BDNF are infused. BDNF also induced NPY, which depresses mossy fiber transmission and has been shown to be anticonvulsant. It is intriguing to consider that BDNF potentiates the mossy fiber pathway, and also induces a potential 'brake' by increasing the synthesis of NPY. One would predict that an imbalance in BDNF and NPY might lead to seizures. Indeed, NPY knockout mice have increased seizure susceptibility, possibly by leaving BDNF–mediated excitation 'unchecked.'

Additional Studies from Other Laboratories

Studies from other laboratories have provided substantial evidence that BDNF plays a role in epilepsy. Seminal studies of Gall and colleagues first showed that BDNF message and protein were elevated after seizures, and the effect was extremely robust and rapid in granule cells – possibly more rapid here than in any area in the brain. In light of these data, as well as results from more recent studies, some have suggested that BDNF may be functionally similar to an immediate early gene, initiating a cascade of events that leads to changes in gene expression, which in turn alters the structure of synapses, axons, and excitability. These data support the concept discussed earlier that seizure-induced elevation in BDNF could initiate epileptogenesis.

Other studies led to more direct lines of evidence that BDNF was important to epileptogenesis. Using the

kindling model, and a scavenger of BDNF, Binder and colleagues demonstrated that scavenging BDNF impaired kindling. Binder and colleagues also showed the trk was phosphorylated in mossy fibers after seizures. Taken together, the results suggest that seizure-induced trk activation in mossy fibers could contribute to epileptogenesis in the kindling model. Other investigators infused BDNF into the hilus of the dentate gyrus and examined kindling. Given the results summarized earlier, one would predict that kindling might occur more rapidly. Instead, kindling was delayed, a result that caused some confusion in the field at the time. However, the issue was resolved after it was demonstrated that high doses of BDNF can down-regulate its receptor, trkB.

Transgenic approaches also provided evidence that BDNF influenced epileptogenesis. A number of transgenic lines have been developed, and the majority of the data from these mice indicate that BDNF is either proconvulsant or facilitates the process of epileptogenesis in animal models of temporal lobe epilepsy. For example, BDNF-overexpressing mice had a more severe seizures in response to the convulsant kainic acid, and gene mutations leading to elevated BDNF or trkB had similar actions. Interestingly, a conditional forebrain knockout of BDNF did not alter kindling epileptogenesis, but the knockout that lacked trkB had a robust effect: after-discharges were difficult to elicit by stimulation at the kindling site, thus retarding kindling. More recently it was shown that the ketogenic diet may act by blocking BDNF and trkB upregulation after seizures. Use of 2-deoxyglucose to inhibit glycolysis, an approach that simulates the effects of the ketogenic diet, led to a sequence of events that ultimately inhibited BDNF and trkB promoters.

The Role of BDNF in Epileptogenesis

As discussed earlier, the results of many studies implicate BDNF and trkB in seizures and epilepsy. How exactly do BDNF and trkB contribute? It seems likely that the normal actions of BDNF would facilitate the processes currently thought to play a role in epileptogenesis, as shown in Figure 1. These actions are discussed later in the context of the status epilepticus models for temporal lobe epilepsy. In these studies, status epilepticus is initiated in the adult rodent, and then is followed weeks later by recurrent limbic seizures.

One of the first questions one might ask is whether BDNF plays a role in the initial stage of the status models – i.e., in status epilepticus itself. On the basis of studies of a forebrain knockout mouse without trkB, it appears that trkB may indeed play a role in the induction of status epilepticus. In this mouse, it was difficult to elicit after-discharges using implanted electrodes, suggesting seizure activity was 'inhibited' relative to controls containing trkB.

Another question is whether BDNF plays a role in neuronal damage, one of the consequences of status epilepticus that is thought to be important in epileptogenesis. It seems likely that BDNF could increase neuronal damage by increasing glutamate release, which one would predict would contribute to excitotoxicity. Indeed, BDNF exposure does make excitotoxicity worse in CA3. In addition, proBDNF is likely to act on p75 to initiate apoptosis, since this is a normal function of proBDNF. This effect might be increased after status epilepticus, because p75 levels increase at this time. However, BDNF has also been reported to have neuroprotective actions. Therefore, the role of BDNF in seizure-induced neuronal damage is not clear at the present time.

There are several ways that BDNF could contribute to epileptogenesis; status epilepticus increases BDNF levels, and BDNF promotes synaptic plasticity. Therefore, after status epilepticus, elevated BDNF might induce long-term potentiation of glutamatergic circuits. Potentiation of glutamatergic circuits could increase the facility with which seizures propagate through brain areas such as hippocampus, thus enhancing the ability of focal seizures activity to generalize. Independent of its ability to potentiate synapses, BDNF could mediate some of the structural and circuit modifications that are thought to play a role in limbic epileptogenesis, such as increasing recurrent excitatory circuits. However, the evidence that BDNF mediates phenomena like mossy fiber sprouting, a classic example of synaptic reorganization, is unclear – despite numerous attempts to provide a causal link.

Another way that BDNF could facilitate epileptogenesis is related to its ability to increase the rate of dentate gyrus neurogenesis. In the normal brain, BDNF appears to increase survival of newly born granule cells, and the same may be true for granule cells that are born after seizures. However, whether an increase in survival of new granule cells increases or decreases seizure activity is hard to say, because those granule cells that migrate into the granule cell layer after status epilepticus appear to have normal excitability, whereas those that migrate to ectopic locations seem to develop abnormal excitability. At present, the influence of increased neurogenesis in the dentate gyrus on epileptogenesis is unclear.

Figure 1 illustrates these points, and also makes an additional point that is important to the argument that BDNF may contribute to epileptogenesis: even an increase in neuronal activity that is subthreshold for seizure generation can increase BDNF. That fact leads to the prediction that periods of brief, subthreshold seizure activity during early stages of epileptogenesis may increase BDNF repeatedly. Periodic elevations in BDNF may be important for the continued activation of plastic changes during epileptogenesis. After the first spontaneous seizure, a rise in BDNF would also be predicted, and

could explain the progression of epilepsy that many suggest continues long after the first spontaneous seizure.

Relevance of BDNF to Women with Epilepsy

Most studies of BDNF and trkB in rodents have been conducted in males, and clinical studies have not described gender-specific effects. The lack of investigation in females is surprising given that estrogen has a response element on the BDNF gene, and BDNF appears to fluctuate as a function of estrogen, particularly in the mossy fiber pathway. Therefore, the female brain may inherently change BDNF protein content as estrogen varies; that in turn could change seizure susceptibility. In the epileptic brain, when BDNF levels are chronically high, a normal fluctuation in estrogen may elevate BDNF well above the range that is normal and lead to seizures.

This hypothesis is relevant to women with epilepsy where seizures fluctuate across the menstrual cycle – e.g., when estrogen surges just before ovulation (the 'periovulatory period'). It is also potentially relevant to the subset of women who have seizures which increase in severity at the end of the cycle, the 'perimenstrual' period, because estrogen rises and falls just before this time of the cycle also. Therefore, elevated BDNF could occur in the 'perimenstrual period,' when seizures have been reported to increase in a subset of women with epilepsy. Hormonal regulation of BDNF could also play a role in the changes in seizures that occur during pregnancy, when estrogen rises.

We hypothesized that estrogen would induce BDNF in the mossy fibers during the normal preovulatory estrogen surge, and this BDNF increase would lead to a similar increase in CA3 evoked responses as observed in the BDNF-overexpressing male mouse (or normal male rat that was exposed to exogenously-applied BDNF). Using intact female rats, and then ovariectomized and estrogen-replaced rats, we found that BDNF was elevated in mossy fibers after estrogen was increased. In the intact rat, the elevation in mossy fiber BDNF was present on the morning of proestrous, when estrogen reaches a peak. It was also detected for the next 24 h, presumably because BDNF stores had not been depleted. Similar results were obtained from ovariectomized rats when proestrous morning was simulated by timed injections of estradiol to mimic the proestrous surge in estradiol. In slices from these ovariectomized, estrogen-replaced rats, mossy fiber stimuli evoked repetitive population spikes and spreading depression, similar to slices from BDNF-overexpressing male mice, or slices from the normal rat that were exposed to BDNF. K252a, an inhibitor of trk receptors, blocked the repetitive spiking, and the spreading depression.

These data lead to the hypothesis that BDNF plays a role in the hormone-sensitive seizures of women with epilepsy. Is there evidence for this hypothesis from clinical studies? So far there have been no studies of BDNF levels in women with epilepsy. Serum or CSF values of BDNF would be potentially useful, but they are unlikely to be as informative as mossy fiber BDNF levels. To examine mossy fiber BDNF, an animal model would be useful, but there are few animal models that simulate women with epilepsy. Indeed, most animals with recurrent seizures lose reproductive function. However, the data from female rodents that have been administered estradiol suggest that seizure threshold declines in response to estradiol administration (but not always). A mechanism that is dependent on BDNF/trkB has not been explored.

Future Goals

It has been widely hypothesized that BDNF and trkB are proconvulsants, and contribute to epileptogenesis. Exactly how they do so, and how critical they are, remain to be seen. If one could downregulate BDNF in the epileptic brain, would that manipulation stop seizures? These questions become a priority for future studies. Unfortunately, specific antagonists to BDNF and trkB are critical to address these questions, but limited in availability.

Another priority is to establish how important mossy fiber BDNF is to epileptogenesis. Silencing the mossy fiber pathway selectively could address the issue, but compensatory changes could confound such an experimental approach.

A third question is whether women with epilepsy have seizures at particular times when estrogen rises because of BDNF induction. An animal model of epilepsy that replicates the female condition would help address the issue. So also would be a way to block – selectively – the response element on the BDNF gene. Unfortunately, this approach is difficult because most animal models of epilepsy in female rodents lead to a loss of reproductive function.

Finally, if BDNF and trkB are critical, what about the other neurotrophins? Mossy fibers also express NT-3, and seizures appear to downregulate NT-3 when they upregulate BDNF. NT-3 also appears to regulate other neurotrophins. It may be necessary to consider not only BDNF but also other neurotrophins in order to gain a complete perspective and address therapeutic strategies with the best chances of success. There are many hypotheses still to be tested, exploring the potential for new therapeutic approaches to epilepsy based on BDNF mechanisms.

Neuroprotective Strategies in Epilepsy

Introduction

From the earliest attempts to develop treatments for epilepsy, the primary goal of epilepsy therapeutics has been seizure control. Since seizures are not only pathognomonic for epilepsy, but also represent a significant problem for patients, this strategy has been both rational and fruitful. However, in spite of the development of a wide array of anticonvulsant drugs, some patients have poorly controlled seizures while many more report breakthrough seizures. Efforts to seek better anticonvulsant treatments are ongoing, and these efforts have been accompanied by a concurrent effort to protect the brain from the damaging effects of seizures.

Using animal models, epilepsy researchers have discovered that seizures lead to permanent changes in the brain circuitry. Some of these changes, such as mossy fiber sprouting, could potentially be associated with seizure progression. In addition, uncontrolled seizures may cause a loss of brain cells. Humans with chronic temporal lobe epilepsy (TLE) show neuronal loss, sclerosis, and atrophy, especially in the hippocampus. In animal models, the occurrence of severe seizures leads to cell loss in various regions of the brain, especially the limbic system. As illustrated in **Figure 1**, the hippocampus of rodents has proved to be exquisitely sensitive to the excitotoxic cell death induced by seizures, and this cell loss in the animal model reflects the damage profile seen in human TLE. Behavioral studies in animals have also shown that seizure-related cell loss is associated with functional impairments, such as memory decline and emotional deficits, similar to findings in humans where epilepsy has been associated with functional impairments ranging from memory loss to alterations in mood. Protecting neurons in the human epileptic brain may protect against functional impairments.

As a consequence of the realization that seizures beget neuronal loss and behavioral impairment, epilepsy researchers are increasingly interested in pursuing neuroprotective strategies in epilepsy. Protecting neurons from death or functional compromise after seizures would, in the short term, prevent some of the far-reaching consequences of breakthrough seizures. In the longer term, the optimal treatment for epilepsy would simultaneously prevent seizures and protect neurons from the damaging consequences of seizure activity.

Introduction

All neurons and glia maintain an electrical potential across the cell membrane, which is negative relative to the extracellular environment. This negative potential provides a driving force for charged particles to move across the membrane. Every nerve impulse is dependent on this movement of ions. Most of these ions move through ion channels, along concentration gradients generated by electrogenic pumps, but some ions move across membranes on transporters. Abnormalities in the control of ionic movement across membranes can result in abnormalities in neuronal excitability.

With neuronal activity, action potential firing results in movement of potassium out of the cell and sodium into it. A single action potential will result in little change in the ion concentrations in the extracellular space. During seizures (i.e., intense neuronal activity), however, the amount of potassium moving out of neurons exceeds the ability of the brain to regulate precisely the ion concentrations, and the extracellular potassium will increase from a resting level of around 3 to 10–12 mM.

At the same time calcium, magnesium, sodium, and chloride enter cells, and the extracellular concentrations of these ions will decrease. After any activity that alters the ionic gradients, there needs to be 'correction' of the concentrations back to the baseline, to 'resting' state. Potassium, which is elevated, can diffuse away, can be taken up into neurons or glia by active pumps, or can be taken up by passive processes into astrocytes. Ions that are low in the extracellular space (Na^+, Ca^{2+}, Mg^{2+}, Cl^-) can be adjusted by diffusion back into the area of low concentration, or ions can be pumped out of cells back into the extracellular space.

Astrocytes are the most numerous type of glial cell. They are involved in the maintenance of the blood–brain barrier, in the regulation of water and ion homeostasis, and in metabolism of amino acid transmitters. Astrocytes are proposed to play a major role in the maintenance of the extracellular space, including the concentrations of the various ions. In particular, astrocytes are thought to contribute a significantly to the removal of excess potassium through glial 'spatial buffering,' through activation of the glial Na–K pump, and via activation of inwardly rectifying potassium channels. Astrocytes also have sodium, chloride, and bicarbonate transporters and exchangers that contribute to the regulation of these ions in the extracellular space. And astrocytes express multiple calcium channels, suggesting that they also play a role in regulation of calcium levels.

Background

Since ion-selective electrodes have been available, a number of investigators have measured changes in extracellular potassium in a several brain regions during neuronal activity. During seizures or intense neuronal activity, the extracellular potassium increases to 10–12 mM. In the hippocampus, the peak potassium levels measured during seizures are slightly higher in the dentate gyrus than in CA1, but overall the changes are similar. At the same time as the potassium is increasing, calcium, magnesium, sodium, and chloride enter cells, thus lowering the extracellular concentrations of these ions. As a result of these ionic shifts, the extracellular space shrinks and becomes acidic.

Increases in extracellular potassium ($[K^+]_o$) are known to increase neuronal excitability. The small increases in $[K^+]_o$ measured with interictal bursts have been postulated to contribute to the transition between interictal and ictal activity. The increases in $[K^+]_o$ have also been shown to facilitate spread of seizure activity to nearby and synaptically connected regions. Interestingly, during seizure activity, the $[K^+]_o$ increases to a ceiling of about 10 mM – it does not continue to rise with ongoing neuronal activity. This observation suggests that the mechanisms that are clearing the $[K^+]_o$ are keeping pace with the amount of potassium moving out of the neurons with each action potential. Understanding the mechanism(s) that clear the potassium from the extracellular space would lead to an understanding of how the brain can regulate neuronal excitability.

Intracellular and extracellular pH changes may have fundamental importance in regulating neuronal excitability. Small changes in intracellular and extracellular pH have been shown to alter the function of ligand- and voltage-gated channels. Since transient pH changes may be confined to localized regions of the extracellular space, these pH transients may play a role in signaling by altering neuronal excitability locally. Movement of hydrogen ions across membranes in the central nervous system is controlled largely by two families of acid–base transporters. The Na/H (NHE) and the bicarbonate-dependent transport families are a diverse group of transport proteins. The sodium/HCO_3 cotransporter (NBC) is found in glia throughout the hippocampus and in the granule cells of the dentate gyrus, supporting a role of glia in the regulation of pH in the hippocampus and providing a possible explanation for the differential pH regulation in the dentate gyrus compared to CA1. In one model of pH regulation, neuronal activity causes an increase in extracellular potassium and depolarization of astrocytes, which stimulates the movement of H^+ out of the astrocytes; as a result, the intracellular space within the glia becomes more alkaline while the extracellular space becomes more acidic. The combination of the regional diversity in pH regulation and the sensitivity of neuronal excitability to small changes in extracellular pH suggest that pH regulation may play a part in spread of epileptiform activity.

Intracellular and extracellular calcium also contribute to neuronal excitability. Normally intracellular calcium is maintained at very low levels, but measurable increases occur in neurons with action potential firing. Changes in extracellular calcium are somewhat more complex, in that neuronal activity alone does not necessarily result in significant and sustained decreases in calcium. However, any decrease in extracellular calcium would increase neuronal excitability, in part due to a loss of surface charge screen. Decreasing calcium in the perfusion solution results in multiple population spikes in CA1 in response to a single stimulation, indicating multiple action potential firing instead of the normal single action potential. If the extracellular calcium decreases below 0.5 mM, spontaneous epileptiform activity has been reported. In the presence of small elevations in extracellular potassium, neurons in the hippocampus are more sensitive to small decreases in calcium.

Changes in extracellular magnesium, sodium, and chloride have not been studied to the same extent as potassium, calcium, and pH. However, during epileptiform activity, decreases in extracellular sodium and biphasic changes in extracellular chloride have been measured.

Lowering of the extracellular magnesium would be predicted to increase transmitter release from presynaptic terminals, thus increasing neuronal excitability. Lowering of magnesium would also decrease the surface charge screen, and if the decrease is sufficient, NMDA receptors may be affected. Since chloride concentrations affect function of GABA receptors, alterations in the extracellular chloride could produce changes in inhibitory function.

Methods

There have been two major approaches to studying changes in extracellular ion concentrations and their roles in epileptogenesis. One is to monitor ion concentrations (in either anesthetized rats or in in vitro brain slice preparations) with ion-sensitive electrodes – before, during, and after seizure activity induced by any of a number of methods. The second approach is to alter the extracellular ion concentration to determine the effect this manipulation has on epileptiform activity. The latter procedure is most commonly done in in vitro systems of brain slices or organotypic cultures.

Recording of extracellular ion concentrations is carried out using double-barrel ion-sensitive electrodes. Double-barrel electrodes are prepared by silanizing one barrel of the electrode to make it hydrophobic and then filling just the tip of that side with an ion-exchange resin for the ion of interest. The remainder of the electrode is then filled with a solution containing the ion to be measured. The other side of the electrode is filled with a saline solution for recording of the extracellular field potentials. The electrode is calibrated in a series of standard solutions around the expected concentrations of that ion in the brain. The electrode is placed into the brain region of interest, and the ion signal is determined by a differential amplifier. Both barrels of the electrode measure the field potential changes, and the side with the ion-exchange resin also measures the concentration of that particular ion. The differential amplifier then subtracts the field potential from the additive signal, providing an output that reflects the changes in ion concentration. These double-barrel electrodes have been used in both in vivo and in vitro preparations. A newer method involves insertion of one barrel (of a 'double electrode') inside a second barrel. This modification shortens the effective column length of the ion-exchange resin, which improves the response time of the electrode. However, because of the physical properties of this electrode, it works well only in in vitro preparations. Using either method, one can record changes in extracellular ions before, during, and after epileptiform activity.

The effects of changes in extracellular ions can be determined in in vitro systems by altering the perfusion solution to levels of ions recorded in vivo. For example, when recording extracellular calcium in vivo, it was determined that the calcium falls to various levels during different types of epileptiform activity. These levels of extracellular calcium can then be reproduced (in isolation) in vitro to determine the significance of these changes. One can ask, for example, if this lower level of calcium is sufficiently low to block synaptic transmission, or only low enough to increase excitability. Such information is, in turn, used to address the question of whether/how the changes in physiological function due to the change in ionic concentration contribute to epileptiform activity. Of course, changing levels of only one ion does not mimic the situation in vivo, where many ions will change simultaneously during epileptiform activity. However, combinations of ion manipulations can be reproduced in in vitro preparations.

Recent Results

It is well known that extracellular potassium concentrations ($[K^+]_o$) increase during intense neuronal activity, including seizures (Figure 1). Glial cells are believed to play a major role in the regulation of the $[K^+]_o$ increase. Using ion-selective electrodes, we examined the $[K^+]_o$ changes in the dentate gyrus of urethane-anesthetized adult rats, comparing the changes in the presence of reactive astrocytes and after reduction of glial function. The regulation of $[K^+]_o$ in the dentate gyrus was determined by measuring the ceiling level of $[K^+]_o$ and the half-time of recovery of $[K^+]_o$, during and after seizures produced by 20-Hz trains of stimulation to the angular bundle. Reactive astrocytes were induced by repeated seizures and their presence was confirmed by a qualitative increase in glial fibrillary acidic protein (GFAP) and appearance of vimentin immunoreactivity. In the presence of reactive astrocytes, there was no significant change in the peak $[K^+]_o$ during seizures, but there did appear to be

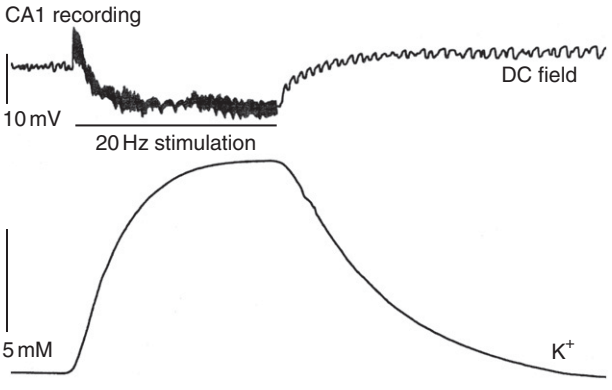

Figure 1 Field recording in CA1 of the extracellular field potential (top) and the extracellular potassium concentration (bottom) before, during and after a 20 Hz stimulation to the contralateral CA3 region in vivo.

a trend toward a faster recovery of the $[K^+]_o$ toward baseline as compared with control animals. To inhibit glial function, fluorocitrate (FC), a reversible metabolic inhibitor, was injected into the dentate gyrus region and the regulation of $[K^+]_o$ was monitored for 8 h. Fluorocitrate significantly slowed the rate of recovery of $[K^+]_o$. Overall, the results suggested that normal glial function is required for the recovery of elevated $[K^+]_o$ after seizures in vivo.

It was somewhat surprising that the ceiling level of $[K^+]_o$ was not elevated after loss of astrocytic function. At this ceiling level, it is presumed that the potassium is in a state of active equilibrium (or steady-state). Active neurons release potassium, which is then taken up by neurons or glia at the same rate. Based on this hypothesis, it would be predicted that changing glial cell function (either increase or decrease) would result in a change in the ceiling level of $[K^+]_o$ during seizures. The results of these experiments did not support this hypothesis. In addition, although there was a statistically significant change in the rate of recovery of $[K^+]_o$ after seizures when glia function was altered, the change was relatively small. One must wonder what physiological significance this small change would have on neuronal function or excitability.

In order to investigate further the mechanisms that might contribute to regulation of activity-dependent variations in $[K^+]_o$, we examined spontaneous recurrent epileptiform activity induced in the dentate gyrus of hippocampal slices from adult rats. Seizures were induced by perfusion with 8 mM potassium and 0-added calcium medium. Local application of TTX blocked local $[K^+]_o$ changes, suggesting that potassium is released and taken up locally. Perfusion with barium (0.2–0.3 mM) or cesium (1–3 mM), blockers of the inward rectifying potassium channel that is postulated to mediate glial uptake of potassium, did not alter any of the measures of $[K^+]_o$ regulation. If gap junctions between glial cells are critical for the spatial buffering of the $[K^+]_o$, then reduction of gap junction conductance should alter $[K^+]_o$ regulation. Decreasing gap junctional conductance only decreased the ceiling level of $[K^+]_o$. Perfusion with furosemide (which blocks cation/chloride cotransporters) or perfusion with low chloride increased the ceiling level of $[K^+]_o$. Bath or local application of ouabain, a Na^+/K^+-ATPase inhibitor, increased the baseline $[K^+]_o$, slowed the rate of $[K^+]_o$ recovery, and induced spreading depression. Together, these findings suggest that potassium redistribution by glia plays only a minor role in the regulation of $[K^+]_o$ in this model. The major regulator of $[K^+]_o$ in this model appears to be uptake via a Na^+/K^+-ATPase, most likely neuronal.

Studies of changes in hydrogen ion concentration (pH) have proved to be quite interesting, in part because the changes during seizure activity are not the same in all brain regions. It is clear that neuronal activity results in alterations in both intracellular and extracellular pH. The measured changes in extracellular pH are within the range of pH values that have been shown to alter neuronal activity. In vivo and in vitro, in the CA1 region, recurrent epileptiform activity induced by stimulus trains, bicuculline, and kainic acid results in biphasic pH shifts, consisting of an initial extracellular alkalinization followed by a slower acidification (**Figure 2**). In CA1, the acidification consistently peaks after termination of the after-discharge, and the peak level of acidification correlates with the duration of the after-discharge, suggesting a contribution of neuronal activity to the level of acidification. Both GABAergic and glutamatergic neurotransmission have been reported to cause alkalinization. In the CA1 region, this alkalinization was decreased by inhibition of carbonic anhydrase and increased by addition of GABA agonists (diazepam and phenobarbital), which is consistent with a key contribution to pH changes by activation of $GABA_A$ receptors (rather than through activation of glutamatergic receptors). The observation that pH fluctuation is linked to synaptic transmission is supported by the observation (in slices) that, in nonsynaptic conditions, there is no initial alkalinization. In the dentate gyrus in vivo and in vitro, seizure activity induced by stimulus trains to the angular bundle, by injection of either bicuculline or kainic acid, or in in vitro nonsynaptic conditions was only associated with extracellular acidification.

The role of astrocytes in these extracellular pH changes during neuronal activity was examined using local injection of fluorocitrate and fluoroacetate into the CA1 cell layer, where there is both alkalinization and acidification. Both glial toxins reduced the peak level of acidification, without changing the lengthening of the after-discharge. The peak level of acidification was still correlated with the total discharge duration, but the levels of acidification were consistently lower than in control animals. Administration of either glial toxin had no effect on the peak alkalinization during the stimulus train, on the rate of recovery from peak level of acidification, or on the amplitude or frequency of the neuronal discharge during the after-discharge. These results suggest that,

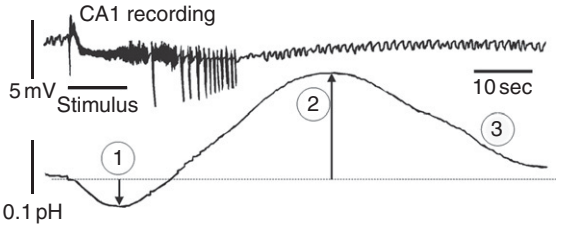

Figure 2 Field recording (top) and extracellular pH (bottom) are shown before, during and after a stimulus train to the contralateral CA3 region in the hippocampus in vivo. Early on (1) synaptic activity results in alkalinization. The peak acidification (2) is dependent on the after-discharge duration. The recovery phase (3) is the least well understood.

in normal conditions, astrocytes contribute to the acidification of the extracellular space that occurs in response to intense neuronal activity. Such acidification may contribute to feedback regulation of neuronal excitability.

Changes in extracellular calcium ($[Ca^{2+}]_o$) have also been studied in the hippocampus in vivo. In urethane-anesthetized Sprague-Dawley rats, changes in $[Ca^{2+}]_o$ were measured in response to stimulus frequencies of 10 and 20 Hz. Maximal changes in $[Ca^{2+}]_o$ were recorded in the cell body layers of CA1 and the dentate gyrus. In the dentate gyrus there was a secondary drop in $[Ca^{2+}]_o$ with the appearance of maximal dentate activation (appearance of the large amplitude population spikes, Figure 3); that is, the largest changes in $[Ca^{2+}]_o$ in the dentate gyrus were recorded during maximal dentate activation. To investigate the role of astrocytes in regulation of in $[Ca^{2+}]_o$, local injections of fluorocitrate, a metabolic toxin selectively taken up by astrocytes, were used. FC, but not vehicle, caused a small but significant decrease in the maximal changes in $[Ca^{2+}]_o$ in CA1, but an increase in the dentate gyrus. The results suggest that astrocytes play a minimal role in the regulation of $[Ca^{2+}]_o$ during epileptiform activity.

Future Goals

Because concentrations of the various ions in the extracellular space clearly contribute to neuronal excitability, understanding the mechanisms by which these ions are regulated will further our understanding of the manner in which neuronal excitability can be controlled. This insight is especially important for understanding the conditions in which seizures begin and how seizures are terminated. Action potentials open channels, allowing ions to flow down concentration gradients, resulting in changes in the extracellular ion concentrations. Much of the work in the past has focused on the significance of these changes in ionic concentrations on neuronal function. But it is also important to determine the mechanisms by which the ion concentrations are returned to the baseline levels, the 'recovery' of the ion concentrations, especially after intense neuronal activity such as a seizure.

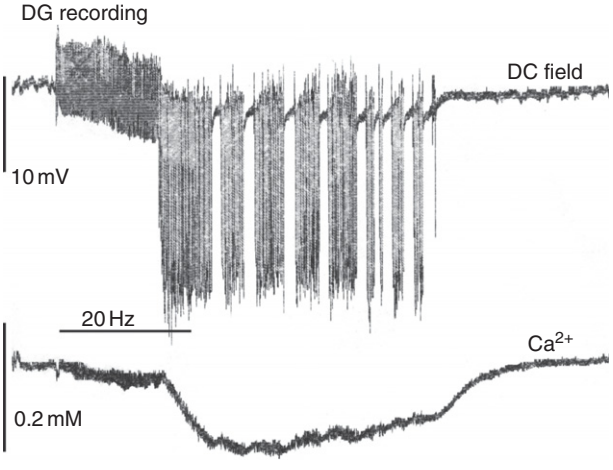

Figure 3 Extracellular DC field recording (top) and extracellular calcium concentration (bottom) in the dentate gyrus (DG) before, during and after a 20-Hz stimulus train to the contralateral CA3 region in vivo.

Largely because they do not fire action potentials, the study of glial cells and their role in brain function is an area of investigation that has lagged behind the study of neurons. However, it is now clear that glia contribute to neuronal function. One way in which they can control neuronal excitability is in the maintenance of the extracellular environment. There are many unanswered questions about the relationship between glial function in controlling extracellular ion concentrations and neuronal activity. For example: Does the glial spatial buffer for potassium slow the recovery of the potassium gradient that is necessary for normal neuronal function? Can the astrocytes regulate extracellular calcium concentrations – and if so, how does that affect neurotransmitter release?

Are there changes in the mechanisms that regulate the extracellular environment in a chronically epileptic brain (compared with 'normal' brain), and do these changes contribute to the epileptic state? It is known that a number of ion channel mutations are present in families with epilepsies. Do these channel mutations alter the ionic composition in the extracellular space? Channel biophysics would suggest that a mutation that results in a channel staying open longer would allow more ions to flow through that channel. But would this difference in ion flow contribute to the seizures in this instance, or are the seizures arising from another mechanism? It is known that a number of pumps, transporters or cotransporters are responsible for the maintenance of ion gradients. One could postulate that a single nucleotide change in a transporter protein could result in a shift in the efficiency of the transport, resulting in an increased (or decreased) seizure threshold.

Finally, are there methods by which one could intervene to influence the regulation of these ion gradients, and thus to reduce the likelihood of a seizure starting – or to augment the ability of the brain to stop a seizure once it has started? For example, more rapid or efficient transport activity could shorten the post-ictal state and improve recovery after a seizure.

Introduction

The global behaviour of a neuronal population is largely determined by its connectivity patterns, established through chemical synapses and gap junctions. The excitability of individual neurons within a network is usually assumed to be fixed once their synaptic inputs and distribution of ion channels are specified. In view of this assumption, it is not surprising that the vast majority of the research on basic mechanisms of, and therapeutic treatments for, epilepsy focuses on synaptic mechanisms and ion channel properties.

Another means through which neurons can communicate is the extracellular space (ECS). Although the role of the ECS in epilepsy has been much less studied than synaptic mechanisms, it has long been hypothesized that alterations of the ECS can modulate neuronal synchrony and excitability – through nonsynaptic mechanisms. ECS-dependent mechanisms that may play important roles in epilepsy include changes in the electrical resistivity of brain tissue, local ephaptic interactions, long-range electric field effects, changes in extracellular ion concentrations, and the diffusion pathways of neuromodulating molecules.

The size of the ECS is a dynamic entity that can undergo both long-term and short-term changes. Two important measurable variables used to quantify changes of the ECS are (i) extracellular volume fraction (EVF), a measure of the relative volume of the tissue that is available for the diffusion (between cells) of extracellular substances and (ii) tortuosity, a measure of the increase in the diffusion path length between two points in the tissue, beyond what it would be without any pathway barriers. The baseline values of EVF and tortuosity, as well as their susceptibility to change, can vary significantly between

Changes in the Extracellular Space as a Modulator of Excitability and Epileptogenicity

D W Hochman, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The global behaviour of a neuronal population is largely determined by its connectivity patterns, established through chemical synapses and gap junctions. The excitability of individual neurons within a network is usually assumed to be fixed once their synaptic inputs and distribution of ion channels are specified. In view of this assumption, it is not surprising that the vast majority of the research on basic mechanisms of, and therapeutic treatments for, epilepsy focuses on synaptic mechanisms and ion channel properties.

Another means through which neurons can communicate is the extracellular space (ECS). Although the role of the ECS in epilepsy has been much less studied than synaptic mechanisms, it has long been hypothesized that alterations of the ECS can modulate neuronal synchrony and excitability – through nonsynaptic mechanisms. ECS-dependent mechanisms that may play important roles in epilepsy include changes in the electrical resistivity of brain tissue, local ephaptic interactions, long-range electric field effects, changes in extracellular ion concentrations, and the diffusion pathways of neuromodulating molecules.

The size of the ECS is a dynamic entity that can undergo both long-term and short-term changes. Two important measurable variables used to quantify changes of the ECS are (i) extracellular volume fraction (EVF), a measure of the relative volume of the tissue that is available for the diffusion (between cells) of extracellular substances and (ii) tortuosity, a measure of the increase in the diffusion path length between two points in the tissue, beyond what it would be without any pathway barriers. The baseline values of EVF and tortuosity, as well as their susceptibility to change, can vary significantly between

different anatomical regions. These region-specific differences are due, in part, to differences in cell packing and geometry, the relative proportion of glial cells to neurons, and metabolic rates. For example, Nicholson and colleagues have reported that the resting EVFs of the CA1 and CA3 regions in hippocampal slices are approximately 0.14 and 0.20, respectively – a difference that reflects the denser cell packing in the CA1 region. Pathological conditions, such as those observed during ischemia, have been noted to cause rapid and distinctly different effects on the EVFs and tortuosities of the different hippocampal regions. In particular, ischemia causes a dramatic reduction of the EVF in area CA1 with little effect on its tortuosity, whereas the tortuosity of area CA3 significantly increases with much smaller effects on its EVF. It might be expected that conditions which favor a significant reduction in the EVF in a region may enhance electric field interactions between neurons, by increasing the electrical resistivity of the tissue and by bringing neuronal cell bodies closer together. In contrast, conditions that favor an increase in tortuosity of a region may enhance the duration and magnitude of transient increases in extracellular potassium, since the K^+ is less capable of dissipating through passive diffusive forces.

Background – Overview of Mechanisms and Evidence of ECS Modulation of Epileptogenicity

Specific ECS-related mechanisms are often described as if they are independently acting mechanisms. However, it is important to note that ECS-dependent mechanisms are coupled, interdependent, and work in parallel with each other and with synaptic mechanisms. For example, changes in extracellular potassium concentrations following large increases in neuronal activity may cause a reduction of the size of the ECS that can further concentrate extracellular ions and increase ephaptic interactions, thus leading to an additional enhancement of neuronal firing and synaptic activity.

Modulation of Epileptogenicity Through Osmolarity Effects on the ECS

It has long been noted in the clinical literature that decreases in plasma osmolality, which presumably lead to cell swelling and a decrease of the ECS, increase electrographic brain activity and the likelihood of developing seizures. Examples of this phenomenon are seen in patients suffering from hyponatremic seizures resulting from water intoxication. The acute hyponatremia, induced by the dilution of extracellular fluids, leads to significant cerebral cell swelling. In contrast, increased plasma osmolality has been observed to suppress seizure susceptibility. In support of this notion, it has been reported that intravenous administration of large quantities of osmolytes such as urea can stop status epilepticus in human patients.

The effects of changes in osmolality can be reproduced and studied in a variety of experimental settings. Osmolytes such as mannitol, when administered intravenously in sufficient quantities, can block kainic acid induced status epilepticus in rats and suppress interictal spiking in human subjects. Epileptiform activity in various in vitro slice models can also be up- or down-regulated by decreasing or increasing the osmolarity of the perfusion medium. Observations that osmolarity alters both the size of the ECS and epileptogencity in parallel have been interpreted as supporting the view that the size of the ECS itself may directly modulate epileptogenicity.

Extracellular Ion Concentrations

Changes in the extracellular concentrations of all ion species are associated with increases in neuronal activity. For example, in vivo rat studies with ion-selective microelectrodes have shown that normal increases in neuronal activity in the hippocampus and neocortex can result in the increase of extracellular potassium concentrations ($[K+]_0$) from 3 to 5–6 mM, and intense epileptic activity can further increase this concentration to 12 mM. At the same time, extracellular calcium ($[Ca^{2+}]_0$) can drop from its resting levels of 1.0–1.4 mM to as low as 0.6 mM with intense neuronal activity. In vitro slice studies by Stringer and Lothman have shown that simultaneous alterations of $[K^+]_0$ and $[Ca^{2+}]_0$ can work synergistically to modulate epileptogenicity. Even moderate alterations of the concentrations of these ion species together can dramatically influence the propensity of tissue to develop spontaneous discharges. Observations such as these suggest a number of possibilities through which the ECS and ion concentrations can interact to modulate excitability and epileptogenicity. For example, an impairment of the ion homeostatic mechanism in the ECS, as observed in some experimental seizure and trauma models, might increase seizure susceptibility. Additionally, conditions that lead to a significant alteration of the ECS, such as changes in neuronal firing activity or in osmolarity, in effect, change the concentration of extracellular ions by shifting water between intra- and extracellular compartments.

Cation-Dependent Chloride Cotransport

In vitro hippocampal slice studies (using tissue from adult rats) have shown that the loop diuretic, furosemide, a cation chloride cotransporter antagonist, blocks epileptiform activity in a wide variety of seizure models, regardless of the underlying synaptic mechanisms. For example, furosemide blocks epileptiform activity in the 'zero-calcium' model in which all chemical synaptic activity is

absent, and in which the epileptiform discharges must be mediated entirely through mechanisms other than chemical synapses. Other in vitro studies have shown that furosemide diminishes glial cell swelling during conditions of increased $[K^+]_0$, and blocks decreases in the ECS of hippocampal slices during stimulation-evoked and epileptiform discharges. Some evidence suggests that the furosemide blockade of epileptiform activity occurs concomitantly with the blockade of activity-evoked cell volume and ECS changes.

Taken together, these results suggest that cation chloride antagonists affect some mechanism common to all the tested seizure models (even those that are not dependent on chemical synaptic interactions) that is necessary for the maintenance of epileptiform activity. The antiepileptic effects of furosemide may be related to its action on an ECS-dependent mechanism, such as its blockade of activity-evoked cell swelling.

Ephaptic and Other Electrical Interactions

There are several ways in which neurons that are not physically connected through gap-junction or chemical synapses can interact electrically through the ECS. One such type of electrical interaction, called ephaptic coupling, is usually meant to describe electrical interactions between neuronal processes that are in close apposition. This interaction occurs when the extracellular potential generated by a neuron causes depolarization of other nearby neurons. Ephaptic interactions are increased with increasing electrical resistivity of the tissue. Ephaptic interactions may be an influential neuronal synchronizer under conditions where the resistivity of the tissue is significantly increased or when neuronal processes are brought closer together. Such changes would occur when water moves from the ECS into intracellular compartments, causing cell swelling and the reduction of the EVF. Intense neuronal activity and increases in plasma osmolality are two examples of conditions that can lead to enhanced electrical coupling through this mechanism.

Other types of longer-range electrical effects are also present in neuronal tissue, and are usually referred to as electric field interactions. Electric fields generated by the activity of a subpopulation of neurons have been shown to influence the excitability of inactive neurons, nonsynaptically, by decreasing their membrane potentials and thus bringing them closer to threshold for action potential generation. For example, intracellular recordings of transmembrane potentials of CA1 hippocampal neurons have demonstrated that population spikes can excite inactive neurons within the population. Evoked field potentials in laminar structures such as hippocampus and neocortex can be relatively large, reaching over $50\,\mathrm{mV\,mm^{-1}}$ in hippocampus. Electric field oscillations, such as 1 Hz slow waves observed in neocortex, can reach several millivolts per millimeter. Under normal conditions, the amplitudes of these types of electric field effects are not of sufficient magnitude to elicit action potential firing from surrounding neurons. However, they may contribute importantly to action potential firing and the spread of epileptic activity under conditions in which the excitability of neurons has already been increased through other means. Shrinkage of the ECS following intense neuronal activity has been shown to enhance these electric field effects, enabling them to elicit action potentials from neurons that would otherwise be below their firing threshold.

Effects of Osmolarity and Cell Volume Changes on Neuronal Ion Channels

The transition of an ion channel between its open and closed states can be thought of as a change between two conformational states of a protein. A channel spanning a cell membrane has an aqueous core with an internal osmolarity that is different from the osmolarities of the solutions comprising the intra- and extracellular spaces. For the channel to open in the presence of solutes inaccessible to its pore, it must do work to extract water from the solutions outside of its opening. The amount of work that a channel must do to transition between these states is determined by an osmotic pressure gradient (i.e., by the differences in the concentrations of solutes between the inside of the channel and its external environments). It is a theoretically intractable problem to calculate how changes in the osmolarity of the ECS might bias the state-preference of a channel, since osmolarity is a concept defined within the framework of equilibrium thermodynamics, whereas the physiological situation is one of nonequilibruim due the different concentrations of solutes within the fluids comprising the intracellular and extracellular compartments. Therefore, empirical measurements are required to determine whether the kinetics of a given type of channel is affected by changes in the osmolarity of the ECS in a way that can influence the excitability of a neuron. In view of this requirement, it is important to test the effects of osmolarity on channel properties in preparations in which in the various subpopulations of neurons and their synaptic contacts are present, and under conditions that mimic the types of osmolarity changes that might be observed in vivo.

Studies performed on hippocampal slices demonstrate that osmolarity can affect properties of specific channels, on subtypes of neurons, in important ways that could modulate network epileptogenicity. Yaari and colleagues have shown that changing the osmolarity of the ECS by 13% can significantly affect the persistent Na^+ current in hippocampal CA1 pyramidal neurons, a current that plays an important role in determining neuronal excitability and synaptic integration. In their studies, a reduction of

the osmolarity of the ECS converted nonbursting pyramidal cells into bursting neurons. Baraban and colleagues demonstrated that decreasing the osmolarity of the ECS by 10% in hippocampal slices resulted in a significant enhancement of a voltage-activated potassium current of inhibitory CA1 interneurons, while leaving the corresponding current in excitatory CA1 pyramidal cells unaffected. This effect would likely reduce the firing activity of inhibitory cells and thus contribute to an overall increase in network excitability.

A number of studies on cultured neurons have demonstrated the presence of volume-sensitive, stretch-activated ion channels. Many cell types undergo a regulatory volume decrease (RVD) in response to cell swelling following a decrease in extracellular osmolarity. A number of mechanisms are known to be involved in mediating the RVD, including changes in the activities of various ion cotransporters and the activation of volume-sensitive K^+ and Cl^- channels. Okada and colleagues have reported that volume-sensitive outwardly rectifying Cl^- channels are activated in cortical neurons during cell-swelling. These channels could contribute to altering neuronal excitability, and have been linked to apoptotic cell death; blockade of these channels prevents swelling-evoked cell death in various types of cultured neurons. It has not yet been determined whether these volume-sensitive anion channels are present and play a role in modulating epileptogenicity and apoptosis in vivo or in acute slice preparations.

Methods – Measuring Ion Concentrations and Properties of the ECS

Quantitative measurements of activity-evoked changes in extacellular ion concentrations, EVF, and tortuosity have most commonly been accomplished with ion-selective microelectrodes (ISMs). A typical ISM consists of a double-barreled glass microelectrode, with the tip of one barrel containing a liquid membrane that allows for selective transport of a specific ion (i.e., the ion exchanger), and a second barrel that is a potential-sensing electrode, used as a reference. The barrel with the liquid membrane tip is filled with an electrolyte solution containing the ion of interest, so that a Nernst potential is generated across the ion-exchanger when the tip of the ISM is immersed in solutions containing different concentrations of the ion. The signal recorded by the potential-sensing reference barrel is subtracted from the one recorded by the ion-selective barrel as a means to compensate for changing background potentials. Ion exchangers are available that make it possible to measure the concentrations of various ions of physiological interest, including K^+, Na^+, Ca^{2+}, Cl^-, and H^+. In practice, ISMs have poor sensitivity for measuring extracellular changes in Na^+ and Cl^- because activity-evoked changes of these ions are relatively small with respect to their ambient concentrations.

ISMs can also be used to measure changes in tortuosity and volume fraction of the ECS. This measurement process involves iontophoresing the membrane-impermeant treamethlyammonium ion (TMA^+) into the tissue at a fixed location, and measuring the concentration-time profiles of this ion with an ISM at a known distance from the TMA^+ source. Software can then be used to fit these data to a solution of the diffusion equation, from which EVF and tortuosity can be numerically estimated. References providing the details involved in making these types of measurements are provided in Further Reading.

Recent Results

Molecular Mechanisms Associated with the ECS

Aquaporin-4 and epileptogenicity

The aquaporins are membrane-bound proteins that function as water channels and are found in a variety of cell types. The presence of these water channels facilitates the transport of water between the intra- and extracellular spaces, and they may play an important homeostatic role under conditions of osmolarity changes. The predominant aquaporin found in the brain is aquaporin-4 (AQP4), which has been found to be expressed in glial cells, lining surfaces that are in contact with cerebrospinal fluid in the ventricular system and subarachnoid space. AQP4 is also expressed in the process of astrocytes that are in contact with blood vessels.

The putative role of AQP4 in epileptogenesis has recently been investigated in knockout mice (AQP4−/− mice). AQP4−/− mice have been found to have higher seizure thresholds than normal mice in response to PTZ and electrical stimulation-evoked seizures. The expression of AQP4 has also been studied in sclerotic hippocampal tissue acquired from patients suffering from medically intractable temporal lobe epilepsy. A significant increase in AQP4 expression has been observed in sclerotic, but not in nonsclerotic hippocampal tissue. These data suggest that alterations in the expression of AQP4 – which likely plays a role in the redistribution of water between cellular, ECS, and ventricular/subarachnoid/vascular compartments during increased neuronal activity – may modulate epileptogenicity.

Volume changes regulating phosphorylation and activity of ion cotransporters

Transient volume changes in the ECS involve the redistribution of water between intra- and extracellular spaces, resulting in either cell swelling or shrinking. There are several cell volume-regulating mechanisms in neurons and glia that may play a role in modulating the epileptogenicity of neuronal tissue. Critical for maintaining

transmembrane chloride gradients in neurons are the Na^+–K^+–$2Cl^-$ (NKCC1) and K^+–Cl^- (KCC2) cotransporters. NKCC2 typically transports solutes, and in particular, chloride, from extracellular to intracellular spaces, using the abundance of extracellular sodium to drive potassium and chloride into cells. Conversely, KCC2 moves solutes from intracellular compartments into the ECS by using the high intracellular potassium concentration to drive chloride against its concentration gradient.

In addition to being important regulators of intracellular chloride (and therefore of $GABA_A$-mediated synaptic events), these cotransporters are thought also to be important regulators of cell volume. Evidence suggests that during cell-swelling, KCC2 becomes upregulated and increases its cotransport activity, becoming more efficient in moving solutes from intracellular into extracellular spaces. Oppositely, NKCC1 becomes less active, reducing the influx of solutes from the ECS. The net result is that intracellular osmolarity is reduced so that that water influx is diminished. When neurons are shrunken below their normal resting state, perhaps from an increase in the osmolarity of the ECS, KCC2 and NKCC1 are again regulated oppositely in such a way as to restore osmotic balance. Several families of protein kinases, including WNK and SPAK, that may play a role in regulating transporter activity have recently been identified; the presence of these kinases themselves may be directly modulated by changes in cell volume. These cotransporter-related mechanisms represent another means through which changes in the ECS can modulate excitability.

Pharmacological and Electrophysiological Investigations of the Role of ECS in Human Epilepsy

Rationale

We have recently begun intraoperative experiments on the effects of ECS-altering treatments in consenting patients undergoing surgical treatment for epilepsy. In this context, we have shown the effects of mannitol and furosemide on spontaneous interictal spiking and stimulation-evoked afterdischarge activity. Mannitol is an inert osmolyte – i.e., it is not significantly metabolized in the body and does not participate in pharmacological interactions; its physiological effects are believed to be limited to the changes it elicits in plasma osmolality. Furosemide is a loop-diuretic and an NKCC1 cotransporter antagonist. As mentioned earlier, evidence from in vitro slice studies suggests that furosemide suppresses epileptiform activity, possibly through its effects on the ECS.

Methods

Several aspects of the usual surgical procedure for the treatment of epilepsy offer a fortuitous opportunity to acquire experimental data directly relevant to the study of ECS alterations. After a craniotomy is performed to expose the cortex, a focal area of interictal activity is localized and an array of EEG recording electrodes is placed on the surface of the cortex. These electrodes allow for the recording of spontaneous interictal spiking directly at its site of initiation, as well as from adjacent sites that show no abnormal activity. Electrophysiological data from the EEG electrodes are acquired before and after i.v. administration of furosemide or mannitol, which are commonly administered during neurosurgical procedures to prevent brain swelling. The EEG data are digitized, and automated software is used to quantify changes in spike frequency and amplitude over time. In some experiments, a stimulating electrode is also placed on the cortical surface to test for the effects of mannitol and furosemide treatments on afterdischarge activity. The cortex is initially stimulated for 4 s with currents of increasing amplitudes. A stimulating current is found that is just sufficient to elicit several seconds of afterdischarge activity (i.e., activity that persists following cessation of the stimulus); this current level is defined to be the 'afterdischarge threshold.'

Results

Four patients were given a single 50-g intravenous injection of mannitol while spontaneous interictal activity was recorded (**Figure 1**). In each experiment, the site of the maximal spontaneous interictal activity was localized, and referred to as the 'interictal focus'; recordings from electrodes 1–2 cm away showed significantly fewer or no interictal spikes. Only those EEG events that were ≥ 3 SD from the average EEG baseline value were counted as spikes. Data were analyzed over two time intervals: (i) a first 20-min duration that was a control period prior to mannitol treatment, and (ii) a final 20-min duration at the end of the 1-h recording session (i.e., starting 40-min after mannitol had been administered). After mannitol administration, the average spontaneous interictal spiking frequencies of the four patients was reduced by ~60%. Several minutes prior to the decrease in interictal activity, there was a noticeable change in the morphology of the interictal spikes; their peak-to-peak amplitudes decreased, with a proportion of spikes losing their biphasic structure and becoming broader. Prior to administration of mannitol, the mean interspike interval was 3.5 ± 0.12 s (99% CI = [3.2 s, 4.0 s]). After mannitol treatment, the mean interspike interval was increased to 8.3 ± 0.36 s (99% CI = [6.3 s, 9.2 s]). A *t*-test rejected the null hypothesis that the mean interspike intervals before and after mannitol administration were the same ($P < 0.0001$). A similar study was performed on five patients in which a single intravenous bolus injection of furosemide (20 mg) was administered (data not shown). Within 10–30 min after administration of furosemide, the

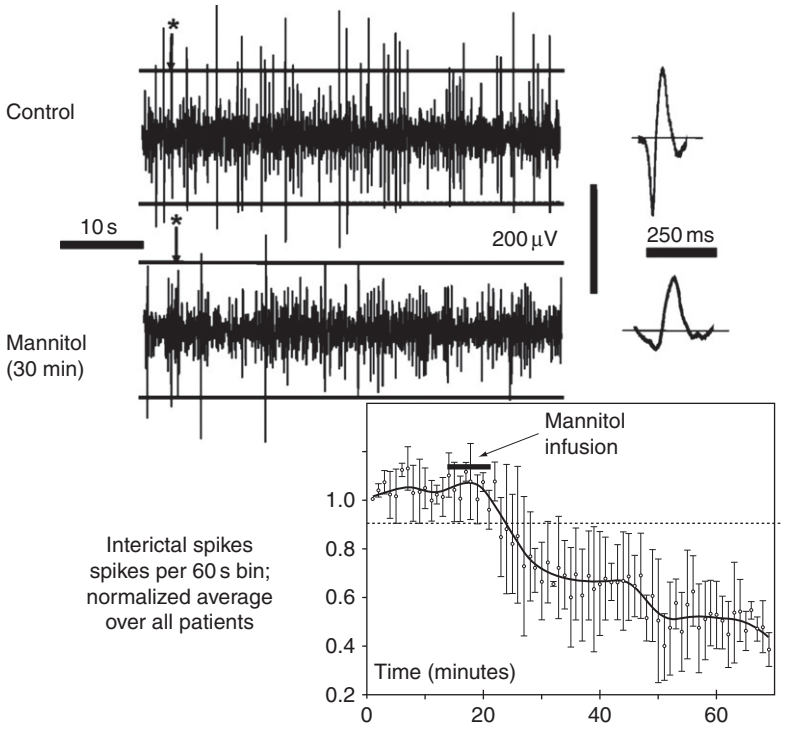

Figure 1 Suppression of spontaneous epileptic spiking activity after mannitol administration. Electrophysiological activity was recorded from EEG electrodes placed on the cortical surface (parahippocampal gyrus) before and after administration of a 50-g intravenous injection of mannitol (data from an individual patient is shown in the top 2 traces, top left). Events that differed from the mean activity by ≥3 SD, indicated by the horizontal lines, were counted as spikes. Mannitol suppressed the frequency of spontaneous activity within 30 min after administration in all patients. Prior to mannitol treatment, all spikes typically had a sharp biphasic waveform (first top right trace). Several minutes prior to the mannitol suppression of the spontaneous activity, many spikes appeared to become broader with diminished peak-to-peak amplitude (second top right trace). The starred arrows on the leftmost side of the traces mark spikes that were plotted at a faster time course (top right traces). A graph of the average number of spikes occurring per minute, averaged over the four patients, is shown bottom right, where a smooth curve was fitted to the data. The black bar indicates the time period over which the mannitol bolus was administered. Error bars show 90% CIs. Reproduced from Haglund and Hochman (2005) *Journal of Neurophysiology* 94: 907–918, with permission from American Physiological Society.

frequency of the interictal spikes was significantly reduced in all five patients, with all spontaneous spiking being abolished during the final 10 min of the recording session in three patients. The average reduction in spiking frequency over these five patients was ~60%. Prior to furosemide administration, the average interspike interval was 9.6 ± 0.65 (SE) s with the 99% confidence interval (CI) of [7.9 s, 11.3 s]. After furosemide treatment, the mean interspike interval was increased to 21.9 ± 3.9 s (99% CI = [11.8 s, 31.9 s]). A *t*-test of the means of interspike intervals before and after furosemide treatment rejected the null hypothesis that the treatment had no effect ($P < 0.0001$).

The effects of furosemide (**Figure 2**) and mannitol treatments on afterdischarge activity were also measured. The duration of afterdischarge activity was defined to be the time during which a train of spikes followed the cessation of the electrical stimulus, where spikes were defined as those EEG events that were ≥3 SD from the mean of the voltage of prefurosemide activity. For each patient ($n = 8$), the minimal current was selected that consistently evoked afterdischarge activity in three consecutive stimulation trials. The furosemide treatment resulted in either a complete blockade (four patients) or in a reduction by >50% (four patients) of the duration and amplitude of the afterdischarge activity. The average reduction in the duration of stimulation-evoked afterdischarge activity over these eight patients was $(85 \pm 14.6)\%$ (mean ± SD). In comparison with the mean duration of the afterdischarge activity before and after furosemide treatment, a Wilcoxon rank-sum test rejected the null hypothesis that the furosemide treatment had no effect ($P < 0.01$). The effects of mannitol were also studied in four patients (data not shown). The mean reduction of afterdischarge duration after mannitol treatments was $(41.8 \pm 8.0)\%$.

Future Goals

Although the roles of the ECS in modulating excitability and epileptogenicity have been investigated over many decades, it has certainly received less attention than

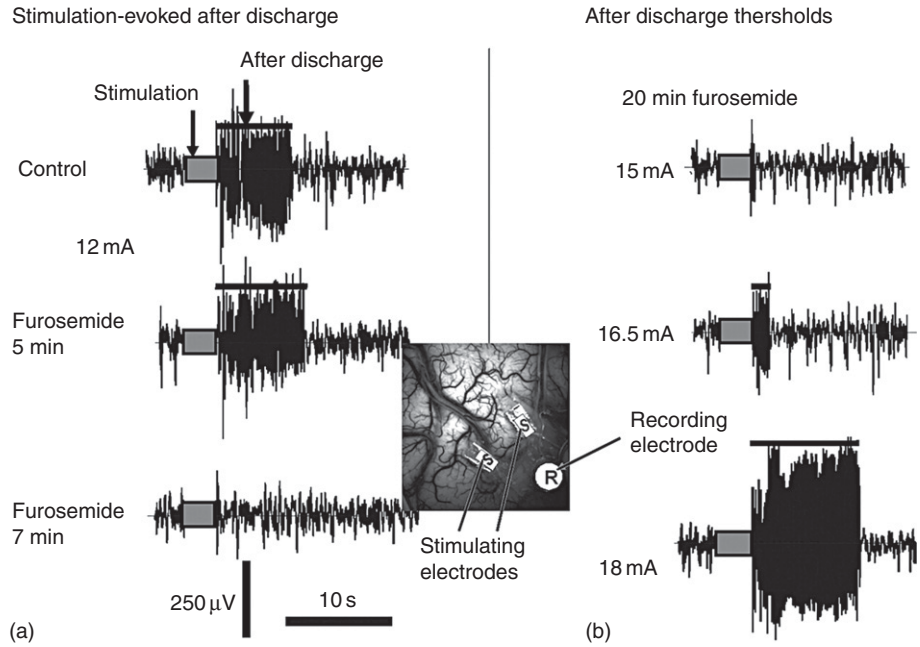

Figure 2 Suppression of electrical-stimulation-evoked epileptic activity in neocortex after furosemide administration. A bipolar stimulating electrode was placed on the cortical surface as shown in the gray-scale image (bottom middle); the distance between the two stimulating electrodes was ~5 mm. A recording electrode was placed within 1 cm of the stimulating electrode. A 4-s stimulus (60 Hz; biphasic; 1 ms per phase) was delivered at various currents; the stimulation duration is represented by gray boxes imbedded in the beginning of the traces. Prior to furosemide treatment, the minimum current necessary to elicit ≥5 s of afterdischarge activity in three consecutive trials was determined; this was defined to be the 'afterdischarge threshold current' (a, top). The black horizontal bars above each trace mark the episode of afterdischarge activity. After furosemide administration, stimulation trials were performed every 2–5 min for the next 40 min. In this patient, the afterdischarge activity was abruptly blocked soon after furosemide treatment (a, bottom). To determine whether the blockade of afterdischarge activity was mediated by an increase in afterdischarge threshold, the stimulation current was incrementally increased (b). It was found that sufficiently large stimulation currents were able to elicit afterdischarge episodes at least as long in duration as those observed prior to furosemide treatment (b, bottom). Reproduced from Haglund and Hochman (2005) *Journal of Neurophysiology* 94: 907–918, with permission from American Physiological Society.

chemical synaptic mechanisms. There is much work remaining to be done in determining the importance of ECS-related mechanisms in modulating excitability and neuronal synchronization. Further elucidation of the regulation and interdependence of the network of ECS-related mechanisms is also required. For example, evidence is accumulating that seizure activity may alter the expression of ion cotransporters and water channels in neurons and glia, and these changes may in turn affect the epileptogenicity of the tissue. There is also some evidence that at least two different splice variants of the NKCC1 cotransporter are expressed in the brain, with functional evidence suggesting that one splice variant is more efficient than the other in transporting ions. It has yet to be investigated whether variations in the expression of these splice variants, or of the protein kinases related to these transporters, play a role in modulating epileptogenicity. Finally, the data presented here support the notion that pharmacologically altered changes in the ECS – e.g., with mannitol or furosemide – can modulate epileptic activity in the human brain. This result suggests that the ECS may be a suitable pharmacological target for the development of novel pharmacotherapeutic treatments of epilepsy.

Introduction

Epileptic foci may result from many different pathological conditions. Among the different causes, perturbations of the extracellular microenvironment – including alterations in different ion concentrations – have been postulated to play an important role in epileptogenesis. Ionic gradients are fundamental for the maintenance of normal neuronal function and excitability. Excessive excitation, defective inhibition, energy failure, mechanical trauma, or blood–brain barrier defects drive ion concentrations beyond normal limits. Abnormal ion distributions influence neuronal function, which in turn aggravates abnormal ion distribution. It is important to determine the nature of these pathological ionic distributions, not only as a window into possible underlying causes of the pathology, but also as potential targets for therapeutic strategies.

Background

Extracellular potassium concentration ($[K^+]_o$) is actively maintained within narrow limits in neuronal tissues, a role essentially played by glial cells. The relation of potassium concentration and potassium clearance mechanisms to hyperexcitability of the neurons has been well studied in both animal models and human tissues. It has been known for some time that exposing brain tissues to a high or a low concentration of K^+ can induce epileptiform discharge, and that excess K^+ is released from neurons during seizures. Ion-selective microelectrodes revealed that early during an ictal discharge, $[K^+]_o$ increases to 7–12 mM and stays more or less steady at this elevated level during the tonic phase. This ceiling phenomenon has also been observed during electrical stimulation. Rising $[K^+]_o$ depolarizes neurons and moves the membrane potential closer to firing threshold, thereby increasing excitability. Elevation of $[K^+]_o$ also leads to excitation of neuronal networks because of: (1) the reduction of the potassium electromotive driving force; (2) the impairment of γ-aminobutyric acid (GABA) receptor-mediated activity; and (3) the perturbation of the extracellular space.

A decreased K^+ driving force causes a reduction of outward (hyperpolarizing) K^+ currents. Such changes bring the membrane potential closer to spike threshold and can potentially activate voltage-regulated conductance. Reduction of the K^+ driving force also decreases the repolarizing conductance of action potentials (mediated by both I_A and I_C) and increases action potential duration; at synaptic terminals, this change might enhance the influx

Introduction

Epileptic foci may result from many different pathological conditions. Among the different causes, perturbations of the extracellular microenvironment – including alterations in different ion concentrations – have been postulated to play an important role in epileptogenesis. Ionic gradients are fundamental for the maintenance of normal neuronal function and excitability. Excessive excitation, defective inhibition, energy failure, mechanical trauma, or blood–brain barrier defects drive ion concentrations beyond normal limits. Abnormal ion distributions influence neuronal function, which in turn aggravates abnormal ion distribution. It is important to determine the nature of these pathological ionic distributions, not only as a window into possible underlying causes of the pathology, but also as potential targets for therapeutic strategies.

Background

Extracellular potassium concentration ($[K^+]_o$) is actively maintained within narrow limits in neuronal tissues, a role essentially played by glial cells. The relation of potassium concentration and potassium clearance mechanisms to hyperexcitability of the neurons has been well studied in both animal models and human tissues. It has been known for some time that exposing brain tissues to a high or a low concentration of K^+ can induce epileptiform discharge, and that excess K^+ is released from neurons during seizures. Ion-selective microelectrodes revealed that early during an ictal discharge, $[K^+]_o$ increases to 7–12 mM and stays more or less steady at this elevated level during the tonic phase. This ceiling phenomenon has also been observed during electrical stimulation. Rising $[K^+]_o$ depolarizes neurons and moves the membrane potential closer to firing threshold, thereby increasing excitability. Elevation of $[K^+]_o$ also leads to excitation of neuronal networks because of: (1) the reduction of the potassium electromotive driving force; (2) the impairment of γ-aminobutyric acid (GABA) receptor-mediated activity; and (3) the perturbation of the extracellular space.

A decreased K^+ driving force causes a reduction of outward (hyperpolarizing) K^+ currents. Such changes bring the membrane potential closer to spike threshold and can potentially activate voltage-regulated conductance. Reduction of the K^+ driving force also decreases the repolarizing conductance of action potentials (mediated by both I_A and I_C) and increases action potential duration; at synaptic terminals, this change might enhance the influx

of Ca^{2+} into the synaptic terminals and increase transmitter release. An indirect excitatory action of increased $[K^+]_o$ involves the impairment of postsynaptic $GABA_A$ receptor-mediated inhibition by inducing a depolarizing shift in the fast Cl^--mediated IPSP reversal potential.

The various mechanisms that glial cells possess to clear excessive extracellular K^+ also render these cells susceptible to osmotically induced swelling when $[K^+]_o$ becomes too high. Glial cell swelling will consequently lead to a reduction in the extracellular space. Reductions in extracellular space have a number of excitatory actions. Reduction of $[K^+]_o$ causes a transient neuronal hyperpolarization, which is followed by a repolarization and subsequent depolarization period. Epileptiform field potentials appear in the late repolarization or early depolarization phase. Reduction of $[K^+]_o$, as well as associated neuronal hyperpolarization, reduces the efficacy of the Na^+–K^+–ATPase pump. Inhibition of the pump causes intracellular K^+ loss, neuronal depolarization, and initially spontaneous discharges. Na^+–K^+–ATPase pump inhibitors also facilitate the voltage-dependent Ca^{2+} conductance, and thereby neuronal excitability. Reduction of $[K^+]_o$ below mean resting level increases EPSP amplitude, which indicates an enhanced transmitter release. At subnormal levels of $[K^+]_o$, the enhancement of transmitter release may be related to the hyperpolarization of the presynaptic terminals and consequent increases of presynaptic spike amplitude.

Cl^- homeostasis is essential for many cell functions including volume regulation and cell signaling. The regulation of extracellular chloride concentration ($[Cl^-]_o$) has a decisive role in neuronal function, especially by setting the magnitude and direction of the Cl^- flux gated by GABA receptors. The intra-as well as extracellular Cl^- concentration of neurons determines their response to the neurotransmitters glycine and GABA. Glycine, $GABA_A$, and $GABA_C$ receptors are ligand-gated Cl^- channels, and their activation leads to a passive influx or efflux of chloride, depending on the electrochemical potential for Cl^-. Activation of these channels therefore leads to an excitatory, or to the more commonly observed inhibitory, response. Alterations of Cl^- homeostasis and GABAergic signaling might contribute to human epilepsy.

Methods

Despite the many studies on the mechanisms of epileptogenesis based on experiments in human tissue in vitro, no data are available regarding $[K^+]_o$ and $[Cl^-]_o$ in human epileptic tissue in vivo. Microdialysis can be used to monitor changes in the composition of the extracellular fluid in living tissue, providing a means for measuring the concentrations of small molecules such as neurotransmitters, hormones, ions, or peptides. It is a rapidly developing tool for monitoring physiological and pathophysiological changes in human brain. Microdialysis is based on the diffusion of water-soluble substances through a permeable membrane. Depending on the permeability of membrane, the molecular weight of these substances can vary between 5000 and 20 000 Da. A microdialysis device consists of a small polycarbonate tube (length of 10–30 mm) through which flows the so-called perfusion fluid. When the tube is placed into an environment of interest (e.g., the brain), substances from the extracellular fluid diffuse into perfusion fluid. This fluid, the dialysate, is then collected and subsequently chemically analyzed. Concomitant electrophysiological recordings and microdialysis of human brain tissues during epilepsy surgery can reveal the relationship of different substances, such as neurotransmitters and ions, to epileptiform discharges. By using cerebral microdialysis in the human brain, we investigated the basic $[K^+]_o$ and $[Cl^-]_o$, as well as their kinetics, after epicortical electric stimulation in patients with medically intractable epilepsy.

For intraoperative microdialysis, a frame was mounted on the operating table, allowing micromanipulators to be fixed directly over the craniotomy for an exact positioning of the dialysis catheters in the brain tissue. The catheters were guided by metal cannulae that were mounted on plates with 6-mm distance between centers of the catheters. In order to restrict the respiratory and pulsatory movements of the brain, pressure feet were guided by micromanipulators to rest on the cortical surface. This procedure prevents disruption of the cortical tissue by movement against the fixed catheters. When the arachnoid was found to be too rough for easy penetration of the dialysis tubes, it was penetrated by a mandril (pushed through the metal cannulae for not more than 0.5 mm).

For intraoperative microdialysis, CMA 70 Microdialysis Bolt Catheters (CMA Microdialysis AB Solna, Sweden) were used. The membrane is made from polyamide, and the shank from polyurethane. The cutoff permeability of the membrane is 20 kDa. The perfusate was moved by battery-supplied pumps and collected in microvials from CMA, sealed by rubber stoppers on both sides. The flow rate was 2.0 µl min^{-1}, and the sample period was 5 min (for 10 periods). $[K^+]_o$ and $[Cl^-]_o$ were measured at room temperature. Cerebral microdialysis was performed with simultaneous recording of electrocorticographic (ECoG) activity in selected targets in the patients' brains. Epicortical stimulation was applied bipolarly via two electrodes on a conventional strip electrode. The first trains of stimuli (50 Hz, 300 µs, 10 mA, 5 trains, intertrain interval 1 min) were delivered at the start of dialysis period 4 (P4) – that is, 20 min after catheter insertion. The second set of stimulus trains, with an increased stimulation intensity (50 Hz, 300 µs, 5 trains, 15 mA), was applied after another 15 min. The levels of potassium and chloride ions were measured

directly by inserting ion-selective microelectrodes into the microvials.

For preparation of ion selective microelectrodes (ISM), double-barreled borosilicate glass fiber microelectrodes were pulled on a vertical microelectrode puller to a tip smaller than 2–3 µm. One barrel was exposed to hexamethyldisilazane. The Cl^- exchanger or K^+ exchanger was then introduced into the tip of the silanized barrel until the exchanger column reached 50–70 µm in length from the tip. The silanized barrel filled with Cl^- exchanger was further backfilled with 100 mM NaCl, and the reference barrel was filled with 150 mM Na_2SO_4. The ion-sensing barrel contained K^+ ion-exchanger, and the reference channel, were backfilled with 100 mM KCl and 150 mM NaCl, respectively. Electrical signals from the two barrels were monitored with a high-impedance differential electrometer amplifier. The potential difference between the two barrels is logarithmically proportional to the ion activity at the microelectrode tip. The K^+-sensitive electrodes were calibrated in solutions with different concentrations of KCl, with NaCl added to preserve isoosmolarity. The selectivity coefficient of ISM was introduced in the Nikolski–Eisenman equation. Only electrodes with a slope in the range of 54–60 mV per 10-fold change in $[K^+]$ were used. The same calibration process was done for Cl^- sensitive electrodes, using solutions with different concentrations of NaCl in the presence of Na_2SO_4. Chloride-sensitive electrodes with a slope in the range of 56–60 mV per decade change in $[Cl^-]$ were used. Linear-regression analysis of calibration data on pre- and postruns was performed. The potential measured by ISMs (mV) was transferred into concentration (mM) by direct analysis.

Results

The average $[K^+]_o$ in the samples collected immediately after placing the microdialysis catheters into the cerebral tissues was 4.93 ± 0.25 mM. Within 10 min of probe insertion, $[K^+]_o$ was significantly reduced – to 3.83 ± 0.08 mM – and was stable for the next 10 min (**Figure 1**; $p \leq 0.001$). The values of $[K^+]_o$ obtained in periods 1–3 have been regarded as basal levels. The mean basal levels of $[K^+]_o$ in dialysates of 11 patients were significantly different from each other ($p \leq 0.001$; ANOVA). ECoG spike activity,

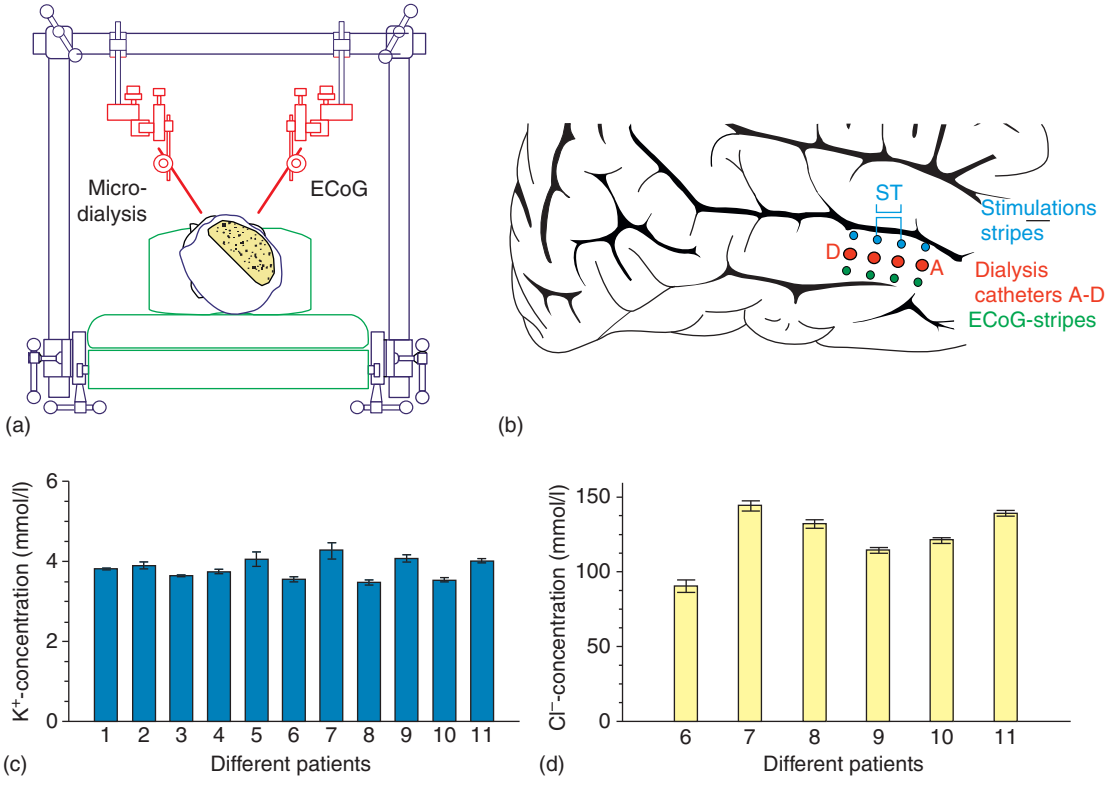

Figure 1 (a) The set-up designed to insert microdialysis catheter and ECoG electrodes during epilepsy surgery. The frame was mounted at the operating table allowing micromanipulators to be fixed directly over the craniotomy for an exact positioning of the catheters and ECoG electrodes in the brain tissue. (b) Schematic of the positioning of dialysis catheters, stimulations stripe, and ECoG electrodes in medial temporal gyrus of epileptic patients during surgery. (c, d) histogram representing baseline levels of extracellular potassium concentration (c; $[K^+]_o$) and chloride (d; $[Cl^-]_o$) in different patients. Dialysates were collected from the medial temporal gyrus of medically intractable epilepsy patients. Results are given as mean ± SEM; n represents the number of samples.

with a rate of 0–3.5 spikes per minute, was observed in most patients (see below for an exception). No correlation was found between the spike frequency and the potassium basal levels. In two patients (patients 3 and 10), $[K^+]_o$ in samples collected at different sites was significantly different ($p \leq 0.003$). In one patient, $[K^+]_o$ ranged between 3.6 and 4.2 mM in different samples collected from various catheters. In the other patient, $[K^+]_o$ varied between 3.7 and 4.1 in different sites. ECoG spike activity recorded close to the area in which different samples were collected did not show any differences in these patients.

Trains of local electrical stimuli applied to the surface of the cerebral cortex increased $[K^+]_o$ in all patients. Application of epicortical stimulation (50 Hz, 300 μs, 10 mA, 5 trains, intertrain interval 1 min) after 20 min of probe insertion induced an increase of $[K^+]_o$ that peaked at 4.55 ± 0.14 mM. The second set of trains, delivered an increased stimulation intensity (50 Hz, 5 trains, 300 μs, 15 mA) 15 min later, increased $[K^+]_o$ to 4.70 ± 0.12 mM.

During microdialysis, ECoG monitoring revealed 0–3 spikes per minute. Epicortical electrical stimulation was accompanied by appearance or enhancement of spike activity recorded by ECoG. Appearance or enhancement of spiking activity lasted 5–10 s after stimulation. In this short period, the repetition rate of spike activity increased to 0.5–4 spikes per second. No correlation was noted between the frequency of spike activity induced by electrical stimulation and the level of potassium enhancement. By 5 min after the stimulation, $[K^+]_o$ returned to the baseline level.

According to the velocity, as well as spatial distribution, of $[K^+]_o$ relaxation to the prestimulation levels, three different types of responses were defined (**Figure 2**).

(i) Slow return to baseline: In three patients, the enhanced $[K^+]_o$ elicited by electrical stimulation gradually decreased and reached the baseline levels within 10–15 min. In all the cases, the slopes of $[K^+]_o$ recovery after the two stimulus trains (delivered at P4 or at P7) were similar.

(ii) Fast return to baseline: In five patients, a transient elevation of $[K^+]_o$ induced by electrical stimulation recovered toward the basal values within 5 min of the last stimulation. In these cases, the dynamics of $[K^+]_o$ recovery was similar after the first (P4) and the second (P7) train of stimuli.

(iii) Fast and slow return to baseline: In three patients, measurement of $[K^+]_o$ in different samples, simultaneously collected in different catheters (i.e., at different sites) revealed a mixture of fast and slow recovery of $[K^+]_o$. In these cases, the elevated $[K^+]_o$ in samples collected by one or two catheters reached the baseline values within 5 min. However, recovery of $[K^+]_o$ in samples from the other catheters, located 6–12 mm apart, was prolonged to 10–15 min.

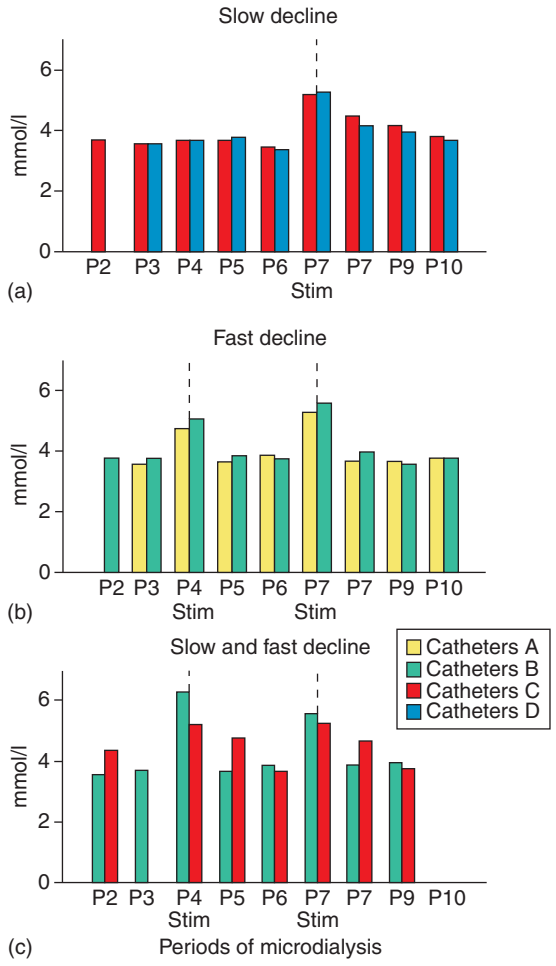

Figure 2 Different types of $[K^+]_o$ reduction to the prestimulation levels after application of epicortical electrical stimulation to the medial temporal gyrus of medically intractable epilepsy patients. According to the velocity of $[K^+]_o$ reduction to the prestimulation levels, three different types of responses, including slow decline (a) and fast decline (b) at any catheter site, as well as slow and fast declines at adjacent catheter sites (c), were observed. Epicortical electrical stimulations (stim) were applied in period 4 (P4, 20 min after probe insertion) and period 7 (15 min later).

No correlation was found between the basal level of $[K^+]_o$ and the speed of potassium recovery to baseline.

Extracellular chloride concentration was measured in the medial temporal gyrus of six epilepsy patients undergoing surgery therapy. The mean basal value of $[Cl^-]_o$ in all patients was 122.9 ± 2.6 mM. However, the average baseline levels of $[Cl^-]_o$ in various patients differed significantly from each other ($p \leq 0.001$). In all patients, 20 and 35 min after catheter insertion, trains of local electrical stimuli (50 Hz, 300 μs, 10 mA and 15 mA) were applied epicortically. These stimuli did not change the $[Cl^-]_o$ baseline values in any cases.

In four patients, $[Cl^-]_o$ ranged between 125 and 154 mM (134 ± 1.8 mM) in dialysates from different catheters (different sites). In these cases, $[Cl^-]_o$ in different samples obtained from four catheters did not differ significantly. Furthermore, in this group of patients, $[Cl^-]_o$ was stable (with <10% deviation) during 45–50 min of microdialysis. The mean chloride concentration of CSF in these patients was 121 ± 1.2 mM. In one patient, $[Cl^-]_o$ was between 110 and 117 mM, a concentration that was significantly lower than in the previously mentioned cases. In this patient, $[Cl^-]_o$ in the dialysate from different cannulae was similar and stable during the microdialysis period (mean chloride concentration of CSF was 120.2 ± 2.6 mM). In another patient, $[Cl^-]_o$ ranged between 65 and 110 mM. In this case, $[Cl^-]_o$ was significantly different from the samples obtained via different catheters ($p \leq 0.001$); $[Cl^-]_o$ was stable in dialysates from three catheters, but was gradually increased by 45% in samples at one position during 50 min of microdialysis. ECoG spike activity recorded close to the sample area in this patient was dramatically reduced during microdialysis. The ECoG recordings in other patients, with higher $[Cl^-]_o$, revealed less spike activity.

Ion concentration data presented here should not be treated as equivalent to 'real' extracellular concentration, because full equilibration does not occur at the site of the membrane. The method presented here shows accuracy rates of >90% for potassium at concentrations between 4 and 8 mM, and accuracy rates of >85% for chloride at concentrations between 100 and 150 mM. In addition to these studies on human epileptic tissue, experiments were performed in an in vivo animal model with the identical microdialysis probes, and ISM revealed similar accuracy rates. Another important concern in this study is the influence of catheter placement on changes of ion content in the extracellular space. The content of potassium may be increased by cell injury. It is a clinical practice to wait ≥1 h before collecting the first microdialysate sample in the intensive care unit. However, in the present study, 5–10 min after catheter insertion (P0), a steady basal level of $[K^+]_o$ was observed. Nearly the same time interval (10–15 min) has been observed between catheter placement and reduction of potassium concentration to the steady level in rats. Histological investigations in rat neocortical tissue revealed that the catheter placement within the brain resulted in minimal cell injury near the catheter.

In our experiments, the depth of the catheter within the cortex was not measured. This factor, as well as the variability in location of probes across the cortical surface, may affect the consistency of equilibration across the dialysis membrane. In most cases, however, two microdialysis catheters with identical membrane lengths, perfusion fluid, and flow rates inserted in two adjacent areas of human frontal cortex, showed equivalent results.

In the majority of patients in our study, $[K^+]_o$ and $[Cl^-]_o$ measured in microdialysate derived from two or four different sites in the temporal lobes were similar and stable during the whole microdialysis. However, $[K^+]_o$ in three patients and $[Cl^-]_o$ in one patient were different from the samples collected from different catheters. No significant differences were found when $[K^+]_o$ and $[Cl^-]_o$ were measured with these same probes in serum and CSF samples of the respective patients. These findings indicate a nonhomogeneous spatial distribution of K^+ and Cl^- in some epileptic patients. Interestingly, measurement of antiepileptic drugs in the same samples in which K^+ and Cl^- were measured revealed considerable variances in drug concentrations in different sites of the temporal lobes. In patients with uniform spatial distribution of K^+ and Cl^-, no significant differences were observed in antiepileptic drug concentrations among different samples collected by different probes. Previous electrophysiological studies of human brain tissue obtained from patients undergoing neurosurgical treatment for medically intractable epilepsy revealed a heterogeneous spatial distribution of spontaneous rhythmic sharp waves. Furthermore, optical monitoring of activity with voltage-sensitive dyes and fast imaging (in vitro) indicates that localized and spatially inhomogeneous neuronal depolarizations underlie spontaneous sharp field potentials.

Directions for Future Research

There is a vast and growing literature dealing with the role of various messenger substances in epileptic brain tissues, and much less attention has been paid to electrolytes in recent years. Yet, it has long been known that moderate shifts in ion distributions can alter neuronal excitability. Normal limits of different ion concentrations in healthy human brain (with noninvasive methods) need to be measured, and comparisons made with measures from epileptic tissue. Furthermore, the effects of altered levels of ions on normal and abnormal brain functions need to be precisely defined. Determining these effects will improve our understanding of basic mechanism of epileptogenicity, which in turn may help in the treatment of refractory epileptic patients.

Introduction

Ion concentration gradients provide the basis for neuronal activity, and neuronal activity in turn leads to changes in extracellular ion concentrations which are very significant during seizures and seizure-like events. These changes are due to transmembrane ion fluxes mediated by voltage and ligand gated ion channels. Ligand gating may occur from the intracellular or/and from the extracellular side of the membrane. Transmembrane transporters contribute only marginally to fast changes in extracellular ion concentrations, since transport protein density and transport capacity are much smaller than those of ion channels. In the long run, of course, the transporters must sustain the transmembrane ion concentration gradients. The transmembrane ion concentration gradient for potassium, and to a lesser extent for sodium and other ions, sets the resting membrane potential negative to −50 mV. This resting membrane potential level, in turn, determines the availability of voltage gated ion channels and thereby strongly influences neuronal excitability. For example, at a membrane potential of −30 mV the voltage-gated Na channels are all in an inactivated state, and neurons are therefore no longer excitable.

The difference between resting membrane potential and the equilibrium potential for a given ion sets the driving force for transmembrane ion flux. For example, at a resting potential of −50 mV, the driving force for Ca influx into the cell is close to 200 mV due to the equilibrium potential for Ca ions beyond +120 mV. Changes in transmembrane ion concentration gradients therefore affect membrane potential and the transmembrane ion currents induced by opening of voltage- and ligand-gated ion channels. During and following periods of increased neuronal activity, ion transporters must restore the normal transmembrane ion concentration gradients by using (directly or indirectly) ATP. The brain's dependence on this function accounts for most of the 15% of the whole organism's oxygen consumption.

Background

Introduction

Ion concentration gradients provide the basis for neuronal activity, and neuronal activity in turn leads to changes in extracellular ion concentrations which are very significant during seizures and seizure-like events. These changes are due to transmembrane ion fluxes mediated by voltage and ligand gated ion channels. Ligand gating may occur from the intracellular or/and from the extracellular side of the membrane. Transmembrane transporters contribute only marginally to fast changes in extracellular ion concentrations, since transport protein density and transport capacity are much smaller than those of ion channels. In the long run, of course, the transporters must sustain the transmembrane ion concentration gradients. The transmembrane ion concentration gradient for potassium, and to a lesser extent for sodium and other ions, sets the resting membrane potential negative to −50 mV. This resting membrane potential level, in turn, determines the availability of voltage gated ion channels and thereby strongly influences neuronal excitability. For example, at a membrane potential of −30 mV the voltage-gated Na channels are all in an inactivated state, and neurons are therefore no longer excitable.

The difference between resting membrane potential and the equilibrium potential for a given ion sets the driving force for transmembrane ion flux. For example, at a resting potential of −50 mV, the driving force for Ca influx into the cell is close to 200 mV due to the equilibrium potential for Ca ions beyond +120 mV. Changes in transmembrane ion concentration gradients therefore affect membrane potential and the transmembrane ion currents induced by opening of voltage- and ligand-gated ion channels. During and following periods of increased neuronal activity, ion transporters must restore the normal transmembrane ion concentration gradients by using (directly or indirectly) ATP. The brain's dependence on this function accounts for most of the 15% of the whole organism's oxygen consumption.

Background

The extracellular space is narrow, although very tortuous. It accounts for about 15% of the overall brain volume. This space is filled with proteins and electrolyte. The colloid osmotic pressure is low. The electrolyte

contains significant concentrations of the amino acids GABA (20 μM), taurine (20 μM), and glutamine (500 μM – 2 mM). GABA and taurine may activate high affinity $GABA_A$, $GABA_B$, and glycine receptors, providing for tonic inhibition. Glutamine is generated in glutamine synthetase-containing astrocytes from glutamate, and is exported into the extracellular space; neurons then take up glutamine for GABA and glutamate synthesis. Lack of glutamine contributes to hepatic coma. The extracellular space also contains glucose necessary for brain metabolism. The pH of the extracellular space is 7.4.

The electrolyte composition in the extracellular space is similar, but not identical, to that of cerebrospinal fluid. The potassium concentration ($[K^+]_0$) is between 2.7 and 3.2 mM at rest, the sodium concentration ($[Na^+]_0$) is about 155 mM, the chloride concentration ($[Cl^-]_0$) 135 mM, the calcium concentration ($[Ca^{2+}]_0$) 1.6 mM, and the magnesium concentration ($[Mg^{2+}]_0$) about 1–1.2 mM. The bicarbonate concentration is about 21 mM. There is iso-osmolarity between the interstitial and intracellular space, and the sum of cation concentrations equals the sum of anion concentrations.

Salts are not fully dissociated in the extracellular electrolyte (as described by their activity coefficients). Unfortunately, we do not know all ion interacting partners, so that our view of ionic concentrations is based on comparison to calibration solutions. In the case of calcium, this point is particularly important, as Ca binding proteins exist in the extracellular space and bicarbonate can interact with Ca to form an almost insoluble complex. The 1.6 mM Ca concentration given earlier compares to a calibration solution containing also 21 mM bicarbonate.

The transmembrane ion movement through ion channels is determined by the driving force and the conductance. The relevant formula is $Ix = gx\ (E_m - E_x)$, with I being the transmembrane current carried by a defined ion x, E_m being the actual membrane potential, gx the conductance for the ion x, and E_x being the equilibrium potential for the ion species x. The resultant ion changes in the extracellular space depend not only on the transmembrane ion fluxes themselves but also on the size of the extracellular space, and on regulatory processes such as diffusion and transport. An open blood–brain barrier can be a confounding variable in trying to measure extracellular ion concentrations; in such conditions, the Ca and Mg binding of plasma proteins will lower apparent concentrations of these ions, while the higher and more variable K concentration in plasma will affect baseline extracellular K concentrations. In fact, in many conditions with epilepsy, for example, temporal lobe epilepsy, tumors, inflammations, hypoxia, and ischemia, the blood–brain barrier is not tight.

As indicated earlier, the magnitude of ion shifts is influenced by extracellular space (ES) size changes. Shrinkage of the ES due to water uptake into cells (and subsequent cell swelling) will increase baseline ion concentrations, while widening of the ES (e.g., due to increases in colloid osmotic pressure as a consequence of protein exsudation from the plasma into the interstitial space) will lower baseline concentrations. During seizure-like events, shrinkage of the ES by up to 30% has been reported. This change would elevate Na and Cl concentration to near 200 mM, while K, Ca, and Mg concentration would be much less affected. For quantitative estimates of the transmembrane ion fluxes, therefore, ES size changes must be taken into account.

The intracellular space is, of course, shared between neurons and the different types of glial cells. This space is always larger than the extracellular space, and hence the ionic changes are usually thought to be smaller than indicated by ion concentration changes in the extracellular spaces – but this is not necessarily the case. Assume for a moment that extracellular Na decreases by 10 mM, but the ES shrinkage is 30%. As a result of the ES change, baseline sodium would increase to near 200 mM. For that change to occur, 60 mM Na would have to move across membranes into the cell. If the interneuronal volume fraction is 40%, then the increase in intracellular Na concentration would amount to about 25 mM; however, due to the extracellular space shrinkage, the Na concentration declines only by 10 mM (instead of the projected 60 mM). Thus, the ES size change compensates, in part, for the large transmembrane movements.

Shrinkage of the ES has a further consequence. It increases the extracellular resistivity, thereby augmenting extracellular potentials and potential gradients generated by glial cell and nerve cell transmembrane currents. This influence is particularly important in conditions where (e.g., due to trauma or hypoxia) the ES is already reduced, or in areas such as rodent hippocampal CA1 pyramidal cell layer where the ES size is about 10% and thus smaller than elsewhere in cortical structures. Indeed, ionic changes and extracellular space size changes are not uniform in cortical structures. The largest ionic changes are usually seen in layer IV/V of neocortex and in the cell layers of the hippocampus (granule and pyramidal cell layers). At those sites, ES shrinkage during seizure-like events and/or prolonged repetitive stimulation are also maximal, while at remote sites (such as in superficial cortical layers or in stratum moleculare of the hippocampus) a widening of the extracellular space has been seen.

Methods

Changes in ion concentrations, inside or outside neurons, can be measured with ion selective microelectrodes. These electrodes are filled at their very tips with a resin which can resolve the activity of specified ions (e.g., K, Ca,

or Na). Within the electrode (above the tip), this resin is superfused by a defined solution containing the ion of interest. When the electrode tip is immersed into an ionic solution, the ion for which the resin is selective will move into the resin and create a 'border potential.' The difference between the border potential inside the electrode (at the resin–electrolyte border) and outside the electrode tip (at the border between the resin and the outside medium) responds in a Nernstian manner to a change in ionic concentration (provided the measurements are done within the range of concentrations at which the ion-sensing microelectrode is selective). Such an electrode measures field potentials also. Therefore, a second electrode is required to measure the local field potential, and that field is then subtracted from the signal of the ion selective microelectrode. In practice, we use double barreled microelectrodes (one barrel filled with resin, the other to measure field potentials), the sensitivity of which is determined before and after the experiment. For such measurements, specialized amplifiers with a high input impedance, negative capacitance compensation, and DC potential correction are required.

Changes in ES size can be measured by monitoring the apparent increase in concentration of a substance which can not enter cells by transport processes or movement through ion channels. In practice, we use tetrapropylammonium or tetraethylammonium. These substances may be applied locally by pressure pulses or ionophoresis, or may be present in the ES due to experimental perfusion. An increase in concentration of such a marker substance is inversely correlated with the decrease in ES size.

Results

Changes in Extracellular Na Concentration

Repetitive stimulation, seizures, and seizure-like events usually lead to biphasic changes in extracellular sodium concentration ($[Na]_0$), with an initial decline and a subsequent increase above baseline. Such alterations have been seen in different species and cortical regions. Similar changes in $[Na]_0$ were also observed when AMPA or kainate were focally applied. The second, overshoot component of this response is probably due to shrinkage of the ES. The consequences of these changes for Na-dependent uptake processes – for glutamate and GABA or glucose into glial cells – are probably minimal, as the transmembrane Na gradient will not be strongly affected. In neurons, the Na equilibrium potential might decline by about 20 mV (from 60 to 40 mV), thereby reducing driving force for Na inward currents. This change will also reduce Na-dependent secondary transport for glucose and amino acids into neurons. In addition, the intracellular Na accumulation will activate the electrogenic sodium–potassium pump, which will transport excess Na out of the cell to shift the membrane potential in the hyperpolarizing direction. Activation of the sodium–potassium pump thereby contributes to seizure termination. In addition, intracellular Na accumulation may lead to activation of potassium channels of the slick or slo family.

Changes in Extracellular Cl Concentration

As is the case with Na concentration changes, Cl signals are also usually biphasic in response to repetitive stimulation, seizures, and seizure-like events. Following an initial decrease in Cl concentration, there is a small overshoot (by about 10 mM). Based simply on the decrease in ES size, one would expect a larger increase (overshoot) in Cl concentration. Consequently, some 15 mM of Cl will accumulate within neurons, shifting the E_{Cl} in a depolarizing direction to levels beyond or equal to the membrane potential. This intracellular Cl accumulation contributes to the depolarizing shift of the equilibrium potential for $GABA_A$-mediated synaptic potentials. A reduced electrochemical gradient for Cl will also increase the contribution of the transmembrane bicarbonate gradient to the $GABA_A$-mediated synaptic potentials. As glucolysis and respiration are increased during seizures, the bicarbonate equilibrium potential may be shifted in a depolarizing direction, thus accounting for depolarizing inhibitory potentials during seizures.

Changes in Extracellular Potassium Concentration

Increases in extracellular potassium concentration as a function of action potential generation were first noted by Frankenhaeuser and Hodgkin in 1956; they saw that hyperpolarization after an action potential (AHP) became smaller with each action potential in a train of action potentials. It was, therefore, no surprise that changes in extracellular potassium in the central nervous system occur during motor system activation, during sensory stimulation and during different states of mentation. These changes do not exceed 2 mM above baseline. During pathophysiological states, much larger changes in potassium concentration have been noted. In particular, during seizures in adult neocortex and hippocampus, potassium can increase to near 12 mM, a level that is surpassed during seizures in developing cortex and hippocampus. In adult tissue of monkeys, cats and rodents, this ceiling level of 12 mM is usually preserved, unless blood flow or metabolism is disturbed. If K accumulates to between 15 and 18 mM, it is likely that spreading depression (SD) will be induced, which is frequently observed in cortical structures during early postnatal development, but also after brain trauma and subarachnoid hemorrhage. The increased probability for induction of spreading depression during ontogenesis may be due to delayed

maturation of the NaK ATPase, delayed maturation of glial cell properties, and a delayed maturation of the blood–brain barrier. Disturbances in ion regulation due to compromised blood flow, disturbances in mitochondrial function, or reduced availability of ATP later in life will increase the likelihood of the induction of spreading depression. If blood flow is interrupted or synthesis of ATP is stopped, then a rapidly spreading depolarization develops which – if not rapidly reversed – leads to cell death. During SDs, potassium increases to about 60 mM, while Na and Cl (and extracellular Ca) concentrations decrease. The ion movements across the membrane lead to a strong reduction of the extracellular space size.

Elevation in K has a number of different effects. In most situations, potassium accumulation leads to depolarization of neurons. In axons, the hyperpolarization mediated by voltage activated K currents will be reduced, leading not only to prolonged action potentials but also to changes in firing rate. In presynaptic terminals, elevation in K causes augmented spontaneous and evoked transmitter release. Postsynaptically, in neurons, the $E_{(EPSP)}$ is shifted in a depolarizing direction, and the reduction in outward currents will contribute to increased excitability. $GABA_B$-mediated inhibitory currents decline in amplitude; indeed, part of the depolarization observed during repetitive stimulation is due to the activation of $GABA_B$ receptors. K accumulation also has effects on chloride transport. The KCC2 transporter reverses transport direction when K increases to beyond 5.5 mM, so that instead of Cl extrusion, Cl is transported into the neuron – thereby shifting Cl equilibrium potential in depolarizing direction and impairing the efficacy of synaptic inhibition. The depolarizing effect of K accumulation onto neurons is mostly mediated by two-pore-domain potassium channels but Kir channels will also contribute.

K accumulation in the ES also leads to depolarization of passive (or simple) astrocytes. These astrocytes are also described as glutamate transporter cells (they express high levels of Na-dependent glutamate transporters) and are usually strongly coupled by gap junctions and form an electrical and metabolic syncytium. Depolarization of astrocytes by local K accumulation will spread within the glial syncytium, leading to facilitated K uptake at sites of maximal K accumulation and facilitated K release at remote sites. At sites of maximal K accumulation, this K uptake contributes to shrinkage of the ES, whereas at remote sites, spatial K buffering can lead to increases in the ES size. The spatial K buffering is associated with generation of slow field potentials, which are (at least in part) due to glial cells.

The spatial K buffer mechanism may contribute to vasodilation with subsequent increased blood flow. This effect is due to an increase of K conductance in Kir channels which are expressed in smooth muscle cells. These cells have a rather depolarized membrane potential which is paradoxically shifted in the hyperpolarizing direction when potassium concentration increases. The widening of the ES at sites of K release, presumably at astrocytic endfeet, may contribute to increased blood flow by reducing transepithelial pressure.

Depolarization of astrocytes has effects on Na-dependent glutamate and GABA uptake, as the transmembrane electrochemical Na gradient necessary for effective uptake is reduced in depolarized glial cells. This effect will further lead to the accumulation of transmitters in the extracellular space. Whether glutamate transport can be reversed under conditions of anoxia and spreading depression depends on the transmembrane Na gradient; in such conditions, as the Na concentration gradient declines the transport may be slowed (but not reversed).

It is generally believed that K accumulation in the extracellular space is due to K release from neurons, mediated by voltage-dependent K conductances. That this assumption is not really true is shown by experiments in which A-type and delayed rectifier K currents are blocked by TEA and 4-AP – leading to increased extracellular K accumulation. Most of the K release is therefore due to K movement through two pore domain (2P) K channels, that are sensitive to quinine, quinidine, and bupivacaine. These agents reduce stimulus induced K signals considerably. Interestingly, blockade of 2P K channels or of Kir channels augments iontophoretically induced K signals, presumably due to reduced potassium uptake into glia and prevention of spatial K buffering. Down-regulation of glial Kir 4.1 channels in neuronal tissue is an early reaction after lesions to the brain and after opening of the blood–brain barrier. This down-regulation causes a facilitated accumulation of potassium in the extracellular space, and leads to early transformation of physiological responses into epileptiform events during normal processing of information in the brain.

Experiments on mature neocortex have shown that K accumulation does not trigger seizure activity. However, the situation is less clear in the hippocampus, where both in vivo and in vitro studies have shown that elevation of extracellular K concentration can trigger generation of seizure-like events. This sensitivity to extracellular K was also seen in human tissue from drug refractory patients. In such patients, elevation of K, when combined with bicuculline, could trigger seizure-like events in neocortex. Elevations in extracellular potassium concentration may support seizure generation by associated shrinkage of the extracellular space and a resultant increase in extracellular resistivity. Transmembrane currents will then cause larger extracellular potentials. Potential gradients in the order of $8\,mV\,mm^{-1}$ have been shown to affect neuronal excitability. Spatial buffering of potassium causes elevation of potassium at sites which are not yet recruited into

seizures. Spread of potassium by diffusion and spatial K buffering seems to underlie the slow spread of low Ca-induced seizure-like events in rat hippocampus. The speed of spread in this condition compares to spreading velocities of Jacksonian march, of experimentally induced seizures caused by lowering Mg concentration, and by the application of 4-aminopyridine. It may well be that K accumulation, by reversing Cl transport and by increasing the driving force for generation of EPSPs, is involved in recruiting new tissue into a seizure. This effect may be enhanced by ephaptic interactions due to shrinkage of ES and build-up of large field potential gradients.

Changes in Extracellular Mg Concentration

The interstitial Mg concentration is probably close to 1 mM, and changes in extracellular Mg concentration are difficult to detect due to the lack of appropriate sensors. In favorable conditions, small decreases in Mg concentrations have been observed. Mg is intracellularly bound to ATP but is free when ATP is consumed. Hence, the intracellular magnesium concentration may fluctuate, and in some condition may be as large as 1 mM. Such an intracellular level would result in a Mg equilibrium potential close to 0 mV, and provide a driving force for Mg ions to move in the inward direction. The major pathway for Mg ions to enter cells is through NMDA receptors. Indeed, measurement of Mg concentration changes in response to iontophoretic application of NMDA under conditions of zero Ca (when measurement of Mg loss is facilitated) indicates that Mg enters neurons. This observation would suggest that the Mg blocking site within the NMDA channel is deep within the pore. Larger changes in Mg concentration, in both plasma and CSF, may occur during eclamptic seizures, when a sudden and large increase in blood pressure opens the blood–brain barrier. Lowering Mg concentration causes facilitated transmitter release, due to the removal of the Mg block on voltage-dependent Ca channels. In addition, the activation of NMDA type glutamate receptors is facilitated by lower Mg. Both effects cause a rapid accumulation of Ca within neurons. Lowering Mg concentration will also affect surface charge screening, thereby augmenting neuronal excitability. Dependent on the animals' age and the subunit composition of the channel, Mg regulates activation of A-type potassium currents.

Lowering Mg concentration has also been investigated and found to trigger seizure-like events in juvenile hippocampus and in juvenile and adult neocortex. However, the concentrations required are probably lower than achieved under physiological conditions. Whether Mg can decline during eclampsia to levels sufficient to trigger seizures is unclear. However, normalizing Mg is as effective as phenytoin in blocking seizures under these conditions.

Changes in Extracellular Calcium Concentration

Ca concentration declines whenever neurons are activated. The decreases are about 0.1–0.2 mM during physiological activity. However, repetitive electrical stimulation of the thalamus or the cortex can induce decreases by upto 0.4–0.6 mM. As is the case with changes in potassium concentration, the amplitude of decreases in calcium concentration is layer-dependent in cortical structures. Maximal Ca decreases occur in layer II and IV/V of cat somatosensory cortex. In the hippocampus, decreases in Ca concentration are largest in the pyramidal cell layer, followed by changes in stratum granulare of the dentate gyrus. During seizures, Ca has also been shown to decline, and these decreases are generally similar to the decreases seen with repetitive stimulation. However, in some species, decreases in Ca can be much larger; for example, in the neocortex of the baboon *Papio papio*, decreases in Ca concentration reach about 1 mM during seizures induced by photic driving – changes only observed during spreading depression and anoxic depolarization in other animals.

The unique cellular arrangements in the hippocampus permit separation of pre- and postsynaptic Ca signals. Repetitive stimulation of the Schaffer collaterals causes Ca concentration decreases due to activation of P/Q type Ca channels (N type Ca channels inactivate relative rapidly during repetitive stimulation). K channel blockers such as TEA and 4-AP augment presynaptic Ca entry. Antidromic stimulation permits analysis of postsynaptic Ca entry; P/Q type and also L type Ca channels are activated during antidromic stimulation. NMDA receptors mediate postsynaptic – and when present – also presynaptic Ca entry.

While Ca declines monotonically to a new steady state level during the application of NMDA, glutamate or aspartate, Ca only transiently declines when AMPA and kainate receptor agonists are applied; under this latter condition, the initial decline in Ca concentration is followed by an overshoot. The reasons for these kinetic differences are not fully understood. The overshoot in Ca concentration during kainate or AMPA application, however, is removed when the Na–Ca exchanger is blocked.

The decrease in Ca concentration increases neuronal excitability by effects on surface charge screening and facilitation of action potential generation. In addition, the decrease in Ca concentration facilitates activation of NMDA receptors. It is expected that decreases in Ca concentration also lead to reduced transmitter release. Studies in the hippocampus have revealed that during washout of Ca, stimulus-evoked synaptic inhibition disappears before synaptic excitation; the loss of synaptic inhibition was noted at about 0.9 mM extracellular Ca, while postsynaptic excitatory potentials were lost at about 0.2 mM. The release of transmitters such as glutamate and GABA depends on the fourth power of Ca entry.

In disynaptic pathways, therefore, the effects of lowering Ca concentration will be cumulative. The loss of feed-forward and feed-back inhibition will therefore be particularly sensitive to decreases in extracellular Ca concentration.

Surprisingly, lowering Ca can also directly activate nonselective cation currents, as originally reported for dorsal root ganglion cells and more lately for central neurons. Whether this effect involves a unitary class of channels or includes different ion channels is presently unclear. The activation of these channels requires only relatively small decreases in extracellular Ca concentration.

Lowering of Ca, similar to lowering of proton or Mg concentration, can increase neuronal excitability by effects on surface charge screening; it can trigger epileptiform activity in rodent hippocampus, provided that K is elevated to 5 mM or more. This effect is not seen, however, in human hippocampus from patients with epilepsy.

Since decreases in extracellular Ca concentration are due to Ca inward currents, effects of changes in extracellular Ca concentration on neuronal activity are not always easy to predict. The net consequences for excitability depend on the intracellular Ca kinetics and the different effects which Ca can have on activation of ion channels, pumps, secretion, etc. With regard to effects of intracellular Ca accumulation, it must be noted that Ca can activate cation channels, and different types of K channels. However, in some cells, Ca may also inhibit activation of K channels. Recent data suggest that certain types of voltage gated Ca channels co-localize with either BK or SK type Ca-activated potassium channels, thus permitting generation of locally limited domains of intracellular Ca concentration changes. Intracellular Ca changes may have effects on metabolism as well. Three enzymes in the tricarboxic acid cycle respond to increases in intramitochondrial Ca concentration. However, larger increases in intracellular Ca concentration lead to mitochondrial depolarization, with potentially impaired synthesis of ATP and increased production of radical oxygen species.

Alterations in pH

Usually, seizure-like events are initially accompanied by alkalosis and then by acidosis. Part of the acidosis may be due to shrinkage in ES size, but also to lactate accumulation in the tissue. While acidosis reduces neuronal excitability, alkalosis increases neuronal excitability. The increase in excitability can, in part, be attributed to reduced surface charge screening. Changes in bicarbonate concentration in babies have been suggested to contribute to generation of febrile convulsions.

Alterations in pH strongly affect seizure susceptibility, and alkalosis in babies may even trigger seizures – perhaps due to the fact that inhibition is less stable and not fully developed, that the blood–brain barrier is still incomplete, and that elevated K can easily be modified by neuronal excitability.

Directions for Future Research

Obviously, changes in extracellular ion concentrations and changes in transmembrane ion concentration gradients have profound effects on neuronal activity, and may often be relevant for seizure induction and seizure propagation. When seizures spread, the 'front' of seizure spread is preceded by an avalanche of strongly increased inhibition. Recruitment of 'normal' brain regions into seizure activity then depends on the break-down of this inhibition. The precise mechanisms by which this break-down occurs are not yet fully understood, but changes in transport efficacy for Cl, as well as changes in bicarbonate concentration, may be involved. In order to maintain, and particularly to recover, relatively normal ion concentration gradients after a seizure or a seizure-like event, the nerve cells must increase production of ATP so that the ion pumps can work efficiently. This demand for ATP requires increases in blood flow and more delivery of oxygen and glucose to sites of ictogenesis. The roles played by ionic changes in neurovascular coupling are far from being understood. The same applies to the precise mechanisms by which neuronal metabolism is adapted to the needs for ATP synthesis in very active neurons. Another still-to-be-resolved question is how ionic changes are altered when the blood–brain barrier is open, or when seizure activity develops in an area with compromised blood–brain barrier. Particularly important are the effects of alterations in glial cell properties on the kinetics of ionic changes in the nervous system since these kinetics may influence the conditions under which seizure progresses into status epilepticus and/or induces damage to the nervous system.

Non-Synaptic Mechanisms in Seizures: The Role of Ion Fluxes and Intrinsic Membrane Properties

G G Somjen, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic seizures are generated by positive feedback excitation. Positive feedback can be mediated through reverberating excitatory synaptic pathways, and also by intrinsic neuronal membrane processes.

Mammalian brains are inherently capable of generating epileptiform seizures. The difference between epileptic and healthy brains is that the epileptic brain can generate a seizure without obvious provocation or in response to an innocuous stimulus, whereas only excessive stimuli or exogenous toxins induce seizures in the healthy brain. This general insight raises several questions. What enables seizures to arise? What prevents them from happening in healthy individuals? What terminates a seizure after it started? This article addresses the first of these problem areas.

Traditionally, an imbalance between excitatory and inhibitory synaptic transmission has been blamed for epileptic seizures. Yet simple forward transmission of excitation, no matter how powerful and unopposed, will not produce a tonic or tonic–clonic seizure. True epileptic discharge must be sustained by some form of reverberating or self-repeating excitation. Excitation can become self-sustained by the action of recurrent synaptic excitation, but brain tissue can generate seizure-like discharges even when all synapses are incapacitated. The most striking examples of nonsynaptic seizure generation occur in slices of brain tissue deprived of calcium. In low extracellular Ca ($[Ca^{2+}]_o$), synapses cease to function; yet Ca-deficient preparations produce 'spontaneous' electrical activity resembling synchronized epileptiform discharges. Moreover, in at least some forms of epilepsy in animals, it has been shown that during a seizure interstitial calcium concentration sinks to such low levels that chemical synapses could not transmit. Still, the seizure proceeds unabated until it is extinguished by the mechanisms that usually terminate it. The conclusion is inescapable – that nonsynaptic mechanisms can, at least sometimes, support ictal events.

This article discusses the effect of ion fluxes and ion concentration changes on ion channels, as these relate to epileptic seizures. Malfunctioning synapses probably play the primary roles in many forms of clinical epilepsy. Defective voltage-gated ion channels can, however, also become epileptogenic. Moreover, ion imbalance affects the intrinsic properties of brain cells and thus shapes the progression of seizures – either in addition to, or independently from, classical synaptic processes.

Non-Synaptic Mechanisms in Seizures: The Role of Ion Fluxes and Intrinsic Membrane Properties

G G Somjen, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic seizures are generated by positive feedback excitation. Positive feedback can be mediated through reverberating excitatory synaptic pathways, and also by intrinsic neuronal membrane processes.

Mammalian brains are inherently capable of generating epileptiform seizures. The difference between epileptic and healthy brains is that the epileptic brain can generate a seizure without obvious provocation or in response to an innocuous stimulus, whereas only excessive stimuli or exogenous toxins induce seizures in the healthy brain. This general insight raises several questions. What enables seizures to arise? What prevents them from happening in healthy individuals? What terminates a seizure after it started? This article addresses the first of these problem areas.

Traditionally, an imbalance between excitatory and inhibitory synaptic transmission has been blamed for epileptic seizures. Yet simple forward transmission of excitation, no matter how powerful and unopposed, will not produce a tonic or tonic–clonic seizure. True epileptic discharge must be sustained by some form of reverberating or self-repeating excitation. Excitation can become self-sustained by the action of recurrent synaptic excitation, but brain tissue can generate seizure-like discharges even when all synapses are incapacitated. The most striking examples of nonsynaptic seizure generation occur in slices of brain tissue deprived of calcium. In low extracellular Ca ($[Ca^{2+}]_o$), synapses cease to function; yet Ca-deficient preparations produce 'spontaneous' electrical activity resembling synchronized epileptiform discharges. Moreover, in at least some forms of epilepsy in animals, it has been shown that during a seizure interstitial calcium concentration sinks to such low levels that chemical synapses could not transmit. Still, the seizure proceeds unabated until it is extinguished by the mechanisms that usually terminate it. The conclusion is inescapable – that nonsynaptic mechanisms can, at least sometimes, support ictal events.

This article discusses the effect of ion fluxes and ion concentration changes on ion channels, as these relate to epileptic seizures. Malfunctioning synapses probably play the primary roles in many forms of clinical epilepsy. Defective voltage-gated ion channels can, however, also become epileptogenic. Moreover, ion imbalance affects the intrinsic properties of brain cells and thus shapes the progression of seizures – either in addition to, or independently from, classical synaptic processes.

Background

Observations in Live Brain Tissue: Ion Concentration Changes Modulate Ion Channel Function

During seizures, ion fluxes result in ion concentration changes that modulate the functioning of the very ion channels through which the ions flowed in the first place.

Intensely stimulated neurons lose K^+ and gain Na^+, Ca^{2+}, and Cl^-. They also discharge HCO_3^- and produce excess CO_2 and acid metabolites. These fluxes result in temporary shifts between intra- and extracellular ion concentrations and pH, as well as cell swelling and consequent shrinkage of the interstitial space (IS). Each of these changes feeds back to influence intrinsic membrane functions.

Elevated Interstitial Potassium

As a rule, the opening of K^+ channels and the resulting outward K^+ current tend to hyperpolarize neuron membranes. If, however, during high frequency firing the efflux of K^+ exceeds the rate of its clearing from interstitial fluid, the elevated ratio of extracellular over intracellular potassium concentration, $[K^+]_o/[K^+]_i$, makes the membrane potential less negative, and the neuron more excitable, at least as long as the imbalance is not too great. Excessive depolarization inactivates Na^+ channels and renders neurons unexcitable. This extreme case is evident only during spreading depression (SD).

It has been known since at least 1929 that solutions of potassium salts introduced into the brain, or into one of its ventricles, can induce epileptiform convulsions in animals. Combining this observation with the ionic theory of action potentials, several authors have proposed, hypothetically, that accumulation of K^+ in cerebral IS is the immediate cause of epileptic seizures.

During normal function, $[K^+]_o$ in the cerebral interstitium is kept within narrow limits by reuptake of K^+ into neurons mediated by the 3Na/2K ATP-fueled ion exchange pump, and by uptake of excess K^+ into glial cells, mainly astrocytes. However, during strong repetitive electrical stimulation, and also at the start of a tonic seizure, $[K^+]_o$ rises from its normal 2.8–3.5 mM to 7–12 mM, and usually, settles at this elevated 'ceiling' level for the duration of the excited state. Thus, excessive excitation elevates $[K^+]_o$, which favors more excitation and more release of K^+, and this circular sequence has the makings of positive feedback. High $[K^+]_o$ stimulates both reuptake into neurons and uptake into glial cells, and the elevated quasi-steady ceiling of $[K^+]_o$ is attained when the release of K^+ from neurons is matched by its enhanced clearing from the IS. After termination of neuronal firing, $[K^+]_o$ decreases gradually and usually sinks below its resting level (the 'undershoot'); this undershoot probably contributes to postictal depression.

Figure 1 illustrates the rise of $[K^+]_o$ during a seizure-like event induced by electrical stimulation. In the hippocampal formation, cell bodies of the principal neurons (granule cells in the dentate gyrus (DG) and pyramidal cells in Ammon's horn) are packed tightly in a compact layer, while branching dendrites, axons and glial processes intertwine in the neuropil of adjacent layers with relatively few interneuron cell bodies. For the experiment of Figure 1, a main input pathway (perforant path) to the DG was stimulated repeatedly for 10 s. In the layer containing the dendritic trees (stratum moleculare), $[K^+]_o$ rose to a 'ceiling' and remained at that steady level until the end of the stimulation. By contrast, in stratum granulosum, among the neuron cell bodies, after about 3.5 s $[K^+]_o$ rose to a new, even higher level, while the baseline (DC) potential

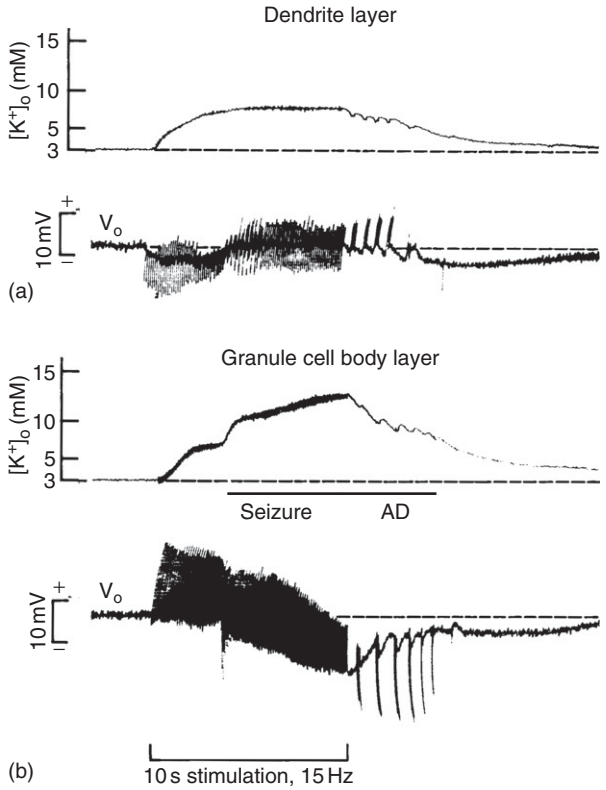

Figure 1 Interstitial potassium concentration ($[K^+]_o$) and DC voltage (V_o) in dentate gyrus of an anesthetized rat during electrical stimulation of an afferent (perforant) path and during clonic afterdischarge (AD). About 3.5 s after the start of stimulation, the responses attained a seizure-like character. At that moment the already elevated $[K^+]_o$ in the cell body layer (stratum granulosum) increased and V_o shifted in the negative direction. In the dendrite layer (stratum granulosum), $[K^+]_o$ remained flat and V_o shifted to a slightly more positive level during tonic seizure-like discharge. Parts (a) and (b) were recorded in the same experiment with 80-min interval. Modified from Somjen GG and Giacchino JL (1985) Potassium and calcium concentrations in interstitial fluid of hippocampal formation during paroxysmal responses. *Journal of Neurophysiology* 53: 1098–1108, with permission from American Physiological Society.

shifted in the negative direction and the nature of the electrical responses changed abruptly. Although not apparent at the slow recording speed shown here, oscilloscope recordings of these and many similar traces showed that the neuronal discharge no longer followed beat-for-beat the electrical stimuli, but acquired seizure-like characteristics. The train of stimuli was followed by afterdischarge (AD), resembling clonic seizure activity. It appears that the rise in $[K^+]_o$ and the associated depolarization were maximal near the site of action potential initiation (in stratum granulosum), not where most of the synapses are located (in stratum moleculare).

Current Source Density Distribution during Seizure Discharge

The difference between the behavior of the neuronal somata and the apical dendrites during paroxysmal firing was also evident in the experiment shown in **Figure 2**. Preparation and stimulation were similar to those in **Figure 1**, but the recording was made with a probe containing a straight row of miniature nonpolarizable contacts. Extracellular current source density (CSD) was computed for the baseline (DC) voltage shift, by sampling the voltages in between spike discharges. (A brief description of CSD analysis is given in Current Source Density Analysis section) CSD indicates the direction in which the predominant extracellular current flows in the IS and also the sites of 'sinks' and 'sources,' indicating where current enters or leaves cell membranes, but it does not resolve the movement of individual ions. The stimulation provoked seizure-like activity and AD, which was followed by SD. During the seizure, a sustained current flowed from the layer of apical dendrites (the source) into the layer of neuron somas (the sink). During SD, the dominant current reversed and a much larger sink appeared in the dendrite layer. Most excitatory synapses in the hippocampal formation are located on apical dendritic branches and excitatory synaptic currents generate sinks in the dendritic layer. Thus, the CSD associated with an excitatory synaptic potential (EPSP) is oriented similarly to that of the SD but its polarity is opposite to the DC component of the current associated with the tonic seizure.

Thus, the sustained firing during a hippocampal seizure appears to be maintained by inward current in or near the cell somata, and not by synaptic currents. This observation then brings up the problem of which ion channels are involved in this epileptogenic current flow – a question to be discussed in Recent Results – Computer Simulation of Nonsynaptic Epileptogenesis.

Low Calcium

In 1901, Regoli and Sabbatani applied citrate and oxalate to the exposed cortex of experimental animals and saw the eruption of epileptiform convulsions. They correctly inferred that the effect was due to the binding of Ca^{2+} in the tissue and not to the toxicity of the anions. Since then, it has been shown that exposing brain tissue slices to low calcium bathing solutions induces epileptiform electrical activity in the tissue. Deleting Mg^{2+} from the solution has a similar effect. The mechanism of the two effects is, however, only partly identical. Both divalent cations screen negative charges on the outer surface of cells, thereby augmenting

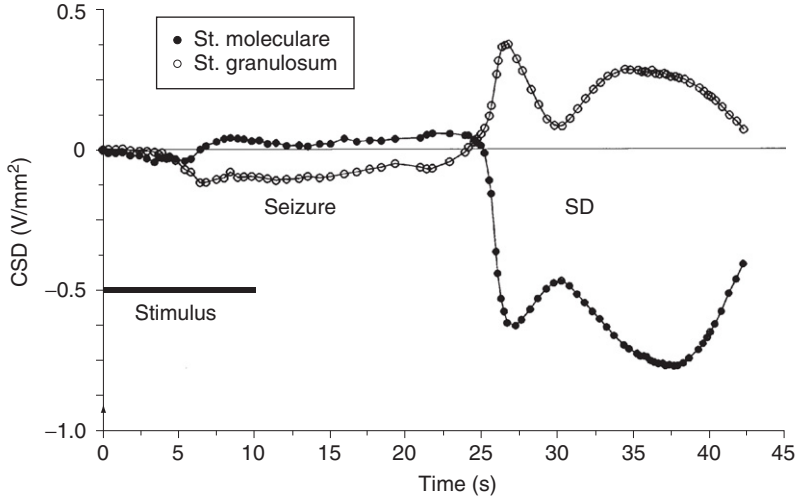

Figure 2 Current source density (CSD) in dentate gyrus of an anesthetized rat during stimulation-induced seizure and spreading depression (SD). The stimulation was similar to **Figure 1**. Recording with a multisensor microprobe. CSD was computed as the second spatial derivative of V_o corrected for tissue resistance variations. Baseline V_o (sustained potential shift) was sampled between synaptic potentials and spike discharges. Current sink is plotted as negative; source as positive. Modified from Wadman WJ, Juta AJA, Kamphuis W, and Somjen GG (1992) Current source density of sustained potential shifts associated with electrographic seizures and with spreading depression in rat hippocampus. *Brain Research* 570: 85–91.

the transmembrane voltage (V_m). Decrease in the extracellular concentration of either of the two divalent cations diminishes charge screening and increases the excitability of nerve and muscle cells. But, beyond this similarity, the two divalent cations have very different effects.

The outer (plasma) membrane, as well as the membranes of several major internal organelles, of brain cells are richly endowed with a variety of voltage and/or ligand controlled calcium channels and transporters. Inward current of Ca^{2+} into cells, like that of Na^+, tends to depolarize membranes. However, as there are many more Na^+ ions than Ca^{2+}, the direct effect of Ca-currents on the membrane potential is relatively small. On the other hand, variations of Ca^{2+} concentrations in- or outside cells modulate the functioning of a number of other ion channels. Furthermore, Ca^{2+} ions regulate a number of other molecular processes. Ca^{2+} entry into presynaptic terminals is required for the release of synaptic transmitters, which is why depletion of $[Ca^{2+}]_o$ blocks synaptic transmission.

Depolarization opens voltage-dependent Ca channels, and the channels controlled by NMDA receptors are also permeable to Ca^{2+}. Thus intense excitation causes Ca^{2+} influx into cells, depleting interstitial Ca^{2+} concentration, $[Ca^{2+}]_o$. Since the majority of Ca^{2+} permeable channels are located in dendrites and presynaptic terminals, the decrease in $[Ca^{2+}]_o$ is maximal in dendritic (neuropil) layers, at least in the hippocampal formation.

Like high $[K^+]_o$, low $[Ca^{2+}]_o$ can also create positive feedback excitation. Low $[Ca^{2+}]_o$ promotes excitation through three different mechanisms. One is the loss of surface screening, mentioned earlier. Another is depression of the slow hyperpolarizing afterpotential or afterhyperpolarization (AHP), which is generated by a Ca-dependent K-channel. In neurons where this channel is present, the slow AHP prevents high frequency firing. When the slow AHP decreases, a depolarizing afterpotential (ADP) emerges, which facilitates high frequency burst-firing. The third important effect is that Ca^{2+} ions at physiological concentration limit the conductance of certain nonspecific cation channels. Lowering $[Ca^{2+}]_o$ opens these cation channels, producing an inward current and depolarization.

Low Magnesium

Less is known about the behavior of Mg^{2+} ions during seizures. It is, however, well established that bathing freshly isolated brain tissue slices or slice cultures in Mg-free ACSF causes the appearance of seizure-like spontaneous electrical discharges. Also, severe Mg deficiency can cause clinical seizures.

As already mentioned, Mg^{2+} is a synergist of Ca^{2+} in the screening of outer charges on cell membranes, and therefore decrease in $[Mg^{2+}]_o$ enhances excitability of nerve and muscle cells. In synaptic transmission Mg^{2+} acts, however, as an antagonist of Ca^{2+} because in physiological concentration Mg^{2+} limits Ca^{2+} influx at presynaptic nerve terminals. Hence, a decrease in $[Mg^{2+}]_o$ augments the release of synaptic transmitters. Finally, normal Mg^{2+} levels tend to keep NMDA-receptor controlled channels closed, and a decrease in $[Mg^{2+}]_o$ enhances the NMDA component of glutamate-induced EPSPs. This last effect is believed to be the most important cause of low-Mg^{2+}-induced seizures.

Ph and Seizures

As a rule, an increase in extracellular proton concentration, $[H^+]_o$, (i.e., a decrease in pH_o, acidosis) depresses neuron excitability and a decrease in $[H^+]_o$ (increase in pH_o, alkalosis) enhances excitability. There are exceptions: specialized acid-sensing neurons, mainly in the respiratory nuclei, are excited by acid pH. The pH of cerebrospinal fluids is slightly more acidic than that of blood plasma and the pH of interstitial fluid in the central nervous system is slightly lower yet.

During intense electrical stimulation and seizure discharge, pH_o becomes transiently alkaline and then more acid. The acidification can persist for minutes after cessation of firing. A host of biochemical reactions produce, consume, and buffer protons. Furthermore, the transmembrane fluxes of H^+ and HCO_3^- mediated by numerous channels, ion exchange, and transport mechanisms can influence pH_o. In spite of much research, there is as yet no consensus concerning the details of the mechanisms mediating the pH changes associated with neuron firing. For our discussion, it is sufficient to remember that the initial alkaline shift can augment excitability, while the subsequent acidification dampens excitation and so can assist seizure termination and can contribute to postictal depression.

Cell Swelling

During intense excitation, both neurons and glial cells gain some solutes and lose others, but uptake exceeds release; therefore, cells accumulate osmotic equivalents accompanied by uptake of water, and swell. Astrocyte plasma membranes contain aquaporin water channels, and water flows more swiftly across their surface than across neuronal membranes. Cell swelling tends to restrict the size of ISs, which in turn favors intercellular electrical interactions known as 'ephaptic' communication. Effective ephaptic transmission of excitation is the likely explanation of the synchronization of epileptiform discharges in the absence of synaptic transmission, such as that occurs in low Ca^{2+} condition.

Brain cells swell when extracellular osmotic concentration is lowered. The clinical equivalent is water poisoning. For example, stokers' cramps are seizures induced by salt loss by sweating followed by excessive water intake. Besides

enhanced ephaptic effects, there is an added factor favoring neuron excitation. Hypotonia augments synaptic transmission, apparently by increasing the release of transmitter from presynaptic terminals. Iso-osmotic lowering of $[Na^+]_o$ has a similar but weaker effect. Placing brain slices in strongly hypotonic solutions can induce seizure-like discharges due to the dual effect of enhanced synaptic as well as ephaptic excitation. Whether these effects are relevant for epileptic seizures is not clear. During seizures induced under isotonic condition, water moves from the IS into cells (drawn by the movement of solutes) without a change in total water content of the tissue, and $[Na^+]_o$ decreases only moderately. The shrinking of the IS is much less severe during seizures than during SD.

Methods Frequently Used in the Study of Nonsynaptic Seizure Mechanisms: A Nutshell Summary

The Induction of Acute Seizures

To study their mechanisms, seizures have to be provoked 'on demand.' The customary means to induce epileptiform discharges in the brains of anesthetized animals include electrical stimulation and convulsant drugs. Strong alternating current of the right frequency applied by electrodes attached to the skull can provoke tonic–clonic convulsions. In the clinic, this is known as electroshock or electroconvulsive therapy (ECT). Better suited to microelectrophysiological analysis are seizures limited to a readily accessible target area. The hippocampal formation is especially prone to experimentally triggered seizures, and it is also the main focus in temporal lobe epilepsy. Repetitive stimulation of the main input pathways to this area can trigger paroxysmal firing of the form illustrated in **Figures 1** and **2**.

Convulsant drugs fall into two broad categories: antagonists of synaptic inhibition and stimulants of neuron excitability. Typical examples of the former include strychnine and bicuculline and of the latter include picrotoxin and 4-amino-pyridine.

As described already in Observations in Live Brain Tissue: Ion Concentration Changes Modulate Ion Channel Function, brain tissue slices kept alive in vitro generate seizure-like discharges when the concentration of K^+ in the bathing solution is raised, or that of Ca^{2+}, Mg^{2+}, or H^+ is lowered.

Ion-Selective Microelectrodes

Ion-selective microelectrodes (ISMEs) are, in principle, similar to pH electrodes. The invention of these ultrafine probes in the early 1970s made it possible to record in live tissues the changes in the concentration of certain ions while these changes happen. ISMEs are made of double barreled glass capillaries, drawn to a common tip a few micrometers across. One of the twin tips is filled with a blend of chemicals that functions as an ion selective membrane, admitting some and rejecting other ions, and generating a voltage that is a function of the concentration of that ion. The other tip contains a physiological salt solution and it serves as the reference electrode. The most successful ISMEs are highly selective to K^+ (see **Figure 1**), Ca^{2+}, or H^+. There is also an anion-sensitive type in use, which, however, does not distinguish Cl^- from HCO_3^-. The scientific world is eagerly awaiting the invention of a truly selective liquid membrane for Mg^{2+}.

Current Source Density Analysis

External electrical signals, including the electrocardiogram and the EEG, are generated when electric current, carried by ions, flows in IS. In technical jargon, an 'open field' is needed to record extracellular electric signals. An open field results when electric charge enters the IS at some limited area, and leaves it at some distance. A region where positive charge flows from the inside of cells into their surround is called a 'source,' and where it disappears into cells is the 'sink.' In fact, of course, positive and negative ions always move in opposite direction in electrolyte solutions, and instruments register only a transient excess of one. An excess of negative ions leaving the IS also creates a 'source,' just like an excess of positive ions entering.

In practice, CSD distribution is computed from voltage recordings made with a regular array of multiple extracellular microelectrodes, spaced as closely as possible within the target tissue. The electrical signals of interest include the currents associated with action potentials, synaptic potentials, or (most importantly for our discussion) the sustained potentials shifts marking seizure-like events (**Figure 2**). The locations of sources and sinks of current are detected as the maxima and minima of the second spatial derivative of the voltage gradient.

There are limitations to the usefulness of this technique. Meaningful CSD maps can be derived only from tissues where assemblies of similar electrically active cells are lined up in parallel, so that they can generate open voltage fields. Such areas in the central nervous system include the cerebellar cortex and the cerebral cortex, but the hippocampal formation probably has the optimal cytoarchitecture for CSD analysis. Here as elsewhere, however, the CSD map shows only the origins and the direction of the *net* current without revealing its ionic composition or the membrane ion channels that generate it.

Computer Simulation of Ion Currents that Generate Seizures

To test mechanistic hypotheses of seizure generation, it would be necessary to register simultaneously the

operation of the many biophysical mechanisms that interact during seizure discharges. Currently available techniques, such as patch-clamp recording, cannot provide the necessary data, but computer simulations can help. Simulations cannot discover what *is*, but they can exclude what is not possible.

The simulations of biological events involve digital computation of analog processes. Nonetheless, the verisimilitude of model neurons has improved over time, and a wide variety of realistic ion channels have been successfully incorporated in the membranes of model neurons and these can generate life-like virtual membrane ion currents.

Seizures are among the phenomena that lend themselves to computer simulations. The majority of published computer-based studies have examined synaptic interactions among populations of neurons and some models had incorporated arrays of thousands of cells. In most studies, however, ion concentrations in and around cells were assumed to remain constant. There have been only few attempts to incorporate ion concentration changes, and their inevitable functional consequences.

The following section of this article presents the salient data and conclusions obtained from simulations by a computer model consisting of a single neuron, the IS surrounding it, and a 'glia-endothelial' compartment enveloping the interstitium. Ion channels that are known to be present in hippocampal pyramidal neurons and astrocytes have been incorporated in the membranes of the model neuron and glia. Activation, deactivation, and inactivation of the ion channels were based on published reports of voltage-clamp experiments using live cells. The flux of ions across the neuron and glial membranes and the resulting concentration changes, and the effect of these ion changes on membrane channels, were continuously computed. A model neuron could imitate the morphology of a real neuron (e.g., with branching dendrites), but the model used to produce **Figures 3–5** was simplified; it had a soma, an unbranched apical dendrite and a short basal dendrite. The simplified cell replicated the behavior of the more realistically-shaped model, as well as that of a 'live' neuron. If undisturbed, it maintained a stable resting potential; when stimulated, it fired action potentials and, with appropriate adjustment of parameters, it produced tonic or clonic seizure-like after discharges, or SD.

Recent Results – Computer Simulation of Nonsynaptic Epileptogenesis

Computer simulation reveals the ion currents that could underlie nonsynaptic seizure-like discharge. Seizure-like discharge was produced when ion imbalance resulted in the activation of slowly inactivating inward current(s).

Simulated Elevation of Interstitial Potassium

Seizure-like AD is enabled by elevated $[K^+]_o$, which can maintain the activation of a slowly inactivating Na^+ current.

A computer model of a single 'pyramidal neuron' can generate seizure-like self-sustained and self-limiting discharge. The model used to produce **Figures 3–5** is described in Computer Simulation of Ion Currents that Generate Seizures.

Figure 3 illustrates the simplest type of simulated paroxysmal AD. The model neuron was stimulated by depolarizing current injected into the neuron soma. During stimulation, the neuron fired action potentials at an increasing rate (**Figure 3(a)**). The acceleration of firing was related to a depolarizing shift of the equilibrium potential of potassium, E_K (the blue line in **Figure 3(a)**). E_K is a function of the logarithm of the ratio $[K^+]_o/[K^+]_i$. The positive shift of E_K curtailed the hyperpolarizing afterpotentials, which are generated by the K^+ currents that follow each spike. Suppression of the AHPs enabled an increase in firing frequency. Following termination of the stimulus, the neuron continued to fire in the absence of an extrinsic stimulus, until the firing frequency decreased and finally ceased. This model AD simulates neuron behavior during a brief tonic seizure.

Figure 3(b) shows the trajectory of $[K^+]_o$ under three different settings for the volume of the 'glia-endothelial' compartment. The black line represents the condition of **Figure 3(a)**. In **Figure 3(c)**, the loss of K^+ from the neuron cytosol is plotted, and in **Figure 3(d)** the accumulation of K^+ inside the 'glia' is plotted. In these three trials, only the relative volume of the 'glia' was varied. The larger this buffer volume, the faster was the clearing of K^+ from the IS and the shorter the AD. The largest glial volume (10 times that of the neuron) is, of course, anatomically absurd. In intact brains, however, astrocytes are connected to one another by gap junctions, greatly increasing the effective volume of dilution for K^+ uptake. The interconnected glial network moves excess K^+ from regions of high $[K^+]_o$ toward regions of low $[K^+]_o$, a process known as 'spatial buffering.' Moreover, the glial network can 'siphon' K^+ ions from the IS around neurons toward the peri-endothelial space around small blood vessels, and the excess K^+ can be temporarily removed by the blood stream. Both the spatial buffer and siphoning mechanisms depend on uptake of K^+ into glial cells – which is equivalent to K^+ being diluted into a large volume. **Figures 3(b)–3(d)** demonstrate that glial buffering of $[K^+]_o$ modulates seizure-like discharge. This effect is particularly interesting, and potentially important, in light of the increasing evidence that in epileptogenic glial scars, the buffer function is defective.

Figure 4 is from another simulation trial, in essential features similar to that of **Figure 3**. **Figure 4(a)** is an expanded plot of the membrane potential of the model

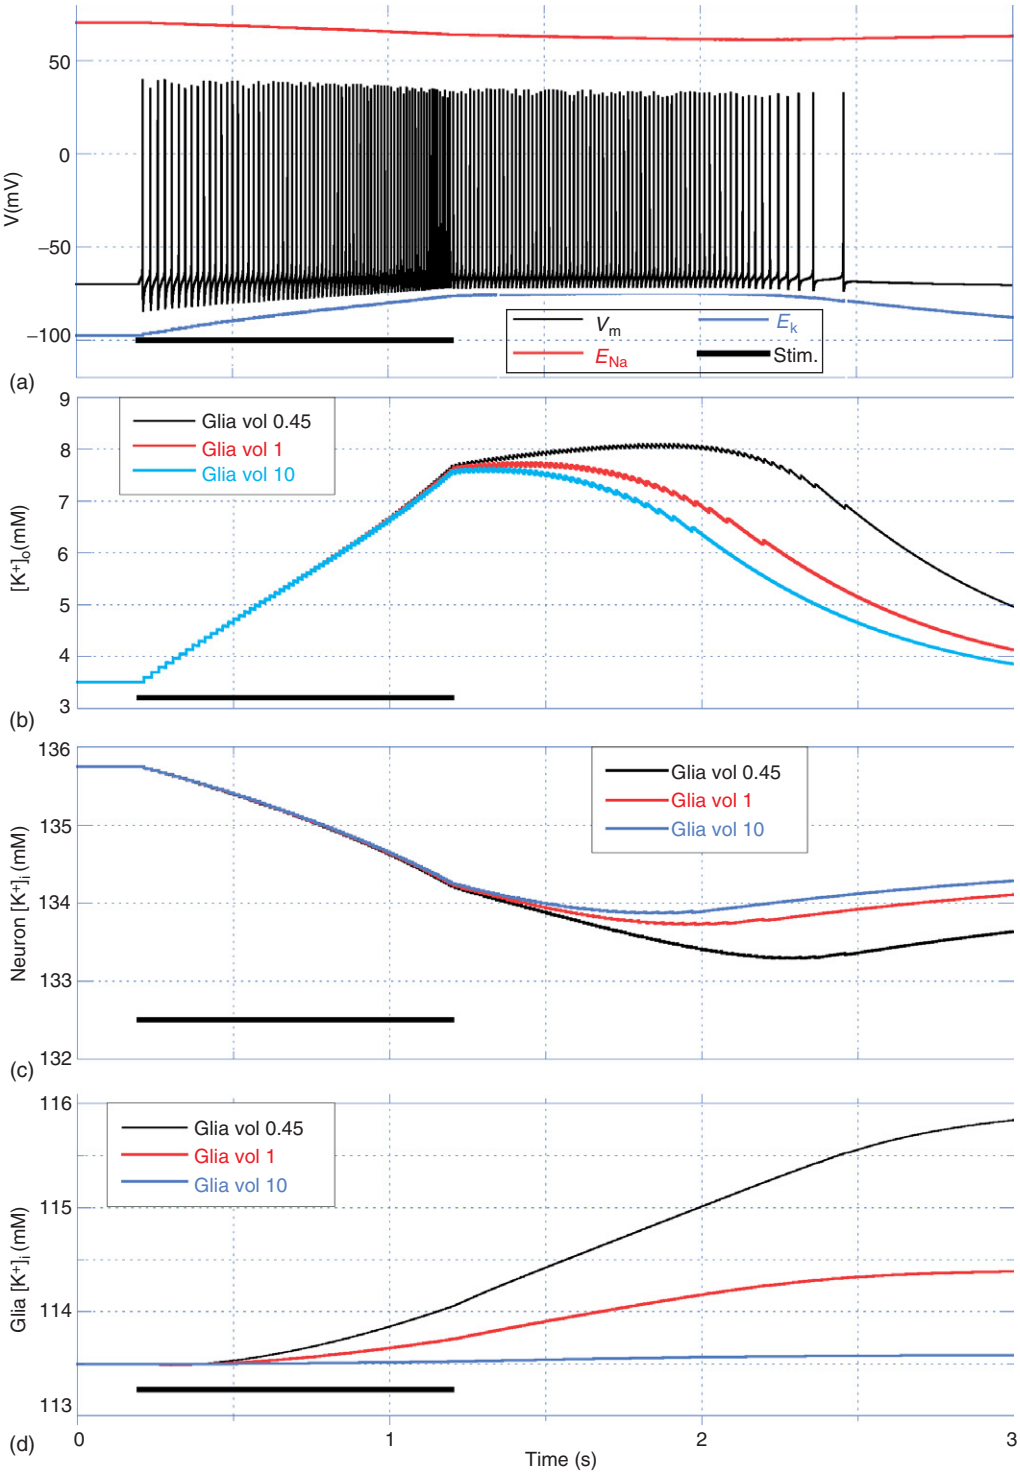

Figure 3 Computer simulation of seizure-like afterdischarge (AD) in a model neuron surrounded by interstitial space and enveloped by a glia-endothelial buffer compartment. (a) Membrane voltage (V<?tfqs-$_m$) of the model neuron and equilibrium potentials of potassium (E<?tfqs-$_K$) and sodium (E<?tfqs-$_{Na}$). The horizontal bar (Stim.) shows the time while a depolarizing current was injected into the neuron soma. (b) Interstitial potassium concentration ($[K^+]_o$ during stimulation-induced firing and AD of the model neuron with three different settings of the volume of the glia–endothelial comportment. Glia volume is indicated relative to the volume of the neuron. Interstitial space was 0.2. (c) Cytosolic potassium concentration ($[K^+]_i$) in the model neuron during the same three trials as in (b). neuron at the end of the stimulation and the start of the AD. **Figure 4(b)** illustrates the voltage-dependent ion currents that cooperatively generate the firing of action potentials. The red line represents the 'classical' rapidly inactivating (transient) Na^+ current ($I_{Na,T}$) that is responsible for the steep upstroke of action potentials. The blue line is the delayed rectifier K^+ current ($I_{K,DR}$). The green line represents a slowly inactivating, persistent Na^+ current ($I_{Na,P}$), which has been shown to exist in many types of central neurons. The black line is the aggregate membrane current (I_m), which is the sum of all currents (both those plotted and those operating in the background and not shown here).

Action potentials are triggered when voltage-dependent fast inward currents exceed outward currents. This state initiates positive feedback because depolarization activates more inward current, which favors more depolarization. In cells whose repertory of voltage-gated currents is limited to $I_{Na,T}$ and $I_{K,DR}$, firing ceases in the absence of an extrinsic stimulus because $I_{Na,T}$ is rapidly inactivated, and the membrane is repolarized by the $I_{K,DR}$, which outlasts $I_{Na,T}$. Firing continues after the end of the stimulation in **Figure 4** because of the presence of the small but persistent inward current of $I_{Na,P}$. As $I_{K,DR}$ subsides, $I_{Na,P}$ continues to flow. Thus, an aggregate I_m is maintained, leading to $I_{Na,T}$ reactivation, generating the first action potential of the AD.

For the scenarios of **Figures 3 and 4** to be played out, it is necessary that $[K^+]_o$ should rise to a high enough 'threshold' level during the stimulation. When $[K^+]_o$ was artificially 'clamped' at or near its resting level, the same stimulation did not trigger an AD – because V_m repolarized and therefore $I_{Na,P}$ became deactivated when the stimulating current was withdrawn.

Seizures Influenced by Ca^{2+} Currents and Ca^{2+}-Dependent K^+ and Nonspecific Cation Current

In the simulations of **Figure 3**, the Ca^{2+} currents $I_{Ca,T}$ and $I_{Ca,L}$ and the Ca^{2+}-dependent K^+ current $I_{K,SK}$ were set to a low maximal conductance, and for **Figure 4** they were altogether absent. However, after appropriately adjusting the maximal conductance of $I_{Ca,T}$ and $I_{K,SK}$ in the dendritic membrane, the apical dendrite generated rhythmic 'calcium spikes' in response to stimulation, and the firing pattern of the neuron changed from 'regularly spiking' to firing in spike bursts. When $[K^+]_o$ was allowed to rise sufficiently, then stimulation was followed by AD in a burst pattern, simulating a clonic seizure (**Figure 5**).

Seizures Promoted by $[Ca^{2+}]$-Sensitive Nonspecific Cation Current

The channels that mediate nonspecific cation currents, I_{NSCC}, form an extensive family with widely diverging properties and are expressed in many cell types. They have in common the property that their activation tends to depolarize membranes. For the present discussion, of special interest is an I_{NSCC} identified in many central neurons, including hippocampal pyramidal cells. It is not voltage dependent, but it is activated by low $[Ca^{2+}]_o$ and it is permeable to monovalent cations – but not to Ca^{2+}. It has been suspected to facilitate seizures and SD. In simulations, we have shown that, indeed, in the presence of a

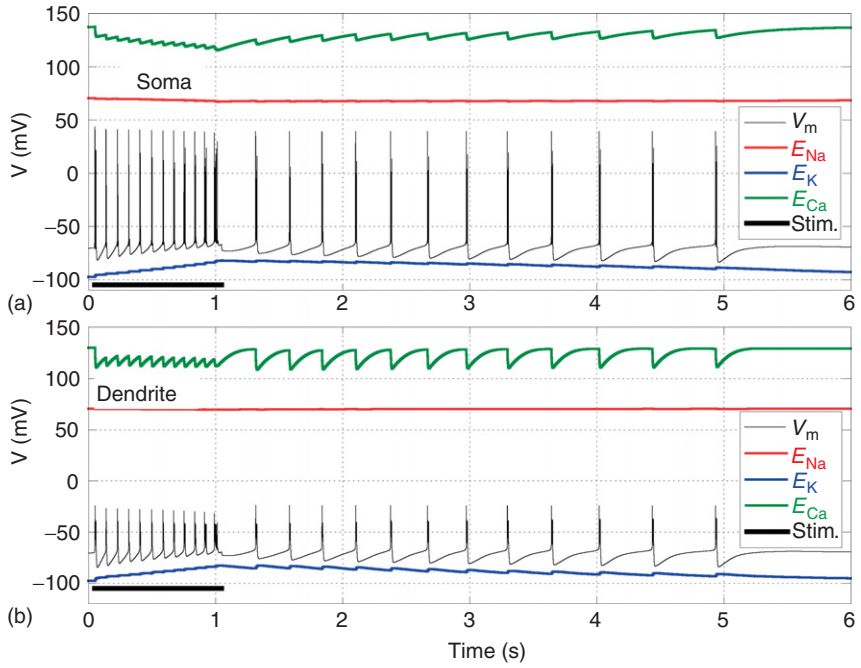

Figure 5 Simulated burst-firing and clonic afterdischarge of the model neuron. Burst-type firing was enabled by setting voltage-dependent calcium currents and calcium-dependent potassium currents to a higher value than those for **Figure 3**. (a) Membrane potential and equilibrium potentials of sodium, potassium, and calcium in the soma of the neuron, during and after injection of a depolarizing current into the soma. (b) The same variables computed for an apical dendrite segment. Reproduced from Kager H, Wadman WJ, and Somjen GG (2007) Seizure-like afterdischarges simulated in a model neuron. *Journal of Computational Neuroscience* 22: 105–128, with permission from Springer-Verlag London.

low $[Ca^{2+}]_o$-activated I_{NSCC}, a model neuron could generate seizure-like AD under conditions where no AD occurred in the absence of the I_{NSCC}.

An other I_{NSCC} was shown to be activated by increase of intracellular free Ca^{2+}, $[Ca^{2+}]_i$. Since during intense firing $[Ca^{2+}]_o$ decreases while $[Ca^{2+}]_i$. increases, in neurons that are endowed by both type of Ca^{2+}-sensitive I_{NSCC} the effect of the two are, presumably, additive.

Conclusions and Challenges

A number of central neurons naturally fire spontaneously. Paroxysmal firing underlying epileptic seizures is different in that it disrupts the normal function of a neuron population. Eruption of seizure discharge requires self-re-excitation.

Figure 6 is a simplified conceptual scheme summing up the parallel positive feedback loops that can support paroxysmal firing independently from synaptic interactions. Depolarization activates $I_{Na,P}$, which enhances depolarization. When the neurons fire repetitively, $[K^+]_o$ increases and $[Ca^{2+}]_o$ decreases. Elevated $[K^+]_o$ favors more depolarization directly and also indirectly because it potentiates the activation of $I_{Na,P}$. Low $[Ca^{2+}]_o$ enhances neuron firing by diminishing neuron surface charge screening and also by activating I_{NSCC}. Such feedback cycles must be initiated by a stimulus that depolarizes a population of neurons. This initial stimulus could be mediated, for example, by excessive

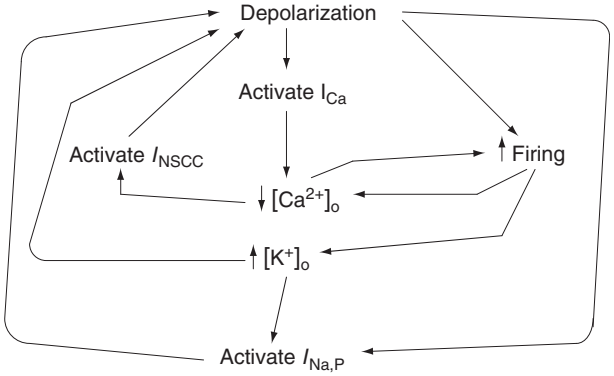

Figure 6 Conceptual chart of parallel positive feedback cycles that can sustain seizure discharge in the absence of synaptic input. Neuron depolarization causes firing, which raises $[K^+]_o$ and lowers $[Ca^{2+}]_o$. High $[K^+]_o$ augments depolarization. Low $[Ca^{2+}]_o$ augments excitability and so enhances firing; it also activates Ca-sensitive nonspecific cation current (I_{NSCC}), which also augments depolarization. Depolarization also activates persistent sodium current ($I_{Na,P}$), which is also augmented by high $[K^+]_o$, and also aids depolarization. Not represented in the diagram to avoid clutter are the processes that limit and ultimately extinguish seizures.

synaptic excitation, or else by head trauma, or electrical stimulation as in ECT.

During seizures, $[K^+]_o$ rises to a more or less steady ceiling level where the release of excess K^+ into the IS is balanced by its removal by augmented re-uptake into neurons and uptake into glial cells. Limitation of the rise of $[K^+]_o$ enables reactivation of $I_{Na,T}$ so that paroxysmal firing can continue. If the ceiling of $[K^+]_o$ is breached, runaway depolarization can persistently inactivate the transient Na^+ channel and SD is ignited. In hippocampal formation and neocortex, tonic seizure discharge is maintained by persistent inward current centered around the neuronal somata, while during SD the inward current in apical dendrites exceeds that flowing into the soma membrane. This spatial separation depends on the distribution (across membrane regions) of ion channels with diverse characteristics. This separation is, however, theoretically not required, and single-compartment computer models can generate either seizures or SD.

In healthy brains, positive feedback that could cause an ictal event is kept in check by inhibitory synapses and by intrinsic negative feedback represented, for example, by various K^+ and Cl^- conductances. Discussion of these control mechanisms fall outside the scope of this chapter.

Computer simulations, such as the ones illustrated in Figures 4–6, can distinguish between the possible and the impossible, but they cannot identify what actually exists in real life. In the simulations, either $I_{Na,P}$ or I_{NSCC} could enable seizure-like discharges. When both were active, seizures were facilitated. Importantly, in live brain cells both can be present. Other slowly-inactivating inward currents could also take their place or augment their actions. Future research must identify which of these currents have roles in clinical epilepsies.

Nonsynaptic Mechanisms of Neuronal Synchronization: A Possible Role in Fast Oscillations

F E Dudek, University of Utah School of Medicine, Salt Lake City, UT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic seizures represent periods of electrical hyperactivity and hypersynchrony in cortical structures. The mechanisms by which cortical neurons become abnormally synchronized are critical to a thorough understanding of how epileptic seizures are generated and propagated. Although chemical synapses clearly play an important role in electrical seizure activity, and their alterations are likely important in the formation of the reorganized neural circuitry that defines the epileptic brain, it is highly likely that nonsynaptic mechanisms of neuronal interaction also play critical roles in the synchronization of electrical activity during seizures.

Electrical mechanisms of neuronal communication have been viewed as important contributors to the synchronization involved in seizure-like activity for many decades. Electrotonic coupling through gap junctions represents a mechanism of electrical synaptic transmission, and it has been proposed to synchronize electrical activity in a wide variety of situations where rapid synchronization is critical to normal neuronal function. The influence of electrical field effects, or ephaptic interactions, which arise through electrical current flow in the extracellular space, has also been debated for many years, but these effects are known to occur between hippocampal pyramidal cells under a variety of circumstances where synchronization and hyperactivity are present. These two mechanisms of electrical interaction are quite different: electronic coupling is based on a membranous structure (i.e., the gap junction) involving connexon channels, mediated by connexin proteins, between cells; electrical field effects, or ephaptic interactions, arise when the extracellular space is small and neurons are arranged in parallel, so that the electrical current flow between neurons can cause abnormal depolarizations during synchronous activity. These two forms of electrical interaction have a very fast mechanism of action, and so they are thought to play an important role in synchronizing action potentials, although they may also contribute to other forms of synchronization.

Another nonsynaptic mechanism involves activity-dependent changes in the concentration of extracellular and intracellular ions. When intense electrical activity occurs, as is expected during seizures, the ionic currents across the membrane cause a change in the extracellular concentration of ions such as potassium and calcium. These changes in ion concentrations can cause a slow form of synchronization, particularly since reduced extracellular calcium would also lower action potential threshold, whereas increases in the concentration of extracellular potassium would depolarize the membrane.

These two mechanisms – electrical interactions and ionic shifts – can work in concert to cause increased excitability. This article will focus on electrical forms of neuronal communication but will also consider ionic interactions.

Background

Electrotonic Coupling Through Gap Junctions

Probably one of the oldest and most controversial issues in neuroscience is the degree to which neuronal communication in the mammalian nervous system involves chemical versus electrical mechanisms. There is no question that chemical synapses – whether they be fast synapses involving transmitters such as glutamate and GABA, or neuromodulatory mechanisms invoking slower processes such as seen with serotonin and neuropeptides – play an important role in both seizure generation and epileptogenesis. During the 1970s and 1980s, however, a wide range of studies suggested that hippocampal pyramidal cells, dentate granule cells, and neocortical pyramidal cells are also electrotonically coupled through gap junctions. One form of evidence in support of this hypothesis was that low molecular weight tracers, such as Lucifer yellow and neurobiotin, can sometimes pass from one neuron to another. This method of analysis has been criticized because some neurons (and other cells) thought to be electrically coupled through gap junctions do not necessarily pass the tracer, whereas tracer has been found in cells that had previously been thought not to be electrically coupled to the injected neuron. Studies in the 1980s, using intracellular recordings with either indirect or direct methods, provided evidence that the fast prepotentials or spikelets sometimes recorded in hippocampal pyramidal cells are due to electronic coupling and reflect the transmission of action potentials from one cell to another (as opposed to representing dendritic action potentials of the recorded cell). This hypothesis, that pyramidal cells could be coupled through gap

junctions, was viewed skeptically and is still criticized by many researchers, because it has been difficult to find morphological evidence of gap junctions between these neuronal types.

Electrical Field Effects

Another mechanism of electrical interaction involves the effects of electrical fields, generated by a population of synchronously active neurons, on adjacent neurons that are not electrically active. Because the electrical field effects, or ephaptic interactions, arise when the extracellular space is small and neurons are oriented in parallel, the structure that has attracted the most attention with regard to this mechanism is the hippocampus. It has long been known that the hippocampus generates particularly large electrical field potentials during synchronous firing, primarily because of the tight packing and parallel polar orientation of hippocampal pyramidal cells (and dentate granule cells). There is a large negativity (the 'population spike') recorded at the cell body layer during synchronous action potentials generated by hippocampal neurons; this negative extracellular field causes a fast transmembrane depolarization that can be detected when electrodes are positioned intracellular and extracellular, so as to record the transmembrane potential (i.e., intracellular voltage minus extracellular voltage in the immediately adjacent extracellular space). The field-effect depolarizations, which can occur either in hippocampal slices or in intact animals, are generally about half the amplitude of the extracellularly recorded population spikes, and so are often many millivolts. These electrical field effects may be particularly important, since they can act together with electrotonic coupling (via gap junctions) to synergistically cause synchronization of action potentials of hippocampal pyramidal cells and granule cells.

Ionic Mechanisms

Electrographic seizures represent extremely intense activity and synchronization, so that the concentration of extracellular and intracellular ions changes significantly. When extracellular potassium increases, and extracellular calcium concentration decreases, neurons become more excitable. A variety of studies in the 1970s and 1980s used ion-selective electrodes to show that major shifts in these ions occur during seizures, and these shifts can dramatically alter the electrical activity of neurons in the hippocampus and neocortex. Because this mechanism acts on a slow time scale, it is unlikely that it is involved in synchronization of action potentials on a millisecond basis; however, these ionic shifts presumably play an important role in slow changes in excitability.

Models of Seizure Activity Based on Nonsynaptic Mechanisms

During the early 1980s, several research groups showed that bathing hippocampal slices in extracellular solutions with little or no extracellular calcium leads to hyperexcitability and hypersynchronous activity (**Figure 1(a)**). In such low-calcium solutions, chemical synaptic transmission is blocked (since calcium is required for transmitter release). Under these conditions, extracellular stimulation of pyramidal cell axons (i.e., antidromic stimulation) causes prolonged afterdischarges and can lead to spontaneous bursts of action potentials with large-amplitude population spikes. Furthermore, it has been shown that hippocampal slices with reduced extracellular calcium and elevated potassium, in the presence of pharmacological antagonists that block glutamatergic and GABAergic receptors, also generate profound seizure-like activity in areas such as the CA1 and the dentate gyrus. During these periods of electrical activity, fast prepotentials or partial spikes can occur within one cell when extracellular recordings show that the population is generating action potentials (**Figure 1(b)**). Furthermore, differential recording across the membrane (i.e., transmembrane recording of intracellular minus extracellular potentials) reveals large field-effect depolarizations, which also contribute to the synchronization (**Figure 1(c)** and **1(d)**). These data have suggested that both electrotonic coupling and electrical field effects play an important role in synchronizing action potentials. Although this change is most profound in the CA1 area of the hippocampus, it can also be detected quite readily in the dentate gyrus, in the CA3 pyramidal cell region, and in medial entorhinal cortex (the field potentials are smaller and the synchronization is less profound in CA3 and entorhinal cortex, presumably because the cells are less densely packed).

Methods

The work in our laboratory, and from several other groups, which has provided the basis for the experiments described earlier, has primarily been done on hippocampal and neocortical brain slices studied in vitro. The early experiments used focal field potential recordings and sharp intracellular recordings to analyze population activity in relation to single-neuron responses. The data obtained from these in vitro preparations have been related to field-potential recordings and traditional electroencephalograms (EEGs) from both animals and human patients with chronic epilepsy. Much of the in vitro work has, in turn, been analyzed with computational models aimed at trying to determine the cellular mechanisms that most likely contribute to electrical and ionic nonsynaptic interactions. More recently, various imaging techniques

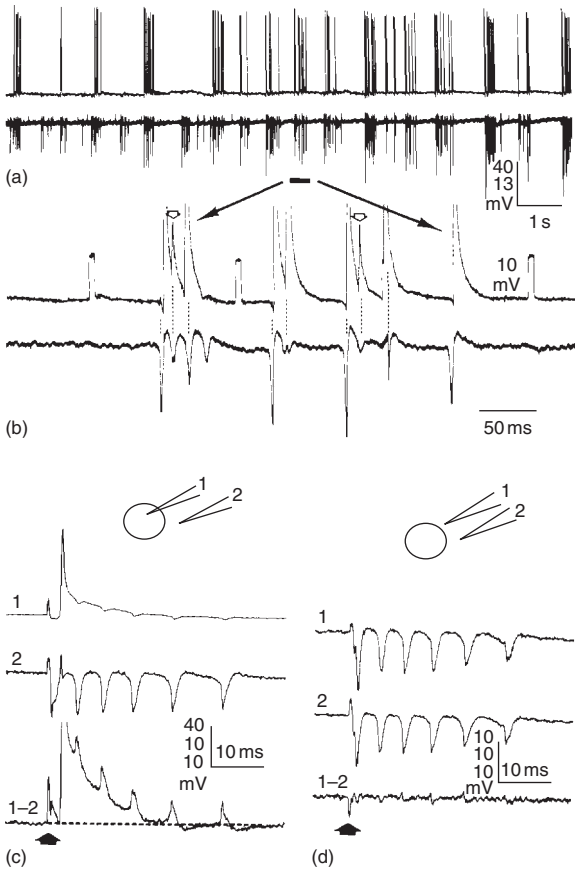

Figure 1 Spontaneous synchronous burst discharges after blockade of chemical synapses in a hippocampal slice with evidence for synchronization from nonsynaptic mechanisms, such as electrotonic coupling and electrical field effects between CA1 pyramidal cells. (a) Spontaneous bursts of synchronous action potentials were recorded from a hippocampal slice bathed in a solution containing 0.5 mM Ca^{2+} and 2.3 mM Mn^{2+} for several hours. Intracellularly recorded action potentials can be seen in the top trace, and these action potentials occurred synchronously with spontaneous bursts of population spikes seen in the extracellular recordings in the lower trace. Part of this record, as shown by the dark bar, is expanded in (b). The open arrows indicate fast prepotentials or spikelets that occurred during small population spikes in the extracellular recordings. In (c), an extracellular recording electrode was positioned close to the intracellular recording site (see inset) to allow differential recording of the voltage across the membrane of the CA1 pyramidal cell (i.e., intracellular minus extracellular), as shown in the bottom trace. Trace 1 shows the 'single-ended' intracellular recording (i.e., referenced to ground) as is traditionally performed in this type of experiment. Similarly, Trace 2 shows the extracellular recording referenced to ground. The lower trace (1–2) is the differential recording, which shows the field-effect depolarizations that occurred in the recorded CA1 pyramidal cell during a brief burst of action potentials in the hippocampal network. In (d), the intracellular electrode was withdrawn from the pyramidal cell, as shown in (c), and now both electrodes (1 and 2) were used to record the extracellular field potential. The differential recording in this condition (1–2) shows little or no voltage change, thus indicating that electrode 2 in (c) recorded the actual extracellular voltage changes immediately outside the pyramidal cell. The key point is that the actual transmembrane voltages 'seen' by the CA1 pyramidal cell are the differential recording illustrated at the bottom of C, not the single-ended recording shown in Trace 1 of (c). Reproduced from Taylor CP and Dudek FE (1982) Synchronous neural afterdischarges in rat hippocampal slices without active chemical synapses. *Science* 218: 810–812.

and gene-targeting strategies (including knockout mice) have been used to analyze specific roles of different types of gap junctions. These studies have yielded new insights into how nonsynaptic mechanisms contribute to seizure activity.

Recent Results

Fast Oscillations at Seizure Onset

As described earlier, early studies in hippocampal slices showed that synchronous action potentials can occur when chemical synapses are blocked. The fast nature of the synchronization, and the waveform of the events, strongly suggested that some form of electrical interaction was responsible. The available evidence for electrotonic coupling and electrical field effects further supported this perspective. This issue has recently become more important in the field of epilepsy research, since a variety of studies have detected very fast oscillations (in the range of 100–500 Hz) in extracellular field-potential recordings in the hippocampus of patients undergoing surgical resection for intractable epilepsy and in animal models with spontaneous seizures (such as the kainate-treated rat). These studies have shown that seizure onset is often, although not always, associated with these very fast oscillations – which likely represent the synchronized activity of action potentials in individual pyramidal cells (**Figure 2**). Although other mechanisms could conceivably generate these fast oscillations, the fact that action potentials have a duration of only about 1 ms makes electrical coupling the most likely candidate for the synchronization mechanism. Investigators have searched for the mechanism(s) that is upregulated in epileptogenic tissue to make these events so prominent and have proposed that electrotonic coupling via gap junctions is increased between injured neurons. Another hypothesis is that the epileptogenic tissue has reduced extracellular space and that higher extracellular resistance makes the electrical field potentials larger – leading to larger effects of ephaptic interactions. Other changes could indirectly lead to an enhancement of very fast oscillations through electrical mechanisms. One prime example is a potential decrease in GABA-mediated inhibition. Since $GABA_A$ receptor activation essentially shunts the membrane, one might expect that a simple reduction in this shunting effect could lead to enhancement of electrical interactions. A critical question is whether these forms of electrical interaction can be shown to mediate fast

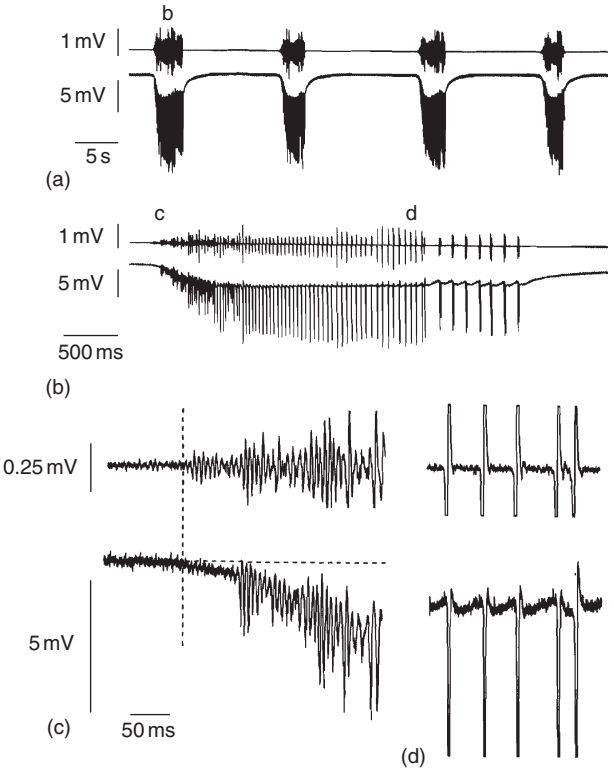

Figure 2 Combined multiple-unit and field-potential recordings of prolonged bursts generated in the CA1 area of a hippocampal slice bathed in a low Ca^{2+} solution with 5 mM extracellular K^{+}. The multiple-unit recordings are shown in the top traces, while the bottom traces illustrate the field-potential recordings. (a) Spontaneous bursts occurred repetitively under these ionic conditions. As expected, the increased multiple-unit activity occurred during the negative field potentials that had large superimposed population spikes. (b) The activity in (a) was expanded temporally (see the burst labeled 'b' in (a)) to show the correspondence between the field potential and the multi-unit recording. (c) The onset of the burst in (b) is shown at higher temporal resolution and gain. The recording shows that the small high-frequency oscillations at the onset of the burst occurred synchronously with the action potentials in the multi-unit recording. (d) Later in the burst, large population spikes were recorded with both electrodes. Reproduced from Patrylo PR, Kuhn AJ, Schweitzer JS, and Dudek FE (1996) Multiple-unit recordings during slow field-potential shifts in low-$[Ca^{2+}]_o$ solutions in rat hippocampal and cortical slices. *Neuroscience* 74: 107–118.

oscillations directly and, in particular, if these mechanisms could be altered in a manner that could block seizure onset.

Gap Junction Communication Among Cortical Pyramidal Cells

A variety of recent studies have begun to focus interest on the role of specific connexins in electrotonic coupling in the hippocampus and neocortex. Considerable debate has existed on whether multiple types of connexins mediate electrotonic coupling among neurons, but recent freeze-fracture immunogold labeling has provided extremely strong evidence that connexin-36 – and not connexin-32 or 43, or any other connexin identified to date – mediates electrotonic coupling among neurons in the mammalian brain. Interneurons are electrotonically coupled through gap junctions containing connexin-36, but it is currently not clear about the degree to which gap junctions on pyramidal cells also use connexin-36. Previous computer modeling studies suggested that gap junctions are more likely to be present on axons than on dendrites, and recent studies with thin-section electron microscopy and freeze-fracture immunogold labeling suggest that gap junctions are on both pyramidal and granule cell axons. This finding leads to the issue of the functional role of fast prepotentials or spikelets often seen in cortical neurons. The classical view was that these fast prepotentials represent the passive spread of active action potentials in cell dendrites. However, most recent studies strongly indicate that action potentials are initiated near the soma (at the axon hillock) and backpropagate into the dendrites. The combination of the presence of gap junctions, computer modeling studies, and previous electrophysiological research strongly suggests that fast prepotentials are electronic coupling potentials.

Challenges for the Future

Unlike typical chemical synaptic transmitter systems, or even voltage-dependent ion channels, gap junctions and electrical field effects are difficult to block with high selectivity. Recently, a number of compounds have become available to use as gap junction blockers. Probably the most widely used gap junction blocker has been carbenoxolone, but recently mefloquine has been used to suppress transmission between cells electrically coupled via gap junctions. Unfortunately, these compounds may not be selective, and there is concern that experiments with these drugs could involve other mechanisms. Nonetheless, numerous studies have provided evidence that gap junction blockers tend to suppress synchronized electrical activity. A number of studies have also shown that treatments that increase the size of the extracellular space, such as bath application of mannitol and sucrose, suppress synchronized electrical activity when chemical synapses are blocked (and when they are not blocked); furthermore, dilution of the extracellular fluid to decrease the osmolality can induce seizure activity, suggesting that cell swelling promotes seizures. These mechanisms of altering electrical interactions suggest a potential role for them in seizure activity. A major challenge for the future is to develop more specific treatments to affect these types of electrical interaction. Identification of molecules with selective actions on gap junctions and on ephaptic mechanisms could be extremely useful, not only for

identifying the role of nonsynaptic interactions in the generation of fast oscillations and synchronization of action potentials, but also for potentially treating patients with epileptic seizures.

Introduction

Nonsynaptic transmission refers to the mechanisms of neuroexcitation that continue to operate during the complete blockade of synaptic function. The ionic shifts that take place outside of the cell during nonsynaptic transmission occur in extracellular space (ECS) that typically comprises 20% of brain volume. The volume of ECS is not static and can be altered with water flux in and out of brain cells. For example, rapid uptake of water by swelling astrocytes expands the cellular volume, thereby decreasing the surrounding extracellular space. By manipulating the hydration status of patients suffering from epilepsy, it has been shown that dehydration can reduce seizure incidence, possibly by osmotic cell shrinkage and concomitant expansion of the ECS. In contrast, excessive hydration resulted in more frequent seizure events. Subsequent experiments in brain slices demonstrated that altering ECS volume by osmotic manipulation affected the incidence of neuronal bursts, even in the case when synaptic transmission was blocked. Taken together, these studies suggest that changes in ECS volume due to osmotic water movement play a role in the excitability of nervous tissue by modulating nonsynaptic mechanisms.

The glial water channel AQP4 is abundantly expressed in the central nervous system (CNS). AQP provides a

identifying the role of nonsynaptic interactions in the generation of fast oscillations and synchronization of action potentials, but also for potentially treating patients with epileptic seizures.

Introduction

Nonsynaptic transmission refers to the mechanisms of neuroexcitation that continue to operate during the complete blockade of synaptic function. The ionic shifts that take place outside of the cell during nonsynaptic transmission occur in extracellular space (ECS) that typically comprises 20% of brain volume. The volume of ECS is not static and can be altered with water flux in and out of brain cells. For example, rapid uptake of water by swelling astrocytes expands the cellular volume, thereby decreasing the surrounding extracellular space. By manipulating the hydration status of patients suffering from epilepsy, it has been shown that dehydration can reduce seizure incidence, possibly by osmotic cell shrinkage and concomitant expansion of the ECS. In contrast, excessive hydration resulted in more frequent seizure events. Subsequent experiments in brain slices demonstrated that altering ECS volume by osmotic manipulation affected the incidence of neuronal bursts, even in the case when synaptic transmission was blocked. Taken together, these studies suggest that changes in ECS volume due to osmotic water movement play a role in the excitability of nervous tissue by modulating nonsynaptic mechanisms.

The glial water channel AQP4 is abundantly expressed in the central nervous system (CNS). AQP provides a

highly efficient transmembrane route for water transport driven by osmotic gradient or hydrostatic pressure. The deletion of AQP4 in mice has been shown to attenuate neuronal excitability in the retina, inner ear, olfactory mucosa, and cerebral cortex. Recent data indicate that AQP4 may be involved in the nonsynaptic mechanism of seizure development and propagation. Multiple seizure models reveal higher seizure threshold, prolonged seizure duration, and slowed potassium kinetics in AQP4-deficient mice.

Evidence to date suggests that AQP4 may modulate the excitability of the nervous tissue through the following mechanisms. The deletion of AQP4 was shown to cause ECS expansion in brain, thus allowing ions and neurotransmitters to distribute in a larger volume and facilitate their diffusion. In addition, AQP4 colocalizes with the inwardly rectifying potassium channel Kir4.1 in Muller cells of the retina and astrocyte end feet. It has been proposed that AQP4 and Kir4.1 form an ion–water transport cluster, which facilitates the clearance of potassium accumulated during neuronal activity. Based on the available literature, in this article, we dissect these potential mechanisms by which AQP4 may contribute to nonsynaptic mechanisms of epilepsy.

Background

Aquaporins

Water transport and homeostasis are essential for the function and survival of all living cells. Although water can freely diffuse through cell membranes, in some cell types water transport is facilitated by transmembrane water channels called aquaporins (AQPs). At present, 13 members of the AQP family have been identified and they are widely expressed in nearly all mammalian tissues (**Table 1**). The first member, channel-like integral protein of 28 kDa (CHIP28) now named aquaporin-1 (AQP1), was isolated and cloned from red blood cells. The AQP1 channel has high selectivity and permeability for water ($p_f \sim 2 \times 10^9$ water molecules per second) where the flux is driven by osmotic and/or hydrostatic forces. The remarkable water selectivity is explained by high resolution X-ray structure of a single channel unit (**Figure 1**). An AQP1 monomer consists of six tilted transmembrane α-helices, forming a barrel-like structure that harbors a central aqueous pathway of 3 Å, which allows the passage of a single file of water molecules (hour glass topology). In the cell membrane, AQP1 functions as a tetramer, with each of the subunits constituting an independent water selective pore. Many of the subsequent members of the family that were identified demonstrated similar principals of subunit structure and tetramerization. One important exception is AQP4. Freeze fracture electron microscopy of cell membranes rich in AQP4 revealed the formation of higher-order square arrays of particles consisting of hundreds of AQP4 tetramers. These structures were found to represent the previously described orthogonal array particles (OAPs). Whether AQP4 is organized in these OAP structures to better facilitate transmembrane water flux or to provide efficient anchoring of these water transport clusters remains an open question.

Multiple unexpected roles of AQPs have also been demonstrated. The deletion of AQP1 resulted in slowed tumor growth due to reduced angiogenesis and cell migration. Members AQP 3, 7, and 9 expressed in skin, adipose tissue, and the CNS, respectively, were found permeable to glycerol and lactate (aquaglyceroporins), and subsequently shown to play a role in cell energy-metabolism. The AQP with the highest water permeability, AQP4, was shown to facilitate glial scar formation and cell migration in the CNS, and there are also reports suggesting its role in intercellular adhesion.

Aquaporins in the Central Nervous System

AQP1 and AQP4 help regulate water homeostasis in the central nervous system. The movement of water in and out of the brain is facilitated by the polarized expression of these two channels at key locations of water transport, such as CSF–brain- and blood–brain barrier (BBB). AQP1 is expressed in the choroid plexus, where it facilitates the formation of cerebrospinal fluid (CSF). In this process,

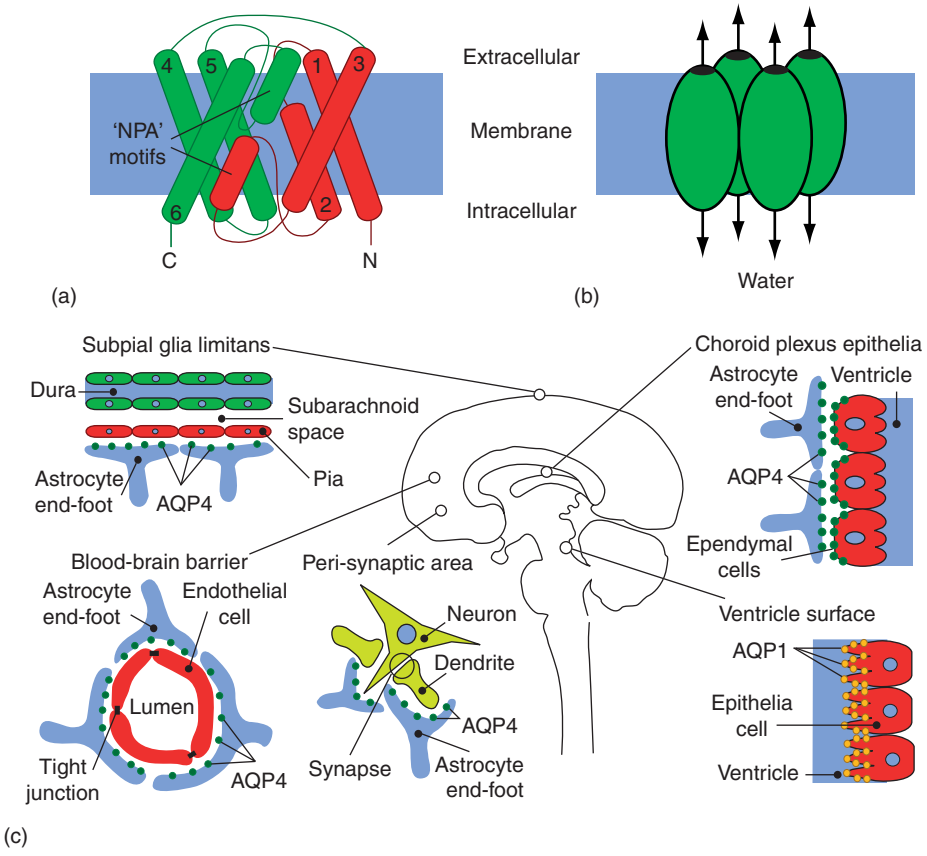

Figure 1 (a, b) Structure of AQP1 monomers and their organization into tetramers. (a) Model showing the six transmembrane α-helices of AQP4 numbered from 1 to 6, forming the highly selective water pore. The conserved 'NPA' motifs are indicated. (b) Tetrameric organization of AQP1 monomers in the plasma membrane. Each AQP1 unit functions as an independent channel. (c) AQP expression at water trafficking interfaces in the CNS. Glial end-feet facing CSF–brain and the blood–brain barrier show polarized expression of AQP4. Ependymal cells a show basolateral localization of AQP4. Apical processes of the choroids plexus cells are rich in AQP1.

active transport mechanisms create an ionic gradient between the choroid epithelial cell plasma membrane and the CSF space, providing an osmotic drive for water flux through AQP1 (Figure 2). The deletion of AQP1 resulted in an approximately 20–25% decrease of CSF production. AQP4 is also expressed at the CSF–brain barrier, where it is localized to the basolateral surface of ependymal cells lining the ventricles, and the subpial processes of astrocytes called the glia limitans. The functional significance of AQP4 in the transepemdymal reabsorption of CSF was demonstrated by the accelerated expansion of the cerebral ventricles and the elevated intracranial pressure in a mouse model of obstructive hydrocephalus. The abundance of AQP4 in the perivascular astrocyte processes suggests a role in water transport at the BBB. AQP4 is the predominant water channel in astrocytes. The deletion of AQP4 results in a sevenfold decrease in astrocyte osmotic water permeability. The intracellular uptake of fluid in cytotoxic edema (seen in stroke and experimental water intoxication) is facilitated by AQP4, whereas the reabsorption and clearance of extracellular edema (extravasated from leaky cerebral vessels associated with tumors and abscesses) were impaired by the AQP4 deletion. These findings demonstrate the important roles of AQP1 and AQP4 in brain water transport in health and disease.

Nonsynaptic Mechanisms of Neuroexcitation

The function and role of neuronal synapses have been widely studied in epilepsy, but processes independent of active chemical synapses – termed nonsynaptic transmission – have also gained considerable recognition. The significance of nonsynaptic transmission was first suggested by the generation and the spread of spontaneous electrical bursts elicited by antidromic stimulation in hippocampal slices. Subsequent experiments have further demonstrated that both ephaptic transmission (electrical current flow through the extracellular space) and ionic concentration changes (most importantly $[K^+]_0$ and $[Ca^{2+}]_0$) contribute to the nonsynaptic spread of neuroexcitation. The brain extracellular space (ECS) contributes the medium for these ionic movements, and accordingly, changes in ECS parameters are expected to modulate nonsynaptic transmission.

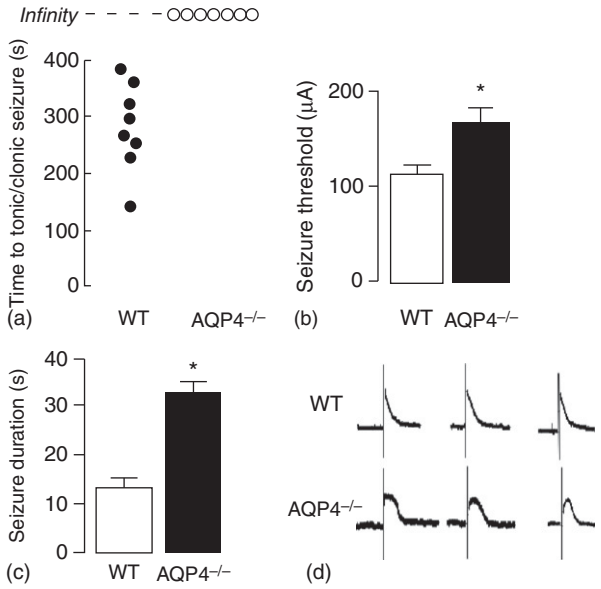

Figure 2 The deletion of AQP4 lowers seizure threshold and prolongs seizure duration. (a) AQP4 deficient mice show decreased seizure susceptibility in response to 40 mg kg^{-1} PTZ. Lowered electrographic seizure threshold (b), prolonged seizure duration (c) and slowed potassium uptake (d) in AQP4$^{-/-}$ mice.

To investigate the impact of ECS changes on neuroexcitation, dynamic changes of ECS volume were correlated with neuroexcitation. With the use of electrical resistance as a measure of ECS size, a small but significant (2%) increase in tissue resistance was recorded preceding seizure generation. Subsequent studies with cortical surface photobleaching have also demonstrated the contraction of ECS prior to the generation of seizures. Additional direct in vivo measurement of ECS volume, using the tetramethylammonium (TMA) method, has demonstrated elevated neuroexcitation in relation to contracted ECS size in the CA1 region of the hippocampus. In vitro alteration of the osmolarity of the bathing solution is known to cause changes in cell volume, which consequently modifies the ECS size and alters neuroexcitation. When manipulating the ECS size by exposure to varied osmotic environments, contracted ECS was shown to facilitate neuronal synchronization through enhancement of spatial effectiveness of nonsynaptic transmission, while ECS expansion eliminated synchronization. ECS expansion does not alter the excitability of the individual neurons; that is, resting membrane potential and action potential threshold of individual neurons are not altered during iso- and hyposmotic challenges. This observation suggests that synaptic and nonsynaptic mechanisms can operate independently.

Methods

We have conducted extensive research into testing different phenotypes of mice lacking AQP4. In initial experiments, isolated brain membrane vesicles and astrocyte cultures from AQP4-deficient mice were found to have significantly slowed swelling in response to an osmotic challenge, demonstrating the dominant role of AQP4 in facilitating water flux in brain tissue. The AQP4-deficient mice show no appreciable alteration in the baseline phenotype: they develop normally and show no gross difference in CNS anatomy. However in pathological states such as cerebral edema from tumors, inflammation, ischemia, and trauma, these mice have phenotypes that demonstrate the central role of AQP4 in brain water homeostasis.

AQP4-deficient mice have been tested using numerous models of neuroexcitation, such as cortical spreading depression, chemically or electrically evoked seizures, and light and auditory evoked potentials. Phenotypes were characterized in cell cultures and live animals, using whole cell patch clamp recordings, field recordings, and in vivo measurement of extracellular potassium kinetics with potassium sensitive electrodes.

Fluorescent methods for measuring diffusion in brain ECS environment have also been developed (**Figure 3**). The basic principle of FRAP (fluorescence recovery after photobleaching) was used in two different applications to assess macromolecular diffusion in brain ECS. Membrane impermeant, noninteracting fluorescently labeled dextrans were loaded into brain ECS via topical application or by microinjection delivery. With dedicated optics (immersion objective or microfiber optics), a bleach pulse was applied to the brain volume loaded with the fluorophore. Following this very brief (ms length) bleaching stimulus, the fluorescently labeled molecules from the surrounding unbleached areas diffuse into the bleached volume, giving a recovery signal (**Figure 3(a)**, right). The fluorescent signal is recorded by the optics and displayed as a recovery curve (**Figure 3(a)**, left). The speed of diffusion in brain is subsequently compared with free diffusion in a control solution to yield a measure of relative diffusion in the ECS.

Recent Results

AQP4 Modulates Neuroexcitation

The first finding to suggest a role for AQP4 in modulating neuroexcitation was its wide expression in electrically excitable tissues. AQP4 is most abundant in support cells such as astrocytes in the brain and spinal cord, Muller cells of the retina, and the Claudius and Hensen cells of the inner ear. At these sites AQP4 was found to co-localize with the inwardly rectifying potassium channel Kir4.1, which led to the idea that water flux and potassium flux might be coupled. Supporting this hypothesis, multiple models using AQP4 deficient mice demonstrated attenuated neuroexcitation and slowed potassium kinetics. Increased auditory brainstem evoked response threshold

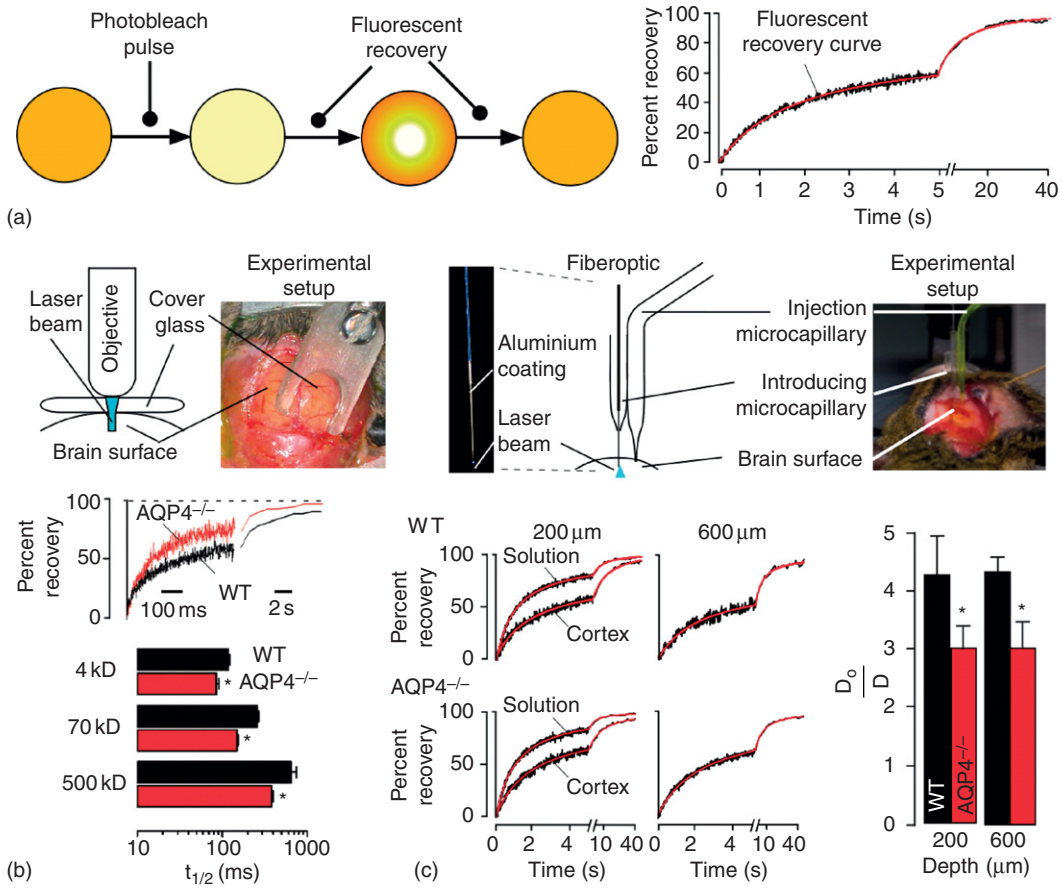

Figure 3 Principle of fluorescence recovery after photobleaching (FRAP). A high intensity laser pulse is applied to bleach a volume of fluorescent dye in brain ECS. Fluorescent molecules are replenished via diffusion from surrounding brain regions. The recovery of the fluorescent signal gives a fluorescent recovery curve reflecting the speed of diffusion. and reduced retinal potentials were seen in AQP4-deficient mice. These results indicate a role for AQP4 in modulation of neuroexcitation.

AQP4 Modulates Ion Fluxes in Seizures

Similar to the previous models of neuroexcitation, phenotypic analysis of AQP4-deficient mice was conducted using both chemical and in vivo electrical stimulation and electroencephalographic (EEG) recording (**Figure 2**). The AQP4-deficient mice proved to be less susceptible to seizures, requiring a higher dose (50 mg kg^{-1} vs. 40 mg) of the chemoconvulsant pentylenetetrazol (PTZ) or higher intensity electrical stimulation (167 ± 17 µA vs. 114 ± 10 µA) to produce seizures. Once initiated, AQP4-deficient mice showed significantly prolonged seizure duration compared to wild type controls (33 ± 2 s vs. 13 ± 2 s). The possibility that the slowing of potassium kinetics could account for the seizure phenotype of AQP4-deficient mice was tested directly. Parallel measurements of ECS potassium using ion sensitive microelectrode demonstrated similar baseline potassium values and peak potassium values during seizure discharge; however, there was a significant prolongation in potassium recovery to baseline in the AQP4-deficient mice ($t_{1/2}$ = 6.6 ± 0.7 s vs. 0.5 ± 0.1 s in wild type). The development of a new long wavelength potassium sensor dye also helped to reveal significant slowing of potassium uptake during cortical spreading depression in APQ4-deficient mice. It was proposed, based on these studies, that AQP4-dependent water transport was coupled to potassium flux through Kir4.1.

To test whether there was a functional association between AQP4 and Kir4.1, freshly isolated CNS astrocyte and Muller cells were subjected to whole cell and single channel patch recordings. During these experiments, seizure equivalent conditions of elevated potassium ($[K^+]_0$ = 20 mM) were reconstituted. Surprisingly,

whole cell patch of AQP4-deficient cells did not show significant differences in barium-sensitive Kir4.1 current or current-voltage curves. Single channel recordings failed to reveal differences in Kir4.1 unitary conductance, voltage-dependent open probability or voltage–current relationship. However, more recent results have provided evidence demonstrating a functional association of AQP4 and Kir4.1. The protein Dp75 is responsible for anchoring AQP4 and Kir4.1 at the end feet of the Muller cell, and its deletion was shown to reduce AQP4 expression, producing a partial AQP4 knockout while leaving Kir4.1 levels unchanged. Freshly isolated Muller cells of Dp75-deficient mice, exposed to an elevated potassium ($[K^+]_0 = 50$ mM), showed decreased potassium currents compared to wild-type controls. It is possible that in the earlier experiments with the AQP4-deficient cells, they were exposed to an insufficient transmembrane $[K^+]$ gradient (20 mM). These conflicting results suggest that further studies are needed to define the functional role of the AQP4–Kir4.1 ion–water transport complex. It should also be noted that during seizure events, the ceiling level of potassium reaches about 12 mM, which is considerably less than the 20 or 50 mM used in these experiments. Therefore, the functional significance of the Kir4.1-AQP4 interaction remains uncertain in seizures.

AQP4 Modulates ECS Parameters in Seizures

Another potential mechanism by which AQP4 may affect neuroexcitation is via modulating nonsynaptic transmission through changing ECS parameters such as diffusion hindrance and ECS volume fraction. The expression of AQP4 was demonstrated to affect both baseline as well as dynamic changes in ECS. Mice lacking AQP4 were shown to have enhanced macromolecular diffusion as demonstrated by cortical surface photobleaching and mirofiber-optic epifluorescent photobleaching (**Figure 3**). These results have been interpreted to reflect an expanded ECS volume fraction in the AQP4-deficient mice. Although the differences in ECS diffusion were as subtle as ~20%, based on in vitro results from brain slices, they may well account for the alterations seen during neuroexcitation. Experiments using hypersmotic media to modulate ECS volume fraction have demonstrated that increasing osmolarity by as low as 5–30 mOsm kg^{-1} inhibits high $[K_0]$ induced seizure events in brain slices. The correlation established between ECS volume fraction and ECS osmolarity dictates that ECS volume fraction is increased to 21.5–23.6%, from the physiological value of ~21% – which corresponds to the range of potential differences between AQP4-deficient and wild-type mice based on measurements of ECS diffusion. Confirmation of these differences will require direct measurement of ECS parameters.

AQP4 function may also affect nonsynaptic transmission by modulating dynamic changes of ECS volume. The relevance of ECS volume fraction changes in neuroexcitation has been demonstrated by multiple studies. Experiments with hippocampal slices showed a subtle but progressive increase of tissue resistance indicative of ECS volume contraction that preceded seizure initiation. The subsequent synchronized neuronal firing has been shown to be associated with reduced ECS volume fraction, as assessed by direct measurement with the TMA method, changes in the intrinsic optical signal, and reduced diffusion assessed by cortical surface photobleaching. ECS contraction in acute seizures has also been studied with diffusion weighted imaging (DWI) that shows reduced diffusion indicating cell swelling. In vitro data suggest that these dynamic changes in cell size may be dramatically altered by the lack of AQP4. As previously discussed, osmotic cell swelling is greatly reduced in AQP4-decicient astrocytes. We have also seen similar reduction in cell swelling in astrocytes exposed to an elevated potassium ($[K^+]_0 = 50$ mM). These data suggest that AQP4-dependent astrocyte swelling may contribute to ECS contractions and subsequently modulate concentration of ions and neurotransmitters during synchronized neuronal activity.

Future Goals

Based on the current data, AQP4 may modulate nonsynaptic transmission via its effects on the ECS and potassium flux, two mechanisms that most likely coexist during seizure events (**Figure 4**). The main challenge is to further explore these interrelated mechanisms. Further experiments, examining potassium conductance in AQP4-deficeint astrocytes exposed to potassium concentrations ranging from near physiological levels to the higher concentrations observed during CSD, are needed to resolve the current conflicting data regarding the functional interaction of AQP4 and Kir4.1. The biophysical association between water and ion fluxes also needs to be studied with respect to the effects on the intra- and extracellular compartments. For example, potassium fluxes driven by the existing electrochemical gradient may subsequently create an osmotic drive for water flux that requires AQP4 to facilitate transmembrane water transport. This question may be addressed using an in vitro cellular system where AQP4 and Kir4.1 are substituted with different members from their respective families to determine whether this is a general mechanism of coupled ion–water transport, or a mechanism specific to the AQP4–Kir4.1 interaction.

Capitalizing on the available evidence, the significance of AQP4 in the treatment of epilepsy will be explored along several avenues. If water transport through AQP4

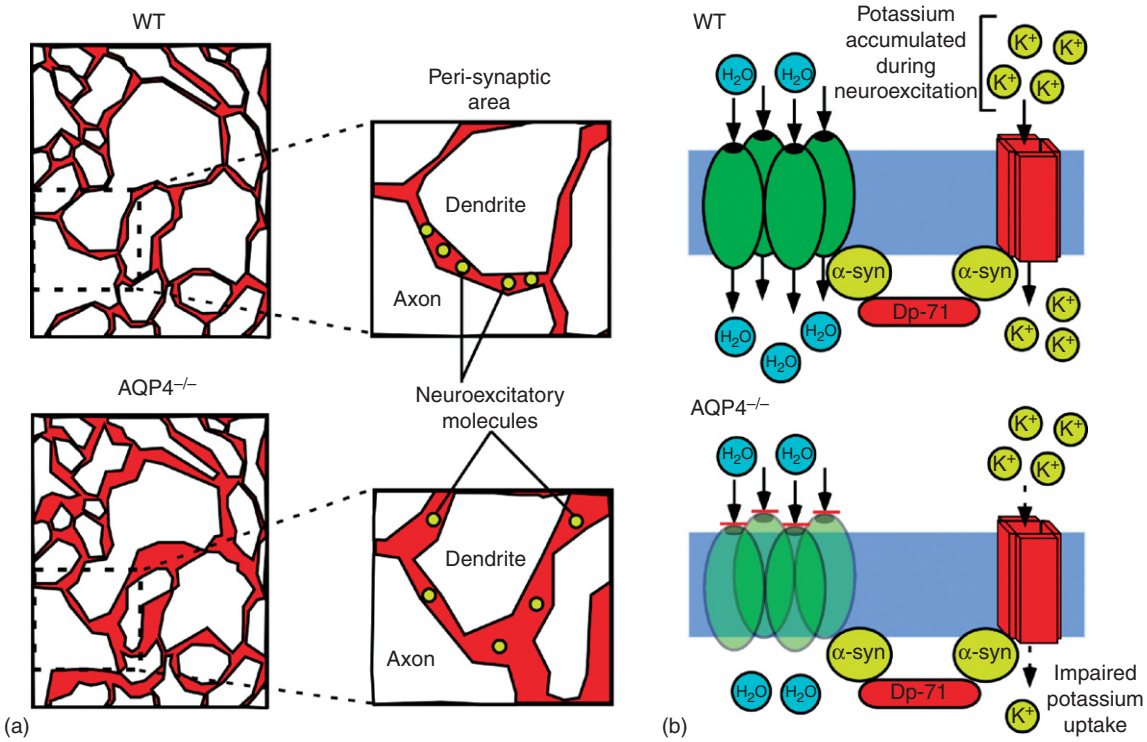

Figure 4 (a) AQP4 modulates ECS diffusion. Neuroexcitatory molecules released during neuronal firing may distribute into a larger volume due to the expanded ECS of AQP4$^{-/-}$ mice, resulting in lower seizure threshold. (b) AQP4 modulates ion fluxes. Potassium is elevated during neuroexcitation and also contributes to seizure progression. The functional coupling between Kir4.1 and APQ4 contributes a water–ion trafficking cluster facilitating potassium uptake into astroglia. Note the molecular scaffolding contributed by members of the dystroglycan complex (α-syntrophin and Dp71). The deletion of AQP4 results in slowed potassium kinetics, which translates to prolonged seizure duration in AQP4$^{-/-}$ mice.

facilitates more efficient transcellular potassium currents, modulation of AQP4 expression may enhance potassium buffering during seizures. Several studies have identified compounds that appear to upregulate AQP4; although the time window of their effect on AQP4 expression may preclude their use for the acute treatment of seizures, their utility for chronic modulation of AQP4 expression should be examined. The inhibition of AQP4 could potentially expand baseline ECS volume, contributing a larger distribution space for potassium and neurotransmitters released during neuronal firing. Exploration of this effect, however, will require the development of inhibitors of AQP4, which to date have not been successful. When available, AQP4 inhibitors could be administered to determine whether they can achieve chronic ECS expansion and increase seizure threshold. The continued exploration of the role of AQP4 in the nonsynaptic mechanism of epilepsy will likely lead to a better understanding of the complex interrelationship of ion and water transport, cell swelling, and the ECS in health and disease.

Finally, the function of AQP4 in ECS dynamics should be tested. A series of ultrastructural studies in cortical spreading has shown cell swell during cumulative neuronal firing, followed by a subsequent recovery to baseline as the neuronal activity terminates. These changes in cell volume translate to dynamic changes in ECS; as cells initially swell, ECS contracts and subsequently recover to baseline. Such ECS changes may impact on neuronal excitation by altering the volume or distribution of ions and neurotransmitters. We speculate that by facilitating transmembrane water flux, and thus cell volume changes, AQP4 is likely to enhance ECS dynamics and again modulate neuroexcitatory processes. Further experiments and mathematical modeling of these phenomena will help to relate ECS dynamics to the characteristic changes in extracellular potassium concentration during neuroexcitation.

Role of Gap Junctions in Epileptic Synchronizations

S Gigout, J Louvel, and R Pumain, Inserm U894, Centre Paul Broca, Paris, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Intercellular communication through gap junctions (GJs) in brain is increasingly recognized as playing an important role in neuronal synchrony and seizure generation, participating in both normal and pathological conditions. In this article, we describe the effect of GJ blockers on epileptiform activities generated in vivo and in vitro in an animal model of generalized absence epilepsy, and in vitro in neocortical tissue excised from patients presenting with partial epilepsy.

GJs are formed of specific proteins named connexins (Cx) or pannexins. GJ channels consist of two hemichannels (connexons), each made up of six Cx surrounding a central aqueous pore that permits the passage of ions, second messengers, and metabolites (up to 1 kDa). Cx 26, 29, 30, 32, 36, 37, 40, 43, 45, 46, and 47 are expressed in the brain, with marked variation according to the developmental stage and cell type. GJs have been described between neurons or between glial cells, rarely between glia and neurons. Cx43 is the major Cx in astrocytes while Cx36 and Cx45 are detected only in neurons. In the rodent neocortex and in the nucleus reticularis thalami (nRT), GABAergic interneurons are interconnected via electrical synapses and express Cx36, while very few GJs exist between pyramidal cortical neurons.

Background

It has been shown in several in vitro and in vivo models of epilepsy that blocking or enhancing GJ function respectively decreases or increases epileptiform neuronal synchronization. For example, carbenoxolone (CBX: the succinyl ester of glycyrrhetinic acid), a GJ blocker, has an inhibiting or delaying action on epileptiform activities in various models of epilepsy when locally applied in vitro or injected i.p in vivo. Recent studies in mouse knockouts for the Cx36 gene (the major neuronal Cx) did not reveal any obvious developmental or behavioral abnormalities, but showed a decreased intensity of epileptiform discharges induced by convulsant drugs, a result consistent with reduced electrical coupling between interneurons. In addition, neuronal synchronization reflected in field potential/EEG activity at various frequencies – gamma rhythms or high-frequency oscillations in the ~200-Hz

Role of Gap Junctions in Epileptic Synchronizations

Introduction

Intercellular communication through gap junctions (GJs) in brain is increasingly recognized as playing an important role in neuronal synchrony and seizure generation, participating in both normal and pathological conditions. In this article, we describe the effect of GJ blockers on epileptiform activities generated in vivo and in vitro in an animal model of generalized absence epilepsy, and in vitro in neocortical tissue excised from patients presenting with partial epilepsy.

GJs are formed of specific proteins named connexins (Cx) or pannexins. GJ channels consist of two hemichannels (connexons), each made up of six Cx surrounding a central aqueous pore that permits the passage of ions, second messengers, and metabolites (up to 1 kDa). Cx 26, 29, 30, 32, 36, 37, 40, 43, 45, 46, and 47 are expressed in the brain, with marked variation according to the developmental stage and cell type. GJs have been described between neurons or between glial cells, rarely between glia and neurons. Cx43 is the major Cx in astrocytes while Cx36 and Cx45 are detected only in neurons. In the rodent neocortex and in the nucleus reticularis thalami (nRT), GABAergic interneurons are interconnected via electrical synapses and express Cx36, while very few GJs exist between pyramidal cortical neurons.

Background

It has been shown in several in vitro and in vivo models of epilepsy that blocking or enhancing GJ function respectively decreases or increases epileptiform neuronal synchronization. For example, carbenoxolone (CBX: the succinyl ester of glycyrrhetinic acid), a GJ blocker, has an inhibiting or delaying action on epileptiform activities in various models of epilepsy when locally applied in vitro or injected i.p in vivo. Recent studies in mouse knockouts for the Cx36 gene (the major neuronal Cx) did not reveal any obvious developmental or behavioral abnormalities, but showed a decreased intensity of epileptiform discharges induced by convulsant drugs, a result consistent with reduced electrical coupling between interneurons. In addition, neuronal synchronization reflected in field potential/EEG activity at various frequencies – gamma rhythms or high-frequency oscillations in the ~200-Hz

domain (ripples) – were also affected in these mice, both in the cortex and hippocampus. It has also been postulated that changes in Cx expression may play a role in epileptogenesis. Elevated levels of the astrocytic Cx43 have indeed been reported in the human epileptogenic tissue.

Over the last few years, several studies have highlighted a paradoxical role for GABA receptor-mediated mechanisms in initiating and maintaining epileptiform synchronizations; in particular, GABA-mediated synchronous activities can be instrumental in triggering epileptiform discharges. These epileptiform events continue to occur during application of glutamatergic receptor antagonists, and are abolished by application of the $GABA_A$ antagonist bicuculline. In this context, investigators have speculated that GJs between GABAergic cells may represent an important mechanism for such epileptiform synchronization. This hypothesis has been supported by the observation that CBX abolishes the synchronized negative-going field potentials generated in rodent CA3 pyramidal neurons during application of the K^+ channel blocker 4-aminopyridine (4AP), and also blocks the 4AP-induced neocortical seizures in rats in vivo. Such GABA receptor-mediated synchronous events can also be recorded in the presence of 4AP in neocortical slices obtained from patients undergoing surgery for epileptic disorders such as temporal lobe epilepsy (TLE) or focal cortical dysplasia (FCD).

Seizures are generated in the thalamocortical system in typical absence epilepsies. We investigated in vitro the role of GJs in thalamocortical synchronizations using thalamocortical slices from Genetic Absence Epilepsy Rats from Strasbourg (GAERS), a well-established rodent model of absence epilepsy, and in Non-Epileptic Rats (NER). We tested whether epileptiform activities recorded in thalamocortical slices prepared from GAERS or NER were equally sensitive to GJ blockers. We also examined whether CBX had an antiepileptic effect on spontaneous spike-wave discharges (SWD) recorded in the GAERS in vivo.

Finally, we sought evidence for a functional role played by GJs in the human neocortex during generation of synchronous GABA receptor-mediated potentials, as recorded in neocortical slices obtained from TLE patients during bath applications of 4AP and of glutamatergic receptor antagonists. In addition, we tested the effects of GJ blockers on the spontaneous synchronous activities occurring in some FCD neocortical slices in the absence of any pharmacological manipulation.

Methods

Tissue

Samples of human neocortex were obtained from the anterior part of the second temporal gyrus in the course of neurosurgical interventions for medically intractable seizures associated with TLE, or from FCDs in temporal or frontal external cortices. The tissue used for the in vitro electrophysiological investigations was part of a block of brain tissue removed for strict therapeutic reasons. Informed consent was obtained according to the guidelines of the ethics committees of the Hôpital Sainte-Anne (Paris, France) and of the Montreal Neurological Institute and Hospital (Montreal, P.Q., Canada).

In vivo studies were performed in GAERS and in NER aged 3–4 months. In vitro experiments were performed on brain slices from GAERS and NER, both young (aged 20–25 days) and adult (aged 40–50 days). All animal experiments were performed in accordance with the rules of the European Community Council Directive of November 24, 1986 (86/609/EEC), and the French Department of Agriculture.

Slices

The techniques used for preparing and maintaining human or rat brain slices in vitro were similar to those previously reported. For studies on rat tissue, combined thalamocortical slices (500 μm thick) were obtained using procedures described previously (see Further Reading section).

Slice Preparation Recordings

Extracellular field potentials were recorded with electrodes filled with artificial cerebrospinal fluid (ACSF) positioned under visual control in the supragranular neocortical layers (supposedly layer III) in human slices, or in neocortex or ventrobasal thalamus (VB) in rat thalamocortical slices. To test the effect of GJ blockers (CBX, octanol, and quinidine) on neuronal excitability, constant current stimuli (0.02–1 mA, 80 ms) were delivered every 5 s to the infragranular cortical layers and the fiber responses were measured in supragranular layers; measures were made before drug application, 60 min after application of GJ blockers, and 60 min after drug washout. Slices obtained from TLE patients were continuously perfused with a medium containing 4AP and ionotropic glutamate receptor antagonists. FCD slices were kept either in normal ACSF or in 4AP-containing ACSF. The degree of phase unlocking (more details in the Further Reading section), as assessed in measurements of synchrony recorded from two sites, was determined during 10 min blocks under control condition, 20 min after GJ blocker application, and 60 min after GJ blocker washout.

ECoG Recordings in GAERS and NER

Adult GAERS and NER were implanted with four epidural electrodes over the frontoparietal cortex. All the

animals were allowed 1 week recovery and handled twice a day. All GAERS displayed spontaneous SWD (Figure 1 (a)). After a reference ECoG recording period of 30 min, saline or CBX (50 or 100 mg kg^{-1}) was injected i.p and the recordings were carried on for 90 min. The experimental protocol was as follows: day 1: injection of saline; day 3: injection of CBX 100 mg kg^{-1}; day 5: injection of saline; day 6: injection of CBX 50 mg kg^{-1}. The mean duration, the frequency, and the cumulative duration of SWD episodes were measured during a reference period of 30 min and during three consecutive periods of 30 min after the injection. We also determined the effect of CBX on the EEG power spectra in GAERS and NER, under saline vs. CBX conditions.

Recent Results

Effects of Carbenoxolone Administration *in vivo* in GAERS and NER

Following i.p. CBX injections, the animals' behavior was apparently not impaired, except for a somewhat reduced locomotor activity lasting up to 90 min. At 50 mg kg^{-1} i.p. in GAERS, CBX decreased the SWD cumulative duration nonsignificantly, while at 100 mg kg^{-1} the decrease was highly significant during the first 30-min period (to 41% of the reference period value), due to a reduction of both SWD episode frequency and duration (Figure 1(b)). The frequency and amplitude of spike-waves within a SWD episode were, however, not affected. During the

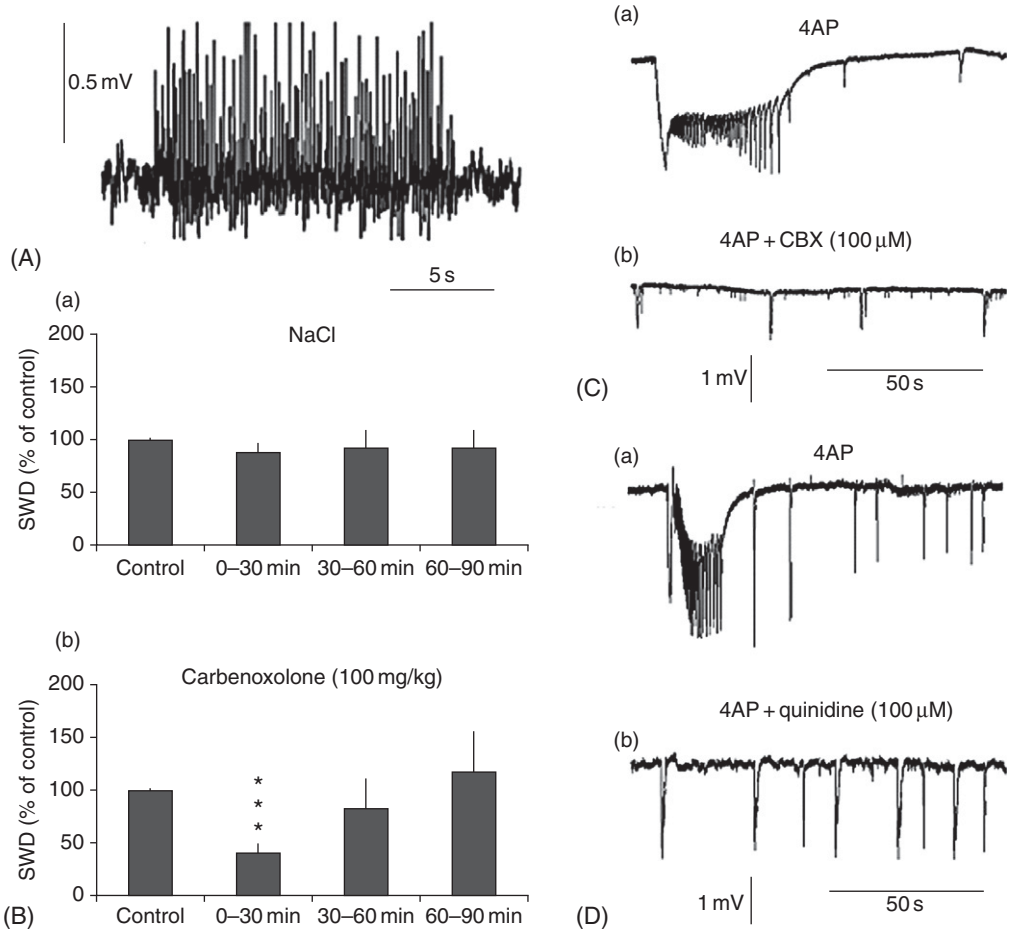

Figure 1 Effects in vitro and in vivo of gap junction blockers on epileptiform activities recorded in genetic absence epilepsy rats from Strasbourg (GAERS). (a) ECoG recordings showing an example of spike-wave discharges (SWD) recorded in freely moving GAERS. (b) Effect of i.p. injections of NaCl (a) and carbenoxolone (CBX) (b) in GAERS on the cumulative duration of SWD. The percentages obtained after CBX injections are compared with those obtained after NaCl injections (***$p < 0.005$). The cumulative duration is significantly decreased during the first 30-min period after CBX injection. (c) Field potential recordings in functional thalamocortical slices. a – ictal-like activity (ILA) induced at the neocortex by bath application of 4-aminopyridine (4AP), triggered by a GABA-dependent negative field potential. b – bath applied CBX (100 μM) abolished the 4AP-induced neocortical ILA after about 30 min while the GABA-dependent negative field potentials remained. (d) a – 4AP-dependent neocortical ILA. b – effect of bath-applied quinidine (100 μM) – a gap junction blocker more specific for the neuronal connexins – on the 4AP-induced neocortical ILA. The GABA-dependent negative field potentials remained but the ILA vanished after about 50 min. Modified from Gigout S, Louvel J, and Pumain R (2006a) Effects in vitro and in vivo of a gap junction blocker on epileptiform activities in a genetic model of absence epilepsy. *Epilepsy Research* 69: 15–29, with permission from Elsevier.

second and third 30-min periods after the injections, no significant effect could be detected. At 100 mg kg^{-1}, CBX induced a significant reduction (to 45% of control) of the spectral power of the frequencies corresponding specifically to the SWD (peak at 6.2 Hz) during the first 30 min. In NER, CBX at 100 mg kg^{-1} did not modify the power of frequencies corresponding to that of SWD, suggesting that CBX had no obvious non-specific effect.

Effects of Carbenoxolone *in vitro*

Effects induced by 4AP on thalamocortical slices

After introducing 4AP at 50 μM in the perfusion medium, synchronous ictal-like activities (ILAs), characterized by an initial tonic phase followed by afterdischarges (superimposed on a characteristic slow field potential shift) were recorded (within 10–40 min) in the neocortex of thalamocortical slices. ILAs were simultaneously observed in the thalamus, we viewed these thalamic events as volume conduction reflections of activities generated at the cortex. ILAs frequency became stable within 60 min, with interevent intervals ranging between 126 and 690 s. Independent briefer and faster activities were recorded in the hippocampus. 4AP induced occurrence of GABA-dependent negative field potentials that were recorded in the somatosensory neocortex but not in the thalamus. These large negative potentials were often observed at the onset of cortical ILAs and appeared as the triggering factor for ILAs in slices from both young and adult animals (**Figure 1(c)**). The $GABA_A$ receptor antagonist bicuculline abolished these GABA-mediated potentials, and also prevented occurrence of ILAs. There was no significant difference between slices from GAERS and NER (from both young and adult animals) regarding the latency of the appearance of the ILAs, their mean duration, their average frequency or their cumulative duration.

Carbenoxolone effects on synchronous activity

The amplitude, and the stimulus intensity threshold, of the fiber and synaptic components of the corticothalamic and thalamocortical field responses were not altered following CBX application, indicating that CBX does not exert its antiepileptic effect via a general, non-specific depressant action on cellular excitability. Bath application of CBX produced a progressive decrease of the frequency of the 4AP-induced ILAs, until they were abolished (**Figure 1(c)**). Quinidine, another GJ blocker more specific for neuronal GJs, also abolished the ILAs in 20–40 min (**Figure 1(c)**). Surprisingly, the 4AP-induced GABA receptor-mediated negative field potentials remained without decrease in amplitude during the 40 min after CBX or quinidine application, even after the disappearance of the ILAs. After 40 min of application, their frequency decreased progressively until they disappeared during the second hour of application; there was no recovery on wash-out.

The decrease in ILAs frequency after CBX was faster in NER slices than in GAERS slices. This difference was significant for the 0–20 min and 20–40 min periods after drug application. In NER, the mean duration of ILAs first increased (during the 20–40 min period after CBX), while in GAERS it decreased progressively. The resulting effect is that during the 0–20-min period after CBX, the cumulative duration of ILAs in GAERS and NER decreased similarly. After a prolonged washout (60–80 min), ILAs could reappear but at a very low frequency.

Effects of Gap Junction Blockers on 4AP-Induced Synchronous Activity in TLE Tissue

Synchronous activities induced by 4AP in human TLE epileptogenic tissue

We never observed spontaneous field potential activity in any of the neocortical slices obtained from TLE patients perfused with physiological ACSF. During superfusion with a medium containing 4AP and ionotropic glutamatergic receptor antagonists, all slices generated spontaneous negative or positive–negative GABA-dependent field potentials (amplitude: 0.2–3 mV; duration: 0.2–0.6 s; intervals of occurrence: 3–27 s). When simultaneous recordings were performed at two sites (distance: 1–5 mm) along an axis parallel to the pial surface (depth: 600–1 000 μm below the pial surface), the field events were phase locked (measured by a phase unlocking index, see Further Reading section for more details). One event (leader) usually preceded the other (follower), with time lags ranging from 25 to 400 ms depending on the distance between the recording sites (**Figure 2**). By measuring the time lags between the synchronous events, an apparent velocity of propagation of 15 mm s^{-1} was calculated. Followers and leaders could sometimes invert their roles.

Effects of gap junction blockers

Bath-application of CBX (0.3–0.5 mM), quinine or quinidine (0.5 mM) had no significant action on the amplitude, or on the stimulus intensity threshold, of the fiber component of the field responses, indicating that these drugs did not exert a marked non-specific effect on neuronal excitability at these concentrations. After bath-application of GJ blockers, the synchronous 4AP-induced negative field potentials remained and their amplitude or shape was not substantially modified during the first 60 min of perfusion – although their frequency could decrease. However, at the largest doses and for more prolonged periods of applications, these could disappear (and their amplitude decreased just before complete disappearance).

The most striking finding was that GJ blockers disrupted the phase locking of the negative field potentials recorded in the cortex at distances of 1–5 mm, at a time

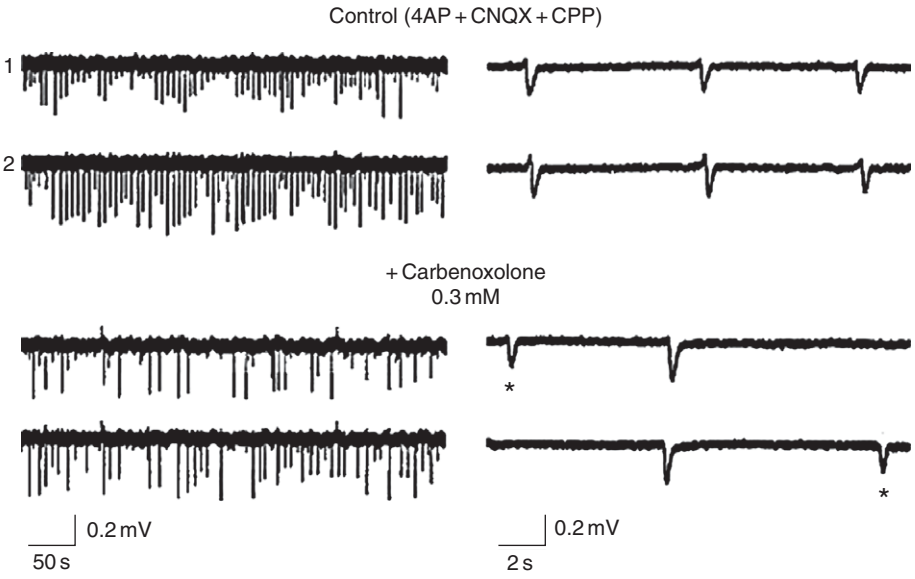

Figure 2 Effects induced by carbenoxolone on synchronous negative field potentials recorded in neocortical slices obtained from patients suffering from temporal lobe epilepsy during 4AP and ionotropic glutamatergic receptors antagonists applications. The spontaneous field events recorded from two sites located 2 mm apart along an axis parallel to the pia (depth: 700 μm) are displayed at two different time bases. These events occurred in synchrony in control conditions (upper right panel). About 30 min after further addition of carbenoxolone (0.3 mM), their frequency was decreased. This effect was accompanied by a disruption in their synchronization (asterisks in the right lower panel). Modified from Gigout S, Louvel J, Kawasaki H, *et al*. (2006b) Effects of gap junction blockers on human neocortical synchronization. *Neurobiology of Disease* 22: 496–508, with permission from Elsevier.

point after application at which their frequency was not reduced. After 20 min of application, CBX (at 0.1, 0.3, or 0.5 mM) produced a significant increase in the phase unlocking index, indicating disruption of phase locking. Quinidine or octanol produced the same effect. Recovery of phase locking was observed after washout of CBX at 0.3 mM, but not at 0.5 mM. Apparent velocities of propagation for the spontaneous activities were not modified by quinidine 100 μM, carbenoxolone 300 μM or octanol 0.5 mM.

Effects of Carbenoxolone on the Synchronous Activity Generated in Focal Cortical Dysplasia Tissue

The only neocortical slices in which spontaneous field potential activities were observed in normal ACSF were prepared from tissue removed from patients suffering from FCD. These events were generated at different sites in the slice and were characterized either by simple field potentials consisting of 1–3 fast negative transients, or by the rhythmic sequence of fast transients riding on a slow negative shift with duration up to 8 s. These events occurred in synchrony when simultaneously recorded from two sites along an axis parallel to the pia (distance up to 3 mm) with time delays between 10 and 50 ms (apparent velocities of propagation of 45–142 mm s^{-1}). Application of NMDA receptor antagonists reversibly abolished, within 5–10 min, these spontaneous events. Single-shock electrical stimuli induced prolonged after discharges (duration of 1–4 s) which were also abolished within 5–10 min by NMDA receptor antagonists.

These spontaneous synchronous activities were markedly reduced or abolished by CBX applications (0.3 mM), within approximately 30 min. These effects were characterized by disruption of phase locking between activities recorded at two different neocortical sites (as identified by analyzing the interevent histograms or the mean phase unlocking measure). The effects induced by CBX were partially reversed during prolonged washout (over 60 min). The stimulus-induced responses recorded under control conditions in these FCD neocortical slices were also reversibly abolished by CBX applications.

Conclusions and Future Goals

These experiments were performed in a model of generalized absence epilepsy and in human cortical tissue excised from patients suffering from partial epilepsy. In both cases, blockade of GJs decreased the expression of epileptic manifestations. More specifically,

- GJ blockers reduced the frequency of spontaneous SWD in vivo.
- The main effect of CBX on the 4AP-induced epileptiform activities in vitro was to abolish the ILAs, without suppressing or modifying the GABA-mediated potentials which initiated them. This observation indicates

that, surprisingly, CBX does not prevent synchronization of interneurons (which was expected in view of the specific electrical coupling of interneurons in the neocortex) but rather interferes with transfer of interneuronal synchronization into seizure activity in the cortex.

- GJs contribute to the spread and phase locking of synchronous GABA-mediated events in neocortical slices from TLE patients, as seen during blockade of ionotropic glutamatergic transmission.
- GJs play a role in the generation of synchronous activity recorded in FCD slices superfused with normal medium.

Very little is known concerning the expression of the various Cx in cortical tissue excised from patients with epilepsy. It would be of interest to determine the nature of the Cx expressed in this tissue and to quantify their expression using RT-PCR. Comparison with 'control' tissue (although difficult to obtain) would be necessary. It would also be very interesting to examine whether GJs are present between interneurons and pyramidal cells in the human epileptogenic cortex or in rodent models of epilepsy. The available GJ blockers have been criticized for their lack of specificity, and the development of drugs that are able to discriminate between the various Cx would constitute a major advance in deciphering the role of electrical coupling in brain.

Introduction

The traditional hallmark of epileptiform discharge is entrained electrical oscillatory activity in a large enough volume of cerebral tissue to be measurable in the context of a possible seizure disorder and cerebral dysfunction. This oscillatory activity seen in seizures is usually characterized by reduced complexity and increased widespread synchrony as compared with 'normal' brain activity. We are trying to understand the mechanisms underlying the various forms of oscillatory activity and their transitions. As such, the big questions are as follows:

1. How do we measure and characterize these oscillatory activities and their transitions?
2. What are the sources of these oscillations: subcellular, cellular (which cells?), local clusters, small or large neural networks? Are there multiple sources of seizure activity? Do seizures tend to arise from a single focus or is a seizure largely an emergent property of a distributed network?
3. How do transitions from interictal to ictal modes occur? Are seizures a manifestation of coupled oscillators? Are transitions to seizure due to internal or external factors?
4. How can one intervene to change these oscillatory modes from an epileptic to a nonepileptic mode?

To answer these questions, we approach the neuronal system as a nonlinear dynamical system where, conceptually, epileptiform seizures are modes of the system's oscillatory activities. Our research includes both *in vitro* and *in vivo* measurements, as well as modeling and analyses of the system dynamics. Understanding the mechanisms of complex oscillations and transitions will be critical for diagnosing and ameliorating the negative effects of seizures. Insight into these mechanisms may also enhance our understanding of the manner in which other transitions in brain activity take place during nonseizure phases and cognitive processing.

Background

Sources and Scales of Oscillatory Activity

Brain oscillations emanate from many sources at many different levels. Although one often thinks of cellular-level sources, in fact there is a rich supply of oscillatory activity within the cell itself (both biochemical and electrical), as well as multiple sources at the whole network level.

Subcellular oscillations

Oscillations are seen within the nucleus and also within subcellular organelles such as mitochondria. Oscillations

of intracellular ionic concentrations such as calcium and pH have been measured, and there are rhythms of molecular processes and intracellular protein cycling at a range of frequencies.

Cellular oscillations

From an electrical perspective, measures of the neuronal membrane potential have shown a wide range of spontaneous oscillatory frequencies (sometimes called 'noise'). These oscillatory activities arise from several sources, including afferent synaptic inputs (both action potential-evoked and spontaneous), intrinsic ionic current fluctuations, and ephaptic (electric field) effects (which are frequently ignored). These spontaneous membrane fluctuations are as yet little studied and their contributions to the extracellularly-measured field fluctuations are not well understood. Furthermore, the contribution of the more numerous non-neuronal cells, such as glia, are even less well-studied, but could be of greater importance than heretofore realized. Cell types, each type with its signature oscillatory activity, make their own specific contribution to the measures of oscillatory activity.

Intercellular connectivity

The interconnectedness of neurons to each other, and to other cell types, is a further factor contributing to the overall measures of brain oscillations. The more a group of cells oscillates together at specific frequencies, the higher are the expected amplitudes of the emanating common signals. There are several factors that will unite a group of cells. The most obvious are chemical synapses. However, direct intercellular connections via gap junctions are particularly evident in cortical and hippocampal interneurons, and there is a growing literature showing a role for gap junctional communication in the genesis of seizures. Another means of synchronizing groups of cells is via synchronous afferent synaptic input, be it excitatory or inhibitory. For example, synchronous inhibitory input into thalamocortical and cortical–thalamic neurons plays a large role in the generation of thalamocortical oscillations in absence seizures. Ephaptic (field) effects can also be a powerful entrainment force, as can be demonstrated by the application of an electrical field to neural tissue via direct or transcranial brain stimulation. Less recognized but of significant importance are the synchronizing actions of changes in extracellular chemical elements such as potassium, pH, glucose, oxygen, and various hormones.

Clusters

An important emerging concept is that of cellular clusters, a group of synchronized cells (usually thought of as neurons, but glia could also be involved), which oscillate together at the same frequency or frequencies. A cluster provides local synchrony for a period of time in a spatial context. The cells involved in a cluster could be coupled together by various mechanisms for brief to prolonged periods, following which individual cellular units of this cluster could become attached to another spatially contiguous cluster. Thus, there might be an ongoing rearrangement of these cellular clusters, giving rise to a constantly changing source of local oscillatory activity. Finally, we conceive that these clusters are physically interdigitated or intermingled.

Networks

From the local clusters of synchronized cellular elements, the next conceptual level is that of the network. Networks may range from connectivity between 'local' units to connectivity across larger brain regions, to the coupling of brain regions (e.g., the limbic system), to connections between distal sites in opposite brain hemispheres. Whatever the scale, the concept of a network is important for the understanding of brain oscillatory activity and its propagation. Brain networks not only comprise several levels of size and complexity but are also likely to be constantly and dynamically re-arranging and regrouping themselves. Moreover, the various subcellular, cellular, and network sources of oscillations are undoubtedly interacting simultaneously across different levels in an ongoing and dynamic manner.

Oscillations and Complexity

Early investigations into chaotic and epileptic brain activity provided convincing evidence that the dynamics seen during various cognitive conditions were significantly more complex than those seen during a seizure. For example, Babloyantz and Destexhe. reported that electroencephalogram (EEG) recordings of human absence seizures showed simple attractor dynamics as compared with sleep brain activity. In general, most such studies have provided strong evidence in favor of the suggestion that epileptic seizures corresponded to a lowering of complexity in brain electrical activity.

Synchrony and the Unbinding Problem

In contrast to these findings indicating the lowering of complexity during seizures, researchers such as Netoff and Schiff have argued that certain types of seizures may actually be associated with an *increase* in complexity in the form of a reduction in synchrony. Moreover, reductions in complexity have been found in response to ordinary sensory stimulation during cognitive processing. For example, by studying the EEG recorded from the olfactory bulb and the prepyriform cortex of the rabbit, Freeman reported that when the rabbit is presented with a familiar odor, the normally high-dimensional chaotic activity suddenly bursts in a regularized pattern. Singer and many other researchers have also suggested that synchrony and other forms of reduction in complexity can explain how the brain might generate coherent representation by spatio-temporal 'binding' of neural activity.

Although transient reductions in complexity may indeed be observed across cognitive conditions, epilepsy has taught us that, in most cases, it is precisely the strong entrainment of activity and reduction in complexity that is most likely to interfere with cognitive processing. It is a defining feature of neural systems that they avoid prolonged simple and entrained activity and that they tend toward complexity. With the exception of conditions such as status epilepticus, even the entrainment seen during seizures is transitory. Although a great deal of the current literature has focused on synchrony and binding, the study of epilepsy suggests that we need to understand how the brain *avoids* binding and urges us to ask what brain anatomical and physiological principles enable complexity?

Even if one assumes that synchrony and the lowering of complexity may be necessary for cognition, the question remains as to what mechanisms ensure the escape from this entrainment. The question is not simple. Ohayon *et al.* have suggested that the tendency toward synchrony and limit-cycle activity is ubiquitous in certain network models and that this problem of locked-in periodic oscillations may worsen in the presence of some forms of plasticity. How does the brain solve this unbinding problem? What are the mechanisms of transition between the various modes of oscillatory activity that avoid 'lockup?'

Transitions, Intermittency, and Modulation

Although the specific nature of the transitions into and out of seizures is a central question in the field, the basic mechanisms of transition and the triggering factors – if any – are often unknown. Lopes da Silva *et al.* have outlined several potential routes to seizures. One possibility is the switching between two pre-existing 'attractor' brain states via a perturbation or noise. In this scenario, the brain might switch from interictal oscillatory activity to seizures following a stimulus, as in the case of certain photosensitive epilepsies. Another potential route involves an increase in susceptibility to seizure brought about by a parametric change in the system, as might happen over time with a hormonal shift or hypoglycemia.

Beyond these two routes there also exists another possibility in which the shift into and out of seizures may occur autonomously of any external stimulus or change in the system. Specifically, *intermittency* is a form of activity wherein a dynamical system may continually alternate between two modes of activity independently of an external perturbation. Velazquez *et al.* have reported intermittency in human partial epilepsy. There are various known forms of intermittency, and various statistical techniques may help identify the type of transition that precedes a given seizure.

The identification of alternate transition categories and an understanding of the mechanisms underlying brain dynamics could play an important role in clinical treatment. In particular, seizures may be modulated or altogether avoided by carefully applying small perturbations to a system, thereby eliminating low-complexity activity. For example, Schiff *et al.* were able to use small electrical brain stimulations to induce a change from lower complexity 'periodic' behavior to high-complexity 'chaotic' responses, suggesting that the technique might be applied to activity in epileptic foci. Other studies have since followed, demonstrating the feasibility of using various forms of stimulation to modulate ictal activity both in models and in vivo.

Methods

Human EEG and Biological Models of Epilepsy

The conventional and still current standard for measuring epileptiform phenomena is extracranial electrographic field recordings – the EEG. In humans, the primary measure is the scalp EEG, which, in cases where the site(s) of origin of the epileptic activity is unclear, is augmented by intracranial recordings. Because seizures are usually spontaneous events, prolonged (days to weeks) recordings are often required before enough seizure activity has been observed for appropriate diagnosis and localization. Until recently, human EEG recordings, including intracranial EEG, were almost always done with filtering of all high-frequency activity above 70 Hz, thus ignoring important data relevant to our understanding of the brain oscillatory activity associated with epilepsy.

There are in vivo and in vitro models of epilepsy and seizures, too numerous to mention. In in vivo models, extra-cranial and/or intracranial EEGs are generally recorded in association with a stimulus (e.g., repetitive subthreshold intracranial stimulation – 'kindling'), introduction of a chemical (e.g., kainic acid, pilocarpine, cobalt, tetanus toxin), or an insult (e.g., cerebral trauma) given to elicit seizures. These seizures can directly follow stimulation, or occur spontaneously, which is more akin to the human situation. In vitro models provide direct access to cerebral tissue for local electrical field recordings, whole-cell or intracellular recording, cellular or local network imaging of ionic changes (e.g., calcium), or electrical changes monitored by voltage sensitive dyes. In vitro models also provide control of the extracellular environment. However, the relation of these in vivo and in vitro models to the oscillations and basic mechanisms of clinical epilepsy is not always clear.

Coupled Oscillators Modeling

To further examine the basic mechanisms of oscillations, there has been extensive use of computational models. For example, the mapped clock oscillator (MCO) first described by Bardakjian and Diamant is quantitative in nature and its parameters can be obtained directly from the measured intrinsic transmembrane voltage waveform

in the biological tissue when a segment of the tissue is isolated by partial or complete cuts from its neighborhood. The model thus allows us to explore multiple critical parameters simultaneously at a level of detail not always possible in biological recordings. When such oscillators are coupled together to form networks, they can qualitatively and quantitatively simulate the electrical oscillations recorded in hippocampal neuronal networks. Such models exhibited spontaneous transitions into seizure-like activities and were used to test approaches to predict and then abolish such activities. More details regarding these coupled oscillator models can be found in Further Reading.

Recurrent and Embodied Network Models

To identify the contributions of network structure to oscillations and transitions, we have also modeled activity propagation in more abstract networks, with units governed by probabilistic activation functions (sigmoid, Gaussian) or simple spiking functions with various architectures. For example, we have examined networks with random connections between cells as well as those with spatially organized local connectivity. These models are helping us explore the relation of structure to oscillations in both intact networks as well as in networks with cell deletions (in order to reflect such conditions as posttraumatic epilepsy). There is also active research being done on a range of network architectures, such as small world networks, which may help explain the difference in forms of oscillation (and susceptibility to seizure discharge) across brain structures.

One issue, however, with many of these models is that they are figuratively and literally disconnected from the environment. As such, a recent step has also been the inclusion of 'embodied networks.' These models consist of networks that are connected to external sensors and transducers (robots), and are evolved with genetic algorithms to maneuver in the environment. These embodied models aim at addressing the increasing recognition that behavioral interaction with the environment is critical to brain development, and has an essential role to play in neural oscillations both in epilepsy and other conditions.

Recent Results

Coupled Oscillators – Biological Data

The concept of coupled oscillators is increasingly recognized as useful for the understanding and modeling of brain activity in general and epileptiform activity in particular. We have demonstrated in the isolated mouse hippocampus that recurrent, spontaneous seizures generate bidirectional epileptiform activity along the septotemporal axis (as measured by multiple electrode recordings and optical imaging), indicating a system of coupled network oscillators (see **Figure 1**). Uncoupling the system of oscillators, by partial or complete cuts, resulted in independent bidirectional activity in the separated tissues. Within the same epileptic burst, low- and high-frequency components originated from different locations. A second seizure model (generated by focal tetanic electrical stimulation) also exhibited bidirectional discharges. Clinical data (unpublished), obtained from adjacent intracranial depth electrodes in the hippocampus of epileptic patients, have similarly revealed bidirectional seizure bursting activity, but at a much larger anatomical scale.

Higher Frequencies and Kindling

As mentioned in the Background section, the importance of high-frequency activity has often been overlooked in human EEG and epilepsy. This focus on low frequency at the exclusion of higher ranges has also extended into various seizure models. For example, it has been known for decades that the changes brought about by the repeated stimulations in kindling can have profound long-term effects on low-frequency oscillations. However, changes in high-frequency components were rarely reported, mostly because of limitations in data acquisition equipment and shortcomings in the prevalent approaches to spectral analysis. By increasing the sampling rates and introducing new forms of analysis, we have shown that there are dramatic changes in power and other characteristics of oscillations across all frequencies during kindled seizures. Specifically, we have demonstrated that there is a significant increase in higher frequency events (>80 Hz) during kindled seizures (**Figure 2(a)**). To identify these changes, we recorded the activity at high sampling rates (2–10 kHz) and developed a calibrated amplitude wavelet transform (CAWT) that normalized the power across frequency bands. The normalization of activity by frequency is important because wavelet and other algorithms tend to highlight long period events, thereby drowning out shorter – but likely just as significant – fast events. This application of normalized wavelet analysis across frequency bands could also help elucidate the importance of such events in other models and brain recordings.

Higher Frequencies and Complexity

Although the existence of hippocampal high-frequency electrical activities (greater than 100 Hz) during the progression of seizure episodes in both human and animal experimental models of epilepsy has been previously documented, this information has not been studied between successive seizure episodes or utilized in the application of seizure classification. We examined the dynamical changes of an in vitro low Mg^{2+} rat hippocampal slice model of epilepsy, at different frequency bands, using wavelet transforms and artificial neural

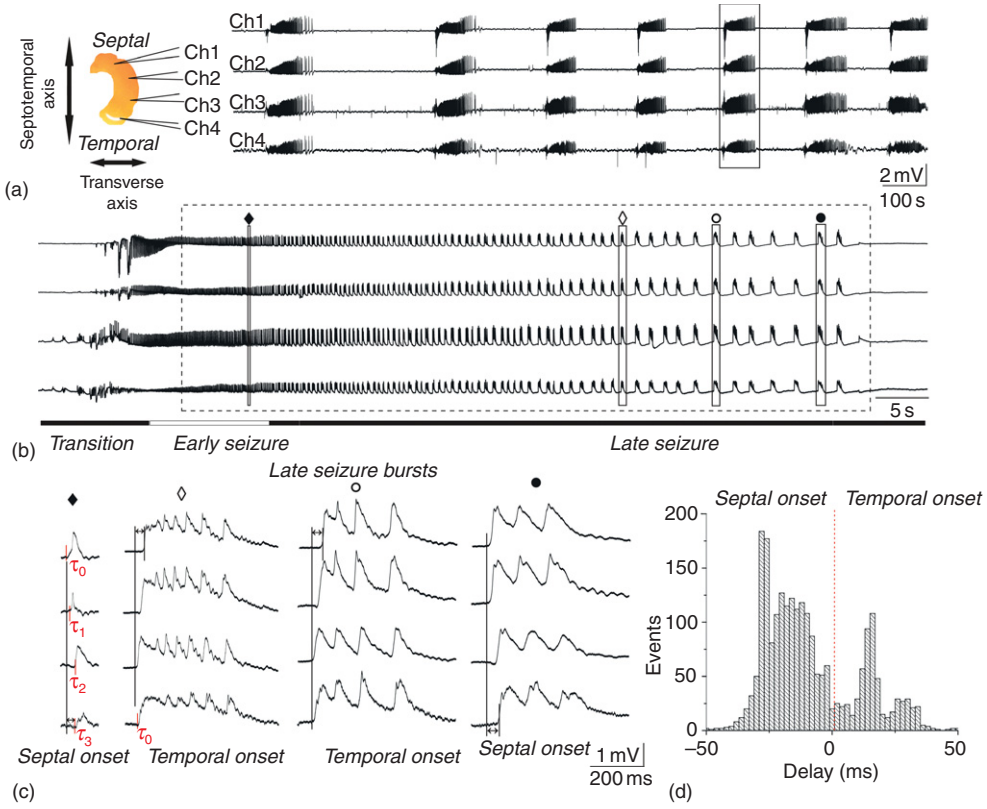

Figure 1 Multisite field recordings illustrate bidirectionality. (a) Four field electrodes in the CA1 subfield (Ch1–Ch4) placed along the septotemporal axis of the hippocampus (left inset-arrows denote direction of two axes) record recurrent, spontaneous seizures from the intact hippocampus. (b) A single seizure (expanded from panel (a)) recorded from all four electrodes shows the three characteristic phases of seizure. The transition phase is characterized by temporal onset during which there is lack of functional coupling, and later during the seizure (early, late phases), epileptiform activity displays bidirectionality and becomes functionally coupled across all four channels. (c) Bidirectionality of single intraseizure bursts (expanded from panel (b)) shows both septal (♦, •) and temporal (◊, ○) onsets. Vertical red lines illustrate beginning of events as represented by their relative times of onset ($\tau_0\tau_0$, τ_1, τ_2, τ_3), and (↔) denotes difference in times between the septal and temporal events. (d) Histogram of the event delays between the two outermost electrodes (Ch1–Ch4) reveals that most epileptic activity in the analysis window is of septal origin, while the average delay between these two channels is irrespective of the site of onset. Adapted from Derchansky M, Rokni D, Rick JT, *et al*. (2006) Bidirectional multisite seizure propagation in the intact isolated hippocampus: The multifocality of the seizure focus. *Neurobiology of Disease* 23: 312–328.

networks (ANNs). By dividing the time–frequency spectrum of each seizure-like event (SLE) into frequency bins, we analyzed their burst-to-burst variations within individual SLEs as well as between successive SLE episodes, using high sampling rates (10 kHz). We demonstrated that the activities of high-frequency oscillations in the 100–400-Hz range increased as the slice approached SLE onsets and in later episodes of SLEs. By examining the time-dependent relationship between different frequency bands, we showed the importance of the higher frequencies for classification of activity. In particular, we demonstrated that activities in the frequency range 100–400 Hz were critical for the accurate classification of electrographic seizure-like episodes – containing interictal, preictal, and ictal states – in brain slices undergoing recurrent spontaneous SLEs. Although preictal activities could be classified with an average accuracy of $77.4\% \pm 6.7\%$ using frequency spectrum in the range 0–400 Hz, we could achieve a similar level of accuracy by using a nonlinear relationship between 100–400-Hz and <4-Hz frequency bands only. We have demonstrated that the decrease in complexity (as measured by the Lyapunov exponent) between interictal and ictal events was significant for the higher frequency bands. These experiments are important in that not only do they examine the change in power across frequencies but also quantify changes in the system's dynamical properties, including complexity (**Figure 2(b)**).

Transitions, Noise, and Intermittency in Coupled Oscillator Models

Coupled oscillator models, based on the biological transmembrane voltage recordings from in vitro hippocampal slices, were used to investigate the following:

1. *The stochastic resonance effects.* That is, we examined the relation of noise to the occurrence of coherent

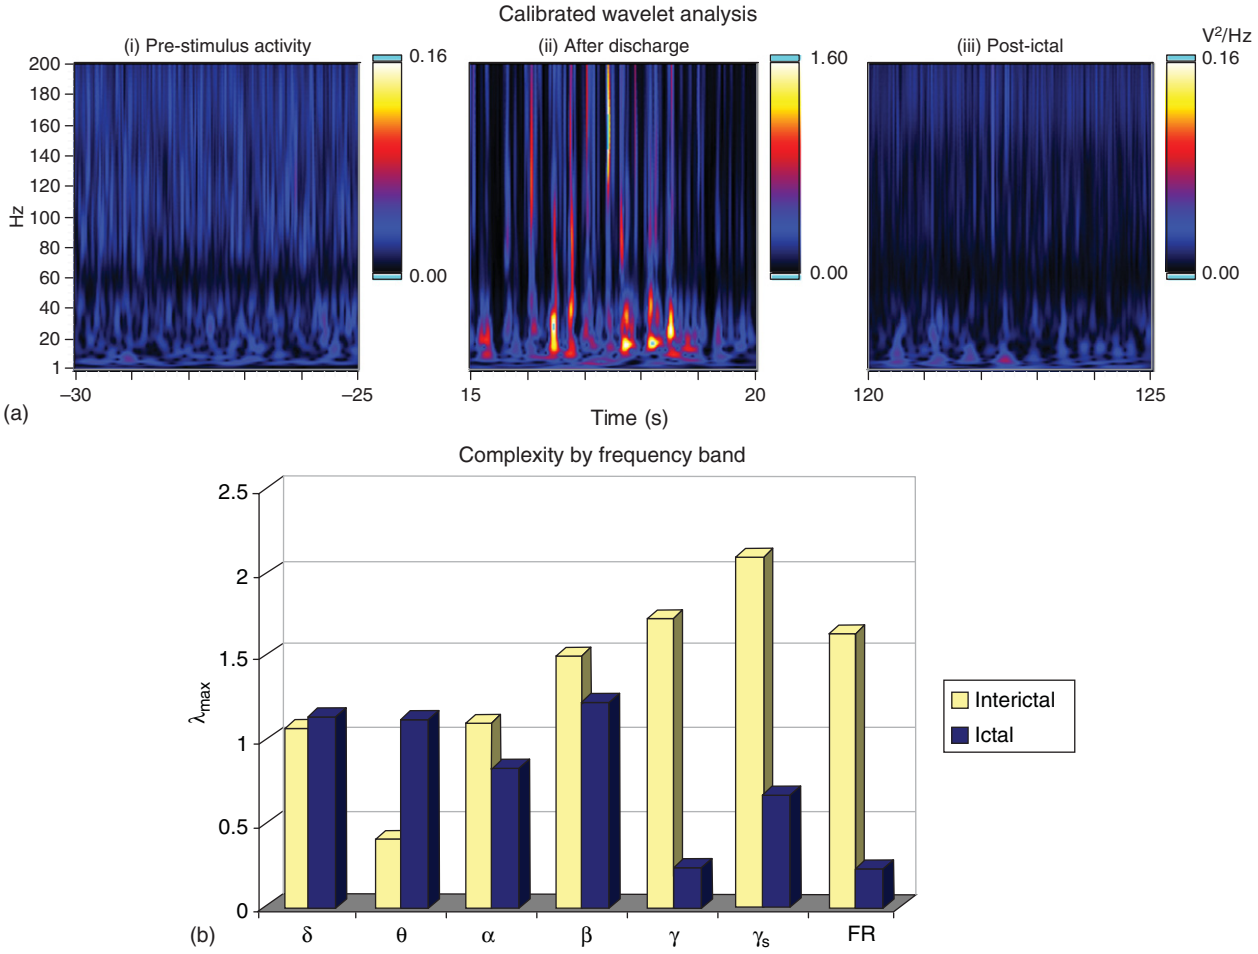

Figure 2 High frequency and complexity. (a) Changes in high-frequency events during kindled seizures. The figure shows the CAWT analysis for 5 s of (i) preictal, (ii) after discharge, and (iii) postictal hippocampal activity in kindled seizures. The kindling stimulus was applied to the perforant path and is indexed here as $t = 0$. This normalized amplitude wavelet analysis confirmed previously reported changes in power at lower frequencies but also demonstrated that changes extended into the high-frequency bands of 80–200 Hz. Note that the *Z* amplitudes are zoomed (10×) for the pre- and postictal events in order to show the activity in these periods. As such, the changes in activity are even more pronounced than the graphs otherwise indicate. The darker banding at 60 Hz is due to a notch filter. Adapted from Ohayon EL (2000) Connectionism and Wavelets in the Modeling and Analysis of Neural System Dynamics. M.Sc. Thesis., Ottawa: National Library of Canada, Ottawa. (b) Complexity measures across frequency bands. The maximum Lyapunov exponents (λ_{max}) were computed for each frequency band in hippocampal recordings in the Mg^{2+} model of epilepsy. A time series at each frequency band was constructed from the average wavelet coefficients in frequency. It is shown that the most significant decrease in complexities occurred in the higher frequency dynamics (>40 Hz). The frequency ranges shown are as follows: delta (δ, <4 Hz), theta (θ, 5–8 Hz), alpha (α, 8–15 Hz), beta (β, 15–40 Hz), gamma (γ; 40–100 Hz), super gamma (γ_s, 100–250 Hz), and fast ripples (FR, 250–400 Hz). Adapted from Chiu AWL, Jahromi SS, Khosravani H, Carlen PL, and Bardakjian BL (2006a) The effects of high-frequency oscillations in hippocampal electrical activities on the classification of epileptiform events using artificial neural networks. *Journal of Neural Engineering* 3: 9–20.

oscillations. We found that field and gap junctional coupling pathways exhibited significant stochastic resonance effects in the 4–8-Hz frequency range, but did not exhibit stochastic or coherence resonance phenomena at 0.5 Hz. This helped explain why reported in vitro seizure control strategies using pulse-trains could be effective at 0.5 Hz.

2. *The mode transitions from higher to lower complexity modes.* We were also interested in how the transitions might occur. We found spontaneous intermittent mode transitions, from higher complexity modes (possibly chaotic) to lower complexity (possibly rhythmic) modes, similar to those observed in in vitro hippocampal slice models under low-magnesium conditions. Mode transitions from high to low complexity were also shown to be associated with epileptic seizures in humans and onset of SLE in hippocampal in vitro slice models.

Synchrony, Complexity, and Intermittency in Network Models

In addition to the observations in the coupled oscillator models, the importance of intermittency for understanding autonomous transitions in epilepsy (and the potential therapies based on an understanding of intermittency) was explored in networks with random connectivity. When we tested networks with initial random connectivity and random activity, the vast majority of networks quickly stopped oscillating (**Figure 3(a)**) or settled to limit-cycles with periodic and fully synchronized activity (**Figure 3(b)**). These findings suggest that the inherent propensity of clusters and larger networks to enter into periodic synchronized activity – and, by extension, seizures – may be more prevalent than previously recognized.

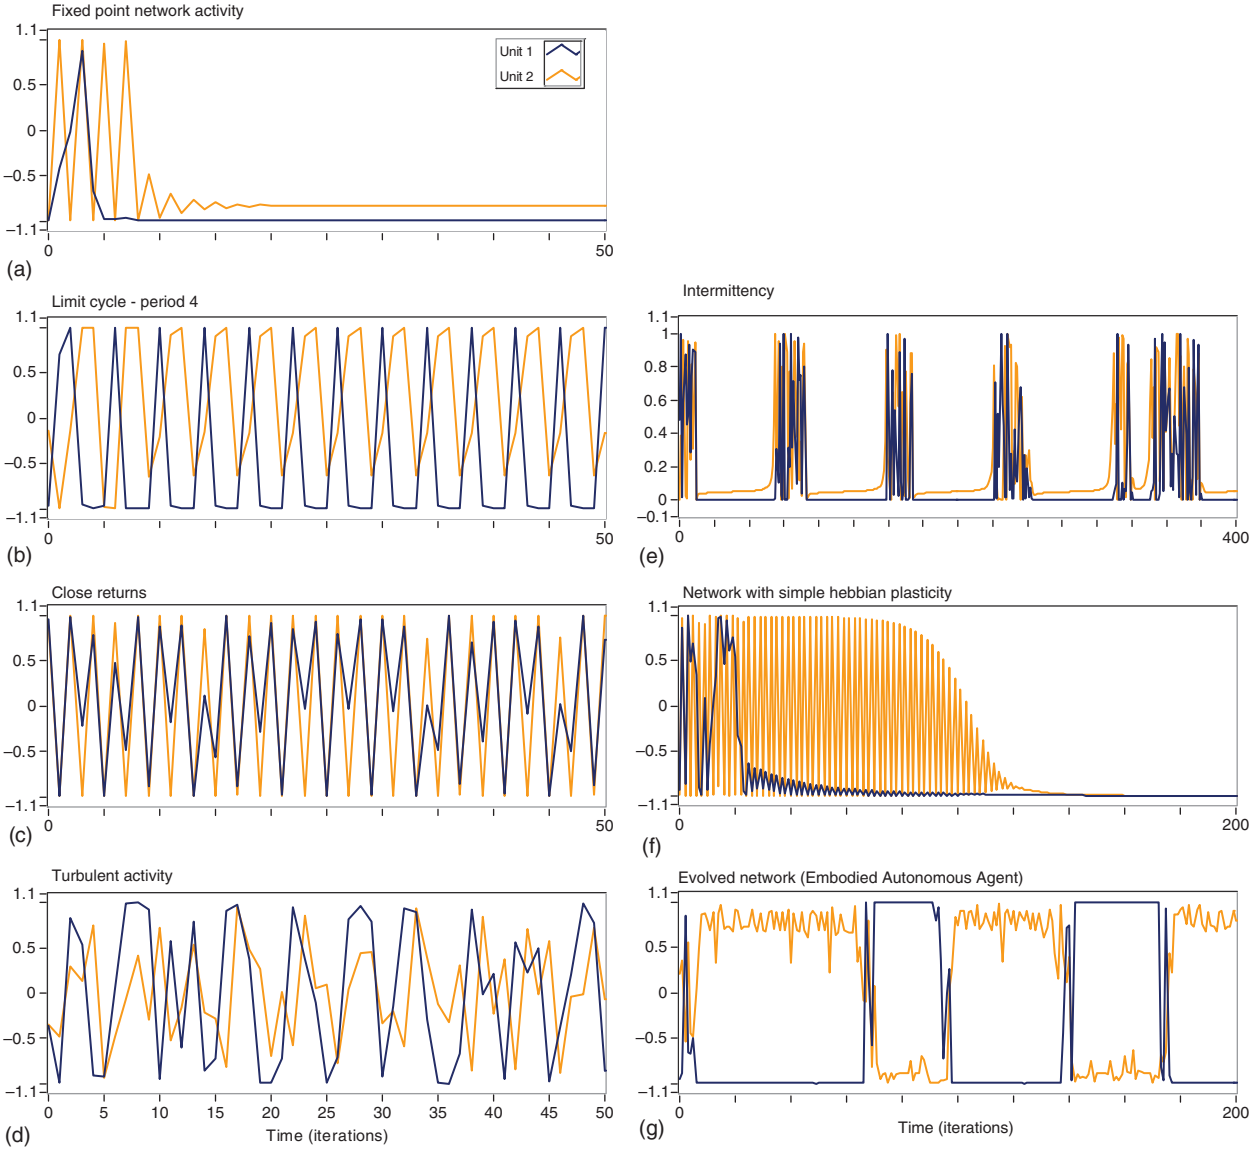

Figure 3 Activity dynamics in random and embodied neural network models. Most random networks settled to (a) fixed point and (b) limit-cycles characterized by periodic, synchronized activity (81% in the sigmoidal random networks). The remaining networks showed activities that were either (c) close to periodic but never precisely repetitive (13%) or were entirely (d) turbulent (6%). A subset of the nonperiodic networks showed (e) intermittent changes in phase reminiscent of transitions seen in epilepsy. The addition of simple Hebbian plasticity reduced complexity in random networks and quickly led to fixed points (f). On the other hand, embodied networks that were evolved to interact with the world showed (g) persistent nonperiodic activity. (Graphs show activity of 2 of 5 units; *y* axis is activity level normalized so that a value of 1 represents full excitation.) Reproduced from Ohayon EL, Kalitzin S, Suffczynski P, *et al*. (2004) Charting epilepsy by searching for intelligence in network space with the help of evolving autonomous agents. *Journal of Physiology-Paris* 98: 507–529.

However, these models have also demonstrated that complex oscillatory patterns can be an emergent property of network structure. For example, some networks were shown to generate complex oscillatory activity even if the constituent units were not themselves oscillators. In these cases, the nonperiodic activity showed either close to periodic but never precisely repetitive activity ('close returns') (**Figure 3(c)**) or highly turbulent activity (**Figure 3(d)**). By further examining these nonperiodic networks, we were able to demonstrate that in certain cases, the activity could switch autonomously between turbulent and quiet phases (**Figure 3(e)**). The change between the two phases of activity in these networks showed a distribution known to be characteristic of intermittency. Given that the units in all of these models were identical, the model demonstrates that intermittency can be the direct result of network structure and need not depend on changes to intrinsic cell properties. The autonomous switching in these models due to network structure thus demonstrates that some transitions into and out of seizures may be occurring in the absence of external perturbation or noise, and possibly without any change to neuronal properties. The continuous nature of these autonomous transitions also suggests that the very notion of a distinct epileptic 'state' may be questionable.

Although ongoing changes to the structure were not *necessary* for intermittency in these models, the activity was shown to exhibit changes in the statistics of transitions as a result of alterations to connectivity. In other words, changes in network structure could modulate the properties of the intermittency. As such, the model illustrates that intermittency mechanisms of transition are in fact compatible with the other mechanisms of seizure transitions enumerated by Lopes da Silva *et al.* (see Transitions, Intermittency, and Modulation in Background), and that the various mechanisms of transition are probably taking place concurrently in an interactive manner.

With regards to changes in connectivity, it is interesting to note that the addition of simple Hebbian plasticity drove even the most complex network activity to synchrony and eventually to the cessation of oscillations (**Figure 3(f)**). This finding suggests that it will be critical to identify the types of plasticity that generate brain structures that can maintain complex persistent activity and avoid seizures.

Interaction with the environment may be another factor important in avoiding periodic oscillations or fixed point activity. To demonstrate this point, the random networks were connected to external sensors and transducers (robot chassis). These embodied networks were then evolved over several generations, using an evolutionary algorithm that selected for continuous movement and the ability to avoid obstacles. As the behavior evolved, so did the dynamics of the activity, going from the largely fixed point and synchronized periodicity of the random networks to more complex multistable activity (**Figure 3(g)**). This demonstration is the first embodied modeling of epilepsy, illustrating the importance of the environment in producing structural changes that avoid seizures.

Future Directions

Technical Considerations

Our research highlights the need to consider multiple sources and scales when studying oscillations and transitions to seizure. Many challenges remain for the future. There are important questions of measurement and other technical issues. For example, the location and method of measurement, the chosen frequencies, and the use of linear versus nonlinear techniques are all ongoing debates in the field. Should we continue to rely primarily on electrical measures or is the better measure of epileptiform activity a reflection of something else, such as magnetic fields or chemical movements?

Autonomous Neurodynamics, Environment, and Embodiment

Our research demonstrates that the analysis must consider events in the higher frequencies, and forms of transition that go beyond simple attractors and parametric changes. In particular, the various intermittent forms of activity seen in the biological and model systems suggest a possible explanation for how certain transitions might occur autonomously, without a triggering stimulus. The research into autonomous neurodynamics is currently a major interest of our group, both in terms of understanding neural activity in epilepsy as well as how transitions in brain dynamics might occur in other cognitive conditions. As such, our research paradigms and models must also increasingly consider the role of bidirectional interactions of the embodied brain and the environment. Many laboratories are now uncovering the importance of enriched environment on development in general and susceptibility to seizures in particular. Our own research has shown that modeling of embodied networks connected to the environment can lead to increased complexity in oscillatory activity and to the escape from seizures. These connections – involving interaction within the environment, plasticity, and resultant oscillatory activity – need to be further explored. The attention to evolutionary sensorimotor modeling is also notable in that it moves away from modeling seizures as the primary goal and turns toward modeling the manner in which biological systems *avoid* pathological synchrony.

Relation between Network Structure and Oscillatory Activity

Another important frontier is the uncovering of the relation between network structure and the propagation of oscillatory activity. Netoff *et al.* and other groups have demonstrated that small world architectures, for example, can be an important factor in seizure dynamics. Our own work with random networks suggests that many seizure-like phenomena may arise even in the absence of complex architectures or plasticity. Current work is concentrating on modeling the propagation in spatial networks; results to date suggest that heterogeneity in structure (not just unit properties) may play a critical role in the form of oscillations and their propagation. These findings might help explain why the probability of seizures rises following cell damage or cell death in cases of trauma and aging. The most recent findings suggest that architecture may even override factors such as the balance between inhibitory and excitatory components.

Prediction of Seizure Activity

An artificial neural network possesses the ability to learn, generalize, and solve complex problems, and it is ideally suited for biological systems because of its inherent nonlinearity and its capacity to adapt its synaptic weights in response to changes in external environment. Our group's wavelet-based ANN design has been shown to be capable of classifying modes of brain activity and their transitions in an in vitro model of epilepsy from hippocampal extracellular recordings. Such a network was able to predict the onset of the ictal state within *minutes*. This delay provides a feasible time to facilitate appropriate modulatory actions to suppress the ictal state, avoid the 'locked-in' oscillatory low-complexity modes of a seizure, and increase system autonomy. This approach can lead to further success as the investigation is expanded to include both various signal features and the many new decision-making tools available to computer scientists (e.g., support vector machines).

Concluding Remarks

The brain is a complex, dynamic compilation of many interacting systems, which can adopt many oscillatory modes in space and time. To understand seizure modes, we need to consider the intrinsic properties of the multiple elements of the different systems, the network structure, connectivity, and the dynamics of interaction across spatiotemporal scales and with the external environment. This knowledge will provide us with the framework to develop therapeutic tools to measure, anticipate, and prevent (or eradicate) epileptic seizures.

Cellular Mechanisms of Network Oscillations Occurring Prior to, and during, Seizures

Introduction

Epileptiform discharges consist of the synchronized firing of principal neurons, usually in the form of bursts. The discharges, however, may repeat so as to form an oscillating activity pattern, at frequencies ranging from <1 Hz to over 20 Hz. In addition, neuronal network oscillations can occur prior to, during, and following the seizure proper, and there is a wide range of frequencies at which such oscillations can be recorded. Consideration of the oscillation mechanisms is important. An understanding of these mechanisms may allow prediction of an incipient seizure. And if there is a causal relationship between the events generating a pre-seizure oscillation and the events constituting the seizure proper, then that relationship might suggest a specific approach to therapy. Understanding the intricacies of this subject is not straightforward. The relevant oscillations involve a number of distinct mechanisms – synaptic and gap junctional – and the relation between different types of oscillation can be subtle. Furthermore, data are incomplete. We will present several examples illustrating some of the issues, and the interested reader can then delve further into the literature.

Background

In vitro models have been widely used to gain some understanding of the cellular mechanisms underlying epileptic activities in the intact brain. Until about 1999, most of the work with in vitro models employed experimental techniques that were designed to alter the balance between synaptic excitation and inhibition, in accord with what might be called the 'classical' idea of how epilepsy works. For example, synaptic inhibition might be reduced or suppressed completely with bath-applied GABA receptor blockers; recurrent excitation might be enhanced, by increasing NMDA receptor mediated currents in low $[Mg^{2+}]_o$ media (which also suppress synaptic inhibition); or axonal excitability might be enhanced and large depolarizing GABA currents produced with 4-aminopyridine. It is now apparent, however, that the generation of epileptiform activity involves more than a disturbed balance between synaptic excitation and inhibition. There are numerous phenomena associated with epileptiform discharge, including a variety of network oscillations, that can only be understood in terms of electrical coupling via gap junctions. The realization that gap junctions must play a critical role came largely from two experimental observations: first, that very fast oscillations (VFO) can occur without chemical synaptic transmission; and, second, that most experimental models of gamma and beta oscillations were dependent on gap junctions.

Methods

In our studies, we use both physiological experimentation and computer modeling. In vitro slice experiments have been carried out on hippocampus, entorhinal cortex, neocortex, and cerebellum, with tissue from rats, mice, or human patients (obtained, with proper consent, during neurosurgical procedures for medically intractable epilepsy). In parallel, we have generated detailed network models simulated on a supercomputer. In this latter work,

Cellular Mechanisms of Network Oscillations Occurring Prior to, and during, Seizures

Introduction

Epileptiform discharges consist of the synchronized firing of principal neurons, usually in the form of bursts. The discharges, however, may repeat so as to form an oscillating activity pattern, at frequencies ranging from <1 Hz to over 20 Hz. In addition, neuronal network oscillations can occur prior to, during, and following the seizure proper, and there is a wide range of frequencies at which such oscillations can be recorded. Consideration of the oscillation mechanisms is important. An understanding of these mechanisms may allow prediction of an incipient seizure. And if there is a causal relationship between the events generating a pre-seizure oscillation and the events constituting the seizure proper, then that relationship might suggest a specific approach to therapy. Understanding the intricacies of this subject is not straightforward. The relevant oscillations involve a number of distinct mechanisms – synaptic and gap junctional – and the relation between different types of oscillation can be subtle. Furthermore, data are incomplete. We will present several examples illustrating some of the issues, and the interested reader can then delve further into the literature.

Background

In vitro models have been widely used to gain some understanding of the cellular mechanisms underlying epileptic activities in the intact brain. Until about 1999, most of the work with in vitro models employed experimental techniques that were designed to alter the balance between synaptic excitation and inhibition, in accord with what might be called the 'classical' idea of how epilepsy works. For example, synaptic inhibition might be reduced or suppressed completely with bath-applied GABA receptor blockers; recurrent excitation might be enhanced, by increasing NMDA receptor mediated currents in low $[Mg^{2+}]_o$ media (which also suppress synaptic inhibition); or axonal excitability might be enhanced and large depolarizing GABA currents produced with 4-aminopyridine. It is now apparent, however, that the generation of epileptiform activity involves more than a disturbed balance between synaptic excitation and inhibition. There are numerous phenomena associated with epileptiform discharge, including a variety of network oscillations, that can only be understood in terms of electrical coupling via gap junctions. The realization that gap junctions must play a critical role came largely from two experimental observations: first, that very fast oscillations (VFO) can occur without chemical synaptic transmission; and, second, that most experimental models of gamma and beta oscillations were dependent on gap junctions.

Methods

In our studies, we use both physiological experimentation and computer modeling. In vitro slice experiments have been carried out on hippocampus, entorhinal cortex, neocortex, and cerebellum, with tissue from rats, mice, or human patients (obtained, with proper consent, during neurosurgical procedures for medically intractable epilepsy). In parallel, we have generated detailed network models simulated on a supercomputer. In this latter work,

we provide detail in the representation of individual neurons, in the number of neurons (thousands), and in the synaptic and gap junctional connectivity. These studies rely on a continual interplay between computer modeling and experimental discovery. The data from slice experiments are sometimes hypothesis-driven (including the testing of specific model predictions), but also sometimes serendipitous. The computer modeling attempts to replicate experimental observations, with economical assumptions, that sometimes lead to predictions. In addition, we draw on published in vivo data from patients and experimental animals, and collaborate with a molecular neurobiologist (Hannah Monyer), who is often able to engineer a genetically modified mouse that sheds light on oscillation mechanisms.

Recent Results

Figure 1 shows subdural recordings from an infant with intractable seizures of focal origin. Each seizure began with some slow waves, and then very fast oscillations (VFO, >70 Hz that appear fuzzy in Figure 1(a) but are seen clearly in Figure 1(b). The burst discharges in the seizure proper are of much higher amplitude than the VFO, and recur here at about 1 Hz. Interestingly, as Figure 1(c) shows, VFO are also superimposed on burst discharges. These patterns of pre-seizure VFO, and VFO superimposed on synchronized bursts, are both seen in in vitro and in vivo epilepsy models. The in vitro modeling shown in Figure 2 helps to sort out the respective mechanisms.

Figure 2-I (and also other data, see later) indicate that, under special 'epileptogenic' conditions such as disinhibition, neurons tend to fire bursts of action potentials that are synchronized on two different time scales. The first time scale is on the order of tens of ms, and synchronization on this time scale can be accounted for by the fact that principal neurons in cortical regions have recurrent excitatory (chemical synaptic) connections with one another, provided that at least some of these recurrent connections are sufficiently strong that a burst of action potentials in one pyramidal cell can induce a similar burst in a monosynaptically-connected second pyramidal cell. [Note: It is not clear if this situation holds in neocortex, and the situation becomes complicated when gap junctions are present; action potentials may be able to spread via the gap junctions as well as across chemical synapses.] The second time scale is much faster, as illustrated by the epileptiform burst shown in Figure 2-IB2; these bursts often have a superimposed VFO. The VFO is not reproduced by models of neuronal populations interconnected solely by chemical synapses. However, as shown in Figure 2-II, addition of electrical synapses (gap junctions) to the population model does generate the superimposed VFO. Presumably, a similar mechanism applies to the human case, as shown in Figure 1(c).

The gap junctions used in the model of Figure 2-II were located on the axons of pyramidal neurons. This choice was motivated by a body of physiological and dye-coupling evidence (see 'Further Reading'). More recently published ultrastructural data indicate that gap junctions can be found on hippocampal mossy fibers (axons of the excitatory dentate granule cells). The putative axonal location of gap junctions has critical physiological implications. At such a location, action potentials can, in principle, cross from axon to electrically coupled axon – that in turn permits the generation of very fast network oscillations amongst pyramidal and other principal neurons in a local population. Axonal coupling also allows the generation of other types of network oscillations, as further figures demonstrate.

Figure 3 illustrates data from a disinhibited neocortical slice, and from an extremely detailed thalamocortical model. The figure shows a pair of synchronized epileptiform bursts in succession. One might consider this pattern the in vitro correlate of an EEG polyspike. Each of the individual bursts resembles the epileptiform event shown in Figure 2-I, with the bursts of action potentials in individual cells riding on a large synaptic depolarization, along with some superimposed VFO. There are some differences with Figure 2-I, however. First, in the neocortex the epileptiform activity involves a number of distinct principal cell types simultaneously. Next, layer 4 spiny stellate cells fire continuously between the bursts, and this activity is coincident with the very fast oscillatory activity in the field potential recording (bottom trace). In simulations, one can show that the VFO are generated by gap junctional coupling, and that the VFO help to initiate the second burst. Indeed, under conditions of sufficient excitability, the pattern of activity observed in cortical neurons can continue in the form of a lengthy series of bursts at >10 Hz. Such activity resembles so-called 'fast runs' occurring in vivo, and consist of a series of epileptiform bursts at 10 Hz to about 25 Hz.

It is presumed that the VFO occurring before a seizure are generated by mechanisms similar to those of the VFO occurring on top of and between bursts. This presumption remains to be proved.

EEG oscillations at beta (10–30 Hz) and gamma (30–70 Hz) frequencies also are known to occur prior to seizures in some patients. It is therefore necessary to consider the cellular mechanisms of oscillations at these frequencies. In vitro studies and computer models provide access to this analysis, but the experimentalist must recognize the possibility that the EEG oscillations occurring in the clinical context may perhaps be generated differently.

Gamma oscillations arise in various physiological contexts, including brief sensory or electrical stimulation.

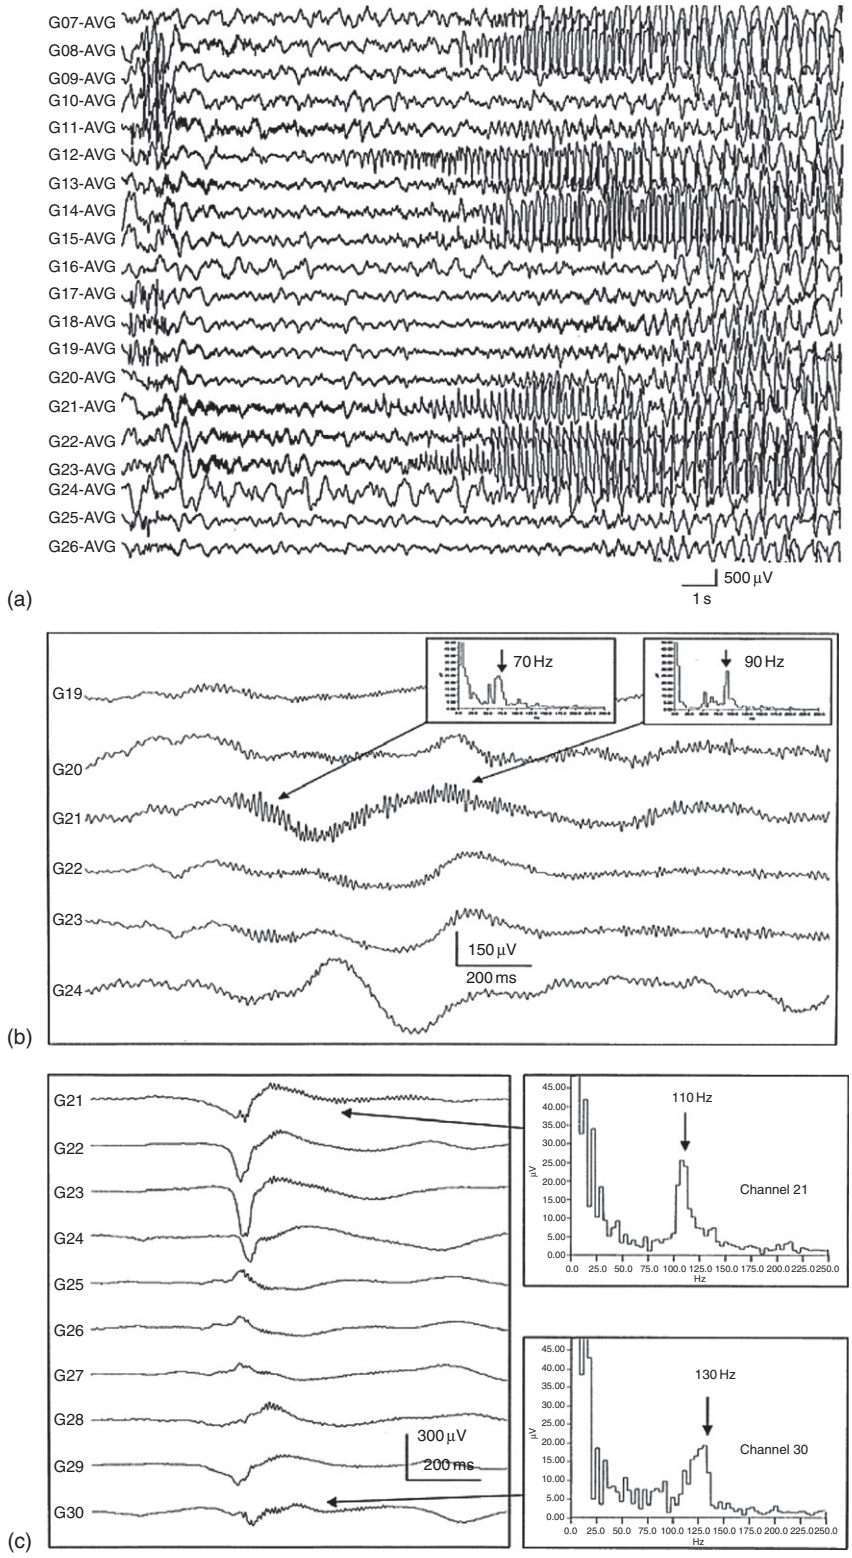

Figure 1 Very fast oscillations (VFO) recorded in subdural grid EEG signals, prior to and during seizures in a 13-month old child with a right frontal subcortical dysplasia. (a) widespread electrographic seizure activity is preceded by low-amplitude VFO in selected derivations, including G21-G23. (b) A different recording technique shows the pre-seizure VFO at 70–90 Hz. (c) 110–130 Hz low-amplitude EEG oscillations also occur during and immediately following burst complexes during the seizure itself. The seizure proper consists of EEG spikes and spike-wave complexes recurring at ~1 Hz. Adapted from Traub RD *et al*. (2001) A possible role for gap junctions in generation of very fast EEG oscillations preceding the onset of, and perhaps initiating, seizures. *Epilepsia* 42: 153–170.

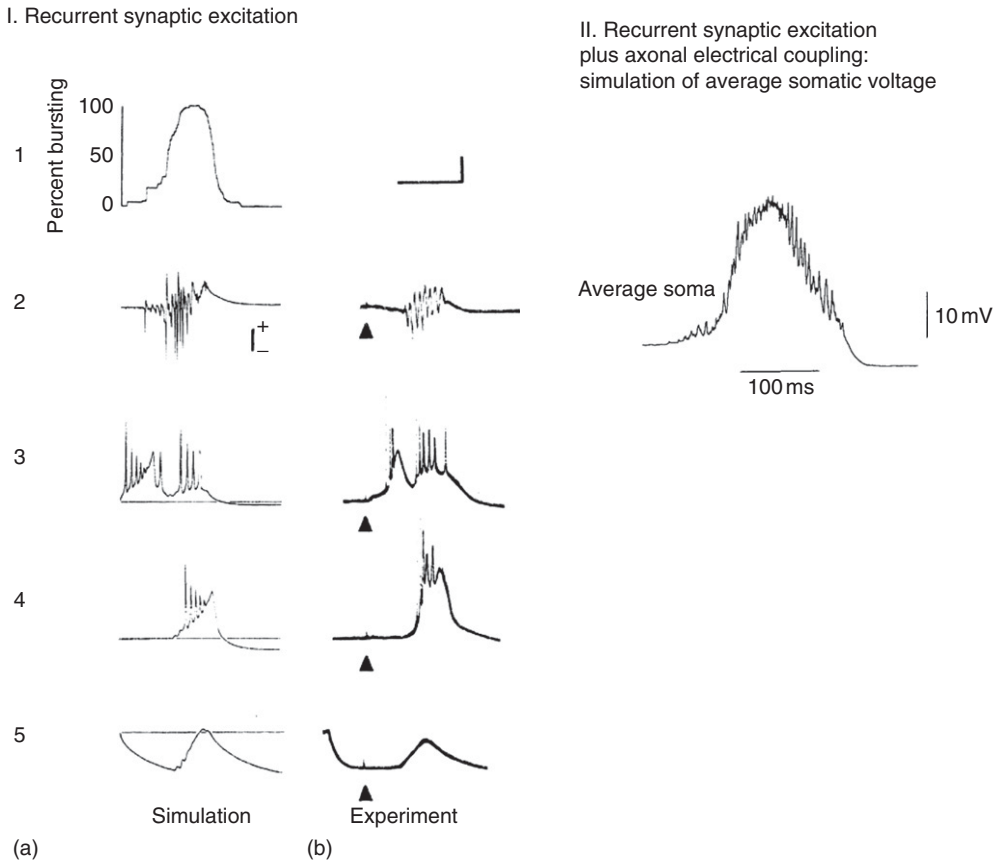

Figure 2 In the disinhibited hippocampal CA3 region in vitro, the primary mechanism of synchronization of bursting activity is by recurrent excitatory chemical synapses; electrical coupling between pyramidal cells may, however, be responsible for the VFO superimposed on an epileptiform burst. (I) Experiment (b) shows stratum pyramidale field potential (line 2) in a disinhibited hippocampal slice, CA3 region, following a small localized extracellular stimulus (arrowhead): note the latency of tens of ms prior to the epileptiform field potential, as well as the comb-shaped appearance of the latter, due to a superimposed VFO. Line 3 shows an intracellularly recorded burst in a pyramidal cell that happens to burst early on, and then generates a second burst. Line 4 shows a more typical pyramidal cell, that has negligible depolarization during the latent period, but then bursts during the field event. Line 5 shows the same cell as in line 4, hyperpolarized with current injection so as to prevent firing: this reveals the large EPSP during the field event, but no apparent activity during the latent period. A network model with 100 pyramidal neurons (a) produces exactly these features under conditions of (i) intrinsic bursting; (ii) sparse recurrent excitatory synaptic connections; the synaptic connections have the property that a burst in one cell can induce a burst in follower cells. The combination of sparseness with connection strength accounts for the growth of synchronization, the long latent period, and the absence of synaptic inputs in most cells during the latent period. However, this model does not generate a VFO superimposed on the epileptiform field potential. Scale bars: 50 ms (simulation), 60 ms (experiment); 4 mV (b2), 25 mV (a3, a4, a5), 20 mV (b3, b4, b5). (II) A simulation was performed according to the principles of I, but with more pyramidal neurons, and with axonal electrical coupling. The synchronized epileptiform burst now has a superimposed VFO. Data in I appeared originally in Traub and Wong (1982); data in II appeared originally in Traub *et al*. (1999). This figure reproduced from Traub *et al*. (2005c) Combined experimental/simulation studies of cellular and network mechanisms of epileptogenesis in vitro and in vivo. *Journal of Clinical Neurophysiology* 22: 330–342.

Probably the type of gamma oscillation most relevant to epileptogenesis is so-called 'persistent' gamma, discovered by Eberhard Buhl and collaborators. This type of gamma oscillation can be induced in entorhinal, neocortical, and even cerebellar slices by inclusion of an appropriate drug in the bath – for example, carbachol, kainate, or the metabotropic glutamate receptor agonist DHPG. Generation of persistent gamma oscillations involves an interplay between electrical coupling via gap junctions, and synaptic excitation and inhibition. Gap junctions between interneurons and between pyramidal neurons are involved, the former being modulatory and the latter critical. The most plausible mechanism is as follows: Electrical coupling between pyramidal cell axons (not too far from the soma) leads to high-frequency bursts of action potentials that cause barrages of rapid EPSPs in interneurons. The interneurons then fire almost synchronously and the resulting perisomatic inhibition onto pyramidal cells not only produces IPSPs in the pyramidal cell somata, but also terminates the pyramidal cell axonal

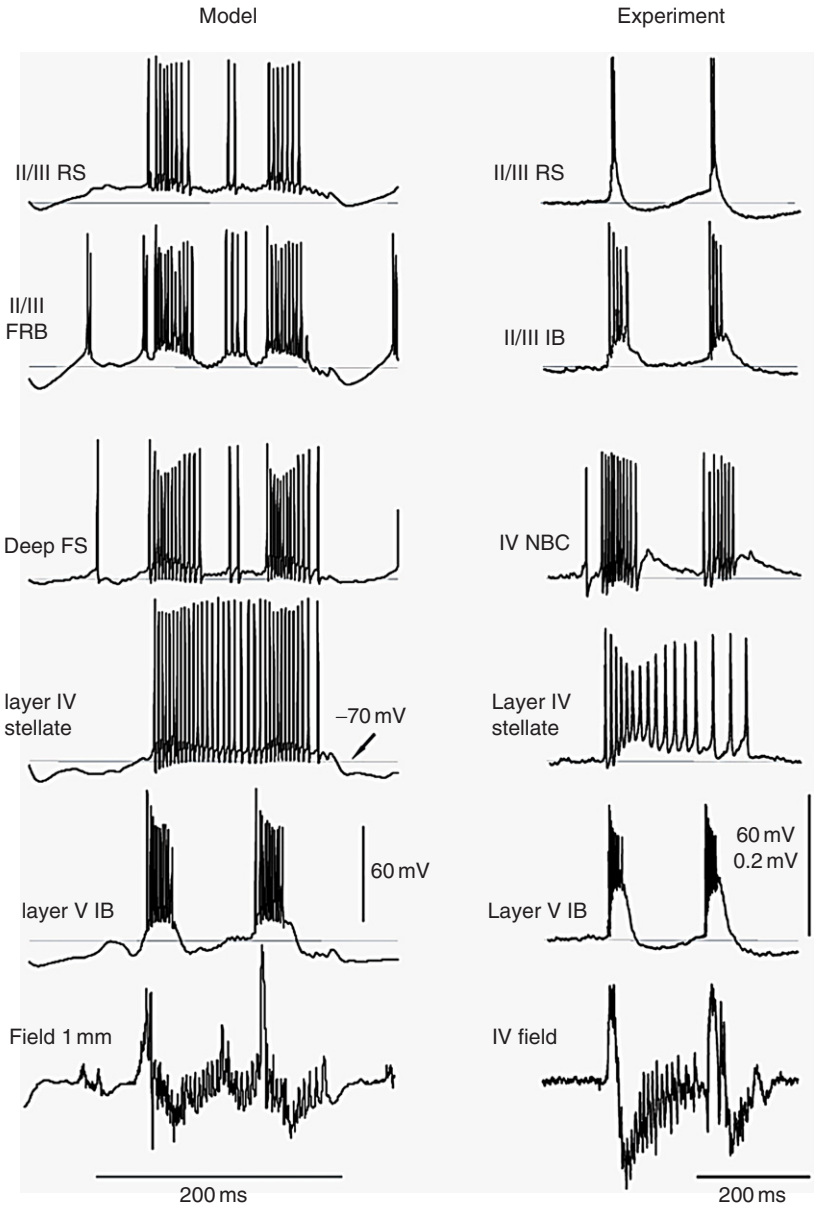

Figure 3 VFO during and after an epileptiform burst in neocortex occur in vitro, as well as in vivo. The VFO also contributes to the initiation of the second burst in this in vitro 'polyspike.' In similar model conditions, sustained ~10 bursts can occur, similar to 'fast runs' of epileptic bursts in vivo (not shown here). The model data are from a large neocortical network simulation, in which layer 4 spiny stellate cells were interconnected by voltage- and magnesium-independent NMDA receptors; in addition to conventional types of chemical synaptic interactions, there were axonal gap junctions between superficial pyramidal cells, spiny stellate cells, and layer 6 pyramidal cells. A synchronized epileptiform burst occurs, but note the prominent VFO in the field, as well as the prolonged firing of the layer 4 spiny stellate neuron. Experimental data show epileptiform activity in rat auditory cortex in vitro, bathed in kainate and picrotoxin. Note the similar very fast oscillatory activity in the field, as well as the prolonged depolarization in the layer 4 stellate neuron. Adapted from Traub *et al*. (2005a) Single-column thalamocortical network model exhibiting gamma oscillations, sleep spindles and epileptogenic bursts. *Journal of Neurophysiology* 93: 2194–2232.

firing. The inhibitory period – tens of ms – is the main determinant of the gamma oscillation period. This scheme accounts for pharmacological data – specifically, the sensitivity of persistent gamma to blockers of glutamate receptors, to blockers of $GABA_A$ receptors, and to blockers of gap junctions. It also explains the existence of a very high frequency peak in the power spectrum, a peak that is not a harmonic of the main gamma peak. Modeling further indicates that excessive recurrent excitation between pyramidal cells should disrupt gamma, while synaptic excitation of fast-spiking interneurons should stabilize the gamma. The data shown in **Figure 4** are

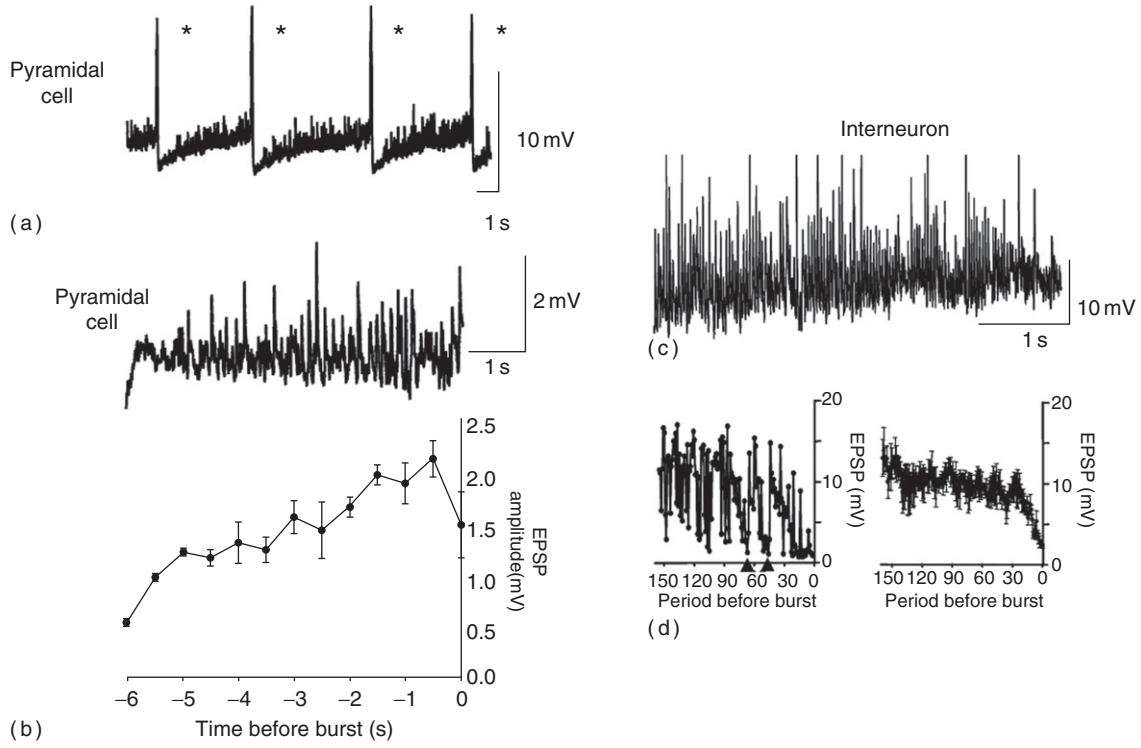

Figure 4 During between-burst gamma epochs induced by DHPG (a metabotropic glutamate receptor agonist), gamma-frequency EPSPs in pyramidal cells increase in amplitude, while EPSPs in interneurons diminish. (a) intracellular recording of repeating synchronized epileptiform bursts (*) in a CA3 pyramidal cell, with current injection to give mean resting membrane potential of −70 mV. (b) high-pass filtered data, showing EPSPs in the pyramidal cell. Graph below is pooled data (three interburst intervals from each of five pyramidal cells), showing increase in mean EPSP size during the interburst interval. (c) EPSPs in a fast-spiking s. pyramidale interneuron (injected with −0.2 nA current, to give a mean resting membrane potential of −70 mV), during the interburst interval. Action potentials truncated. (d) *left* shows EPSPs in the interneuron plotted as a function of gamma oscillation period, working backward from burst initiation. *Right* shows pooled data (mean ± standard error) from five burst intervals. Note the sudden decline in EPSP amplitude in the ~25 gamma periods (~750 ms) prior to the burst. Adapted from Traub *et al.* (2005b) Transient depression of excitatory synapses on interneurons contributes to epileptiform bursts intermixed with gamma oscillations in the mouse hippocampal slice. *Journal of Neurophysiology* 94: 1225–1235.

consistent with this prediction. These data also shed some light on how gamma oscillations might be relevant to epileptogenesis.

Figure 4 illustrates data from the CA3 region of a mouse hippocampal slice bathed in DHPG. In these conditions, epochs of several seconds of gamma oscillation alternate with brief epileptiform bursts (asterisks (*) in **Figure 4(a)**). Interestingly, short term plasticity occurs during the gamma intervals, consisting of gradual enhancement of EPSPs in pyramidal cells (**Figure 4(b)**), and collapse of EPSPs in interneurons (**Figure 4(c)**). As noted above, modeling suggests that these changes should destabilize the gamma, and that is what occurs. We do not understand, however, how the epileptiform burst resets the conditions so that a new gamma cycle can start. Intriguingly, it is a reasonable hypothesis that, during the gamma that can occur prior to a seizure in a patient, a similar type of short-term synaptic plasticity takes place, and that this plasticity leads to a switch to epileptiform discharge.

A robust in vitro model of beta oscillations occurs in intrinsically bursting (IB) cells in layer 5 of somatosensory cortex bathed in kainate (**Figure 5**). The in vivo correlate of this type of beta oscillation appears to occur during the immobile state of waiting for a sensory cue (as seen in rat, monkey and human). Currently, we can only speculate that pre-seizure beta oscillation is physiologically similar to this state-dependent beta; however, the tendency of seizures to begin, in certain seizure models where this feature has been tested, in layers 4 and 5 makes this a reasonable speculation. Additionally, kainate receptor-induced beta oscillations (as well as gamma and VFO) occur on upstates (i.e., during sustained – hundreds of ms – intracellular depolarizations of cortical neurons) during the slow (<1 Hz) oscillation of sleep; the upstates are the times when seizures are likely to be initiated.

Kainate-induced beta oscillation is quite remarkable. It depends on gap junctional coupling, but not on chemical synapses. One observable correlate of the electrical

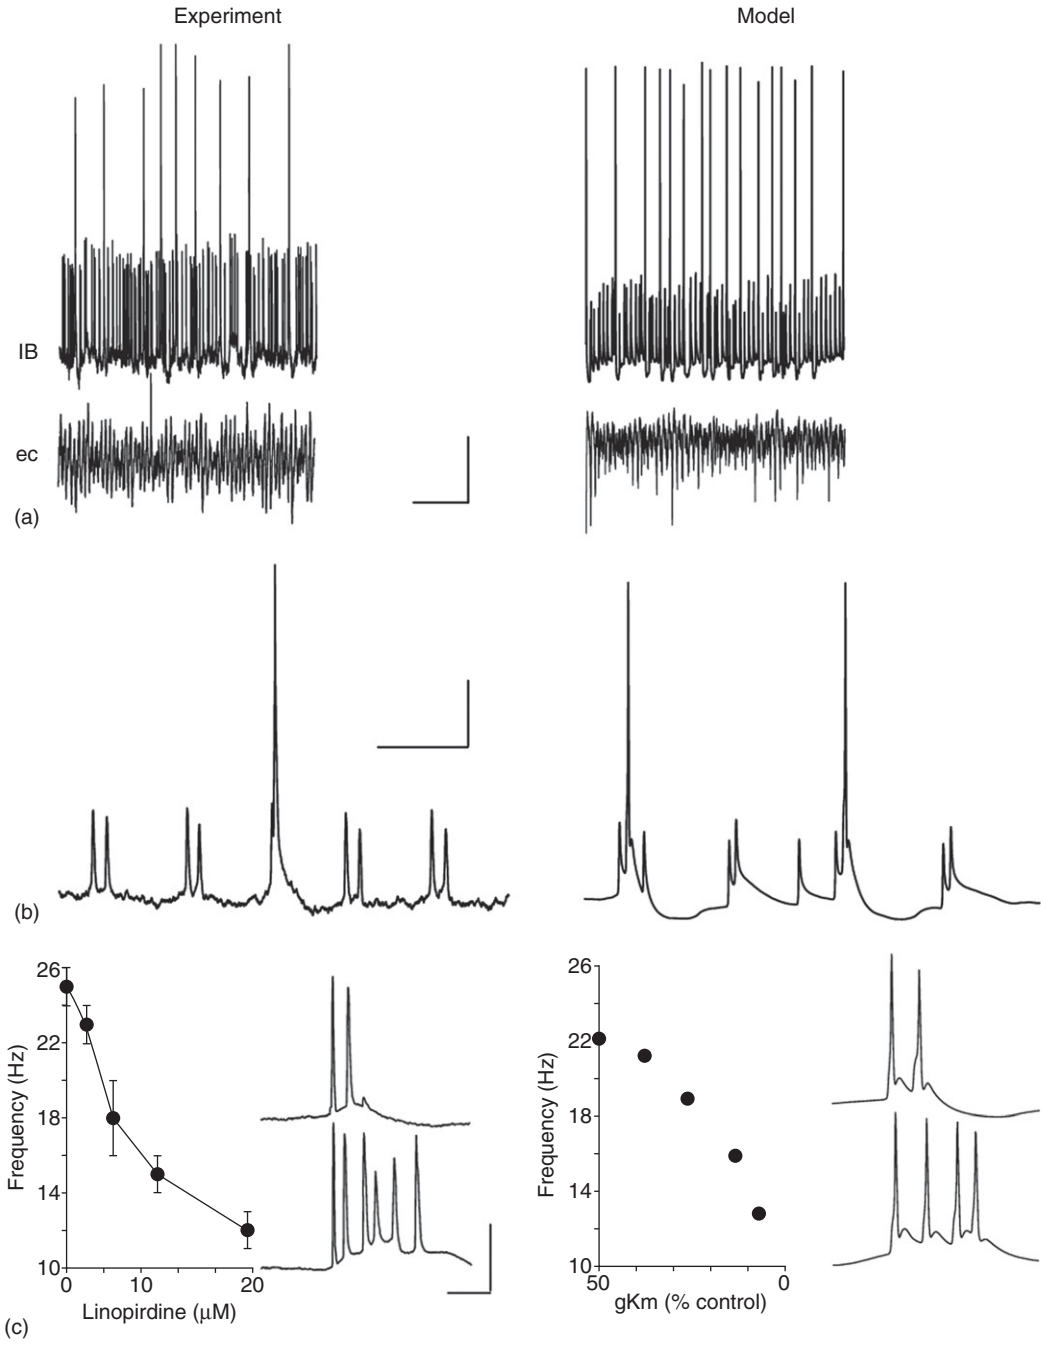

Figure 5 Kainate (400 nM) induces a beta2 (~25 Hz) population rhythm in layer 5 intrinsically bursting pyramidal neurons in vitro, with prominent spikelets. The rhythm period is determined by the M type of K^+ conductance, and the oscillation can be accounted for with a network model of pyramidal neurons electrically coupled via their axons. This type of oscillation may be related to beta-frequency activity prior to a seizure. (a) (left panel). 2.5 s example trace from an electrophysiologically and anatomically identified layer V intrinsically bursting (IB) cell reveals combinations of spikelets (fast prepotentials), single action potentials and action potential-bursts at beta2 frequencies, coherent with the local field (ec, extracellular). (Right panel) Field and tufted IB cell data are accurately predicted from antidromic spiking in a network model that includes 2000 IB pyramidal cells, electrically coupled through their axons, along with other model neurons. Scale bars 10 mV (experiment intracellular), 100 μV (experiment field), 15 mV (model intracellular), 500 ms. (b) Expanded timescale examples of layer V IB cell activity during field beta2 rhythms. Note the spikelets, that can occur in pairs, as well as the notch on the rising phase of the action potentials (arising from axonal spiking in the model, antidromically conducted). Scale bars (experiment) 10 mV, 15 mV (model), 10 ms. (c) Beta2 frequency is correlated with $g_{K(M)}$-mediated control of burst duration. Left panel shows mean peak frequency ($n = 5$) of layer V field potentials. The decrease in population frequency with M-current reduction (linopirdine 0–20 μM) was accompanied by increased IB cell burst duration and slowing of the population frequency. Right panel shows peak population frequency of model IB cells using different $g_{K(M)}$ from 50% to 5% of control. Scale bars (experiment) 30 mV, (model) 40 mV, 10 ms. From Roopun *et al*. (2006) A beta2-frequency (20–30 Hz) oscillation in non-synaptic networks of somatosensory cortex. *Proceedings of the National Academy of Sciences of the United States of America* 103: 15646–15650.

coupling is the frequent occurrence of spikelets, or fast prepotentials, readily observable in Figure 5(a) and 5(b). While the period of gamma oscillations is primarily determined by the time course of inhibitory synaptic conductances, the period of kainate-induced beta is primarily determined by an intrinsic membrane potassium current, the M current (Figure 5(c)).

To the best of our knowledge, there is no experimental model that sheds light on how a beta-frequency network oscillation might transform into a seizure. Modeling indicates that speeding up of M current kinetics could produce a transition from beta to VFO, but it is not known if that transition occurs physiologically (but see below for another alternative). It also remains to be determined how a run of VFO can be transformed into a seizure.

Future Directions

A current challenge for us is to obtain a more refined and quantitative understanding of VFO in the cortex. One new body of data is proving useful in this context. McCormick and colleagues have shown, using patch recordings of the axons of layer V pyramidal cells, that the axons contain a large transient K^+ conductance (a so-called D type conductance), blockade of which leads to axonal depolarization and hyperexcitability. As our published simulations to date had not incorporated such a conductance, we may have been simulating, in effect, over-excited axons. Preliminary simulations, in which a large transient K^+ conductance is included in axons, indicate that axonal gap junction conductance exhibits a threshold phenomenon; below this threshold, networks of layer V pyramids make beta oscillations, whereas above the threshold, there is VFO, with frequency depending on the gap junction conductance. If these preliminary data can be confirmed experimentally, it would provide an important link between beta oscillations and VFO. VFO also tends to occur in situations where chemical synaptic transmission is reduced or suppressed, and it will be necessary to determine how such a state might arise in vivo.

A final, and major, outstanding issue remains the ultrastructural demonstration of gap junctions between pyramidal cell axons, preferably using FRIL (freeze-fracture immunogold labelling). Knowing that axonal gap junctions exist on dentate granule cell axons (mossy fibers) is a start, but is not sufficient.

High-Frequency Weakly-Synchronized Activity at the Onset Focal Seizures

J G R Jefferys and P Jiruska, University of Birmingham, Birmingham, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In the majority of cases of epilepsy, brain activity looks normal for most of the time. A fundamental question is how the transition is made from this relatively normal interictal activity to the hypersynchronous hyperactivity of an epileptic seizure. A related key question is whether the transition is sudden or a slow progressive process that starts significantly before the actual seizure onset. These questions are important for understanding the basic mechanisms of epilepsies. The answers have implications for treatments, both in finding novel and potentially more specific drug treatments, and also in developing better prediction or early detection, of seizures that can be used to trigger warnings and, potentially, responsive treatments such as therapeutic stimulation or focal drug application. In this article, we focus on the events which occur immediately at the onset of the seizure, and particularly on high-frequency activity (HFA).

Background

Transition to Seizure

Several mechanisms have been proposed to explain the transition to epileptic seizures. Modulation of glutamatergic synaptic transmission can cause changes in excitation and further promote seizure-like events in brain slices. Activation of presynaptic receptors can modify neuronal activity and has significant impact on seizure generation. Changes in interneuronal function have been implicated in transition to seizure, and may be more important than changes in excitatory transmission. Potential mechanisms involving interneurons include: decrease in probability of GABA release due to activation of presynaptic $GABA_B$ receptors; depletion of the available pool of GABA stores due to intense interneuronal activity; desensitization of GABA receptors; depolarizing block of interneurons; and depolarizing inhibitory synaptic potentials (IPSPs may become depolarizing instead of hyperpolarizing due to impaired Cl^- homeostasis and/or intracellular accumulation of Cl^- due to excessive neuronal activity).

All these changes occur at the cellular level. At the network level, inhibitory transmission controls not only the excitability of individual cells, but also the spread of epileptic activity across the neuronal network. Failure of GABA transmission may lead to disappearance of surround inhibition, resulting in a loss of ability to 'contain' the epileptic focus, and the subsequent spatial expansion of epileptic activity – which then may lead to transition to seizure, and further to the spread of epileptic activity to more distant regions. This type of expansion of the region of hyperexcitability may be essential to recruit a minimal population of neurons required to trigger seizure activity – the epileptic aggregate or critical mass.

High-Frequency Activity

HFA has been linked with the initiation of epileptic seizures since the early 1990s. Allen and Fisher simultaneously presented observations from human patients implanted with invasive electrodes (**Figure 1(a)**). They reported that seizures in some patients could start with low-amplitude HFA. Frequencies of HFA are typically >100 Hz, outside the range of frequencies recorded by most clinical recording systems. Preseizure HFA typically occurs in a small volume of tissue, which makes it useful in localizing the seizure onset zone, but complicates its detection because it is best detected with relatively small, preferably intracerebral, electrodes – and of course, those electrodes have to be in the right place. These early

In this article, we focus on the events which occur immediately at the onset of the seizure, and particularly on high-frequency activity (HFA).

Background

Transition to Seizure

Several mechanisms have been proposed to explain the transition to epileptic seizures. Modulation of glutamatergic synaptic transmission can cause changes in excitation and further promote seizure-like events in brain slices. Activation of presynaptic receptors can modify neuronal activity and has significant impact on seizure generation. Changes in interneuronal function have been implicated in transition to seizure, and may be more important than changes in excitatory transmission. Potential mechanisms involving interneurons include: decrease in probability of GABA release due to activation of presynaptic $GABA_B$ receptors; depletion of the available pool of GABA stores due to intense interneuronal activity; desensitization of GABA receptors; depolarizing block of interneurons; and depolarizing inhibitory synaptic potentials (IPSPs may become depolarizing instead of hyperpolarizing due to impaired Cl^- homeostasis and/or intracellular accumulation of Cl^- due to excessive neuronal activity).

All these changes occur at the cellular level. At the network level, inhibitory transmission controls not only the excitability of individual cells, but also the spread of epileptic activity across the neuronal network. Failure of GABA transmission may lead to disappearance of surround inhibition, resulting in a loss of ability to 'contain' the epileptic focus, and the subsequent spatial expansion of epileptic activity – which then may lead to transition to seizure, and further to the spread of epileptic activity to more distant regions. This type of expansion of the region of hyperexcitability may be essential to recruit a minimal population of neurons required to trigger seizure activity – the epileptic aggregate or critical mass.

High-Frequency Activity

HFA has been linked with the initiation of epileptic seizures since the early 1990s. Allen and Fisher simultaneously presented observations from human patients implanted with invasive electrodes (**Figure 1(a)**). They reported that seizures in some patients could start with low-amplitude HFA. Frequencies of HFA are typically >100 Hz, outside the range of frequencies recorded by most clinical recording systems. Preseizure HFA typically occurs in a small volume of tissue, which makes it useful in localizing the seizure onset zone, but complicates its detection because it is best detected with relatively small, preferably intracerebral, electrodes – and of course, those electrodes have to be in the right place. These early

clinical papers have led to a line of epilepsy research focusing on mechanisms of HFA, with the aim of gaining insights into ictogenesis and epileptogenesis.

Methodological Approaches

Experimental models of clinical conditions such as epilepsy exist to provide better control and reproducibility than is possible with clinical material. They also need to provide appropriate levels of simplification, to allow the development of insights into the fundamental mechanisms that can be used to formulate hypotheses for progressively more realistic, and complex, models.

Some of the more simplified models of epileptic seizures are those generated in brain slices in vitro, in the absence of any synaptic transmission. Decreasing extracellular calcium concentration to <0.2 mM effectively blocks synaptic transmission. Hippocampal slices perfused with low-Ca^{2+} artificial cerebrospinal fluid generate spontaneous, repeated seizure-like activity, with each episode lasting tens of seconds. This observation shows that nonsynaptic mechanisms are sufficient for the generation of prolonged seizure-like discharges. Similar observations have been described in the high-potassium model, in which synaptic activity is functional. In this latter case, seizures persist even when excitatory transmission is blocked. Methods for recording such activities in brain slice (in vitro) studies include: intra- and extracellular recording, usually with glass micropipettes; monitoring of extracellular ion concentrations with ion-sensitive electrodes; assessment of network activity with electrode arrays; and optical recording to measure the spread of activity across large areas of tissue.

While in vitro approaches with acute slices provide a useful simplification, chronic models of epilepsy provide closer parallels with the clinical situation. In such models, the tissue exhibits abnormalities of structure and function that lead to spontaneous seizures (or in the case of kindling, reduced seizure threshold). Tissue from these chronic models can be, and is, studied in slices in vitro. However, in situ analysis – in the intact animal – allows investigations of seizures in a 'complete' system, consisting of structures involved in the complex generation and modulation of seizure activity. The intact preparation is not constrained by problems of in vitro maintenance (e.g., proper oxygenation of the tissue), or the absence of inputs from and outputs to other brain regions, or by the complex changes in tissue milieu that are eliminated by brain slice recording. The main chronic models that have been used in the context of HFA studies to date are those in which a period of status epilepticus is induced (e.g., by intrahippocampal injection of kainic acid). After a latent period of a week or two, spontaneous seizures start and recur for the rest of the life of the animal. In some intact models, spontaneous epileptic activity (often spike and wave discharges) occurs in the absence of a prior stimulus or insult, presumably a product of gene abnormalities. The main recording methods used in intact animal preparations include monitoring of electrical activity (EEG and cellular discharge) with chronically implanted electrodes, often microwires. Some studies on anesthetized animals involve the introduction of glass microelectrodes and ion sensitive electrodes, as in slice experiments.

Detailed recordings from human patients are often made during clinical evaluation for potential surgery. Technical details for such recordings vary among centers, but typically include subdural strips and grids, and depth electrodes. The invasive electrodes usually have relatively large recording surfaces, but can include microwires (or microcontacts on larger electrodes) similar to those used in some animal studies; that type of electrode has proved particularly useful in the context of HFA analysis.

Important Results to Date

HFA in vivo

Bragin *et al.*, working in vivo on the kainate model of temporal lobe epilepsy, described the presence of HFA in the range 100–600 Hz. Similar observations were later described in human patients with epilepsy who were implanted with specially designed microelectrodes. These investigators identified two different subtypes of HFA which differed in morphology and spatial properties: ripples (80–160 Hz) and fast ripples (200–500 Hz). Fast ripples usually had a shorter duration, amplitudes reaching up to 1250 μV, and were spatially confined to the epileptic focus. Fast ripples could occur alone or superimposed on interictal spikes. The volume of tissue generating this epileptiform pattern was estimated at 1 mm^3. In the kainate model, the presence of fast ripples during the latent period was a marker for the subsequent development of spontaneous recurrent seizures. The most common seizure onset pattern was hypersynchronous spiking, typical for seizures originating in the hippocampus in both experimental animals and humans. In this pattern, the seizure usually starts with a discharge of the same morphology as interictal discharges, with HFA (typically high amplitude) superimposed on a slower component. The similarity of the interictal and ictal fast ripples suggests that they share common pathophysiological mechanisms.

In human TLE patients, Bragin *et al.* found that ripples and fast ripples could be present in the same recordings but that fast ripples were limited to epileptogenic areas. On the basis of these findings, the investigators proposed that fast ripples could be used as a surrogate marker for epileptogenic tissue. Whether this subclassification of HFA is useful remains a matter of debate in the literature.

Spontaneous spike-and-wave seizure activity in anesthetized cats provides another in vivo model, in neocortex, in which HFA occurs at the onset of seizures. In this model, HFA had even greater amplitudes than observed in the rat kainate model, reaching nearly 5 mV. Grenier *et al.* reported that HFA was present not only in the seizure onset zone but also in areas to which epileptic activity propagated; HFA was not spatially restricted and could be synchronized over distances of 9 mm. However, the HFA had its greatest amplitude in the seizure onset zone.

HFA in Brain Slices

HFA at the beginning of seizures has also been described in various in vitro models of epileptic seizures, including those in which synaptic activity is blocked. In the low-Ca model, low-amplitude HFA in the frequency range of 150–200 Hz occurs during several seconds before the seizure onset (**Figure 2**). This HFA pattern consists of repeated very small, negative, population spikes which have maximal amplitude in the pyramidal layer of CA1. The spikes are correlated with the firing of individual pyramidal cells, but each of these neurons fire at much lower rates (as one might expect for this type of neuron), typically at around 30 Hz – that is, once every several cycles of HFA. It appears that small groups of neurons fire synchronously, within 1–2 ms, and that the collective activity of multiple groups leads to the net HFA of 150–200 Hz. The full seizure-like event emerges as these small groups fuse into a single large synchronous population that discharges at a few tens of Hertz The fact

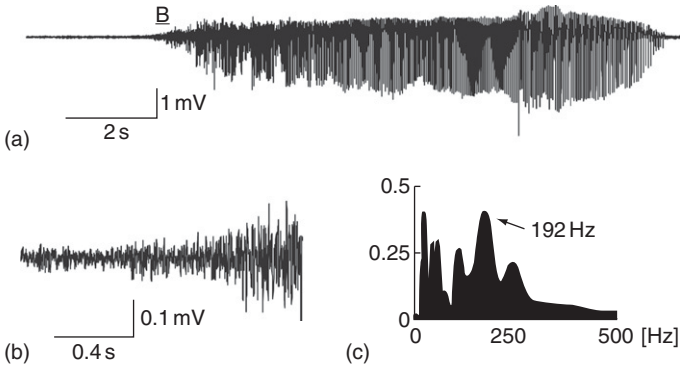

Figure 2 Low-calcium in vitro model of epileptic seizures. (a) Hippocampal slices perfused with artificial cerebrospinal fluid containing low levels of calcium generate spontaneous repeated seizure-like events. (b) Onset of the seizures is characterized by presence of HFA. (c) Corresponding power spectra demonstrating that HFA has peak at 192 Hz.

that HFA appears when chemical synapses cannot function normally suggests that nonsynaptic mechanisms must be responsible for synchronizing neuronal activity (see the following sections). Very similar HFA appears before seizurelike events in the high-K model, where although synaptic activity is preserved, there is some evidence that nonsynaptic mechanisms play a major role.

Cellular Mechanisms of Synchronization

Several theories exist for the cellular mechanisms of HFA. Under physiological conditions, HFA has been implicated in cognition and memory processing; in these cases. HFA is thought to result from interaction between fast spiking interneurons and pyramidal cells. Interneuronal activity generates inhibitory postsynaptic potentials on pyramidal neurons which restrict pyramidal cells to firing action potentials during 2–3 ms windows, resulting in ripple activity (**Figure 3(a)**). As outlined earlier, under pathological conditions, HFA may also represent synchronous action potential firing, probably due to pathologically interconnected hippocampal neurons. It is well known that one of the morphological changes in temporal lobe epilepsy is the sprouting of axons of principal neurons (mossy fibers, CA1 pyramidal cell axons), which potentially can then create autosynapses and synaptic contacts with adjacent neurons (**Figure 3(b)**). Activity in one neuron would be able to quickly evoke activity in synaptically coupled neurons and synchronize their action potential firing.

Work on the low-Ca model shows that nonsynaptic mechanisms are sufficient for HFA, although we cannot conclude that they are necessary. There is some evidence of electronic coupling between pyramidal cells by gap junctions, based on: (1) electrophysiological recordings of 'spikelets' (miniature action potentials that can be recorded intracellularly and believed to be generated sufficiently far from the recording site to attenuate them to a few mV); (2) pharmacological disruption of HFA (although the agents, such as octanol and carbenoxolone are nonspecific and far from ideal); and (3) rare cases of dye coupling. The synchronization of action potentials, on a millisecond time scale within the individual cycles of HFA, makes gap junction coupling at the soma or dendrites seem unlikely, given the membrane time constants of these structures are substantially slower; axons have

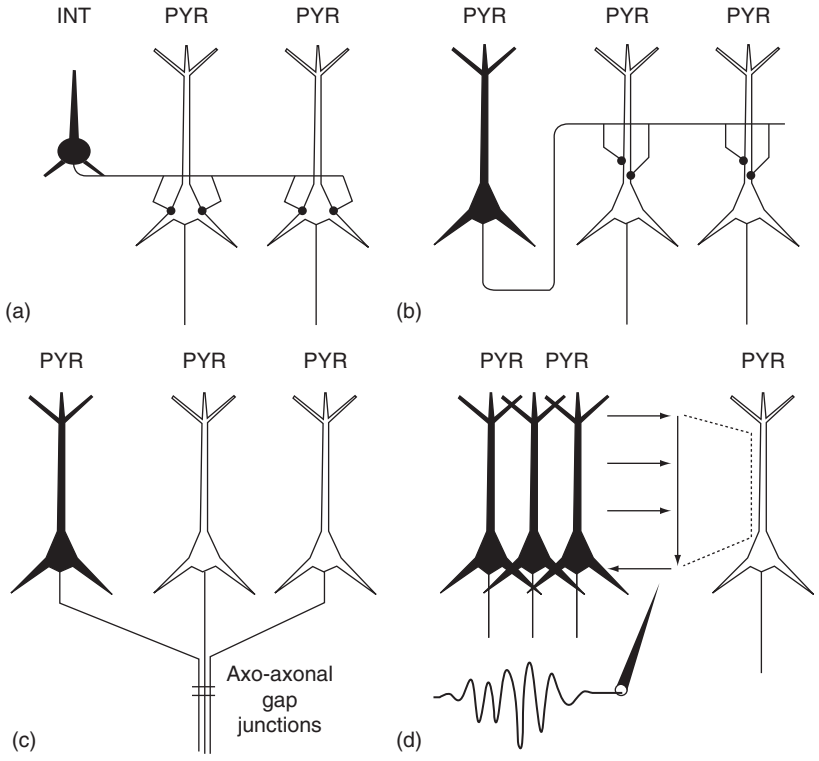

Figure 3 Mechanisms of HFA genesis. (a) Synchronous interneuronal input generates synchronous IPSPs and hence pyramidal cell firing, summation of which creates individual cycle of HFA. (b) Pathologically interconnected neuronal cluster. Physiological or abnormal axonal sprouting makes connection with adjacent neurons. There activation of one neuron effectively depolarizes synaptically coupled neurons into the action potential firing. (c) Axo-axonal gap-junction. Action potential generated in one neuron can electronically spread via gap-junction and depolarize coupled neurons and recruit them into synchronous activity. (d) Ephaptic interactions. Groups of neurons generate synchronous activity, which creates large field potentials in extracellular space. This large electric field can then depolarize adjacent cells and entrain them into synchronous activity.

faster time constants and provide a more plausible point of contact (**Figure 3(c)**). Computer simulations suggest that an axo-axonal syncytium could generate HFA. The other major class of fast nonsynaptic synchronization is ephaptic and field effect coupling (**Figure 3(d)**). Electric fields clearly can modulate neuronal excitability, with field strengths of $\sim$1 mV mm^{-1} being effective. The synchronization of individual HFA cycles is of a short range (a few hundred micrometers). Computer simulations suggest the maximum extracellular action potential of single neurons is at the axon hillock, and its effects on neighbouring neurons are fast and localized to within a few tens of micrometers. In the case of the HFA associated with spike-and-wave epilepsy in the cat, its large amplitude makes ephaptic coupling very likely indeed.

Challenges for the Future

The theories outlined in this article need experimental testing and translation to humans. The underlying cellular and network mechanisms remain a central challenge, particularly in terms of the behavior of individual neurons of various classes, their synchronization, and the role of HFA in transition to seizure. Examples where HFA precedes seizure onset by tens of seconds are particularly important and may provide novel targets for therapy.

The HFA that precedes seizures tends to be of a low amplitude and spatially localized to the seizure initiation zone. Under conventional clinical recording conditions, HFA can result in a flattening of the ECoG, or an electrodecremental pattern. The spatial restriction and small amplitude of HFA mean that it needs to be recorded with intracranial electrodes; scalp electrodes are too far from the highly localized sources of HFA (the large cortical area contributing to each electrode and the poor signal-to-noise ratio result in a loss of HFA). In contrast, HFA associated with evoked potentials can be recorded with surface electrodes, because of extensive averaging and the larger cortical volumes producing synchronous HFA.

Even with subdural electrodes or depth electrodes, the small size of the areas generating synchronous HFA can present problems. While conventional subdural and depth electrodes can record HFA, they do so less reliably and less well than microwires and other microelectrodes. Essentially, the larger the electrode, the greater the spatial averaging of the signal – which in turn will reduce signal-to-noise ratio, or create interference between multiple independent small HFA generators. Increasing knowledge about HFA and its association with epileptic foci and seizure genesis led to the development of novel 'hybrid' electrodes, which combine conventional macroelectrodes with microelectrodes. These electrodes have already been used in clinical practice with promising results.

Similar approaches are needed in in vivo studies of chronic animal models of epilepsy, both for comparison with clinical data (as part of the evaluation of those models), and for improving our understanding of mechanisms. In this experimental context, implanted microwire electrodes and/or multichannel probes (silicone probes, etc.) and perhaps tetrodes will provide the multichannel recordings that are needed to provide new insights into the temporal and spatial dynamics of the neuronal populations that generate HFA. The chronic animal models also are important in determining the applicability to intact functioning brain of mechanisms identified in vitro by intracellular studies (using sharp electrodes or patch-clamp with multichannel local field potential recordings).

Recordings of the kinds outlined here present challenges for analysis. Developments in time and frequency domain analyses have played a major role in recent advances in HFA research, particularly in dealing with spatial and temporal structure. Analyzing large numbers of channels of data remains a challenge in the investigations of HFA in epilepsy, and more generally in the analysis of neuronal networks.

Ultimately, the key question for us is whether HFA will provide useful leads into understanding or treating epilepsy and epileptic seizures. Improved seizure prediction, or at least early detection, would facilitate responsive treatments such as therapeutic stimulation or focal drug application. Understanding the process of transition to seizure may provide new, and hopefully more specific, therapeutic targets for novel drugs or stimulation protocols.

Introduction

Experimental animal models of epilepsy attempt to reproduce as many of the clinical and electrographic features of human epilepsy as possible in order to learn more about the neuronal mechanisms of epileptogenicity. In many of the chemically induced seizure models, focal application of chemical agents to the mammalian cortex produces acutely a seizure focus characterized by synchronous neuronal burst firing. Intracellular recordings within the focus reveal that a large percentage of neurons discharge bursts of action potentials that often are superimposed on a large amplitude depolarizing slow wave. This neuronal event, known as a 'paroxysmal depolarization shift,' occurs during the generation of epileptiform discharges and is believed to be the primary cellular mechanism contributing to the abnormal excitability and synchrony associated with epilepsy.

Unlike acute models, however, studies in patients (who require intracranial depth electrode recordings to locate brain areas where seizures begin) show that there is considerable variability in the number of neurons with abnormal firing properties in epileptogenic regions. Single neuron studies using chronic microelectrode recordings have not been able to provide consistent evidence for the extent of synchronous neuronal burst firing that is commonly observed in experimental seizure models. Yet, during some behavioral states such as sleep, it has been shown that greater burst firing and synchrony of discharges occur in brain areas ipsilateral to ictal onset (compared to remote contralateral sites). These changes in action potential firing and synchrony are due, in part, to changes in neuronal network oscillatory activity associated with particular states of vigilance.

The importance of network activity for information processing has been recognized for many years. However, the significance of pathological alterations in such networks has recently attracted considerable interest, because pathological network oscillations may be associated with abnormal synchronous discharges that contribute to epileptogenicity. Numerous studies have focused on fast network oscillations commonly referred to as 'high-frequency oscillations' (HFOs). Among the best studied physiological HFOs are Ripples. Ripples are brief, sinusoid-like oscillations, between 100 and 200 Hz, that occur within the hippocampus and entorhinal cortex of a number of mammalian species, including rats, mice, bats, cats, nonhuman primates, and humans. It is believed that the synchronous neuronal activity associated with Ripple oscillations may play a role in the consolidation of new memories. The pathological counterpart to Ripples are Fast Ripples (FRs). These pathological HFOs, typically between 200 and 600 Hz, are absent from normal limbic structures and occur primarily in areas of spontaneous seizure generation. FRs have been hypothesized to reflect the neuronal substrate of epileptogenicity.

Studies in animals with chronic limbic seizures and patients with temporal lobe epilepsy have identified a number of distinguishing features between Ripples and FRs with respect to their spatial distribution, spectral characteristics, and network properties, but the neuronal mechanisms supporting their generation are unclear. For several years our laboratory has used electrophysiological, histological, and neuroimaging techniques to study

Introduction

Experimental animal models of epilepsy attempt to reproduce as many of the clinical and electrographic features of human epilepsy as possible in order to learn more about the neuronal mechanisms of epileptogenicity. In many of the chemically induced seizure models, focal application of chemical agents to the mammalian cortex produces acutely a seizure focus characterized by synchronous neuronal burst firing. Intracellular recordings within the focus reveal that a large percentage of neurons discharge bursts of action potentials that often are superimposed on a large amplitude depolarizing slow wave. This neuronal event, known as a 'paroxysmal depolarization shift,' occurs during the generation of epileptiform discharges and is believed to be the primary cellular mechanism contributing to the abnormal excitability and synchrony associated with epilepsy.

Unlike acute models, however, studies in patients (who require intracranial depth electrode recordings to locate brain areas where seizures begin) show that there is considerable variability in the number of neurons with abnormal firing properties in epileptogenic regions. Single neuron studies using chronic microelectrode recordings have not been able to provide consistent evidence for the extent of synchronous neuronal burst firing that is commonly observed in experimental seizure models. Yet, during some behavioral states such as sleep, it has been shown that greater burst firing and synchrony of discharges occur in brain areas ipsilateral to ictal onset (compared to remote contralateral sites). These changes in action potential firing and synchrony are due, in part, to changes in neuronal network oscillatory activity associated with particular states of vigilance.

The importance of network activity for information processing has been recognized for many years. However, the significance of pathological alterations in such networks has recently attracted considerable interest, because pathological network oscillations may be associated with abnormal synchronous discharges that contribute to epileptogenicity. Numerous studies have focused on fast network oscillations commonly referred to as 'high-frequency oscillations' (HFOs). Among the best studied physiological HFOs are Ripples. Ripples are brief, sinusoid-like oscillations, between 100 and 200 Hz, that occur within the hippocampus and entorhinal cortex of a number of mammalian species, including rats, mice, bats, cats, nonhuman primates, and humans. It is believed that the synchronous neuronal activity associated with Ripple oscillations may play a role in the consolidation of new memories. The pathological counterpart to Ripples are Fast Ripples (FRs). These pathological HFOs, typically between 200 and 600 Hz, are absent from normal limbic structures and occur primarily in areas of spontaneous seizure generation. FRs have been hypothesized to reflect the neuronal substrate of epileptogenicity.

Studies in animals with chronic limbic seizures and patients with temporal lobe epilepsy have identified a number of distinguishing features between Ripples and FRs with respect to their spatial distribution, spectral characteristics, and network properties, but the neuronal mechanisms supporting their generation are unclear. For several years our laboratory has used electrophysiological, histological, and neuroimaging techniques to study

FR in order to better understand the role of pathological HFOs in the human epileptic brain and appropriate animal models. Our goal is to determine how functional and structural modifications in networks of neurons contribute to the generation of pathological HFOs and epileptogenicity. Studies that focus on pathological HFOs such as FR will provide insights that may lead to new strategies to treat, and possibly prevent, epilepsy.

Background

Studies investigating Ripple oscillations in rodents show that Ripples occur chiefly during periods of immobility or episodes of slow wave sleep (SWS). During theta-related states, such as during exploratory behaviors and rapid eye movement (REM) sleep, Ripples are largely absent. Ripples occur prominently in areas CA1 and CA3 of the non-primate hippocampus, and subicular and entorhinal cortices; there is little evidence for the presence of physiological Ripples within the dentate gyrus. One hypothesized role for Ripples is that they facilitate information transfer during sleep between hippocampal and cortical structures. This presumed role for Ripples is based on evidence that Ripples are temporally coupled with forebrain spindle oscillations that occur regularly during episodes of SWS. Coordinated discharges along hippocampal and neocortical pathways may be related to processes associated with memory consolidation when short-term hippocampal memory traces are transferred to long-term neocortical stores.

Much of what is known regarding the neuronal activity associated with Ripple oscillations derives from in vivo wide bandwidth recordings in rat hippocampus. In behaving rats, Ripples are often superimposed on large amplitude slow waves called sharp waves. During the large-scale neuronal activation associated with sharp waves, Ripples are typically largest in amplitude in the CA1 pyramidal cell layer. In vivo extracellular recordings during Ripples show that pyramidal cells tend to fire infrequently, but when they do fire their discharges are time-locked to the negative wave of the oscillation. In contrast, interneurons may fire during every cycle of the oscillation in a pattern that is consistently phase-aligned with respect to the Ripple. Intracellular recordings from pyramidal cells reveal the presence of a ripple-frequency potential that is smallest in amplitude at membrane potentials between -70 and -80 mV, and reverses in polarity relative to the extracellular Ripple at membrane potentials more negative than -80 mV. According to these data, it is likely that the fast intracellular potential is mediated by chloride ions due to the activation of $GABA_A$ receptors by GABAergic interneurons. While the mechanisms contributing to the synchrony of neuronal discharges during Ripples is not completely understood, one possibility is that phasic activation of interneurons by external input may produce rhythmic inhibitory post-synaptic potentials (IPSPs) that strongly regulate pyramidal cell discharges. This synchronous interaction between interneurons and pyramidal cells is thought to generate active inward and outward extracellular currents that contribute to the Ripple field potential.

Inhibitory interneurons can entrain discharging pyramidal neurons (or other interneurons) into a rhythmic pattern, but it is unclear whether interneuron-generated IPSPs facilitate the synchrony of discharges associated with Ripples. In vitro studies using hippocampal slices show that suppressing $GABA_A$ receptor activation does not abolish spontaneous or evoked Ripples in CA1. In contrast, application of agents such as octanol or carbenoxolone that interfere with the presumed electrical coupling between hippocampal neurons suppresses Ripples. These latter findings are consistent with the absence of Ripples in CA1 of rats under halothane anesthesia, and are predicted by computer models of Ripples generated from neuronal networks that include axon-to-axon gap junctions between pyramidal cells. These data indicate that inhibitory transmission may not be required for the generation of Ripples, but excitatory transmission mediated through chemical and possibly electrical synapses may contribute to the synchronous neuronal discharges associated with Ripples.

Ripples studied in the absence of inhibition, however, are often associated with epileptiform discharges, which raise questions about whether neuronal mechanisms generating Ripples in vitro are the same as those supporting physiological Ripples in vivo. Indeed, blocking $GABA_A$-mediated inhibition also produces Ripple-frequency oscillations in the isolated dentate gyrus, a region where Ripples are not found in the normal rat but occur in the seizure-generating dentate gyrus of epileptic rats. Evidence from the in vitro studies mentioned above show that these pathological HFOs in dentate gyrus reflect synchronously bursting granule cells that are dependent on AMPA/kainate-receptor mediated glutamatergic transmission.

In contrast to physiological Ripples, FRs are present only in spontaneously epileptic structures, and limited to regions in or adjacent to the epileptogenic lesion in epileptic rats. In epileptic patients, interictal rates of FR are significantly higher in seizure generating hippocampal areas compared to contralateral (nonseizure generating) sites. Simultaneous multiunit activity (MUA) and field potential recordings indicate that FRs reflect population spikes from bursting principal neurons. A number of studies, using acute models of epilepsy and hippocampal slices prepared from acute or chronic epileptic animals, show that blocking GABAergic transmission is an effective means of producing abnormal neuronal synchronization that contributes to the generation of population spike activity. In the systemic kainic acid (KA)

epileptic rat model, population spike bursts can be evoked in dentate gyrus showing extensive loss of parvalbumin interneurons; this observation indicates that even selective disruptions in inhibition may contribute to abnormal population synchrony. And in the penicillin model of epilepsy, population spike bursts, at a frequency greater than 200 Hz, occur in dentate gyrus and CA1. These data, too, indicate that the suppression of inhibition promotes abnormal neuronal synchrony, although it has not been determined how, and to what extent, local disturbances in inhibitory and excitatory networks contribute to the generation of pathological HFOs.

Methods

Epilepsy studies in our laboratory use chronic animal models of epilepsy that include the intrahippocampal KA rat, the systemic pilocarpine rat and mouse, and the self-sustained status epilepticus rat. Twenty-hour per day video and electrophysiological recordings of EEG, local field potentials, and single unit and MUA (using moveable and fixed microelectrodes) are regularly carried out in these animals with spontaneous epileptic seizures, as well as in treated animals that do not develop spontaneous seizures. Studies include analysis of ictal and interictal abnormalities.

Living brain slices are prepared from some epileptic animals at the end of chronic recordings for in vitro extracellular and intracellular recordings, to study the generation of local field potentials and single and MUA. Regularly, brain slices are fixed and stained following chronic in vivo recordings to locate the position of the microelectrodes in hippocampus and dentate gyrus. In addition, neo-Timm staining is used to evaluate the extent of mossy fiber reorganization that commonly occurs in dentate gyrus in animals that develop spontaneous limbic seizures.

A significant component of our research, that complements our investigations in experimental models, includes chronic microelectrode recordings in patients with medically intractable complex partial seizures that are suspected to arise from mesial temporal lobe limbic structures. Patients are candidates for epilepsy surgery, but require chronic intracranial depth electrode monitoring to locate the brain area where their seizures begin. During the 1–3 week period when patients are on the epilepsy telemetry ward for continuous video-EEG monitoring, we record from bundles of nine microwires (40 μm in diameter) that extend beyond the tip of each clinical depth electrode. These microwire bundles or 'microelectrodes' are regularly positioned within mesial temporal (amygdala, hippocampus, subiculum, entorhinal cortex, parahippocampal gyrus), extratemporal (orbital frontal, cingulate gyrus, supplementary and presupplementary motor), and other clinically relevant brain areas. Wide bandwidth EEG (1–6000 Hz) is recorded continuously during overnight polysomnography studies and analyzed for interictal and ictal abnormalities in relation to changes in states of vigilance (e.g., sleep and wakefulness), and in relation to epileptogenicity. Anatomical data obtained from resected epileptogenic tissue and MRI are correlated with EEG, local field potentials, single and MUA to correlate structural with functional abnormalities.

Results

Spatial Distribution of HFO Networks

Ripples occur simultaneously on both sides of the brain, with oscillations in either hemisphere leading the other. Ripples in epileptic rats, as well as in human patients with epilepsy, occur with equal probability in areas ipsilateral and contralateral to the hemisphere of seizure onset. Fast Ripples, in contrast, are strongly associated with sites ipsilateral to seizure onset. They occur simultaneously or separately between adjacent structures (e.g., dentate gyrus and entorhinal cortex) or at different recording sites within the same structure (separated by distances of 1 mm or more). These latter data highlight the spatial and occasional functional independence between networks generating interictal FR. In addition, these data and results from other FR studies indicate that individual FR generation sites are small and widely distributed throughout epileptogenic tissue.

Studies of hippocampal sharp wave-Ripple complexes indicate a unidirectional pattern of generation, beginning in hippocampal CA3, propagating to CA1 and subiculum, and then towards entorhinal cortex. Analysis of spontaneous FR show that there is a tendency for FR generated in entorhinal cortex to lead (by several milliseconds) FR in dentate gyrus. Yet, FR in dentate gyrus may precede those in entorhinal cortex. Thus, there appears to be no clear unidirectional propagation pattern for FR along the hippocampal trisynaptic circuitry, which suggests that the generation and synchronization of FR are not preferentially initiated from any one of potentially many distributed FR sites.

Structural and Functional Characteristics of Networks Supporting Pathological HFOs

Hippocampal neuron loss and synaptic reorganization are common pathological features found in KA-treated rats, as well as in patients with mesial temporal lobe epilepsy. In epileptic rats, FRs occur in areas of cell loss and intense mossy fiber sprouting. FR, however, can appear as early as 24-h following status epilepticus. The delay in the appearance of FR corresponds with excitotoxic cell loss

associated with status epilepticus; however, FRs clearly occur before the sprouting of new axon projections from surviving neurons in dentate gyrus and hippocampus. Once established, FR-generating sites are fixed spatially and surrounded by areas not generating FR. In patients with hippocampal sclerosis, reduced hippocampal volumes and neuron densities correlate with higher rates of FR and lower rates of physiological Ripples. Furthermore, neuron loss in CA1 most strongly predicts ratios of FR to Ripple rates. Based on these animal and patient data, it appears that morphological alterations linked with neuron loss promote the generation of FR but disrupt networks supporting Ripples.

In brain slices from epileptic rats, stimulation of perforant path fibers evokes FR-like responses – that is, burst of population spikes – in dentate gyrus; these bursts can be recorded within a radius of 3 mm from the KA lesion. FR-generating areas are estimated to be as small as 1 mm^3 (based on multisite recordings). Outside of these limited FR areas, stimulation evokes excitatory postsynaptic potentials that may or may not contain a single population spike. The volume of tissue supporting FR is determined, in part, by the functional circuitry maintained within and surrounding these pathological networks. Application of bicuculline to epileptic dentate gyrus slices enlarges the area from which FR can be evoked, and elicits spontaneous FR from the same sites where evoked FRs arise. In spite of the presence of intact inhibitory circuitry surrounding FR-generating areas, paired-pulse stimulation in FR networks generates augmented population spike responses at interstimulus intervals between 30 and 200 ms. Furthermore, test pulses at intervals between 100 and 500 ms can evoke enhanced FR-like responses. These data show that robust feedback inhibition is present surrounding FR generating areas, but suggest that local excitatory connections in FR areas are strong – and synchronous discharges may overcome feedback inhibition. Changes in inhibition can increase the size of individual FR-generating areas, and likely the synchrony between FR sites, that may lead to a seizure.

Sites Generating Physiological and Pathological HFOs

Voltage versus depth analysis of HFOs recorded from 16-contact electrodes that traverse CA1 and dentate gyrus of epileptic rats show that spontaneous Ripples are largest in amplitude on contacts positioned within stratum pyramidale of CA1 and absent from dentate gyrus (**Figure 1(a)**). FR, in contrast, occur in CA1 or dentate gyrus, with a maximum amplitude in CA1 pyramidal cell layer or dentate gyrus granular layer. CA1 Ripples reverse in polarity just below the pyramidal cell layer; the profile of CA1 FR is similar to the profile of Ripples, but the location of polarity reversal extends towards the hippocampal fissure (**Figure 1(b)**). This latter difference

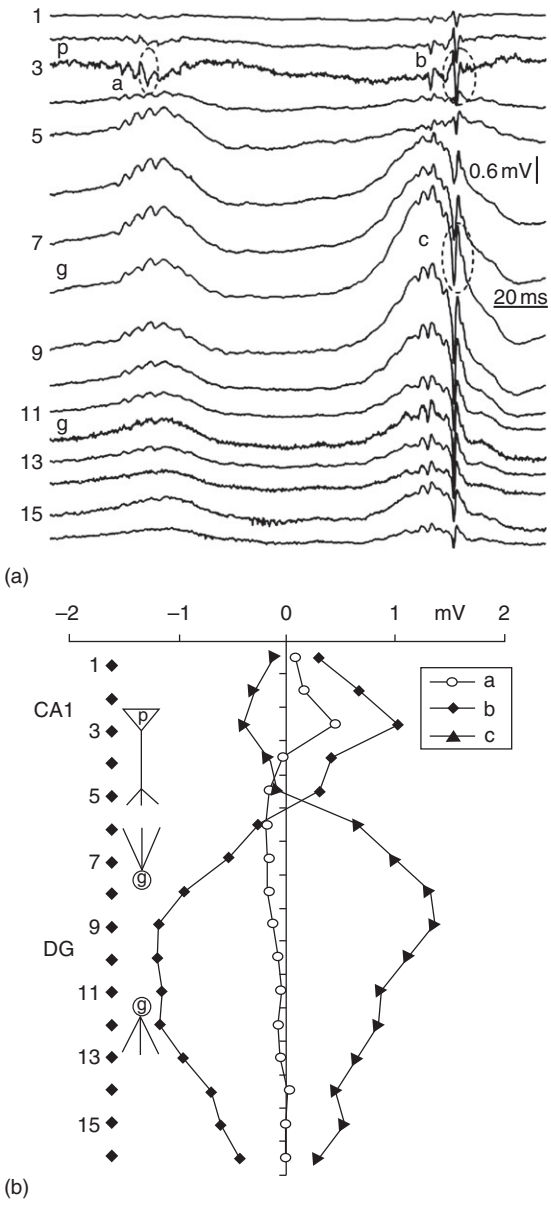

Figure 1 (a) Two-hundred millisecond continuous recording from a 16-contact recording electrode positioned in the hippocampus of a rat. Example of a spontaneous Ripple oscillation and associated positive sharp wave in CA1 ('a'), followed by a spontaneous HFO that occurs synchronously in CA1 ('b') and dentate gyrus ('c'). Dashed circles corresponding to a, b, and c indicate recording site of maximum amplitude. Approximate location of pyramidal cell and granule cell layers are denoted by 'p' and 'g', respectively. (b) Voltage depth profiles of HFOs a, b, and c from panel (a). Note that the maximum amplitude of the Ripple ('a') and pathological HFO ('b') occur within cellular layers, but the Ripple reverses in polarity just below the pyramidal cell layer, while the pathological HFO reverses near the hippocampal fissure. Reproduced from Bragin *et al*. (2007) *Epilepsia* 48(5): 35–40, with permission from Wiley-Blackwell.

may reflect back propagation of the population spike along dendrites and/or activation of a greater number of neurons associated with pathological HFOs. Ripples in CA1 are lower in amplitude compared to FR, and appear

as smooth sinusoid-like oscillations. FR recorded in either CA1 or dentate gyrus appear as bursts of population spikes, with intraburst population spike frequencies between 80 and 600 Hz (Figure 2). Outside these cellular layers, FR amplitude sharply decreases and the shape changes from sharp, irregular population spikes to a smoother oscillation.

In entorhinal cortex ipsilateral to the seizure onset region in epileptic rats, FR recorded simultaneously from sites 1.5 mm apart often do not reverse in polarity. These data suggest that FR networks in entorhinal cortex may be larger than those in dentate gyrus. Using microelectrodes with spaced tips oriented perpendicular to cortical laminae, we have shown in patients that FR are maximum in amplitude and reverse in polarity in middle layers of entorhinal cortex. Stimulating the afferents to entorhinal cortex reveals that these middle layers correspond with locations in which the evoked population response is largest in amplitude. In contrast, Ripples recorded from these same sites more often do not reverse in polarity across entorhinal cortex laminae. These data indicate that FR-generating areas in cellular layers are likely to be much smaller than networks supporting Ripples.

Neuronal Correlates of Ripples and FR

Similar to hippocampal Ripples, FR are most likely to occur during SWS, both in animals and patients with epilepsy. Unlike Ripples, FR occurrence remains elevated during REM sleep, and equivalent to rates during wakefulness. In these mesial temporal limbic areas, analysis of single neurons shows distinct changes in neuronal firing that correspond with occurrences of Ripples and FR. Single unit firing rates, burst firing, and synchrony of action potential discharges between pairs of neurons are higher during SWS compared to REM sleep. However, during REM sleep, neurons ipsilateral to seizure-generating areas have significantly higher firing and burst rates, and greater synchrony of discharges compared to neurons in contralateral sites. These data demonstrate that enhanced neuronal excitability and synchrony of discharges are associated with Ripple- and FR-generating areas. Yet, the neurochemical systems that govern REM sleep and suppress neuronal excitability (and large scale thalamo-cortical rhythms) have less influence on abnormal neuronal synchrony and local FR oscillations in primary epileptogenic brain areas.

Analysis of the relationship between neuronal discharges and occurrences of Ripples and FR in entorhinal cortex of epileptic patients reveals that MUA increases markedly during Ripples and FR, but the increase during Ripples is half that seen during FR. Analysis of single neurons indicates that the increase in MUA observed during Ripples is due, in part, to an increase in pyramidal cell discharge, because presumed pyramidal cells show maximum firing rates that coincide with the highest amplitude of the Ripple. Putative interneurons also increase their firing, but maximum firing rates occur before the Ripple oscillation. These data suggest that interneuron discharges may inhibit pyramidal firing at

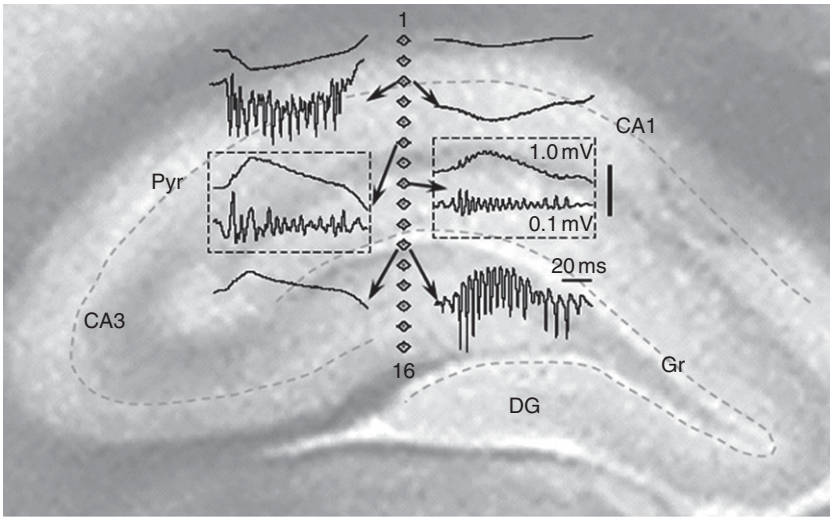

Figure 2 Two examples of pathological HFOs recorded from the hippocampus of a rat using a 16-contact recording electrode with intercontact spacing of 100 μm. The HFO on the left has a maximum amplitude in the pyramidal cell layer of CA1, while the other on the right has a maximum amplitude within the granule cell layer of dentate gyrus. Both HFOs reflect a burst of population spikes. Traces inside the dashed boxes correspond in time to the same bursts of population spikes, but at sites ~300 μm from the cellular layers. The bottom trace in each box is amplified 10 times and bandpass filtered 80–600 Hz. Reproduced from Bragin *et al*. (2007) *Epilepsia* 48(5): 35–40, with permission from Wiley-Blackwell.

the beginning of the local field oscillation, but pyramidal cells are 'released' to fire during the Ripple oscillation. Phase analysis between unit discharges and each Ripple cycle reveals that pyramidal cells fire preferentially during the negative phase, while interneuron discharges lag by approximately 0.5 ms. This coordinated pattern of firing during Ripples includes precisely timed discharges from interneurons that may regulate pyramidal cell discharges and control activation of postsynaptic targets.

Currently, there are no patient data regarding cell-specific discharges contributing to FR, but limited in vivo evidence from epileptic KA-treated rats shows that pyramidal cells fire during the negative phase of the extracellular FR oscillation. However, cellular recording has revealed no consistent firing pattern relationship between interneurons and FR, and recordings fail to show that either interneurons or pyramidal cells fire at FR frequencies. Thus, it is likely that FR emerge from synchronized action potential discharges from groups of neurons that include principal neurons primarily, but probably interneurons as well. How abnormal synchrony is generated in vivo during FR is unknown, but in vitro studies show that normal rat hippocampal slices bathed in a high potassium medium generate spontaneous FR-like field bursts in CA3. This hippocampal region contains a high density of recurrent excitatory connections between pyramidal cells. Chemical agents that block ionotropic glutamatergic signaling reduce synchronous discharges between pyramidal cells and attenuate FR bursts. Manipulations that increase the fidelity of pyramidal cell discharges increase FR amplitude, whereas disrupting intrinsic action potential generating mechanisms decreases FR amplitude. These data indicate that excitatory synaptic transmission may synchronize discharges between pyramidal cells that contribute to FR.

Future Goals

A challenge in studying neuronal networks supporting pathological HFOs is to reliably capture pathological HFOs at the source of their generation. FR-generating sites are small and distributed across seizure-generating brain areas, which make these pathological networks difficult to target in animals, and particularly in patients with epilepsy in whom the primary epileptogenic area is often not limited to a single structure. However, because higher rates of FR correlate with areas of greater atrophy and cell loss, MRI could help to identify atrophic hippocampal areas that may then be used to guide the placement of chronic microelectrodes in suspected FR-generating areas. Also, recent patient studies using conventional subdural or depth electrodes positioned in neocortical areas have found HFOs that are presumed to be pathological. These data suggest that the neuronal generators of neocortical HFOs may be larger than those in mesial temporal limbic areas, and therefore may be captured using noninvasive techniques – for example, magnetoencephalography (MEG).

Our past studies using chronic microelectrode recordings in animals and patients with epilepsy emphasized significant differences in spatial distribution and spectral frequencies between Ripples and FR. Our more recent analysis suggests that HFO shape is an important feature that may be useful to distinguish physiological and pathological HFOs (that is, pathological HFOs with Ripple frequencies). In addition, HFO shape may be especially important for studies using conventional depth electrodes in patients with epilepsy because large diameter electrodes are more likely to record HFOs from sites that are distant from the source of generation. Studies are needed to analyze and compare the spatial, temporal, and waveform electrophysiological features of HFOs recorded simultaneously on microelectrodes and clinical depth electrodes.

In order to identify neuronal mechanisms underlying pathological HFOs, additional electrophysiological studies are needed that specifically characterize neuronal cell types and their discharges during FR (e.g., in animal studies describing physiologically identified principal cells and interneurons during endogenous network oscillations). It is essential to determine how local excitatory circuits and inhibitory interneurons contribute to generation of pathological FR. A powerful approach, using juxtacellular labeling and immunohistochemical identification following in vivo recordings, will provide important morphological and neurochemical information about the roles of pyramidal cells, granule cells, and various classes of interneurons in generation of pathological HFOs.

Studies of HFOs suggest that pathological HFOs have tremendous potential as a surrogate marker of epileptogenicity, which may provide valuable localizing information to identify areas for surgical resection. Furthermore, the presence of FR in primary epileptogenic areas may be an indication of pharmacologically resistant epilepsy, and assist in determining effective treatment. In addition, pathological HFO may be used to screen for potential anti-epileptic compounds. Finally, there is evidence that FR are involved in epileptogenesis, and studies are needed to investigate pathological HFOs in animal models and, if possible, in patients who are at risk for developing epilepsy.

Introduction

Over a century ago, on the basis of clinical investigations, Gower suggested that 'seizures beget seizures.' Implicit in that notion is that seizures lead to long-lasting alterations in the mode of operation of neurons and networks, and that these alterations in turn induce the chronic epileptic state – i.e., a permanent reduced threshold for seizure generation. How this transformation occurs – from a naïve network to one that generates seizures – is a basic question in neurobiology, since it serves as a template for how episodes of hyperactivity may profoundly and often irreversibly alter the molecular and cellular properties of neurons. The transformation is of obvious major interest in relation to the epilepsies; its elucidation should lead to improved understanding of epileptogenesis, including the unique features of epileptic tissue, the mechanisms that lead to the transformation, and their relation to neuronal plasticity. Further, understanding these transformative mechanisms should also provide insight into treatments that might prevent epileptogenesis (antiepileptic drugs) and drugs that only block seizures (anticonvulsive agents).

Studies relying on experimental adult animals have provided a solid rationale for the concept that seizures beget seizures. Indeed, recurring seizures such as those produced by kainic acid lead to long-lasting alterations in the circuit, including cell loss and the formation of novel aberrant synapses that are now known to play a central role in the generation of seizures by the reorganized (now 'epileptic') network. The inaugurating status epilepticus induced by kainic acid injection is followed by a latent phase, during which overt behavioral (or electrographic) seizures are not readily generated; it is only a few weeks later that a chronic epileptic state, with spontaneous seizures and a reduced threshold for the generation of additional seizures, is apparent. During this latent phase, a plethora of genes often expressed in the developing – but not the naïve adult – brain are reexpressed and lead to the sprouting of fibres and the formation of novel aberrant synapses that will directly contribute to the generation of

Introduction

Over a century ago, on the basis of clinical investigations, Gower suggested that 'seizures beget seizures.' Implicit in that notion is that seizures lead to long-lasting alterations in the mode of operation of neurons and networks, and that these alterations in turn induce the chronic epileptic state – i.e., a permanent reduced threshold for seizure generation. How this transformation occurs – from a naïve network to one that generates seizures – is a basic question in neurobiology, since it serves as a template for how episodes of hyperactivity may profoundly and often irreversibly alter the molecular and cellular properties of neurons. The transformation is of obvious major interest in relation to the epilepsies; its elucidation should lead to improved understanding of epileptogenesis, including the unique features of epileptic tissue, the mechanisms that lead to the transformation, and their relation to neuronal plasticity. Further, understanding these transformative mechanisms should also provide insight into treatments that might prevent epileptogenesis (antiepileptic drugs) and drugs that only block seizures (anticonvulsive agents).

Studies relying on experimental adult animals have provided a solid rationale for the concept that seizures beget seizures. Indeed, recurring seizures such as those produced by kainic acid lead to long-lasting alterations in the circuit, including cell loss and the formation of novel aberrant synapses that are now known to play a central role in the generation of seizures by the reorganized (now 'epileptic') network. The inaugurating status epilepticus induced by kainic acid injection is followed by a latent phase, during which overt behavioral (or electrographic) seizures are not readily generated; it is only a few weeks later that a chronic epileptic state, with spontaneous seizures and a reduced threshold for the generation of additional seizures, is apparent. During this latent phase, a plethora of genes often expressed in the developing – but not the naïve adult – brain are reexpressed and lead to the sprouting of fibres and the formation of novel aberrant synapses that will directly contribute to the generation of

further seizures. This 'reactive plasticity' is instrumental in the pathogenesis of many forms of epilepsy. A concept similar to the 'seizures beget seizures' hypothesis is intrinsic to the 'kindling' process, in which recurrent electrical brain stimulation that initially generates only a brief response eventually triggers (after many stimuli) a generalized convulsive seizure. Here, also, reactive plasticity may occur and contribute to the deleterious sequelae.

Instrumental to our understanding of these processes are parallel observations made by researchers on the mechanisms of synaptic plasticity. These studies have focused on how short episodes of augmented activity leads to persistent alterations of synaptic efficacy. These studies on long-term potentiation and depression (LTP and LTD) have unravelled important basic mechanisms of synaptic plasticity, including the short lasting rise of intracellular calcium (mediated by activation of NMDA receptors and/or voltage-gated calcium currents) that triggers a cascade of events that induces a postsynaptic insertion of novel AMPA receptors. A similar rational applied to epileptic activities has led to the idea that hyperactivity first leads to increased synaptic efficacy followed by long-lasting synaptic rearrangements. Seizures are now known to trigger LTP processes triggered by NMDA receptors and associated with a more efficient glutamatergic responses. 'Epileptic' LTP (or other forms of pathological LTP) differs, however, from the memory-related LTP; in classical memory-linked LTP, NMDA receptors are required for the induction of the process but are not modified during its expression. In contrast, in epileptic LTP, NMDA receptor-mediated signals are persistently augmented, and this persistent change is an important factor in the resulting functional pathology. Nevertheless, these classical LTP-related observations provided a framework studying the relation between hyperactivity and its long-lasting consequences. They also suggest a link between physiological and pathological alterations of synaptic plasticity and their consequences.

Yet, another major player must be considered in studying the transformation of naïve tissue to the epileptic state. GABAergic neurons and synapses control the activity of neural networks and play a central role in the generation of behaviorally-relevant oscillations and pathological patterns. They also provide a source of inhibition that prevents the generation of hyperactivity. Extensive investigations have shown that GABAergic inhibitory postsynaptic currents (IPSCs) are obliterated quite rapidly by episodes of hyperactivity. Subsequent studies showed that some GABAergic neurons are also vulnerable to seizures; subtypes of interneurons, such as the somtostatin OLM interneurons, readily degenerate after seizures. Also, recordings made weeks after the insult show a permanent reduction of the inhibitory drive onto dendrites of pyramidal neurons, suggesting a permanent loss of inhibitory drive; no reactive plasticity or sprouting of GABAergic axons appear to compensate for the loss. Recent studies have suggested that a shift of polarity in the action of GABA (from hyperpolarizing to depolarizing) plays a central role in epilepsy. Recordings made in chronic human epileptic foci showed a persistent accumulation of intracellular chloride in neurons, leading to excitatory effects of GABAergic synapses. Since GABAergic synapses are also excitatory in immature neurons (for the same reason), this observation has suggested that 'epileptogenesis recapitulates ontogenesis.'

In this review, we shall briefly deal with the long-lasting consequences of seizures in the developing brain. The developing brain is known to have a high incidence of seizures, and exhibits significant (and long-term) seizure consequences. Recurring seizures in newborns may lead to life-long deleterious sequelae, suggesting that seizures at that stage of development may transform naïve networks into networks that generate seizures. Paradoxically, in spite of their low threshold for seizure generation, immature neurons are more resistant to insults than adult cells. For example, immature neurons are not readily killed by anoxic episodes or recurrent seizures. Thus, in the very young postnatal rat, seizures generated by kainic acid activate limbic networks but do not lead to cell loss in the hippocampus; however, by the 2nd postnatal week this resistance to injury disappears. Therefore, the long-lasting consequences of seizures in the very young brain may well be due to mechanism other than cell loss and reactive plasticity. One plausible mechanism is that seizures alter developmental programs in a time- and developmental stage-dependent manner, thereby leading to persistent maladaptive construction of networks (including malformations) and synapses. These networks, in turn, are responsible for the long-term seizure sequelae. Hence, it remains important to test whether seizures, even those not associated with structural damage, beget seizures in the developing brain at an early developmental stage.

Background

Activity Dependent Alterations of $[Cl^-]_i$

The regulation of $[Cl^-]_i$ by neuronal activity has been studied extensively by Poo and colleagues, using various preparations to determine how altering neuronal activity modifies the chloride gradient and thus the actions of GABA. In an earlier paper, they showed a progressive reduction of $[Cl^-]_i$ in neuronal cultures, which is associated with an expression of the chloride transporter KCC2. This shift was prevented by applications of a GABA receptor antagonist, suggesting that GABA itself contributes to the reduction of $[Cl^-]_i$. These investigators then showed that postsynaptic action potential generation shifted the reversal potential of GABA-induced Cl^- currents (E_{Cl^-}) toward positive levels in a duration- and frequency-dependent manner. This activity-dependent shift is regulated by cytosolic Ca^{2+} elevation and mimicked by releasing Ca^{2+}

from internal stores. This activity-dependent effect plays an important role in seizure generation, inasmuch as it is quite persistent. Indeed, in earlier studies in the adult hippocampus in vivo, investigators showed that high frequency stimulation produced long-lasting increases in the efficacy of glutamatergic synaptic currents and an elimination of GABAergic synaptic currents. This opposite action of electrical activity on excitatory and inhibitory currents can lead to higher excitability.

Alterations of $[Cl^-]_i$ also Regulate Construction of Cortical Networks

GABA receptors are present well before synapses are formed, and their activation can modulate early cellular function. Indeed, the ongoing release of GABA exerts an important tonic and phasic action on neuronal migration in neurons that bear no operative synapses. In addition, alterations of $[Cl^-]_i$ can affect the construction of networks. This point was directly demonstrated using a transfection technique to express KCC2 (the late-appearing chloride co-transporter) in immature neurons; such expression led to the excitatory-to-inhibitory shift of the actions of GABA. This shift also led to an unexpected and dramatic increase in the density of GABAergic synapses and of miniature GABA currents, indicating that more functional synapses are established when the chloride shift occurs. In subsequent experiments, Poo and colleagues used an in utero electroporation technique to introduce KCC2 into a subpopulation of rat progenitor cells. This introduction did not alter radial migration to layer II/III of the somatosensory cortex, but did impair the morphological maturation of neurons. These results are consistent with earlier studies that suggested a trophic action of excitatory GABA on neurons, and illustrate how early actions of excitatory GABA (and the underlying chloride gradient) act to modulate the construction of networks. Alterations in the polarity of GABA action would be expected to have long-lasting consequences on excitability. For example, drugs that alter GABA function at an early stage of brain development may also affect cortical networks and lead to malformations; such results have been shown in recent studies devoted to test the effects of in utero drugs on the formation of heterotopic masses. It is also likely that early seizures, and other episodes of enhanced activity, lead to long-lasting sequelae mediated by these mechanisms.

Seizures Beget Seizures in vitro in the Hippocampus

To determine if seizures produce long-lasting alterations of network activity, we developed an intact in vitro hippocampi preparation in which the two intact hippocampi from immature rodent were dissected together with their commissural connections. This preparation is placed in a chamber with three independent compartments (one compartment for each hippocampus and one for the connecting commissures). Since the compartment are isolated from each other, we can independently perfuse the two hippocampi and the connections with different liquids. Using this preparation, we generated seizures in one hippocampus (with kainate or bicuculline) while recording from fields and single neuron activity in both the stimulated and naïve hippocampus. The connections between hippocampi can be reversibly interrupted – e.g., after the propagation of a single or multiple seizures – by applications of TTX. We found that the propagation of single seizure did not lead to long-lasting consequences; ongoing spontaneous and evoked activity was restored to baseline levels after the seizure event. In contrast, after recurring seizures, the naïve hippocampus – i.e., the hippocampus that had not received a convulsive agent but was subjected to recurring propagated seizures – became epileptic: it generated spontaneous long-lasting ictal episodes, and electrical stimuli elicited all-or-none epileptiform events. This transformation was long-lasting; slices prepared from the epileptic hippocampus still generated epileptiform activities 48 h later. We concluded that recurring seizures do transform a naïve hippocampus to one that generates seizure activity.

Interestingly, blocking NMDA receptors in the recipient naïve hippocampus did not block the generation of propagated seizures, but did prevented the transformation of the naïve hippocampus into an independently epileptic seizure-generating site, suggesting that NMDA receptors are required for this transformation. This observation is consistent with the involvement of alterations of synaptic efficacy in this process, analogos to those changes seen in LTP (and other paradigms of synaptic plasticity) that also necessitate the activation of NMDA receptors. Somewhat more unexpectedly, blocking GABA receptors also prevented the transformation. Therefore, the activation of GABA *and* NMDA receptors is instrumental for seizures to beget seizures.

Persistent Increase of $[Cl^-]_i$ in the Mirror Focus

A major role for GABA and chloride was suggested by the observations that in the epileptogenic 'mirror focus' (as described above), GABA again excites neurons. Recurring seizures appear to down-regulate the mechanisms that control chloride extrusion, thus leading to an accumulation of intracellular chloride. Extensive investigations now suggest that the chloride co-transport extruder KCC2 is vulnerable to insults, and is reduced by lesions and traumatic injuries. Other observations also suggest that recurring activation of neurons favors an accumulation of chloride and a shift of the actions of GABA to more excitatory actions. This observation on the plasticity of $[Cl^-]_i$ suggests that this mechanism plays a central role in long-lasting effects of

neuronal activity on the excitatory/inhibitory actions of GABA (also see below). The importance of these observations is also reflected in the excitatory actions of GABA consequent to the high $[Cl^-]_i$ reported in human epileptic neurons recorded in vitro following surgery.

Methods

Intact neonatal hippocampi are dissected and placed in a triple chamber. Both neuronal and population activities are recorded, and a mathematical analysis of the activities is carried out to describe the power spectra of the observed oscillations.

Recent Results

High Frequency Oscillations are Required for Seizures to Beget Seizures

Why do recurring seizures lead to long-lasting alterations and transform a naïve network into one that generates seizure activity? Why are both GABA and NMDA receptors required for seizures to beget seizures? The development of our triple chamber, and our confirmation of the formation of an epileptogenic mirror focus in that preparation, gave us a unique opportunity to test the mechanisms. Toward this goal, we applied drugs separately to the generating hippocampus and the transformed one, and compared the properties of seizure activity that effectively begat seizures to properties of seizures that did not cause this transformation. We found that only seizures that included high frequency oscillations (HFOs, above 40 Hz) lead to long-lasting consequences. Seizures with only lower frequency components fail to so initiate the transformation; after a large number of recurring seizures, the naive hippocampus will not generate spontaneous or evoked seizures (when it is disconnected from the treated hippocampus).

How are HFOs generated? When GABA and/or NMDA receptors are blocked, the seizures fail to generate HFOs – and loose their long-term consequences. In other words, the activation of these receptors enables the generation of HFOs, that in turn trigger the events that lead to the formation of an epileptogenic mirror focus. It is likely that seizures activate GABA PSCs, leading to the activation of NMDA receptor channels (by the removal of the voltage-dependent Mg^{++} block), thereby enabling both the generation of HFOs and long-lasting potentiation of synaptic currents. The parallel loss of regulation of chloride removal, by an activity-dependent inactivation of KCC2, becomes progressively irreversible (by an as yet unknown mechanism), leading to a positive feedback loop (i.e., more excitatory actions of GABA, more seizures, more intracellular chloride, etc.). To summarize, the induction of the transformation is due to HFOs generated by the activation of GABA and NMDA receptors; the expression of the mirror focus is in part due to a permanent accumulation of chloride and excitatory actions of GABA. The clinical implications of these observations may be quite important, both in terms of diagnosing deleterious seizures that require aggressive treatments and also in differentiating the inhibitory and the apparently pro-epileptic actions of GABA (since the activation of GABA receptors is needed for seizures to beget seizures).

In preliminary experiments, we've recently made single GABA channel recordings (cell attached configuration) from neurons in the mirror focus. We found significant alterations of $[Cl^-]_i$ associated with the expected changes of E_{GABA}. These observations provide direct evidence that there is, in the mirror focus, an increased intracellular chloride concentration.

Future Goals

Observations from our experimental model clearly suggest that seizures do beget seizures, and that GABA-chloride plasticity plays a central role in long-term consequences of seizures and other insults. A deficit in the regulation of chloride during episodes of hyperactivity is central to this effect, in that neurons loose their capacity to respond adequately to hyperactivity and even to physiologically relevant episodes of enhanced activity that can be triggered under these conditions. Future experiments should focus on confirming these observations in vivo, using appropriate recording techniques (and in particular, with single GABA channels recordings that prevent intracellular dialysis of chloride and provide an adequate measure of chloride shifts). Also crucial will be the determination of the dynamic of chloride shifts; methods used at present are less than adequate considering that they rely on invasive whole cell recordings. Most important and difficult will be the determination of the type of mechanisms that can transform a transient shift of chloride to a quasi-permanent one: At what point is a neuron unable to return to its normal baseline?. How is that shift controlled? Answers to these questions will, in turn, give important insights into the mechanisms that underlie the transformation of a transiently seizing network to one that is genuinely epileptic. The use of the triple chamber in vitro, combined with powerful imaging techniques, will provide a unique opportunity to investigate the relation between HFOs and epileptogenicity. Single GABA channel recordings in the epileptic tissue will provide a unique opportunity to investigate how the epileptic networks and GABA signalling behave and respond to various stimuli, including behaviorally-relevant oscillations.

Parallel studies on human brain slices, removed after surgical interventions, will enable investigators to test the relevance of the proposed mechanisms. While it is already apparent that GABA excites epileptic neurons, it is still unknown how many neurons, which ones, and in relation to what patterns of activity (e.g., HFOs?). The use of in vivo preparations that enable experimenters to perfuse the cortex and hippocampus while recording from identified neurons will provide opportunities to test in situ the propagation of seizures in animals that been made epileptic by treatment with convulsive agents. Finally, the impact of fast imaging techniques in determining the mechanisms of epileptogenicity should not be underestimated. The generators of various patterns of epileptiform activities are now being unravelled in brain slices, using fast two photon imaging. The identification of the generators of spontaneous seizures will be of the utmost importance, as this determination will provide an approach to some of the most difficult questions in that field: What are the relations between physiologically- and behaviorally-relevant patterns of activity and seizures? Are they produced by the same generators? What are the neuronal properties of these generators, and how do they shift from one pattern to another?

Age-Specific Responses to Antiepileptic Drugs

Introduction

When treating infants and children with epilepsy, two things become obvious. First, seizures are prevalent at these very young ages of life and second, the seizures and epileptic syndromes occurring in the pediatric population have a wide variability in semiology and evolution, as well as in their response to therapies, which distinguish them from those in adults. These unique features of the pediatric epilepsy patient are due, in part, to the fact that the developing brain first encounters stressors (and other conditions) that can trigger epileptic events – at a developmental stage when its defense mechanisms have not fully matured. For example, certain seizure-controlling networks may not have been fully formed, and/or there is a relative abundance of excitatory/synchronizing mechanisms with respect to inhibitory control mechanisms. Furthermore, paradoxical "excitatory" effects may be triggered from classical inhibitory systems, as is the case in $GABA_A$ receptor signaling. In fact, the maturation of the mechanisms that control excitability is a dynamic and asymmetric process across brain regions and cell types, presenting interneuronal communication patterns that are more complex and diverse, when compared not only to adults but also to any given developmental stage.

In this article, we briefly introduce the factors responsible for the age-specific effects of antiepileptic drugs (AEDs) and then focus on $GABA_A$ signaling, describing how its role in seizure control and brain development changes with age. We also present recent advances that demonstrate how $GABA_A$ signaling is influenced by intrinsic and epigenetic factors, which may therefore modify the effects of AEDs on the brain.

Background

Age-Specific Effects of AEDs: Treating a Moving Target

Given the often stormy course of many neonatal and childhood seizures, the first priority of the pediatric epileptologist is to find the most effective anticonvulsant

therapy. The armamentarium of available AEDs is similar across ages, and, AEDs that are effective in adults can also be useful in the pediatric population. However, unlike the adult epileptologist who typically treats temporal lobe or extratemporal focal-onset epilepsies, pediatric epileptologists encounter a richer spectrum of epileptic seizures and syndromes that may differ in their responsiveness to AEDs. This variability in responsiveness reflects, at least in part, the many different pathophysiological processes underlying early life seizures and epilepsies – mechanisms that are distinct from those seen in adults. Such is the case, for instance, with epilepsies of genetic, metabolic, or febrile etiology that tend to appear in young patients. Of equal importance is the fact that the developing brain operates differently than the adult. As a result, seizure semiology may differ widely with age. A dramatic example of this feature is seen in infantile spasms, a classical seizure type of infancy that requires its own specialized types of therapies (e.g., adrenocorticotropin hormone (ACTH)). Alternatively, the effects of drugs may differ (between adult and pediatric case) because the targeted neurotransmitter systems may have different signaling consequences in immature versus more mature neurons, or their effects may be less pronounced in a specific age group due to differences in the expression of related receptors (Table 1). The effects of AEDs may be further diversified by age-specific differences in the organization of the brain, and its still developing interactions with other systems (e.g., the endocrine or immune systems) and with the environment.

Age not only matters when considering AED efficacy, but also influences the effects of AEDs on brain development and function. The age-specific vulnerability of the patient who is still developing has best been exemplified by drug-induced neurodegenerative changes. Ikonomidou's group first observed increased apoptosis in multiple areas of the brain in seizure-naïve neonatal rats, a result that was not nearly as dramatic as in more mature animals. Existing evidence supports the view that AEDs may interfere with higher cognitive functions, even during early postnatal life. Comparison of clinical studies across ages and populations is hampered by the fact that etiology and frequency/severity of epilepsy may independently affect the cognitive function. There are limited studies that specifically address the neurodevelopmental impact of AEDs on immature animals with seizures. Existing studies suggest that at least certain AEDs may not have significant adverse effects in animals that had experienced prior seizures. Obviously, this issue needs to be explored further.

Developmental Changes in $GABA_A$ Signaling

GABA has a central role in epilepsy research, as it is the classical inhibitory neurotransmitter in the mature brain and a favorite target of many of the available AEDs. GABAergic interneurons control the activity of regions involved in seizure generation, such as the hippocampus, but are also major components of subcortical nuclei involved in the control of seizure propagation, such as

Table 1 Age-specific differences in selected neurotransmitter systems

Factor	*Immature brain*	*Mature brain*	*Potential significance*
NMDA receptors			
– binding studies	Peak at ~PN5	Intermediate	– Higher excitability of immature brain – Different sensitivity to selective inhibitors
– subunit expression	NR2B vs NR2A High	NR2B vs NR2A: Low	Shorter NMDA-postsynaptic currents
AMPA receptors			
– binding studies	Peak at PN10	Intermediate	– Higher excitability of immature brain
– subunit expression	GluR2B expression: Low	GluR2B expression: High	– Increased calcium permeability in immature neurons – Different sensitivity to selective inhibitors
Kainate receptors			
– binding studies	Low	High	Different sensitivity to selective inhibitors
Glutamate uptake	Low	High	Higher excitability of immature brain
GABAA receptors			
– signaling effects	Depolarizing	Hyperpolarizing	– More effective GABAA inhibition in mature neurons – Age-specific translational effects
– subunit expression	α2/α3 vs α1: high	α2/α3 vs α1: low	Higher affinity for benzodiazepines in mature brain
GABAB receptors			
– binding studies	High	Low	Higher sensitivity to $GABA_B$-acting drugs
GABA reuptake			
– GAT expression	Higher GAT-3	Higher GAT-1 (peak at PN10–30)	Different sensitivity to specific GAT inhibitors

Simplified summary of the known age differences in neurotransmitter systems. It should be noted that cell type, region, and sex specific differences have been reported.
GAT is the GABA transporter.

the substantia nigra pars reticulata (SNR). The role of the SNR and the age- and sex-specific changes in the function of its GABA-sensitive seizure controlling networks is the focus of another article in this volume (see Scantlebury *et al.*). Here, we will rather address how the age-related changes in $GABA_A$ receptor signaling – from depolarization to hyperpolarization – may impact both the effects of $GABA_A$ergic drugs in seizure control and also their effects on brain development.

$GABA_A$ receptors are pentameric ligand-gated Cl^- channels that can assume both excitatory and inhibitory functions, depending on the existing Cl^- gradient across the plasma membrane. They play central roles in brain development and neuronal communication. Very immature neurons maintain high intracellular Cl^- concentrations due to overabundance of inward Cl^- transporters, such as the sodium potassium chloride cotransporter NKCC1 (Figure 1). Consequently, the opening of $GABA_A$ receptors leads to depolarization, activation of L-type voltage-sensitive calcium channels (L-VSCCs), and activation of calcium-sensitive processes that are important for neuronal differentiation. The depolarizing effects of GABA are important for a number of processes, including neuronal proliferation, migration, synaptogenesis, transcriptional regulation, and neuronal electrical activity. During development, there is a gradual shift in the balance of cation chloride cotransporters (CCCs) that transport Cl^- through the cellular membrane, and this shift ultimately decreases intracellular Cl^- to favor hyperpolarizing $GABA_A$ responses in mature neurons. These changes occur via a gradual decline in Cl^- importers (like the sodium potassium chloride cotransporter NKCC1) and a concomitant increase in the neuronal-specific potassium chloride cotransporter KCC2. These changes have been

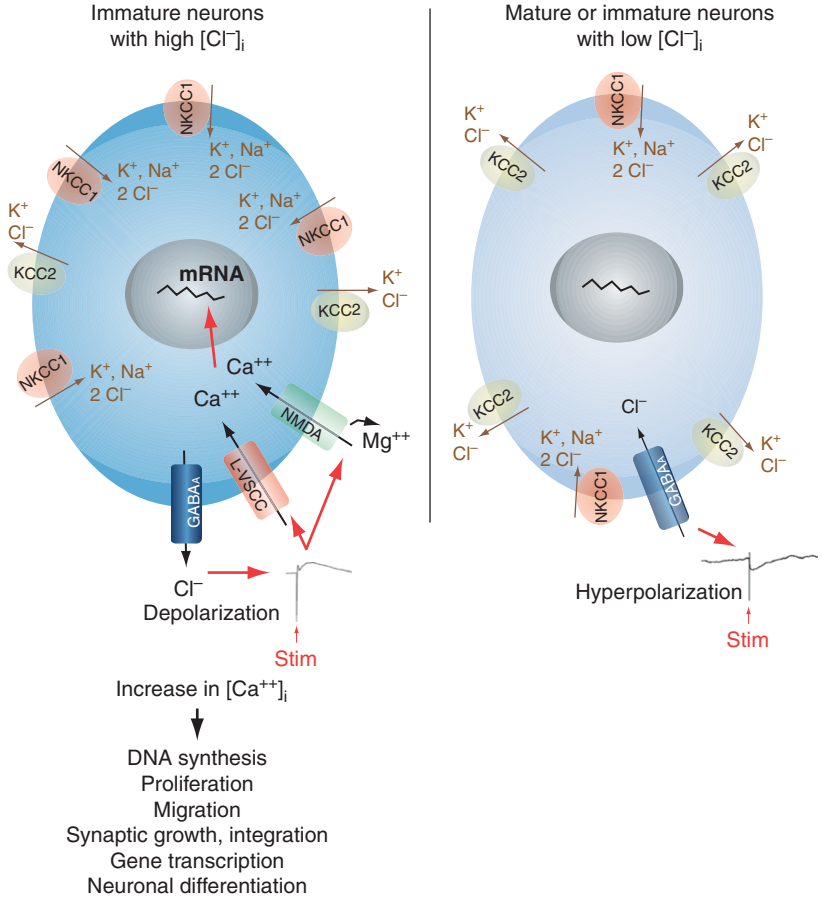

Figure 1 Developmental changes in chloride cotransporters and $GABA_A$ signaling. In immature neurons (left panel) there is a high $[Cl^-]_i$, due to a relative abundance of NKCC1 over KCC2. As a result, activation of $GABA_A$ receptors leads to depolarization, activation of L-VSCCs and NMDA receptors (via release of Mg^{2+} block) and increase in intracellular calcium. This promotes many calcium-sensitive signaling cascades that are involved in brain development. During development, there is a gradual increase in KCC2 and decrease in NKCC1 which decreases $[Cl^-]_i$ and therefore facilitates the appearance of hyperpolarizing actions of $GABA_A$ receptors (right panel). In this scenario, $GABA_A$ activation cannot influence directly the calcium-sensitive processes. Modified from Galanopoulou AS (in press) GABAA receptors in normal development and seizures: Friends or foes? *Current Neuropharmacology*, with permission from Bentham Science Publishers.

shown, with antisense knockout animals or in functional inhibition experiments, to trigger the functional switch of $GABA_A$ signaling from depolarizing to hyperpolarizing. This functional switch occurs at specific time points during development, and in a cell type and sex-specific manner.

Several studies have indicated that the presence of depolarizing $GABA_A$ signaling may increase the excitability of very immature neurons and, under certain conditions, trigger ictal epileptiform events. Untimely re-appearance of depolarizing $GABA_A$ signaling or shift in the balance of CCCs to favor depolarizing GABA has been described in human tissues from temporal lobectomies of adults with temporal lobe epilepsy, as well as in tissue from pediatric epilepsy surgeries for cortical dysplasias. Paradoxically, drugs that normally trigger epileptiform activities in naïve adult neurons, like the $GABA_A$ receptor antagonists bicuculline or picrotoxin, can suppress epileptiform discharges in certain neurons with depolarizing $GABA_A$ signaling. Consistent with these results, functional inhibition of NKCC1 with bumetanide has been shown to suppress neonatal seizures in vivo in the kainic acid model. However, in in vitro studies, bumetanide suppressed ictal epileptiform activities only in the high potassium model, but not in the low magnesium or kainic acid model. These results suggest that age, as well as the type of seizures or the timing of bumetanide administration, may be an important factor in determining the bumetanide effects on seizure control. It is, however, difficult at the moment to speculate on the efficacy of such treatments in vivo, in humans, as the NKCC1-selective inhibition by bumetanide occurs only at very low concentrations of the drug.

In human patients, it is not yet known when the $GABA_A$ switch occurs. In the only available human postmortem study of patients dying from nonneurological causes, the levels of KCC2 and NKCC1 were compared and a transition from a NKCC1-dominant state to a KCC2-dominant state was reported to occur during the perinatal period, suggesting that this period may also correspond to the time of the $GABA_A$ switch. Occasional reports of paradoxical exacerbation of seizures by $GABA_A$-acting AEDs in premature, low-birth weight infants do exist. It is tempting to speculate that this may indeed be due to excitatory effects of $GABA_A$ signaling. These reports also raise the possibility that, in premature babies and possibly in a subpopulation of older patients with epilepsy, one of the reasons for medical refractoriness of their seizures to $GABA_A$ergic AEDs is the presence of depolarizing $GABA_A$ signaling.

In our laboratory, we have been particularly interested in the effects of $GABA_A$-acting AEDs on brain development, when given in seizure-naïve rats or in rats that had prior seizures. As discussed above, a number of studies have clearly demonstrated that the developmental changes in $GABA_A$ signaling lead to age-specific effects of $GABA_A$ergic AEDs on processes involved in neuronal differentiation. Recent advances have indicated that chronological age does not always correspond to biological age. Endogenous factors like sex, as well as epigenetic influences like seizures, stress, or drugs, may change the ontogeny of signaling pathways, thus altering the developmental stage of the brain. To understand better how to translate the experimental literature with respect to effects of AEDs on brain development, it is therefore imperative to dissect these mechanisms.

Methods

Our studies have been carried out in Sprague–Dawley rats (Taconic Farms, NY). Developmental comparisons of mRNA or protein expression levels are done using in situ hybridization and immunochemistry experiments, respectively. The experiments described below have focused on the SNR, known for its significant role in seizure control, and the hippocampus, well-known for its involvement in the networks that generate seizures, as well as its vulnerability in epileptic patients with memory deficits. Functional characterization of $GABA_A$ signaling is done with gramicidin-perforated patch clamp recordings, a method that preserves the Cl^- gradient and can therefore determine the direction of $GABA_A$ergic responses. In these experiments, slice recordings were carried out in the presence of glutamatergic inhibitors (D(−)-2-amino-5-phosphonopentanoic acid (AP5) 50 μM and 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) 10 μM). Under these conditions, stimulation elicited only $GABA_A$ergic postsynaptic responses. $GABA_A$ergic responses were therefore assessed either by electrical stimulation or by bath application of $GABA_A$ergic agonists such as muscimol (10 μM exposure for 3 min). To assess whether such $GABA_A$ergic agonists can increase intracellular calcium, we used fura-2 AM imaging, in the presence of AP5 and CNQX.

Seizure induction was done with intraperitoneal kainic acid (KA) injections. We induced three episodes of status epilepticus (SE), hereafter referred to as 3KA-SE. In prior studies from other laboratories, brief recurrent seizures or a single episode of SE could impair performance on behavioral tests, but did not suffice to induce neurodegeneration or epilepsy. We wanted to maximize the seizure load (using three episodes of neonatal KA-SE) to test the effects of this level of activation on $GABA_A$ signaling, brain injury, and seizure outcome. Neurodegeneration was assessed by FluoroJade B staining. In vivo electroencephalographic (EEG) and video monitoring was carried out in selected pups either during KA-SE or at 2–3 months of age to detect seizures.

Recent Results

Sex Differences in the Age-Specific Effects of $GABA_A$ergic Drugs, in Seizure-Naïve Rats

Prior studies had indicated that several structures involved in seizure networks, like the SNR and hippocampus, are sexually dimorphic. Given the known role of depolarizing $GABA_A$ signaling in brain development, we wanted to determine whether sex differences existed in $GABA_A$ signaling – and if so, to elucidate their importance for the sexual differentiation of the SNR. Using KCC2-specific in situ hybridization, and subsequently KCC2 and NKCC1-specific immunochemistry, we confirmed that the expression of KCC2 mRNA and immunoreactivity (-ir) increased, whereas NKCC1-ir decreased (as described in the hippocampus and cortex) between the second and fourth postnatal week (Figure 2). As anticipated by these changes, synaptic stimulation of GABAergic SNR neurons, in the presence of glutamatergic inhibitors, elicited depolarizing $GABA_A$ergic responses in male rats prior to PN16 and hyperpolarizing responses after PN17.

Interestingly, the timeline of these changes was accelerated in females. KCC2 mRNA expression was higher in female than in age-matched male rat SNR GABAergic neurons at PN15, PN30, and PN60. Furthermore, the $GABA_A$ switch occurred at a younger age (PN10) in female rat SNR. The pharmacologic effects of muscimol also differed in male and female rat SNR GABAergic neurons, when assessed at PN15. In males, muscimol triggered depolarizations, increases in intracellular calcium, and the phosphorylated form of cAMP responsive element binding protein (pCREB-ir) (which regulates calcium-sensitive gene transcription). In contrast, in females, muscimol caused hyperpolarizations without influencing calcium or pCREB-ir (Figure 3). Independent studies, both from our own laboratory and from others, have shown similar sex differences in CCC expression or the direction of $GABA_A$ergic signaling in the CA1 pyramidal region of hippocampus and in hypothalamus of developing rats. However, the timing of these events follows region-specific patterns.

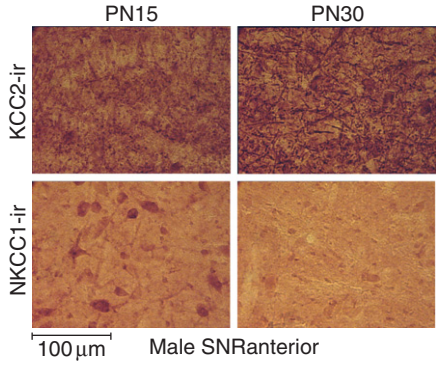

Figure 2 Age-specific changes in KCC2-ir and NKCC1-ir in male rat SNR.Using specific immunochemistries on PN15 and PN30 male SNR sagittal sections, KCC2-ir was detected in both somata and processes (upper panels). A gradual increase in KCC2-ir was noted, which was more evident in the neuronal processes at PN30. In contrast, NKCC1-ir declined with age (lower panels). Photographs were obtained with 400× magnification.

In vivo experiments aiming to evaluate whether the age-specific effects of a systemically administered $GABA_A$ergic drug may be due to the presence of depolarizing versus hyperpolarizing $GABA_A$ signaling have several limitations, if done only in young versus older animals. First, the biology and structure of the brain, and other interacting systems, such as the endocrine and immune systems, are completely different across ages. It is, therefore, difficult to dissociate their impact from the individual impact of the specific drug. Second, the epigenetic influences of the life experiences of a young versus older animal may also interfere. Third, the metabolism and bioavailability of the drug may be different. In our experiments, we took advantage of the sex differences in the direction of $GABA_A$ergic signaling in the neonatal hippocampus; specifically, we tested whether the existence of depolarizing versus hyperpolarizing $GABA_A$ergic responses modifies the effects of $GABA_A$-acting drugs or seizures on the developing hippocampus.

One of the calcium-regulated genes that is transcriptionally controlled by $GABA_A$ signaling is KCC2. GABA can control the timing of the $GABA_A$ switch via altering the expression of KCC2. In our studies, muscimol increased KCC2 mRNA in neurons with depolarizing $GABA_A$ signaling (i.e., immature neurons), but decreased it in neurons with hyperpolarizing signaling (i.e., mature neurons). This demonstration suggests the possibility of age- and possibly sex-specific translational effects of $GABA_A$ergic AEDs. Of interest, it has been shown that prenatal exposure to benzodiazepines leads to sex-specific differences in susceptibility to pentylenetetrazole-induced seizures in adult rats. However, the molecular pathways involved in these late effects have not yet been defined.

The different patterns of $GABA_A$ergic signaling also modify the effects of other pathways that are important in neuronal differentiation or survival. For instance, 17β-estradiol-mediated downregulation of KCC2 mRNA occurs only in neurons in which depolarizing $GABA_A$ signaling can activate L-VSCCs (Figure 3). Such interactions may further amplify the diversity of neurotrophic or translational effects of $GABA_A$ergic drugs, if given at different developmental stages. Interestingly, the neurodegeneration induced by AEDs, including effects of $GABA_A$ergic drugs, is maximal during the first 1–2 postnatal weeks, which correlates with the presence of depolarizing $GABA_A$ signaling in most studied brain regions. It is tempting to speculate that there is a link between the

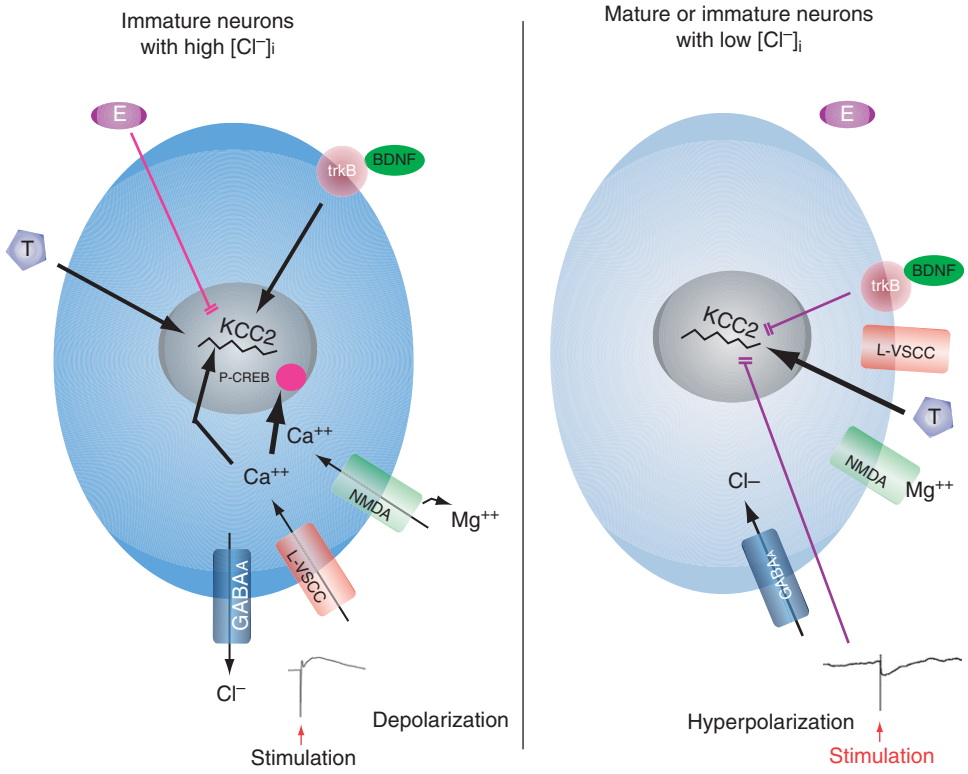

Figure 3 Different modes of regulatory control of KCC2 mRNA and pCREB-ir operate in neurons with depolarizing (left panel) or hyperpolarizing (right panel) $GABA_A$ signaling. *Left panel:* In immature neurons with high intracellular Cl^- ($[Cl^-]_i$), $GABA_A$ receptor activation causes depolarization, increases intracellular calcium and pCREB-ir, via activation of L-VSCCs and/or NMDA receptors. 17β-estradiol (E) decreases KCC2 mRNA; this effect is not seen in the presence of L-VSCC or $GABA_A$ receptor inhibitors. Brain derived neurotrophic factor (BDNF) increases KCC2 mRNA. Testosterone (T) and its androgenic derivatives also increase KCC2 mRNA. *Right panel:* In mature or immature neurons with low $[Cl^-]_i$, $GABA_A$ receptor activation causes hyperpolarization without altering calcium or pCREB-ir. In contrast, it decreases KCC2 mRNA. BDNF decreases whereas estradiol has no effect on KCC2 mRNA. Testosterone and its androgenic derivatives increase KCC2 mRNA regardless of the mode of $GABA_A$ signaling. These data are compilation of our own findings as well as data from the literature (referenced in Further Reading list). Modified from Galanopoulou AS (2008b) GABAA receptors in normal development and seizures: Friends or foes? *Current Neuropharmacology*, with permission from Bentham Science Publishers.

two processes (depolarizing $GABA_A$ signaling and neurodegeneration), but there is no direct proof yet. It is important to remember that these events have been described in seizure-naïve rats. How relevant are they for patients who need to take $GABA_A$-acting AEDs for seizure control (or for other neurological reasons)? This question has been a central focus of research in our laboratory; as described below, there are fundamental differences in $GABA_A$ signaling in the brain of rats with prior seizures or stress, which may help determine the effects of AEDs.

Seizures and Stress Can Modify the Biological Age: Lessons from $GABA_A$ Receptors

Numerous studies have shown that the outcomes after early life seizures differ from seizures first appearing in older animals. The immature brain is more susceptible to seizures. However, the degree of associated brain injury, cognitive deficit, and probability to develop later epilepsy increase with the age of first seizure onset. Many of the previously stated age-specific differences in the structure and physiology of the brain and its interactions with other systems, have been implicated. In our laboratory, we have been particularly interested in deciphering how $GABA_A$ signaling interferes with the late effects of early life seizures for two reasons – first, because of the importance of GABA in brain development and second, because most of the currently available antiepileptic drugs administered in neonates and infants act on $GABA_A$ receptors.

We have used the 3KA-SE model in rats, inducing three episodes of SE, at PN4, PN5, and PN6. In terms of brain development, this age corresponds roughly to a preterm human neonate. 3KA-SE did not induce detectable neurodegeneration as assessed at PN7, and mortality associated with this procedure was very low. However, 3KA-SE at PN4–6 switched the direction of $GABA_A$ signaling during the second week of life. Specifically, in males, it accelerated the functional maturation of $GABA_A$ signaling, causing precocious appearance of hyperpolarizing $GABA_A$ signaling. This influence, however,

can deprive the hippocampal CA1 pyramidal neurons of the neurotrophic influence of depolarizing GABA, and could thus contribute to long-term functional deficits. In contrast, in females, it produced a transient appearance of depolarizing $GABA_A$ signaling between PN8–13 (Figure 4). This influence may reactivate dormant calcium-sensitive processes, which in turn may cause phenotypic changes in the 3KA-SE females. Interestingly, the aberrant 3KA-SE induced switch in $GABA_A$ signaling did not occur in rats that had been treated with bicuculline at the time of KA-SE (i.e., given 10 min prior and 6 h after each KA injection; Figure 4), suggesting that $GABA_A$ receptors are mediators of the effects of 3KA-SE.

Comparison of our findings with published reports on the effects of seizures on $GABA_A$ signaling reveals that the female type of response to seizures resembles that of adults (work by Rivera *et al.*). Kindling in adult rats shifts CCC expression to favor a NKCC1-dominant state. Similarly, studies of human patients with temporal lobectomies have indicated either depolarizing $GABA_A$ signaling in a significant portion of subicular neurons or a shift to favor a NKCC1-dominant state. The only other in vitro developmental study was done on neonatal hippocampal neurons with hyperpolarizing $GABA_A$ signaling at the time of seizure induction; these experiments showed a similar switch to depolarizing $GABA_A$ signaling that drove spontaneous seizures. To determine whether the direction of $GABA_A$ signaling, rather than chronological age, is indeed a key factor in determining the effects of seizures on $GABA_A$ signaling, we examined the effects of 3KA-SE on rats that had been treated with bicuculline at the time of KA-SE (i.e., given 10 min prior and 6 h after

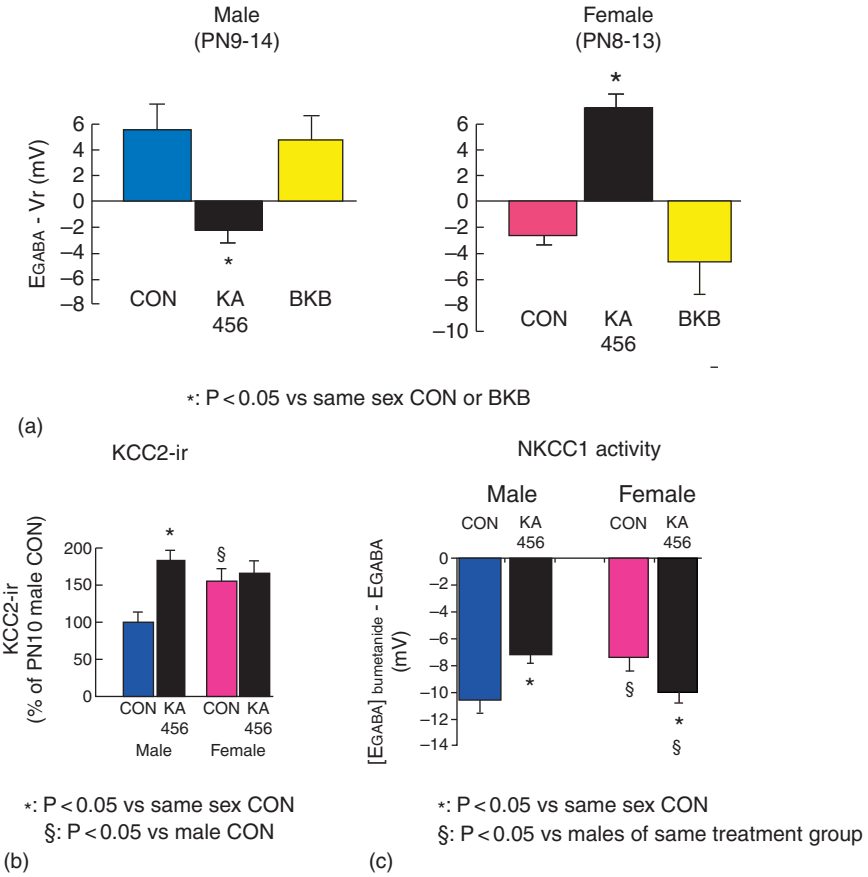

Figure 4 3KA-SE alters CCC expression and $GABA_A$ signaling in rat CA1 pyramidal neurons, via pathways that involve $GABA_A$ receptors. Using gramicidin perforated patch clamp, we assessed the direction of $GABA_A$ signaling in control (CON) pups or pups subjected to 3KA-SE at PN4–6 (KA456). E_{GABA} is the reversal potential for $GABA_A$ responses, in the presence of AP5 and CNQX. Vr is the resting membrane potential. (a) 3KA-SE at PN4–6 (KA456) switch the direction of $GABA_A$ signaling to hyperpolarizing in male PN9–14 and depolarizing in female PN8–13 rat CA1 pyramidal neurons. Such effects do not occur in rats that were injected with bicuculline at the time of 3KA-SE (BKB). (b) 3KA-SE at PN4–6 increases KCC2-ir in male PN10 CA1 pyramidal neurons but has no effect in females. (c) The activity of NKCC1-like Cl^- cotransporters was assessed with the bumetanide inhibition assay. Low doses of bumetanide (20 μM for 10 min) selectively inhibit NKCC1-like activity, shifting E_{GABA} to more negative values. Male PN9–14 KA456 rat CA1 pyramidal neurons had less bumetanide-sensitive NKCC1-like activity. In female PN9–14 KA456 rats, bumetanide-sensitive NKCC1-like activity was stronger than in CON. Modified from Galanopoulou AS (2008a) Dissociated gender-specific effects of recurrent seizures on GABA signaling in CA1 pyramidal neurons: role of GABAA receptors. *Journal of Neuroscience* 28(7): 1557–1567, with permission from Journal of Neuroscience.

each KA injection; BKB group in Figure 4). Indeed, in BKB rats, $GABA_A$ signaling remained similar to control (CON) after the three episodes of SE at PN4–6, suggesting that $GABA_A$ receptors are mediators of the effects of 3KA-SE. Further studies are under way in our laboratory to further delineate the exact molecular pathways involved in, or interacting with, $GABA_A$ receptors that contribute to these effects. Other signaling pathways that seem to be important for the cell type specific patterns of regulation of KCC2 include brain derived neurotrophic factor (BDNF), which is known to be released with seizure activity (Figure 3).

To dissociate the effects of 3KA-SE from those of maternal separation, we subjected pups to maternal separation for equivalent periods of time at PN4–6 (SS456 group). In males, SS456 pups also exhibited accelerated appearance of hyperpolarizing $GABA_A$ signaling, although its effects on CCCs were quantitatively different than seen in 3KA-SE animals. Maternal separation has more robust effects on decreasing bumetanide-sensitive NKCC1-like activity. In females, maternal separation caused a shift in E_{GABA} to more hyperpolarizing values, due to a decrease in bumetanide-sensitive NKCC1-like activity.

Considering the short lifespan and the rapid rate of rat brain development, this week-long disruption of processes that depend on $GABA_A$ pathways could contribute to long-term functional deficits. We were particularly interested in testing whether such changes may lead to late epilepsy. We performed long-term EEG monitoring in 2–3 months old (i.e., adult) female KA456 rats, using hippocampal electrodes. No spontaneous seizures were detected (Figure 5). If indeed the persistence of depolarizing $GABA_A$ signaling may prove important for epileptogenesis, it is possible that the molecular mechanisms involved in the resistance of the immature brain to sustain depolarizing $GABA_A$ signaling after seizures may protect it from subsequent epileptogenesis.

These findings raise a few important points. First, they reiterate the validity of the classical concept that the effects of seizures are different in immature and mature animals, partially due to the immaturity of the existing signaling pathways. Second, the data indicate that changes within the immature brain are not linear, but specific to discrete time windows that may reflect stages of the newborn period, infancy, and childhood. Certain patterns appear only during specific times, and these time points may differ as a function of sex. Third, $GABA_A$ signaling may be an important mediator of these age- and sex-specific effects. Consequently, the commonly used antiepileptic drugs that act upon $GABA_A$ receptors may also interfere with and/or modify these processes. These findings also emphasize that when age is considered, chronology does not always equate with biology. Intrinsic factors like sex, or epigenetic influences like seizures or stress, may alter the course of developmental processes. When administering AEDs, it is therefore important to consider not only age (in broad terms, child vs. adult) as a factor, but also the developmental stage of the targeted brain structures and whether these structures are sexually dimorphic, to improve efficacy and minimize side effects.

Future Goals

GABA is not the only neuroactive factor that shows age-specific roles important to brain functions. However, it provides a window through which to study developmental rules and principles, which may also be operable in other signaling cascades. We need a better understanding of the diversity that exists across ages in these molecular

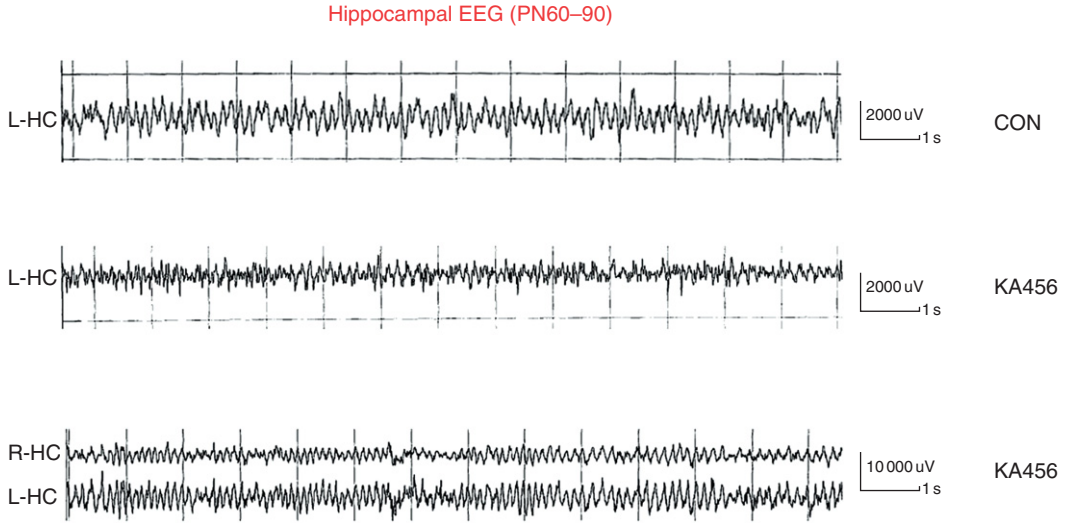

Figure 5 Hippocampal EEG recordings from 2.5 month old female control (CON) and KA456 rats do not reveal any spontaneous seizure activity. EEG recordings were done either unilaterally or bilaterally (R-HC: right hippocampus; L-HC: left hippocampus).

mechanisms to be able to make better predictions about their consequences. However, an important challenge in such efforts will be to translate such findings to the clinical arena. Although experimental studies have offered insights into the mechanisms of AED actions that could not have been obtained from human studies, it is important to remember that there are significant biological and functional differences among species. These differences may influence our ability to study specific outcomes in experimental animals or extend the animal findings into humans. Also, if the net effect of a signaling pathway in vivo is indeed a conglomerate of biological factors and pathways (i.e., age, sex, developmental stage, and epigenetic influences like seizures or stress), we will need better strategies to predict the type of response we expect in vivo. Useful tools may include imaging studies, electrophysiological tests or other specialized functional tests.

Although abundant evidence exists to support the central role of GABA in brain development, neuronal communication, and plasticity, it is important to provide more direct links between the seizure-induced disruption of $GABA_A$ signaling and long-term outcomes. Specifically, it is important to define better the functional and cognitive deficits resulting from disrupted $GABA_A$-related neuronal differentiation, to be in a better position to design specific therapies aimed at curing these deficits without side effects.

A key question is to understand the role of depolarizing $GABA_A$ signaling in epileptogenesis. Such signaling is obviously not sufficient for epileptogenesis, as it is present in normally developing animals. What are the pathological conditions under which seizures can induce the permanent appearance of depolarizing $GABA_A$ signaling? When this state occurs, can it result in epilepsy? Or, given the neurotrophic actions of depolarizing GABA, is it possible that the untimely switch of GABA to depolarization is an adaptive, regenerative process aimed at healing the brain? If so, how can we distinguish these regenerative processes from the epileptogenic processes so that we can create therapeutic interventions that specifically stop epilepsy without interfering with the healing process? Knowledge of the underlying molecular and electrophysiological mechanisms involved will be essential in our quest to understand the significance of these events and to design specific antiepileptogenic therapies without halting restorative processes.

Animal Models of Catastrophic Epilepsies of Childhood

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Catastrophic epilepsies are defined as age-specific epilepsy syndromes, occurring in infants and young children, in which severe seizures become refractory to medical treatment. Seizures in catastrophic epilepsies are accompanied by plateau or regression in developmental milestones (encephalopathy). Examples include relatively common syndromes such as infantile spasms (West syndrome) and Lennox-Gastaut syndrome, and rare epilepsies such as early infantile epileptic encephalopathy with suppression burst (Ohtahara syndrome), severe myoclonic epilepsy of infancy (Dravet syndrome), and epilepsy with myoclonic-astatic seizures (Doose syndrome). These syndromes are caused by a wide variety of brain insults or congenital or genetic causes. Infantile spasms, the most frequent type, have an incidence of ~1 case per 3200 live births, comprising about 9% of childhood epilepsies. Catastrophic epilepsy syndromes wreak havoc on the lives of children, families, and society, as the seizures tend to become refractory over time and are associated with major cognitive impairment that lasts a lifetime. Better seizure control often translates into preservation of intellectual and behavioral function in affected children. Current therapies for these syndromes are serendipitous or inadequate, both in terms of seizure control and prevention of cognitive deficits.

The main impetus for the development of an animal model is to understand the mechanisms and so create more appropriate and specific therapies. So far, attempts to replicate the features of the human catastrophic epilepsies in animal models have been disappointing. Inherent interspecies differences between brains of experimental animals (usually rodents) and humans contribute to the lack of a model. Nevertheless, to truly understand the neurobiological substrates of these catastrophic epilepsy syndromes, animal models must be designed to allow experimental manipulations of seizure frequency, type, and duration, as well as analysis of brain structure and function and behavioral consequences. Furthermore, experimental treatments can be tested on animal models prior to their introduction in humans.

Criteria for an ideal animal model of infantile spasms are listed in Table 1. So far, all animal models of infantile spasms have failed to mimic at least some of those criteria. Although it is not essential that an animal model fulfils each criterion to yield insights about developmental epilepsy, the most informative model will closely mimic the clinical situation. For example, responsiveness to adrencorticotrophic hormone (ACTH) does not necessarily make or break a model, but, as we discuss in this article, it enhances the model's credibility.

A model of infantile spasms that meets some of the criteria was developed in the laboratory of Dr. Tallie Baram. Since infantile spasms have multiple etiologies, Baram and colleagues proposed that infantile spasms occur because of a nonspecific brain insult during a developmental window during which the brain is particularly susceptible to pathological stresses. They hypothesized that stress may increase endogenous corticotrophin-releasing hormone (CRH) levels in seizure-prone areas of the developing brain, leading to neuronal damage, axonal reorganization, long-term cognitive defects, and possibly age-related seizures such as infantile spasms. Rat pups injected with minute doses of CRH intracerebroventricularly (i.c.v.) develop severe seizures, while mature rats develop CRH-induced seizures only at much higher doses, if at all. However, developmental seizures induced by i.c.v. injection of CRH are limbic in nature; they begin in the amygdala and spread to the hippocampus. The seizures in this model are not spasms, but rather consist of face and forelimb clonus, mimicking limbic convulsions. The electroencephalographic (EEG) abnormalities in CRH-induced seizures do not precisely reproduce those in children with infantile spasms. Furthermore, CRH-induced seizures are not responsive to ACTH, though ACTH does reduce CRH gene expression in certain neuronal populations.

Another attempt to model infantile spasms has involved intraperitoneal (i.p.) injection of *N*-methyl-D-aspartic acid (NMDA) in infant rats, which causes a clinical seizure described as emprosthotonus or hyperflexion. Emprosthotonus consists of whole-body tonic flexion with loss of the righting reflex and no clonic component. Although the EEG findings are variable, emprosthotonic

Table 1 Ideal criteria for an animal model of infantile spasms

Unprovoked epileptic spasms or myoclonic seizures during early postnatal development
Interictal EEG abnormalities (hypsarrhythmia)
Ictal EEG correlate (electrodecremental response)
Response to relevant treatment (e.g., ACTH)
Behavioral or cognitive sequelae

seizures are often accompanied by a reduction of EEG amplitude, resembling the electrodecremental response in the human EEG. Interictal hypsarrhythmia (as seen in human EEGs) is lacking, although large-amplitude non-synchronous waves frequently occur interictally, which may represent rat 'hypsarrhythmia'; these high-amplitude waves are never seen during routine EEG recordings. In this model, no spontaneous seizures have been recorded and the seizures are not responsive to ACTH.

Background

Intraperitoneal injection of NMDA induces hyperflexion seizures only in developing rats, with a seizure semiology similar to infantile spasms. These spasm-like whole-body flexions last for several seconds and may repeat in clusters. The ictal EEG shows depression similar to the electrodecremental EEG in infantile spasms. Additionally, interictal EEG often shows chaotic asynchronous high-voltage waves somewhat resembling hypsarrhythmia; this EEG pattern is definitely not normal at this stage of brain maturation in rodents. Learning and memory deficits occur in adulthood in rats having experienced NMDA spasms on postnatal day 15, and the rats have an increased susceptibility to generalized seizures induced by the GABA antagonist pentylenetetrazole in adulthood. However, this model has been limited by the lack of responsiveness to ACTH and other drugs used to treat infantile spasms such as vigabatrin. Clinical studies have demonstrated that patients with infantile spasms have decreased ACTH and cortisol levels in their cerebrospinal fluid. This finding, along with a unique and very specific therapeutic response of infantile spasms to ACTH, indicates that the control mechanisms of their hypothalamus–pituitary–adrenal (HPA) axis are impaired. Experimental studies using prenatal exposure to synthetic corticosteroids, especially to betamethasone, have demonstrated that this prenatal insult also decreases ACTH and cortisol levels. Furthermore, expression of glucocorticoid receptors is decreased in animals prenatally exposed to synthetic corticosteroids. Thus, this experimental approach mimics HPA impairments in patients with infantile spasms.

Methods

The current model involves a '2-hit' approach. Infant rats are exposed prenatally to betamethasone and then are treated postnatally with systemic NMDA. This approach is based on preliminary evidence showing that betamethasone impairs the HPA control systems, which may also have relevance in human infantile spasms. Prenatal betamethasone does not produce any macroscopic cerebral abnormalities, likening this model to one of idiopathic or cryptogenic infantile spasms.

On gestational day 15 (G15), pregnant rats are injected with betamethasone (two doses of 0.4 mg kg^{-1}, i.p., 10 h apart) resulting in the exposure of embryos to betamethasone. Then, on postnatal day 15, the offspring of rats exposed prenatally receive doses of NMDA at 7.5, 15, or 30 mg kg^{-1}, i.p. Pilot experiments showed that this NMDA dose range elicited hyperflexion seizures in more than 80% of rat pups with a greater than 80% survival rate. ACTH treatment was initiated with both the full length ACTH molecule (39 amino acids) as well as a 24-amino acid fragment ($ACTH_{1–24}$). The EEG was recorded in neocortex or hippocampus. Later, c-fos expression was evaluated at different times after spasm onset using immunohistochemistry, and [^{14}C]2-deoxyglucose imaging was used to identify brain structures activated by the flexion seizures.

Results

Several previous studies have shown that NMDA induces hyperflexion spasms in rats. NMDA-injected rats develop severe flexion seizures (emprosthotonus) in spasms lasting up to tens of seconds, with multiple recurrences; the seizures are intermixed with interictal abnormal running or walking behaviors (**Figure 1(a)**). These flexion seizures are insensitive to ACTH. In rats that received betamethasone prenatally, the semiology of NMDA-induced clinical signs was generally similar to that of prenatally naïve rats (i.e., no betamethasone exposure). However, rats having received prenatal betamethasone had significantly decreased latency to onset of tail-twisting and flexion spasms following postnatal NMDA challenge. Thus, these seizure signs occurred earlier in betamethasone-exposed rats than in untreated controls.

Electrographic recordings showed that before NMDA administration, P15 rats exposed prenatally to betamethasone showed no EEG abnormalities. After NMDA injection, two principal patterns were found during flexion spasms in betamethasone-exposed pups. The first was a high-amplitude discharge followed by attenuation of the signal (**Figure 1(b)**). The second pattern was a high-amplitude discharge followed by rhythmic afterdischarge (**Figure 1(c)**). Treatment with ACTH (0.1 mg kg^{-1}, i.p.) significantly delayed the occurrence of all NMDA-induced signs elicited in betamethasone-exposed rats (**Figure 1(d)**). Specifically, ACTH lengthened the latency to onset of tail-twisting, arching, and flexion spasms compared with saline-exposed control rats without ACTH.

Compared with rats treated with NMDA alone, betamethasone-exposed, NMDA-treated rats had markedly increased c-fos immunoexpression in limbic areas, hypothalamus, and brainstem. In the limbic system, c-fos expression was found in the medial amygdala nuclei and in the lateral septum, but not in the dorsal hippocampus. In the hypothalamus, c-fos expression was found in the

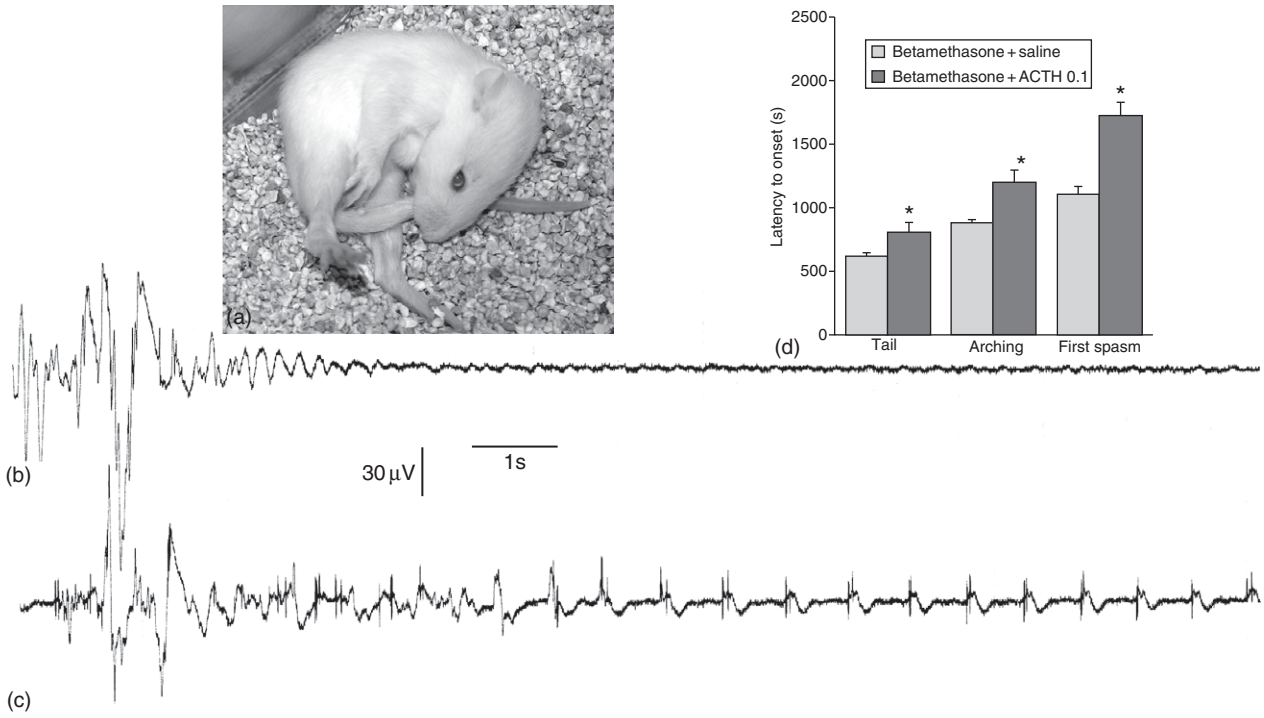

Figure 1 NMDA-induced flexion spasms in a 2-hit model of infantile spasms (1st hit: prenatal betamethasone exposure; 2nd hit: postnatal NMDA-induced seizures). (a) Photograph of postnatal day 15 rat exhibiting a flexion seizure (emprosthotonus). The rat was exposed prenatally to betamethasone and later treated on postnatal day 15 with NMDA (15 mg kg^{-1}, i.p.). The hyperflexion seizure involves the head, limbs, spine, and tail. This behavior is associated with EEG electrodecrement (see (b) and (c)). (b) EEG correlate (cortical recording) of NMDA-induced flexion spasm in 15-day-old rat. Large-amplitude sharp, rhythmic activity is followed by voltage attenuation. (c) Another example of an EEG correlate of flexion spasm consisting of a large-amplitude sharp waves followed by voltage decrement and rhythmic after discharges. (d) Latency to onset (in seconds) of NMDA-induced behaviors in 15-day-old rats prenatally exposed to betamethasone and postnatally treated either with saline or ACTH (0.1 mg kg^{-1}, i.p., in saline) 30 min prior to NMDA challenge (15 mg kg^{-1}, i.p.). Administration of ACTH increased latency to onset of NMDA-induced behaviors, including flexion spasms, consistent with an anticonvulsant effect of ACTH in this model. (a), (b), and (c) are reproduced from Velíšek L, Jehle K, Asche S, and Velíšková J (2007) Model of infantile spasms induced by *N*-methyl-D-aspartic acid in prenatally impaired brain. *Annals of Neurology* 61: 109–119.

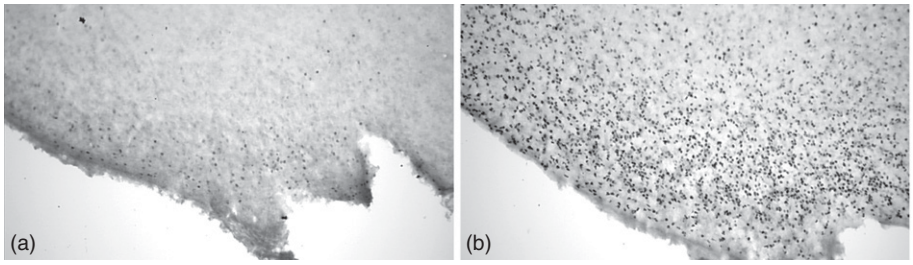

Figure 2 c-fos expression in the arcuate nucleus of the hypothalamus. (a) Section from a rat exposed to betamethasone prenatally and saline postantally. Few c-fos immunopositive cells are seen. (b) Section from a rat exposed to betamethasone prenatally, 1 h after the onset of NMDA-induced spasms. The arcuate nucleus is filled with c-fos immunopositive cells indicating activation of this hypothalamic structure.

supraoptic nucleus, arcuate nucleus, medial tuberal nucleus, and dorsomedial nucleus (**Figure 2**). Throughout the brainstem, nuclei were tagged with c-fos, including the ventral tegmental area, pedunculopontine tegmental nucleus, lateral parabrachial nucleus, dorsal nucleus of the lateral lemniscus, nuclei raphe, and the solitary tract nucleus. Increases in 2-deoxyglucose (2-DG) uptake in the limbic system were found in the lateral septum and significant decreases in the dorsal hippocampus. In the hypothalamus, increases in 2-DG uptake closely mimicked c-fos findings (**Figure 3**). In the brainstem, pedunculopontine tegmental nucleus was activated. These combined c-fos and 2-DG findings suggest the activation of these nuclei by NMDA seizures in betamethasone-treated rats.

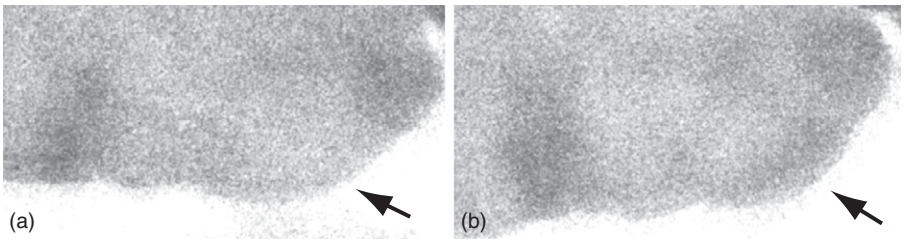

Figure 3 [^{14}C]2-deoxyglucose (2DG) uptake in the arcuate nucleus of the hypothalamus. (a) Section from a control rat injected with betamethasone prenatally and saline postantally. The arrow marks arcuate nucleus of the hypothalamus. (b) Section from a rat exposed to betamethasone prenatally, 2 min after the onset of NMDA-induced spasms. The arrow indicates a significant increase in 2DG uptake in the arcuate nucleus, consistent with an increase in synaptic activity.

The significant contribution of this 2-hit approach to modeling infantile spasms is the therapeutic response to ACTH, which has not been achieved in other models of infantile spasms or in other models of developmental seizures. This model has the potential to screen for novel therapies of infantile spasms.

Future Goals

Creation of an animal model of infantile spasms (the prototype catastrophic epilepsy of childhood) has been a daunting problem for investigators. Infantile spasms have numerous causes, including metabolic disorders, genetic mutations, malformations of cortical development, tuberous sclerosis, congenital or postnatal infections, strokes, and other causes. Therefore, it has been difficult to sort out essential elements of etiology from factors sufficient to provoke infantile spasms.

The studies introduced here aim to develop an alternative animal model of infantile spasms that may be of use in studying mechanisms of this disorder, and eventually in leading to therapeutic interventions. We show that prenatal administration of betamethasone, a corticosteroid that theoretically mimics a stress response, subsequently reduced the latency to postnatal NMDA seizures. That is, in rats prenatally exposed to betamethasone, NMDA at 2 weeks of age elicits flexion spasms resembling infantile spasms. In contrast to NMDA spasms elicited in naïve postnatal rats, spasms in prenatally betamethasone-exposed rats have a delayed onset when the animals are treated with ACTH. Although this ACTH protocol does not eliminate the spasm seizures, the sensitivity of the spasms to ACTH treatment constitutes an important step in the development of a clinically relevant model of infantile spasms. In this 2-hit model, the first hit – the prenatal stress caused by betamethasone – might somehow sensitize the brain to a later insult (NMDA seizures), resulting in enhanced seizure effects manifest by EEG findings reminiscent of infantile spasms. An important limitation of this method is the lack of spontaneous seizures. Given the need for double pharmacological stressors in this 2-hit protocol, perhaps this model should be considered a form of symptomatic infantile spasms, even though no gross structural abnormalities have been documented. However, it is possible that more detailed investigations will reveal changes at the cellular level that may mediate effects of prenatal betamethasone exposure on postnatal seizure susceptibility.

Numerous future studies are needed to complete the model development and validate its relationship to human infantile spasms. Most importantly, prenatal corticosteroids have been shown to alter many aspects of brain development, including subsequent behavioral and cognitive function. These effects must be more closely documented, as must the role of NMDA seizures in the manifestations of stress response. Since ACTH is given only immediately before NMDA, the time course of ACTH effects must be expanded. If cognitive sequelae can be determined in this model, the effect of ACTH on these cognitive changes can be studied. In human infantile spasms, ACTH is not given immediately before the spasms occur (as in this model). Rather, patients receive daily ACTH injections over several weeks once infantile spasms are diagnosed. In such ACTH-treated babies, the time course of ACTH effectiveness is usually on the order of several days (median, 2 days). Consideration of this time course is also important when testing other drugs. Within the infantile spasms spectrum, some drugs seem to be etiology specific. While ACTH seems to be more effective in idiopathic infantile spasms, vigabatrin, for example, is particularly beneficial in children with infantile spasms associated with tuberous sclerosis. The model proposed here might have value in the search for new therapies of infantile spasms. For example, drugs such as melanocortin receptor antagonists could be tested using this model. The interplay between intrinsic physiologic aspects of brain hyperexcitability (as a function of age) must be studied within the context of alterations induced by both of the stress-invoking agents discussed in this article.

Until recently, researchers have been somewhat pessimistic with regard to creating a useful animal model for the catastrophic epilepsies such as infantile spasms.

However, this pessimism is now changing to a tempered optimism. Within the next several years, this model – and hopefully others – will allow researchers to identify underlying mechanisms. Development of new therapeutic interventions based on those mechanisms can then be tested, to alleviate the consequences of the devastating catastrophic epilepsies of childhood.

Animal Models of Infant-Onset Epileptic Encephalopathy

J T Lerner and G W Mathern, University of California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic encephalopathies are age-dependent clinical conditions characterized by severe epilepsy and cognitive disabilities. The interictal and ictal EEG abnormalities are typically so repetitive and frequent that it looks as if patients are in continuous electrical status epilepticus. The repetitive EEG abnormalities and clinical seizures are thought to directly contribute to poor cognitive development and mental retardation in patients with an epileptic encephalopathy. In infants, the best known syndromes are early epileptic encephalopathy with EEG suppression-burst (Ohtahara syndrome), neonatal myoclonic encephalopathy, and infantile epileptic encephalopathy (infantile spasms, West syndrome). Of these, infantile spasms are the most common epilepsy syndrome in the first year of life. This article will focus on infantile spasms and West syndrome as the prototypic infant-onset epileptic encephalopathy which should be modeled in animals, discuss the conceptual framework of current hypotheses attempting

However, this pessimism is now changing to a tempered optimism. Within the next several years, this model – and hopefully others – will allow researchers to identify underlying mechanisms. Development of new therapeutic interventions based on those mechanisms can then be tested, to alleviate the consequences of the devastating catastrophic epilepsies of childhood.

Animal Models of Infant-Onset Epileptic Encephalopathy

Introduction

Epileptic encephalopathies are age-dependent clinical conditions characterized by severe epilepsy and cognitive disabilities. The interictal and ictal EEG abnormalities are typically so repetitive and frequent that it looks as if patients are in continuous electrical status epilepticus. The repetitive EEG abnormalities and clinical seizures are thought to directly contribute to poor cognitive development and mental retardation in patients with an epileptic encephalopathy. In infants, the best known syndromes are early epileptic encephalopathy with EEG suppression-burst (Ohtahara syndrome), neonatal myoclonic encephalopathy, and infantile epileptic encephalopathy (infantile spasms, West syndrome). Of these, infantile spasms are the most common epilepsy syndrome in the first year of life. This article will focus on infantile spasms and West syndrome as the prototypic infant-onset epileptic encephalopathy which should be modeled in animals, discuss the conceptual framework of current hypotheses attempting

to explain the pathogenesis of this disorder, describe the pros and cons of currently available animal models that purport to reproduce this condition, and discuss future directions and goals for clinical and research investigations in this field.

Background

Human Characteristics of West Syndrome/ Infantile Spasms

Infantile spasms are a unique seizure type that occurs mostly during infancy and early childhood. In 1841, William West, a physician, first described the condition in his 4-month-old son. West syndrome consists of the triad of infantile spasms, severe cognitive dysfunction, and an interictal EEG pattern termed hypsarrhythmia. Thus, infantile spasms are the behavioral motor seizures that comprise one clinical component of West syndrome. The incidence of infantile spasms is ~1:3000 live births; the seizures generally begin in the first year of life (85% of cases), peak incidence is between 3 and 7 months of age, and familial occurrence is rare. The behavioral epileptic attacks are brief events, usually consisting of bilateral symmetric contractions of the muscles involving the extremities, neck, and truck (motor spasms). Other associated ictal behaviors may include attenuated responsiveness, eye deviation, respiratory pauses, and autonomic changes. Spasms typically occur in clusters lasting several minutes, appear frequently at sleep–wake transitions, and sometimes after a partial seizure. More than half of patients with infantile spasms exhibit major deficits on neurological examination. A normal developmental outcome is expected in less than 20% of children who have infantile spasms, and children with a history of spasms make up ~10% of all cases of childhood onset mental retardation. Shorter seizure duration is associated with a better long-term cognitive outcome in patients with symptomatic infantile spasms. Around 50% of babies with infantile spasms will eventually develop other therapy-resistant seizure types/ syndromes, such as the Lennox–Gastaut syndrome. Autism spectrum disorder is another common finding in children who have had infantile spasms.

The interictal EEG is almost always abnormal in children with infantile spasms. The most characteristic pattern consists of a disorganized high voltage background of slow waves intermixed with multifocal spikes termed hypsarrhythmia (**Figure 1(a)**). The ictal EEG pattern usually consists of an electrodecremental response associated with the motor spasms (**Figure 1(b)**). Spontaneous remission occurs in 25% of patients with infantile spasms within 12 months of onset. Infantile spasms are usually refractory to traditional antiepilepsy drugs. Medical therapy specific for patients with infantile spasms includes adrenocorticotropic hormone (ACTH) and corticosteroids (steroids), which are effective in half to three-quarter of patients, and vigabatrin, which is especially effective in patients with tuberous sclerosis complex (TSC) and infantile spasms. All of these medical treatments for infantile spasms are potentially toxic or are associated with significant side effects. Interestingly, ACTH is not a successful treatment for other forms of intractable generalized childhood-onset seizures. Thus, response to ACTH is considered one of the traits of patients with infantile spasms. About 5–30% of children with infantile spasms die within 12 months of treatment; 50% of the deaths are related to the medical treatment, and mortality is greater in infants with symptomatic causes. There are long-term negative consequences to those who had infantile spasms. A recent study reported that children who had a history of infantile spasms demonstrated microencephaly on long-term follow-up MRI scans.

There are a large number of etiologies associated with infantile spasms. Nearly 80% of cases of infantile spasms are symptomatic (genetic or structural etiology) and 20% are cryptogenic (no known etiology). There are over 200 identified symptomatic etiologies associated with infantile spasms, including at least 100 genetic conditions, such as Down syndrome, TSC, other gene mutations, and abnormalities of biochemical pathways such as pyridoxine deficiency, amino acid and, neuropeptide abnormalities. Other symptomatic etiologies include cortical and subcortical insults or injuries, such as from trauma, intraventricular hemorrhage, infections, toxins, hypoxia/ischemia, neoplasms, and malformations of cortical development (such as lissencephaly and cortical dysplasia). The most common etiology is hypoxic–ischemic encephalopathy, which is found in 25% of all cases of infantile spasms. Hence, an interesting clinical aspect of infantile spasms is that the time of the provoking etiology can be associated with a range of developmental periods, from intrauterine, prenatal, perinatal to immediately postnatal time points. Despite the temporal variability of the apparent precipitating cause, infantile spasms occur mostly in the first year of life. In addition, even though there are no consistent neuropathologic features found in all patients with infantile spasms, the seizures consists of such a well recognized clinical disorder that it is presumed that there must be a common developmental mechanism or pathway that produces the seizures and the associated encephalopathy.

The Ideal Animal Model of Infantile Spasms

Despite being a fairly rare clinical condition, developing animal models of infantile spasms and West syndrome has been identified as an important goal for research, since current therapies for this disorder are inadequate and prognosis is poor. This priority was established by a panel of experts invited to a workshop on Models of Pediatric Epilepsies sponsored by NINDS (National

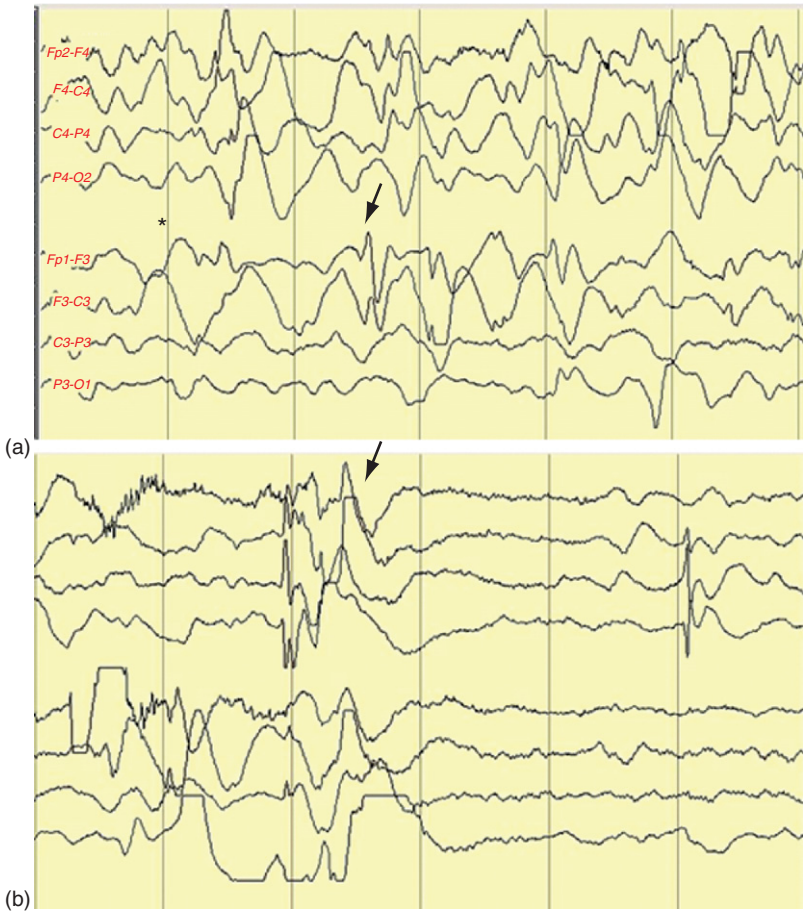

Figure 1 EEG examples of interictal hypsarrhythmia (a) and ictal electrodecremental response (b) in a child with behavioral infant spasms. (a) Interictal EEG shows periods of chaotic high-voltage slowing (asterisk) intermixed with high voltage spike discharges (arrow). (b) Ictal electrodecremental EEG response (arrow) associated with a motor spasm. Notice the lower voltage activity after the spasm. Montage for (a) is the same for (b). Low-frequency filter at 1 Hz, high-frequency filter at 70 Hz, sensitivity is 15 $\mu V\,mm^{-1}$, and each vertical line represents 1 s.

Table 1 Criteria for an animal model of infantile spasms

1. Unprovoked seizures with behavioral characteristics of spasms or myoclonic seizures that occur early in postnatal brain development
2. Ictal EEG correlates of seizure events that consist of electrodecremental response
3. Interictal EEG consisting of hypsarrhythmia or similar pattern
4. Model should respond to ACTH and/or vigabatrin
5. There should be evidence that untreated animals show signs of cognitive and behavioral sequelae from the seizures
6. Initial spasms seizures should eventually transition into generalized motor seizures
7. Not every animal with an etiology should develop characteristics of infantile spasms
8. There should be spontaneous remission of infantile spasm-like events with developmental maturation
9. Animals with infantile spasm-like events should demonstrate some mortality secondary to the seizures

Note: Criteria 1–5 were from the NIH workshop. Criteria 6–9 were added as secondary criteria.

Institutes of Health), the American Epilepsy Society, and the International League Against Epilepsy in May 2004. The goal of developing animal models of infantile spasms was to provide an experimental resource that could be used to develop novel treatments and understand basic mechanisms that produce spasms in the developing brain. The experts at the workshop also developed criteria for an ideal model of infantile spasms and West syndrome (Table 1; points 1–5). Additional secondary criteria are included in this table, based on the clinical features of children with infantile spasms. We will use these criteria to assess currently available animal models of infantile spasms.

Concepts of Pathogenesis

Over the past 40 years, several hypotheses have been proposed to explain the unique clinical characteristics of

infantile spasms, including the age-dependent onset, motor spasms, and a diffuse generalized EEG pattern. While none of these hypotheses have been proven or universally accepted, it is relevant to understand these ideas as they relate to development of different animal models proposed to reproduce infantile spasms.

Brainstem dysfunction

Based on the typical absence of focal clinical signs, the symmetric motor seizures, and diffuse EEG findings, a brainstem origin of infantile spasms has long been suspected. Autopsy studies have found brainstem pathology in individuals with a history of infantile spasms, clinical spasms have been noted in cases of hydranencephaly (no cerebral cortex), and infants with spasms have been found to have abnormal sleep patterns – all consistent with potential brainstem dysfunction. A common theme for several proposals is the notion that there are abnormalities in brainstem excitatory and inhibitory projection systems. One early hypothesis proposed that there was decreased output from excitatory cholinergic fibers arising from neurons of the pontine region, compared with inhibitory noradrenergic and serotonergic output from neurons of the locus ceruleus and dorsal raphe. In this scenario, the clinical spasms result from interference of the descending motor pathways that controls spinal cord reflex activity. Separately, the ascending tracts from the pons projecting to the cerebral cortex would produce EEG hypsarrhythmia. No animal models have been successfully developed based on this idea, however. Furthermore, agents that regulate serotonin or norepinephrine have been ineffective in clinical trials of children with infantile spasms.

Another hypothesis suggests that there are abnormalities of the serotonin–kynurenine pathways. In this scenario, there is an unknown mechanism that causes a metabolic shift in tryptophan metabolism that produces kynurenine or quinolinic acid, rather than serotonin. Quinolinic acid is a neurotoxin that can activate NMDA receptors, which in turn could produce seizures and infantile spasms by exciting neurons in the brainstem and limbic structures. The idea that dysfunction of brainstem neurotransmitter systems, especially those involving serotonin pathways, might be the common pathway in the generation of infantile spasms is an interesting concept. However, despite nearly 40 years of effort, this hypothesis is yet to be validated in clinical and basic science experiments.

Abnormal cortical–subcortical interactions

Many cases of infantile spasms involve patients with known cortical lesions identified by neuroimaging (MRI and FDG–PET), without evidence of brainstem dysfunction. Surgical removal of the cortical lesion stops infantile spasms in these patients, supporting the concept that there was a cortical origin to the seizures. These findings have led to the hypothesis that abnormal cortical dysfunction could be reflected at an early developmental age by subcortical structures that are still maturing. In other words, the primary problem is in the cerebral cortex (rather than the brainstem or other subcortical structures) that at young maturational stages projects abnormal activity onto the brainstem, basal ganglia, and other subcortical structures (including the serotonergic raphe nuclei), that then triggers the clinical spasms. Raphe–striatal pathway activation is suggested to produce the hypsarrhythmic EEG pattern over the cerebral cortex, and the downstream brainstem pathways have been postulated to generate the motor spasms (similar to the brainstem hypothesis). Support for this idea has emerged mainly from FDG–PET studies in children with active infantile spasm that show hypometabolism in regions of cortical dysplasia and hypermetabolism in the lenticular nuclei. Again an interesting hypothesis, this mechanism would only explain infantile spasms in those infants with known cortical lesions, and ignores other etiologies that might affect the brainstem or multiple brain systems (e.g., from genetic defects). This idea would also not explain infantile spasms in those with cryptogenic etiologies.

Hypothalamic-pituitary-adrenal axis dysfunction

As children with infantile spasms often respond fairly rapidly and robustly to treatment with ACTH and corticosteroids (spasms often completely stop within days), the hypothalamic-pituitary-adrenal axis has been suggested to play a role in the pathogenesis of this disorder. Activation of components of the brain stress response is hypothesized to promote neuronal hyperexcitability and provoke hypsarrhythmia and motor spasms. This idea has been supported by clinical studies documenting reduced CSF levels of ACTH and cortisol in children with infantile spasms. One group has hypothesized that the basic abnormality is excess intrinsic brain production of corticotrophin-releasing hormone (CRH), during stress events in utero or early postnatal life. ACTH treatment is proposed to downregulate CRH synthesis through activation of melanocortin receptors. CRH is known to be released from hippocampal, amygdala, and brainstem neurons, and exerts neuronal hyperexcitability partly by reducing after-hyperpolarizations (acting via a G-protein-coupled receptor). Thus, investigators have hypothesized that ACTH stops infantile spasms not by acting as an anticonvulsant, but by reducing expression and secretion of endogenous CRH in limbic structures and the brainstem. Animal models have been developed based on this idea that will be discussed later (see CRH).

Interneuronopathy

Another recent concept has emerged, based on findings of patients with gene defects that alter development of GABAergic interneurons. Gene defects in aristales related homeobox (ARX) and cyclin-dependent kinase-like 5 (CDKL5) have been found to be associated with

cryptogenic infantile spasms in a small group of patients with West syndrome. ARX is expressed at high levels in the neocortical ventricular and germinal zone of the ganglionic eminence, where these proteins are involved in the development and migration of GABAergic interneurons. Mice deficient in ARX have abnormal differentiation and migration of interneurons into the cerebral cortex and can have seizures – although it is not clear if those seizures are similar to infantile spasms. The precise function of CDKL5 is currently unknown, but a high percentage of patients with this mutation develop infantile spasms. Thus, in the first year of life, disturbances of GABA-mediated neurotransmission, due to a reduced number of GABAergic interneurons or alterations in GABA receptors, may be another mechanism that produces infantile spasms. However, animal models with these gene defects have yet to be validated to show behavioral and EEG signs of infantile spasm-like events.

Immune system dysfunction

Several investigators have proposed that defects of the immune system, with inflammation of brain structures, can result in infantile spasms. This idea has been supported by clinical studies showing antibodies to brain tissue in the sera, increased numbers of activated B and T cells, and abnormal human leukocyte antigen in patients with infantile spasms. While such findings indicate that the immune system is altered in some children with infantile spasms, these findings could be the result of ongoing seizure activity and brain damage, and not be the cause of spasms. Also, this concept does not explain the unique age-dependent characteristics of infantile spasms, the EEG findings, and the responsiveness to ACTH. Additional experimental and clinical studies showing a casual relationship between brain inflammation and infantile spasms are needed to further validate this hypothesis.

Developmental desynchronization

A relatively new hypothesis has been proposed that attempts to integrate the many diverse findings and ideas regarding cortical and brainstem dysfunction associated with age-dependent infantile spasms. The general idea is that infantile spasms are a developmentally unique manifestation, not of lesions in particular brain locations or defects in specific biochemical pathways, but of a temporal disturbance and desynchronization of one or more developmental brain processes that are active in the first year of life. In other words, the common denominator is disturbed in early developmental brain maturation – which could be caused by multiple factors. This conceptual approach would help to explain why infantile spasms are associated with so many different anatomical and biochemical abnormalities.

The hypothesis goes on to postulate that the main abnormalities are those that affect genes and pathways governing ontogenesis and transcriptional factors, or those resulting from direct environmental injuries or malformation of cortical development (including tumors) in the first year of life. According to this hypothesis, at least one developmental brain process lags behind others, resulting in abnormal integrated brain functions (desynchronization). If the imbalance among brain functions is sufficiently severe, then infantile spasms would occur. This concept helps explain the fact that in individuals with similar etiologies, only a sub-group of children develop infantile spasms; that no single pathologic factor has been associated with spasms; and that the response to treatment is often inconsistent and unpredictable. If this hypothesis is correct, the basic pathophysiologic substrate for infantile spasms would involve brain systems/processes that are developmentally active and regulated during the first year of life, such as synaptogenesis, myelination, glutamate, and GABA-mediated neurotransmission, development of serotonin, and acetylcholine pathways, and disorders of neuronal migration and differentiation.

This hypothesis is particularly attractive in that it may unite other ideas into a final common concept to understand the pathogenesis of infantile spasms. However, it should be clear from the earlier discussion that no single hypothesis is currently universally accepted to explain all aspects of the clinical features of infantile spasms and their EEG correlates. Therefore, it is anticipated that other ideas and concepts will likely be proposed to explain the pathogenesis of infantile spasms.

Methods and Results

Animal Models of Infantile Spasms

This section will describe the animal models currently purported to reproduce infantile spasms. We will compare and contrast the animal models with the ideal criteria shown in **Table 1**. Our purpose is to illustrate the variability of mechanisms that produce spasm-like events, and to consider how well these models fit with the human epilepsy syndrome. The models are presented in chronological order of publication.

Corticotrophin-releasing hormone

Model description

Baram and colleagues developed this model which was first published in 1991. This model helped develop the hypothalamic-pituitary-adrenal hypothesis of the pathogenesis of infantile spasms (see above). Small amounts of CRH are injected into the ventricle of 5–10-day-old rats. Within minutes, this produces acute behavioral seizures consisting of chewing, tonic–clonic activity of the limbs, and 'swimming' seizures lasting several hours. EEG correlates of the seizures are inconsistent, and when present consist of increased beta activity and semirhythmic sharp

waves (not hypsarrhythmia). The rat brains show long-term signs of hippocampal and limbic neuronal injury and synaptic reorganization. Treatment with ACTH did not alter the induction of acute seizures from CRH. Adult animals that received CRH as infants have not been reported to have chronic seizures, but do display some problems in memory tasks.

Pros and cons

This was the first model purported to test a mechanism that produces infantile spasms in humans, examining abnormal stress during early brain development. There is a developmental element to the model, inasmuch as the dose of CRH necessary to induce seizures in immature animals is less than that required in adult rats, and cause more severe seizures.

There are a number of problems with this model when compared against the ideal criteria for an animal model of infantile spasms (Table 2). The seizures require an agent (chemical convulsant) to induce the events, and are thus provoked (not spontaneous). The resulting ictal behaviors and ictal EEG are not typical of infantile spasms, but show more limbic brain stimulation and the interictal EEG does not show hypsarrhythmia. The seizures do not respond to ACTH and it does not appear that the acute seizures lead to chronic ones. It is also not clear what percent of animals given CRH have acute seizures. Thus, while CRH tests one hypothesis of the pathogenesis of infantile spasms, the resulting model lacks many of the clinical characteristics associated with human spasms and West syndrome.

NMDA/steroids

Model description

This model was developed in two stages by Velisek and colleagues. The model tests two components of pathogenic mechanisms involving disturbance of brainstem, and cortical excitation and inhibition, with prenatal hormonal stress. The first model, published in 1999, involved intraperitoneal injections of *N*-methyl-D-aspartate (NMDA) in 12–18-day-old rat pups. Behavioral seizures acutely developed consisting of hyperflexion emprosthotinic-like events that are prolonged (i.e., not brief) and occurred in clusters. The seizures were accompanied by electrodecremental cortical EEG responses. Interictal EEG consisted of large chaotic waves resembling hypsarrhythmia. Adult rats had impaired cognition after NMDA-induced flexion seizures as infants. However, ACTH and glucocorticoids were ineffective as acute treatments with NMDA injections in infant pups. In 2007, the authors published a revised version of their model, in which pregnant rats were given betamethasone (a steroid) as a form of prenatal developmental stress. The pups from these dams were then injected with NMDA on day 15 of life. Prenatal glucocorticoid exposure increased the sensitivity to NMDA-induced flexion seizures, and treatment with ACTH delayed the onset of the provoked NMDA-induced seizures. The authors concluded that ACTH responsiveness further validated NMDA injection as an animal model of infantile spasms.

Pros and cons

This animal model has more features of human infantile spasms (Table 2). The flexion spasms have similarities with motor spasms in human infants, and the acute interictal and ictal EEG patterns are like those expected in babies with infantile spasms. Also, there appears to be long-term cognitive sequelae in adult rats when they experience NMDA-induced seizures at P15. However, the model also has limitations and has not been completely validated against the ideal criteria for infantile spasms.

Table 2 Comparison of current animal models of infantile spasms

Model	*Seizure behavior*	*EEG*	*Response to ACTH*	*Cognitive sequela*	*Chronic seizures*	*Spontaneous remission*
CRH	No spasms. Acute limbic and tonic seizures. P 5–10	Inconsistent No hypsarrhythmia	No acute response	Yes; memory	None reported	N/A
NMDA/ Steroids	Flexion spasms (emprosthotonus) lasting several seconds P 12–18	Hypsarrhythmia-like Ictal electro-decrement	Partial response	Yes	Unknown	Unknown
TTX	Brief extension and flexion spasms P 20–40	Hypsarrhythmia-like Ictal electro-decrement	Unknown	Unknown	Unknown	Unknown

N/A: Not applicable.

The acute seizures are provoked, and the spasm-like events are more prolonged than the typical motor spasm seen in infants. Also, it is not clear if the animals show acute and chronic damage to the cortex, limbic system, or brainstem, and how that pathology reflects what we know in human patients with infantile spasms. Finally, we do not know if there are long-term intractable seizures in adult rats exposed to NMDA as pups. Thus, further studies are necessary for this animal model of infantile spasms.

Tetrodotoxin

Model description

This model was developed by Swann, Frost, and Hrachovy, and was first published in 2007. The hypothesis of developmental desynchronization is based in part on this model. The model consists of a chronic infusion of the sodium channel blocker tetrodotoxin (TTX) into the hippocampus or neocortex of 10–12-day-old rat pups. Within two weeks, unprovoked behavioral seizures begin, consisting of brief 1–2 s extensor or flexor spasms of the head and upper trunk, and many of the spasms were noted to occur in animals awakening from sleep. Similar to humans, infantile spasm-like seizures developed in about 30% of the animals treated with TTX. Ictal EEG showed voltage attenuation and electrodecrement with superimposed fast activity. Interictal EEG of most of those rats that also had behavioral spasms showed a high-voltage chaotic background resembling hypsarrhythmia. As this model was only recently developed, we do not know if the spasms respond to ACTH, if there are long-term chronic seizures, if there are subsequent cognitive deficits in adult rats that had seizures as pups, or if the spasms show spontaneous remission.

Pros and cons

Of all the animal models developed to date, this one has more of the features fulfilling the ideal criteria for a model of infantile spasms than the others. Unlike the prior two models, the seizures are unprovoked, and the events have behavioral and EEG features that are reasonably similar to human infantile spasms. However, this model also has its limitations. The onset of the unprovoked seizures, 2 weeks after TTX infusion, occurs when the rats are at a minimum of 20 days of age or older. P20 rats are more adolescent-like than infant-like, and thus considerably older than what would be expected if the model was to reflect infant-onset spasms. However, because it is so new, there are as yet few studies to attempt to validate this model – for example, to determine if the spontaneous spasm-like seizures respond to ACTH, if the animals have acute and chronic cortical or brainstem pathology, if there are long-term cognitive deficits, if these animals go on to have spontaneous seizures as adults or if there is spontaneous remission of the seizures. Thus, more studies are necessary before this model is fully characterized.

Summary and Future Directions/ Challenges

As discussed earlier, there is no single unifying hypothesis that explains the pathogenesis of infantile spasms in humans – and probably as a consequence, there is no single animal model that fulfills all the ideal criteria of this condition (**Tables 1** and **2**). Animal models have been developed based only on a few of the proposed hypotheses to explain the pathogenesis of infantile spasms. We lack animal models that effectively test brainstem abnormalities of excitatory and inhibitory axon systems, dysfunction of interneurons, or inflammation as possible causes of infantile spasms. Thus, there is considerable need to develop more and better animal models of infantile spasms based on existing pathogenic concepts. For infantile spasm research, having more than one model may be necessary. As there are multiple known etiologies, having several models that reproduce behavioral motor spasms and the EEG findings would be helpful in exploring common mechanisms, and to develop new treatments. Furthermore, we should not assume that all reasonable hypotheses regarding pathogenesis of infantile spasms have been developed; fresh ideas and concepts are certainly needed.

Any theory regarding the pathogenesis of infantile spasms has to account for the unique developmental features of this seizure disorder. Spasms should occur spontaneously during infancy with multiple genetic and acquired etiologies. The seizures should have characteristic behavioral motor spasms and EEG correlates of hypsarrhythmia. The events should be associated with severe long-term cognitive deficits, and the seizures should respond in some animals to treatment not by antiepilepsy drugs but by a hormone, ACTH. If possible, the model should also display some of the secondary features of infantile spasms, such as the variable response to treatment, and high mortality associated with the seizures. Hence, this field of study is far from complete and much work still remains.

Future studies will likely develop and validate existing and newer models of infantile spasms and West syndrome based both on old and new ideas of pathogenesis. This work is important because current treatments are largely ineffective and most children with infantile spasms have long-term risks of severe developmental disabilities and seizures. The key goal in developing animal models of infantile spasms is to discover underlying mechanisms so that more effective treatments can be designed to stop this

highly disabling seizure disorder. Children with infantile spasms deserve the opportunity to grow up with as near normal cognitive development as possible.

Introduction

Rationale for Studying the Consequences of Early-Life Seizures

There is a predilection for children to develop seizures at an early age. The incidence of epilepsy peaks in the first year of life. Various etiologies cause seizures during the neonatal and early childhood periods. The majority of seizures in this age group are symptomatic of a remote or recent insult. Young children are at higher risk than adults to develop seizures after various insults such as strokes, demyelination, or trauma, reasons for which are not yet fully elucidated (but are likely related, at least in part, to developmental differences in synaptic connectivity and neurotransmitter receptor expression). Of the remaining idiopathic cases, many will fit into an epilepsy syndrome (a constellation of clinical seizure type, developmental stage, EEG findings, and outcomes). Some of these seizure syndromes are benign (i.e., the child's development remains normal in the face of recurrent seizures) but many of these

highly disabling seizure disorder. Children with infantile spasms deserve the opportunity to grow up with as near normal cognitive development as possible.

Cellular, Molecular and Behavioral Consequences of Early-Life Seizures

E D Marsh and A R Brooks-Kayal, Children's Hospital of Philadelphia, Philadelphia, PA, USA

Introduction

Rationale for Studying the Consequences of Early-Life Seizures

There is a predilection for children to develop seizures at an early age. The incidence of epilepsy peaks in the first year of life. Various etiologies cause seizures during the neonatal and early childhood periods. The majority of seizures in this age group are symptomatic of a remote or recent insult. Young children are at higher risk than adults to develop seizures after various insults such as strokes, demyelination, or trauma, reasons for which are not yet fully elucidated (but are likely related, at least in part, to developmental differences in synaptic connectivity and neurotransmitter receptor expression). Of the remaining idiopathic cases, many will fit into an epilepsy syndrome (a constellation of clinical seizure type, developmental stage, EEG findings, and outcomes). Some of these seizure syndromes are benign (i.e., the child's development remains normal in the face of recurrent seizures) but many of these

syndromes are malignant (i.e., the development of the child either slows or regresses). How seizures in any of these settings affect the brain acutely and/or later on as development proceeds is an important clinical question. Indeed, understanding why seizures in the benign syndromes do not cause later developmental problems, but seizures in the more malignant syndromes cause irreparable damage, would help neurologist understand who and what to treat and how to direct future therapies.

The questions of how seizures affect the brain can be asked on many levels.

From the subcellular: How do seizures alter the molecular machinery of neurons? Do seizures alter transcription profiles or neurotransmitter receptors? Do seizures alter the cell cycle or neurogenesis?

To the cellular: How do early-life seizures, whether symptomatic, benign, or malignant, affect the histology and regional anatomy?

And finally to the entire organism: How do seizures alter the development of the brain? Does motor, sensory, and spatial learning change?

The answers to these questions could direct scientist to develop new therapies targeted at the changes that occur after seizures in order to prevent detrimental consequences.

Unfortunately, attempting to answer any of these questions in patients is very difficult. There are many factors that could affect the way seizures alter the developing brain. First and foremost, all children with seizures are treated with the currently available antiepileptic drugs. These drugs may have an independent impact on the brain, or at least interact with how the seizures affect the brain. Second, the child's environmental exposure and/or genetic background can have a profound effect on any developmental changes or how seizures could interact with the developing brain. Third, the etiology of the seizures, which is often not known, most likely affects the impact a seizure can have on early brain maturation. Therefore, neuroscientists, epileptologists, and neurologists have been asking the above questions using various developmental animal models of epilepsy with the hope of developing novel therapeutics to protect the developing brain and to more effectively prevent recurrent seizures.

Background

Various animal models have been developed to study the cellular, molecular, and behavioral consequences of early-life seizures. All the methods used to study early-life seizures produce either prolonged or repetitive seizures by using a chemoconvulsant (lithium pilocarpine, kainate, flurothyl), hyperthermia, or electrical kindling. Details of these models are presented later. Not surprisingly, many studies, particularly those of Greg Holmes and colleagues in the 1980s and 1990s, have found significant differences in the effect that seizures produce in the adult vs. the developing brain. Early studies suggested that very young rats or mice (postnatal day 15 or less), although easily induced to develop prolonged seizures (status epilepticus; SE), did not go on to later develop spontaneous seizures. These early studies also found few or no morphological or histological changes after early-life SE. Some of the studies from Holmes and Stafstrom did show, however, behavioral change following the SE – but without the animals developing spontaneous seizures or having a lowered seizure threshold.

More recent studies from multiple labs suggest that the initial reports underestimated the changes induced by SE. Many authors have confirmed that compared to the adult rodent there is minimal cell loss after prolonged or recurrent seizures in the immature brain, but changes in mossy fiber sprouting, receptor expression (both excitatory and inhibitory), and neurogenesis have all now been documented after early-life SE; the degree and nature of changes seen in the immature animal may be quite different from what occurs in the adult (as detailed later).

Methods

Overview of Models and Techniques

There are many models used to study how seizures can affect the developing brain. Indeed, almost all models currently implemented in adult rodents have been attempted in developing animals. Briefly, these models include using chemoconvulsants, electrical activation of the brain, trauma, and ischemia. Various chemoconvulsants have been studied, including lithium pilocarpine, kainic acid, pentylenetetrazol, tetanus toxin, flurothyl, and penicillin. Lithium pilocarpine and kainic acid are the two most frequently used chemoconvulsants. Both methods are used in developing animals in a similar manner as in adults, although the dose required to produce SE is lower in young animals. The compounds are typically injected via an intraperitoneal route, but kainate can also be given intraventricularly or intravenously. Both drugs cause the initiation of SE if given in sufficient doses, and both are believed to act by activating limbic structures, therefore modeling temporal lobe epilepsy. The electrical methods of inducing seizures include hippocampal kindling and perforant path stimulation. In hippocampal kindling, electrodes are placed in the hippocampus (usually CA1 region) and brief rapid low current electrical pulses are given for a few seconds. These stimuli induce after-discharges, which with repeated stimulation become longer, higher voltage, and eventually self-sustaining electrical seizures. If sufficient stimuli are given, then spontaneous recurrent seizures begin to occur. Perforant path stimulation is applied using a similar protocol, except that the perforant path is stimulated to induce electrical discharges.

Other methods used to generate spontaneous seizures in immature animals include hyperthermia (febrile seizure model), trauma, and hypoxia–ischemia. The febrile seizure model, as employed most often by the laboratory of Baram, uses hot air to increase the body temperature of a very young rat until the rat begins to have seizures; the seizures persist as long as the temperature is maintained. A substantial fraction of these animals (35%) develop spontaneous recurrent seizures weeks to months after the febrile SE, making it of particular interest to the pediatric epilepsy research community. All of the non-chemoconvulsant early-life seizure models are extremely important as they reproduce acute symptomatic etiologies that are frequent causes of seizures in human neonates and infants. Many of these models will be discussed in detail elsewhere in this volume.

The methods used to induce seizures in the developing brain are typically administered between postnatal day (P) 7 and 20 in rats and mice, a time period that is thought to roughly parallel a term human neonate (P7) through mid-childhood. After the administration of drugs or hot air or other insults, the animals are monitored, either with video or both video and EEG, to document the duration and severity of the status. The animals are often then monitored again, after the latent period to determine the latency and severity of the spontaneous seizures if they occur. Then either during or after status, or after the onset of spontaneous seizures, the animals are tested for cellular, molecular, and behavioral consequences of the induced seizures. Many different methodologies have been used to test for the impact of the seizures. For example, to investigate the cellular and molecular consequences of seizures on learning, changes in long-term potentiation (LTP) has been examined in hippocampal slices from controls and in animals that experienced seizures. Learning capabilities after seizures have also been examined using a variety of behavioral tests (e.g., the Morris water maze or elevated T-maze). To study seizure-induced molecular changes, all the currently available molecular, biochemical, and genetic methods have been employed. For example, RT-PCR and reverse Northern blots have been employed to look at receptor changes in particular brain regions and cell types. Finally, to investigate cellular changes, many laboratories have used various histological procedures, including the Timm stain to look for mossy fiber sprouting. In addition, immunohistochemical and electrophysiological techniques are used to test for the cellular alterations induced by seizures.

Recent Results

Seizures and the Developing Brain

Researchers from a number of laboratories have made significant advances in detailing the impact of early-life seizures on development. Although early reports from the laboratory of Holmes and colleagues suggested a preservation of cognitive development after early seizures, more recent studies have uncovered age-specific behavioral and molecular effects. Impaired learning and memory in rodents has now been demonstrated after early-life seizures induced by a variety of methods, including tetanus toxin, corticotropin-releasing hormone (CRH), lithium pilocarpine, kainate, and flurothyl. These results suggest a consistent, model-independent impact of seizures on the developing brain. Potential mechanisms of these behavioral effects include deficits found in hippocampal LTP and 'place cells' in animals that experience early-life seizures. These mechanisms are being actively investigated.

Unlike prolonged seizures in adult animals, which produce significant hippocampal CA1 and CA3 cell loss and dentate granule cell mossy fiber sprouting, most models of early-life seizures, both prolonged and repetitive, do not demonstrate significant cell loss or mossy fiber sprouting. Some models, however, do show some degree of cell loss or mossy fiber sprouting. For example, both CRH-induced and recurrent flurothyl seizures in the first week of life result in moderate cellular and synaptic changes in the hippocampal CA3 region. Damage outside the hippocampus, in various thalamic nuclei (as reported by Druga *et al.*), has also been reported in the lithium-pilocarpine model as early at P10. Taken together, these studies suggest that although cell death and synaptic reorganization can be seen after some types of early-life seizures, it is likely not necessary for early-life seizure-induced memory and learning deficits, as many models show none of these changes yet still demonstrate learning and memory disruption.

If structural changes are not the cause of learning and memory deficits or of recurrent seizures, then what is? One possibility is the impact of early-life seizures on dentate granule cell neurogenesis. Dentate neurogenesis is hypothesized to be important for the formation and stabilization of memories. Any alteration by seizures of this process could potentially result in cognitive changes. In adult animals, seizures have been shown to both induce neurogenesis in the dentate gyrus acutely, but inhibit neurogenesis chronically. In the immature animal, our laboratory and others have shown an increase in cell birth following seizures at postnatal days 14–21; this increase is also accompanied by an increase in cell death of both mature and immature granular neurons. One report by McCabe *et al.* details a reduction in neurogenesis after repetitive flurothyl seizures at postnatal days 1–5. These data in immature animals, along with much of the adult rat literature, suggest that seizures could alter dentate neurogenesis and impact on the process of epileptogensis as well as on learning and memory.

The effects of early-life seizures on neurotransmitter systems and intrinsic neuronal properties are another potential cause of seizure-induced cellular, molecular, and

behavioral changes. Inhibitory and excitatory neurotransmitter receptors and voltage-gated ion-channels all have activity-dependent developmental programs that could be altered by seizures during development. Changes in inhibitory neurotransmission have been studied by several laboratories because of the known association between GABAergic function and memory. Enhancing $GABA_A$ receptor-mediated inhibition with benzodiazepines can disrupt LTP, memory formation, and cortical plasticity. All these cognitive processes could be impaired after early-life seizures if inhibition were enhanced. Increased inhibition after postnatal seizures has been shown on a circuit level after both hyperthermic- and kainate-induced seizures by the Sutula laboratory. Molecular changes reported by our laboratory after early-life lithium-pilocarpine-induced seizures includes increased expression of the $GABA_A$ receptor $\alpha 1$ subunit in dentate gyrus, both immediately after early-life seizures and when the animals reach adulthood. The increase in $\alpha 1$ subunit after seizures was shown to be functionally important and associated with enhanced type I benzodiazepine augmentation of the receptor. The early-life increase of $\alpha 1$ subunit expression following pilocarpine-induced seizures is opposite to the decrease in $\alpha 1$ subunit expression seen after seizures in adult rats. Seizures in young animals also affect transcription of some neurotransmitter receptors differentially between mature and immature dentate granule neurons. Clearly, seizures during development can alter expression of $GABA_A$ receptor subunits in an age-dependent manner, with the $GABA_A$ receptor expression changes after early-life seizures contributing to enhanced inhibition that could lead to cognitive and memory deficits.

Excitatory neurotransmission is also impacted by early-life seizures. Changes in expression of glutamate receptors, the primary excitatory neurotransmitter in brain, may contribute to abnormalities in learning and behavior after early-life seizures. Excitatory signaling through both the AMPA and NMDA receptors are critical for different types of LTP and hippocampal learning. Many of the models described above have reported deficits in AMPA- and NMDA-receptor-mediated excitatory synaptic signaling. In particular, lowered expression levels of the GluR2 subunit was reported by our laboratory in the lithium-pilocarpine model and by Jensen and colleagues in the postnatal hypoxia model. The Swann laboratory has used a postnatal tetanus-toxin model to show a decrease in hippocampal CA3 dendritic spine density and a decrease in hippocampal NR1, NR2A, and NR2B receptor subunits. Recent work (e.g., Cornejo and colleagues) has also shown NR subunit decreases after single seizures induced by kainic acid.

Baram and colleagues, working on the febrile seizure model, reported an impact of early-life seizures on voltage-gated ion-channels – a long-lasting enhancement of the intrinsic hyperpolarization-activated membrane current, I_h. The seizures were shown to decrease hippocampal CA1 neuronal hyperpolarization-activated, cyclic nucleotide-gated channel-1 (HCN1) mRNA with simultaneous increase of HCN2 mRNA expression. Persistent limbic hyperexcitability and a 35% incidence of later spontaneous seizures is hypothesized to be due changes in the I_h current. These data suggest that early-life seizures may permanently affect inhibitory and excitatory neurotransmission as well as intrinsic neuronal properties in the developing and adult brains.

Changes in neuromodulatory pathways have also been reported after early-life seizures. One neuromodulator believed to be critically important for learning and memory is cyclic AMP, the action of which is mediated, in part, by the cAMP response element binding protein (CREB). CREB is a key mediator of changes in gene expression necessary for nervous system plasticity. Chronic decreases in learning-specific CREB phosphorylation has been reported after recurrent febrile seizures. Another neuromodulator that is affected by early-life seizures is corticotropin-releasing hormone (CRH). Hippocampal CRH mRNA expression is chronically elevated into adulthood following early-life seizures, and excess corticotropin-releasing factor and early-life stress have been shown to affect both dendritic arborization patterns and long-term cognitive function.

The earlier-mentioned studies highlight the advances made in understanding how early-life seizures may impact the developing brain. One interesting addition to the earlier-mentioned studies is how these behavioral and cellular changes are altered by changes in the animals' environment. In the Holmes laboratory, timed periods of environmental enrichment given to rats exposed to early-life seizures (lithium pilocarpine and kainic acid) resulted in significantly better performance than that seen in normally-housed rats, on multiple learning tests. This difference in behavioral and learning performance was independent of seizures, as all rats developed seizures and similar hippocampal damage. These studies highlight that seizures are not the only factor that determine the course of development for a child with epilepsy. Aspects of environmental exposure may contribute to the impact of seizures on cognitive outcome.

Future Directions

Significant progress has been made in our understanding of how seizures from different etiologies – genetic, traumatic, ischemic, exposure, and infectious – affect brain development and the resulting change in cognitive potential. More research is needed to fully elucidate the molecular, cellular, and circuit mechanisms that contribute to cognitive dysfunction after early-life seizures or possibly that protect against it. Once these mechanisms are identified, and it has been determined which are causal and

which compensatory, then they can be targeted pharmacologically to prevent or correct seizure-associated learning and memory deficits. As more studies are performed and newer technologies – e.g., protein arrays, conditional transgenic animals, and siRNA – are applied, the missing details can be added to our understanding. As this additional information is accumulated, the potential for new pharmacologic or genetic therapies that could help protect scores of children with epilepsy will become possible.

Cortical Dysplasia and Catastrophic Epilepsies of Childhood

S N Roper, University of Florida, Gainesville, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As described by Shields, catastrophic epilepsies of childhood (CEC) are defined by seizure onset in the first few years of life, by seizures that are refractory to medical therapy, and by a strong association with mental retardation. In addition, CEC often results in frequent seizures, with some affected children experiencing up to 100 seizures per day. In addition to the direct, immediate impact of these severe seizures, there are also concerns about the effect of the seizures on

which compensatory, then they can be targeted pharmacologically to prevent or correct seizure-associated learning and memory deficits. As more studies are performed and newer technologies – e.g., protein arrays, conditional transgenic animals, and siRNA – are applied, the missing details can be added to our understanding. As this additional information is accumulated, the potential for new pharmacologic or genetic therapies that could help protect scores of children with epilepsy will become possible.

Cortical Dysplasia and Catastrophic Epilepsies of Childhood

Introduction

As described by Shields, catastrophic epilepsies of childhood (CEC) are defined by seizure onset in the first few years of life, by seizures that are refractory to medical therapy, and by a strong association with mental retardation. In addition, CEC often results in frequent seizures, with some affected children experiencing up to 100 seizures per day. In addition to the direct, immediate impact of these severe seizures, there are also concerns about the effect of the seizures on

subsequent brain development. Not surprisingly, several studies have shown that children who experience seizure control, through medical and/or surgical therapies, have much better ultimate clinical and cognitive outcomes compared with those who cannot be controlled. The two most common clinical syndromes found in CEC are West syndrome (infantile spasms with mental retardation; typical onset within first year of life) and Lennox–Gastaut syndrome (multiple seizure types, mental retardation, slow spike and wave on EEG; typical onset 1–3 years of age).

In the early 1980s, two important clinical developments altered our understanding of CEC. First, some epilepsy surgery centers began to perform resections on affected children. The surgical decision was based on a variety of diagnostic tests, including MRI, EEG, ECoG (EEG recorded from the surface of the brain), and PET. Subsequent analysis of the brain tissue removed during these surgeries provided a more comprehensive pathological picture of the brains in these children. Malformations of cortical development formed the pathological substrate for a significant number of these cases. The other major development was improved methods for detecting subtle cortical malformations using MRI. This enhanced sensitivity allowed for the diagnosis of these conditions prior to surgical resection. These clinical advances set off a minor explosion in the scientific study of malformations of cortical development, with investigators using both human tissue (from surgical resections) and animal models.

Malformations of cortical development (MCDs) comprise a large number of brain disorders that share the common feature of some perturbation of cortical development during the pre- or perinatal period. Clinical syndromes include lissencephaly, agyria/pachygyria, hemimegalencephaly, subcortical band heterotopia, periventricular nodular heterotopia, polymicrogyria, focal cortical dysplasia, cortical tubers of tuberous sclerosis, and acquired cortical dysplasia associated with perinatal stroke. Over recent years, some of these syndromes – including tuberous sclerosis, type I lissencephaly, X-linked lissencephaly, subcortical band heterotopia, and X-linked periventricular nodular heterotopia – have been found to be the results of single gene defects,. However, the etiology for the majority of malformations of cortical development remains unknown.

At the microscopic level, cortical dysplasia (CD) is characterized by loss of lamination, loss of spatial orientation, abnormalities of neuronal morphology, and abnormalities of cell commitment. Human focal cortical dysplasia has been classified by Palmini and colleagues into three types: Type I shows signs of abnormal lamination and spatial orientation only; Type IIA shows large, dysmorphic neurons in addition to the abnormalities seen in type I; and Type IIB shows all of the above plus 'balloon cells' – large, dysmorphic cells thought to be of glial origin that can, in some instances, stain for markers of both neuronal and glial lineage. A large number of studies have been performed directly on human CD tissue acquired from surgery. The results of these important studies are too numerous to cover in this article, but include abnormalities of excitatory and inhibitory neurotransmitter receptors, abnormalities in genes that regulate cell migration and growth, and loss of interneurons in regions of CD. One study of particular relevance to this article came from Calcagnotto and colleagues, who recorded from pyramidal cells in human type II CD. They found a significant reduction in the frequency of spontaneous and miniature inhibitory postsynaptic currents (sIPSCs and mIPSCs, respectively). As discussed below, this result is very similar to the key findings from CD in irradiated rats.

Animal models of CD fall into two broad categories, genetic and injury-based. Our laboratory focused on in utero irradiation because the histological features of this model are similar to many types of human CD. In this model, pregnant females are exposed to about 200 cGy of external radiation on E17. Other injury-based models use DNA-alkylating agents, methylazoxymethanol (MAM) or BCNU, administered to the pregnant dam. Many of the histological effects in the offspring are similar to those seen in utero irradiation, but physiological features differ across the various models. The perinatal freeze-lesioned rat serves as a model of focal CD and polymicrogyria. Genetic models are numerous and varied. Some are the products of spontaneous mutations (i.e., flathead rat and *tish* rat) while others are modeled after genes known to produce human disease (such as the knockout mouse for the *Lis1* gene, known to be involved in human lissencephaly type I). Other relevant genetic models include animals with alterations in genes known to be important in neuronal migration; that is, *reeler* and *p35*−/− mice. Particularly relevant to the current topic are animals with gene defects that alter migration and development of cortical interneurons; these models include the flathead rat, *Dlx1/2* mutant mice and *uPAR*−/− mice. Although a fascinating topic, a comparison of the various animal models of CD is outside the scope of this article.

Background

As mentioned above, the in utero irradiation model involves exposing a pregnant rat to 200 cGy of external radiation on E17. The offspring exhibits microcephaly, diffuse CD, heterotopic gray matter, heterotopic neurons in the hippocampus, and hypoplasia/agenesis of the corpus callosum. Najm and colleagues have shown that these animals demonstrate spontaneous seizures. However, their seizures are not as frequent or severe as those seen in some of the genetic mutations that may die from seizures early in life. The seizure disorder in these rats is also not as severe as many forms of CEC. At a microscopic level, the involved cortex shows reduced thickness

(i.e., pia to white matter) dyslamination, loss of spatial orientation of neurons, and subcortical heterotopic gray matter. Giant, dysmorphic neurons or balloon cells are not apparent. Therefore, using the Palmini classification system, the irradiated rat would be a model of type I human CD.

CD in the irradiated rat is the end result of two distinct but interactive processes: the initial cell death produced by the radiation and the subsequent continued attempt to build a cortex in a radically altered cellular environment. Radiation exposure occurs at a time (E17) of maximal generation of cortical neurons and neuronal migration. Within 24 h after exposure, extensive cell death is seen throughout the developing telencephalon, being most severe in the intermediate zone – which includes radial glia and migrating, immature neurons. Indeed, using an antibody for nestin to label radial glia, we have documented severe disruption of the radial glia after irradiation on E17. The progenitor cells in the ventricular zone, and the more mature cells in the cortical plate, are relatively spared. After the injury, cortical neurons continue to be born and migrate into the cortical plate. However, cell counting studies from our lab suggest that the neurons that arrive in the cortical plate after the injury are almost exclusively excitatory cells. That is, cortical interneurons either quit being born after the injury or their migratory pathways are so altered that they simply never reach the cortical plate. The fact that interneurons (generated in the ganglionic eminence) have a much longer distance to travel than pyramidal cells (generated in the ventricular zone of the telencephalon) in order to reach the cortical plate may explain why the cortical interneurons are more severely disturbed in this model of CD.

We have discovered a number of other abnormalities in CD from irradiated rats. Most of them reflect a severe disruption of the development of the cortical inhibitory interneurons and their incorporation into the circuitry of the neocortex. Early cell counting studies in adult animals showed a selective reduction in the density of parvalbumin- and calbindin-immunoreactive neurons (markers for two types of interneurons) in CD from irradiated animals. In subsequent physiological studies, we recorded excitatory and inhibitory postsynaptic currents (PSCs) from layer V pyramidal cells (using in vitro brain slices); we found a reduction in frequency of spontaneous inhibitory PSCs (sIPSCs) and miniature inhibitory PSC (mIPSCs), but no reduction in excitatory PSCs (EPSCs). This result, suggesting that there was impaired inhibition in dysplastic cortex at the presynaptic level, was consistent with our cell counting study. If there were fewer inhibitory interneurons, it is likely that there would be fewer inhibitory terminals on the neighboring pyramidal cells and thus a reduced frequency of IPSCs. We also recorded from pyramidal cells in subcortical heterotopic gray matter and obtained similar results.

Methods

Most of our findings have come from physiological study of neurons, using in vitro brain slices. We obtain 400 μm-thick coronal slices through the sensorimotor cortex. The slices are maintained in a submerged slice chamber, where they are perfused with oxygenated artificial cerebrospinal fluid (ACSF) containing (in mM) 124 NaCl, 26 $NaHCO_2$, 1.25 NaH_2PO_4, 2.5 KCl, 2 $CaCl_2$, 2 $MgCl_2$, and 10 D-glucose. Individual neurons are imaged in the living slice using infrared-differential interference contrast (IR-DIC) microscopy (Zeiss Axioskop 2 FS and a Nikon FN1 fixed stage microscopes). We obtain whole-cell recordings in both voltage-clamp and current-clamp configurations. The target cells vary depending on the goals of the particular experiment. Earlier studies from our laboratory focused on layer V pyramidal cells and 'comparable' large pyramidal cells from irradiated rat cortex, and inhibition was examined by studying mIPSCs, sIPSCs, and stimulus-evoked IPSCs in these cells. In later experiments, we recorded directly from inhibitory interneurons to examine membrane properties and excitatory connections in these cells.

In many of our studies, we have used standard analysis techniques – of membrane properties, kinetics of miniature and spontaneous EPSCs and IPSCs, and frequency and amplitude of PSCs – to examine function within the cortical circuit. Because many of our findings suggested a presynaptic impairment of inhibition, we also monitored short-term plasticity (STP) as a surrogate measure of release probability within a group of presynaptic terminals.

Histological and immunohistochemical techniques have been employed to study the dysplastic cortex in the irradiated rat model. Early studies used antibodies for parvalbumin and calbindin to identify two types of cortical interneurons in adult animals. For perinatal studies, we have used an antibody for GABA to identify immature interneurons (since the calcium binding proteins mentioned above are not expressed until later in development). For some cell counting studies, we have used the optical fractionator method of stereological analysis; this technique has been described in detail in many other sources.

Recent Results

We have recorded directly from inhibitory interneurons in layer IV/V of CD and control sensorimotor cortex, concentrating on two broad categories of interneurons that were present in both control and irradiated tissue. Type I interneurons corresponded to fast-spiking (FS) interneurons that have been well-characterized in many

other laboratories. They generate rapid, nonadapting action potentials when the cell is depolarized and show short-term depression of stimulus-evoked EPSCs. Many type I interneurons contain parvalbumin; the category includes basket cells that form dense axonal contacts onto the soma of neighboring pyramidal cells. Our type II cells generate slower action potentials, with frequency-adaptation when the cell is depolarized and short-term facilitation of stimulus-evoked EPSCs. This type II category consists of a mixed group of cells, including low-threshold spiking (LTS) interneurons and regular spiking nonpyramidal cells (RSNPs) that have been described by other investigators. Our findings were the same for both types of interneurons. In CD tissue, they all showed a reduction in frequency, but not amplitude, of mEPSCs and sEPSCs. STP did not differ between irradiated and controls for either type and Sholl analysis did not show a difference in dendritic arborization between the controls and irradiated samples. These findings suggest that there are fewer excitatory terminals onto the interneurons in dysplastic cortex in this model. This profile, in turn, raises the interesting possibility that these CD interneurons might be the 'dormant interneurons' that have been proposed to be the basis of hyperexcitability in other models of epilepsy. According to this scenario, the interneuron is present but does not mediate a sufficient level of

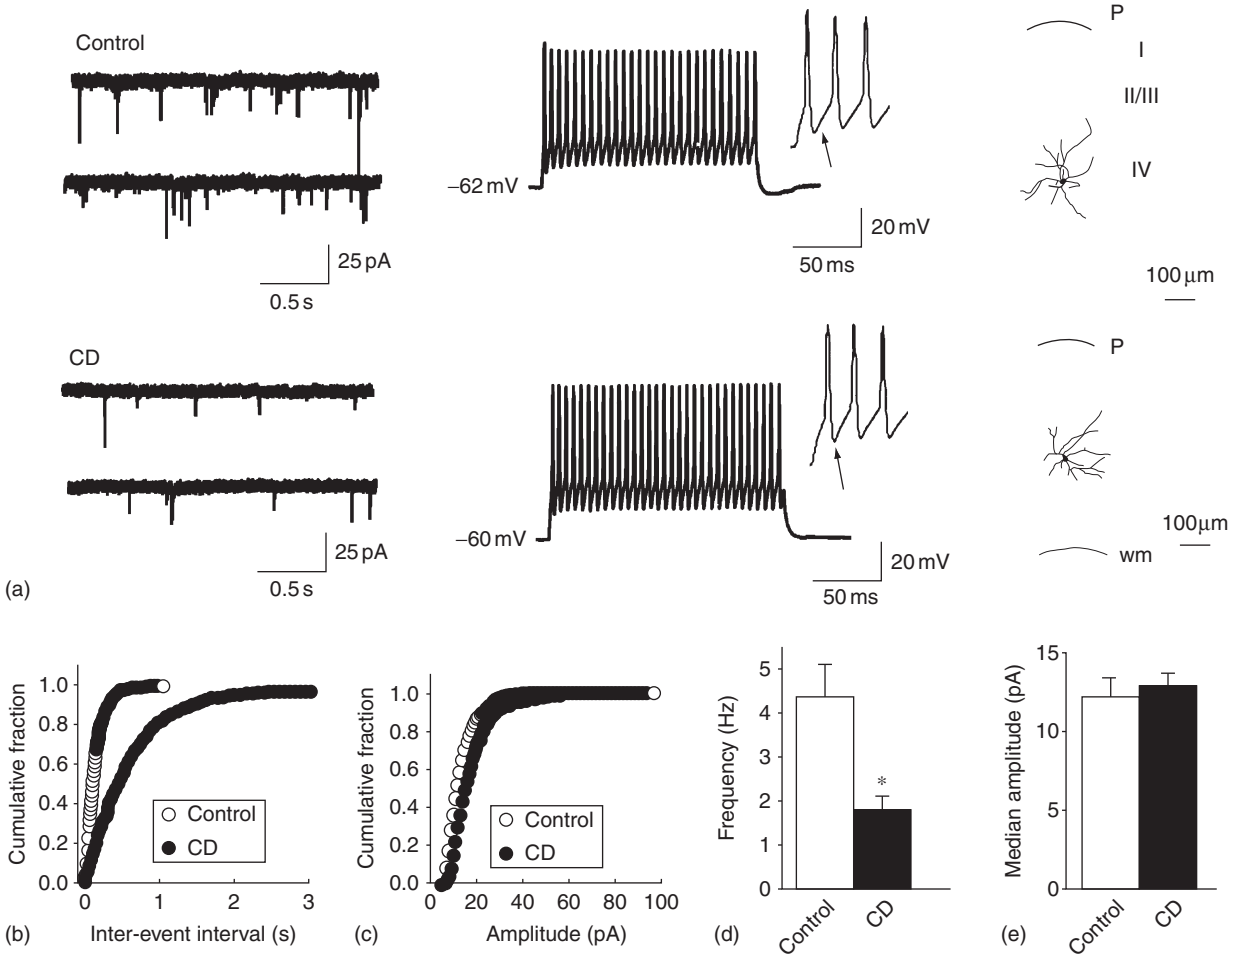

Figure 1 Type I (fast-spiking) interneurons in CD demonstrate a reduction in frequency of sEPSCs compared to controls. (a) The left column shows continuous recordings of sEPSCs from representative Type I interneurons in normal control cortex (upper traces) and CD (lower traces). The middle column shows the typical spiking patterns to current pulses (300 pA, 300 ms) of Type I interneurons from control cortex (upper) and CD (lower). Insets: expanded traces showing large, fast AHPs indicated by arrows. The right column shows camera lucida drawings of biocytin-filled interneurons from control cortex (upper) and CD (lower). (b, c). Cumulative probability curves of sEPSC inter-event interval (b) and amplitude (c) for the two representative Type I cells from control cortex (open circles) and CD (filled circles). (d) Histograms of pooled data from dysplastic and control Type I interneurons showing a reduction in frequency of sEPSCs (control, $n = 16$; CD, $n = 15$) in CD. (e) Histograms of pooled data showing no difference in median amplitude of sEPSCs between control and CD. Asterisk denotes statistical significance ($p < 0.05$). Reproduced from Xiang H, Chen HX, Yu XX, King MA, and Roper SN (2006) Reduced excitatory drive in interneurons in an animal model of cortical dysplasia. *Journal of Neurophysiology* 96: 259–278, with permission from American Physiological Society.

inhibition because it receives a reduced excitatory drive. Interestingly, this reduced excitatory drive appears to be specific to interneurons; our earlier study showed no reduction in frequency of sEPSCs or mEPSCs in excitatory pyramidal cells. These newer findings, coupled with the earlier findings of reduced number of cortical interneurons in irradiated rats, suggest a profound impairment of inhibition. Not only are there fewer interneurons present, but also the surviving interneurons have reduced excitatory drive (**Figure 1**).

Another recent finding involves an alteration in excitatory synapses onto pyramidal cells in irradiated rats. In normal postnatal development, STP of EPSCs in layer V pyramidal cells switches from short-term facilitation to short-term depression between 2 and 4 weeks of age. This change is due, in large part, to a developmental reduction in release probability in the excitatory presynaptic terminals. In earlier studies, we had noted that this switch did not seem to occur in irradiated rat. We performed initial studies in control rats that showed that the developmental switch from facilitation to depression was due largely to increased activation of type 2/3 metabotropic glutamatergic receptors (mGluR 2/3). Because the receptors are already present at 2 weeks, their increased activation between 2 and 4 weeks appears to result from increasing concentrations of ambient glutamate during this period.

Next, we performed detailed analysis of STP in controls and irradiated rats at 2 weeks, 4 weeks, and adults (>60 d). We found that, as expected, control cortex switched from short-term facilitation to short-term depression between 2 and 4 weeks. In contrast, irradiated rats showed short-term facilitation in all age groups, including adults. That is, the normal developmental switch does not occur in dyplastic cortex in this model, reflecting the persistence of an immature increased release probability in the excitatory terminals onto pyramidal cells. The ultimate importance of these findings remains to be seen; however, the literature suggests that factors that increase release probability in excitatory terminals also increase seizure susceptibility.

Future Goals

The work in irradiated rats raises many interesting questions for future research. First, we would like to follow-up the finding of reduced excitatory drive onto interneurons with anatomical studies. We are using antibodies for excitatory and inhibitory presynaptic terminals (VGlut1 and VGAT), in conjunction with biocytin labeling of specific interneurons, to see if anatomical studies will support our physiological findings that suggest a reduced number of excitatory terminals on these interneurons. We would also like to know the identity of the 'lost terminals' (e.g., are they from neighboring pyramidal cells or corticothalamic fibers?) We are performing experiments in slices that maintain both the barrel field structure of the sensory cortex and the ventral thalamus to address this question.

A second, larger issue of interest revolves around the physiological effects of reduced interneuron number and reduced excitatory drive onto remaining interneurons. In particular, how do these features affect the generation of seizures and epilepsy? We are performing slice experiments in the presence of the convulsant, 4-aminopyridine (4-AP), to see how synaptic activity and action potentials are affected in interneurons and pyramidal cells (before and during an epileptiform burst), and how these processes are altered in dysplastic cortex with impaired inhibition. In collaboration with other laboratories, we plan to examine how cortical activity is affected in vivo in irradiated rats, focusing not only on spontaneous seizure activity but also on analysis of single unit activity under baseline conditions and during interictal and ictal events.

Developmental Aspects of Seizures

Introduction

During the first months of life children are particularly at a high risk for seizures, and largest number of new-onset seizure disorders occurs during this time. Because of the birthing process, the infant is at risk for several insults that can result in seizures. These insults include birth trauma and hypoxic-ischemic insults, as well as perinatally-acquired infections, intracranial hemorrhages, and metabolic disturbances. There is a considerable evidence to show that the normal immature brain is more susceptible to seizures than the mature brain.

In addition to being quite common, neonatal seizures are associated with a significantly high risk for subsequent neurological sequelae, including epilepsy, cognitive dysfunction, and motor deficits. While the cause of the seizures is the major determining factor for outcome, there is also evidence suggesting that seizures per se increase the risk of brain injury, regardless of etiology.

Neonatal seizures are associated with an extensive synaptic reorganization of the axons and terminals of the dentate granule cells, reduction in dendritic spines, decreases in neurogenesis, alterations in expression of AMPA and NMDA receptors, and changes in GABA subunit configuration. When animals that had neonatal seizures are tested as adults, deficits in spatial memory and auditory discrimination are found.

The particularly detrimental effects of neonatal seizures may relate to their timing with respect to brain development. Neonatal seizures occur during periods of marked changes in neuronal connectivity and synaptic physiology. For example, the number of inhibitory and excitatory synapses increases; GABA action shifts from excitation to inhibition; the percentage of glutamatergic NMDA-receptor-based 'silent' synapses decreases; the decay of NMDA-mediated postsynaptic responses becomes faster; and some membrane ionic channels and transporters appear and others disappear. Paroxysmal activity may alter normal physiological patterns, and thus influence the developmental process. Increasing evidence suggests that seizures can modify – slow down or accelerate – a wide range of unique processes that take place during development and that are essential for the correct formation and wiring of brain circuitry.

Background

The propensity for seizures or seizure-like activity in the immature brain has been demonstrated in several experimental models, including kainic acid, electrical stimulation, hypoxia, penicillin, picrotoxin, GABA(B) receptor antagonists, and increased extracellular potassium. The underlying mechanisms responsible for increased excitability during this period of life are not completely understood, but are clearly age-dependent. In general, immature neurons and networks tend to oscillate, and this inherent property facilitates the generation of pathological and pathogenic activity such as seizures. This oscillatory propensity is due to the higher input resistance of immature neurons, which enhances the action potential generation and consequent excitability.

Introduction

During the first months of life children are particularly at a high risk for seizures, and largest number of new-onset seizure disorders occurs during this time. Because of the birthing process, the infant is at risk for several insults that can result in seizures. These insults include birth trauma and hypoxic-ischemic insults, as well as perinatally-acquired infections, intracranial hemorrhages, and metabolic disturbances. There is a considerable evidence to show that the normal immature brain is more susceptible to seizures than the mature brain.

In addition to being quite common, neonatal seizures are associated with a significantly high risk for subsequent neurological sequelae, including epilepsy, cognitive dysfunction, and motor deficits. While the cause of the seizures is the major determining factor for outcome, there is also evidence suggesting that seizures per se increase the risk of brain injury, regardless of etiology.

Neonatal seizures are associated with an extensive synaptic reorganization of the axons and terminals of the dentate granule cells, reduction in dendritic spines, decreases in neurogenesis, alterations in expression of AMPA and NMDA receptors, and changes in GABA subunit configuration. When animals that had neonatal seizures are tested as adults, deficits in spatial memory and auditory discrimination are found.

The particularly detrimental effects of neonatal seizures may relate to their timing with respect to brain development. Neonatal seizures occur during periods of marked changes in neuronal connectivity and synaptic physiology. For example, the number of inhibitory and excitatory synapses increases; GABA action shifts from excitation to inhibition; the percentage of glutamatergic NMDA-receptor-based 'silent' synapses decreases; the decay of NMDA-mediated postsynaptic responses becomes faster; and some membrane ionic channels and transporters appear and others disappear. Paroxysmal activity may alter normal physiological patterns, and thus influence the developmental process. Increasing evidence suggests that seizures can modify – slow down or accelerate – a wide range of unique processes that take place during development and that are essential for the correct formation and wiring of brain circuitry.

Background

The propensity for seizures or seizure-like activity in the immature brain has been demonstrated in several experimental models, including kainic acid, electrical stimulation, hypoxia, penicillin, picrotoxin, GABA(B) receptor antagonists, and increased extracellular potassium. The underlying mechanisms responsible for increased excitability during this period of life are not completely understood, but are clearly age-dependent. In general, immature neurons and networks tend to oscillate, and this inherent property facilitates the generation of pathological and pathogenic activity such as seizures. This oscillatory propensity is due to the higher input resistance of immature neurons, which enhances the action potential generation and consequent excitability.

During the early postnatal period, at a time when the immature brain is highly susceptible to seizures, GABA exerts paradoxical excitatory action in all animal species and brain structures (including primates in utero), suggesting that this pattern has been preserved throughout evolution. GABA is depolarizing to approximately postnatal day 14 in rats and until the third trimester in primates. Immature neurons accumulate a high intracellular concentration of chloride, so that there is a chloride efflux – instead of an influx – when GABA receptors are activated to open chloride channels. The lack of efficient GABAergic inhibition enhances excitability and may facilitate synchronicity of epileptic activity.

Although some of the reasons for increased brain excitability in young animals are reasonably well-established, the effects of early-life seizures on subsequent brain excitability are less clear. It is known that following neonatal seizures in the rat there are changes in brain excitability, with a long-standing reduction in seizure susceptibility. Intracellular recordings from hippocampal CA1 and CA3 pyramidal neurons, from rats subjected to a series of 25 neonatal seizures and then studied as adolescents, revealed no significant differences in resting membrane potential, input resistance, membrane time constant, or action potential characteristics. However, CA1 pyramidal cells from these flurothyl-treated rats had marked reductions in spike frequency adaptation and reduced amplitudes of the afterhyperpolarizing potential following a spike train – factors likely to increase excitability of the hippocampal circuitry.

On the basis of this altered excitability, the long-term consequences of neonatal seizures on inhibitory and excitatory neurotransmission, as well as the possible effects of neonatal seizures on the timing of the switch from excitatory to inhibitory effects of GABA has been evaluated.

Methods

Induction of seizures: Flurothyl is used to induce seizures in immature rats. The volatile agent flurothyl (bis-2, 2, 2-triflurothyl ether) is a potent and rapidly acting central nervous system stimulant that produces seizures within minutes of exposure. It has been previously demonstrated that flurothyl seizures during the first days and weeks of life in rats result in several morphological and behavioral changes. Recurrent flurothyl seizures during the neonatal period result in subsequent increases in mossy fiber growth in both the supragranular region and CA3 hippocampal subfield. This sprouting occurs without any cell loss of the principal neurons. Rats are placed in a plastic container and liquid flurothyl is delivered through a plastic syringe and dripped slowly (3 cc/h) onto filter paper in the center of the container, where it evaporates. Rats are exposed to this volatile flurothyl until tonic extension of both the forelimbs and hindlimbs is observed.

Patch-clamp Recordings

Spontaneous inhibitory and excitatory postsynaptic currents (EPSCs) were recorded from visually-identified hippocampal CA3 pyramidal cells in in vitro slices, using voltage-clamp technique in a whole-cell configuration. Spontaneous $GABA_A$ receptor-mediated postsynaptic currents (PSCs) were recorded at a reversal potential of EPSCs (0 mV). In experiments studying the effects of flurothyl treatment on spontaneous EPSCs (sEPSCs), cells were held at 0 mV and incubated in ACSF containing 15 μM bicuculline until detectible spontaneous synaptic activity was blocked; recordings of sEPSCs were then made at −80 mV and +40 mV to separately detect AMPA and NMDA sEPSCs (respectively) on the same cell. Previous studies have shown that at a holding potential of −80 mV, the NMDA component of EPSCs is negligible in extracellular solution containing more than 2 mM Mg^{2+} so we did not used NMDA receptor blockers when measuring AMPA currents. At a holding potential of +40 mV, the sEPSCs consist of both AMPA and NMDA components, so recordings were made in the presence of the non-NMDA glutamate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) (10 μM) in the extracellular solution. The remaining sEPSCs were abolished with the bath application of the NMDA receptor antagonist D-APV (50 μM), indicating that those sPSCs were mediated by NMDA receptors.

Extracellular Recordings

Extracellular recordings of multiple unit activity (MUA) were obtained from the CA3 pyramidal cell layer using metal electrodes of 50 μm diameter; the signal was amplified using a custom-made amplifier with enhanced electromagnetic interference noise suppression (bandpass 0.1 Hz–4 kHz; amplification 1000). Peak-to-peak noise was in the range of 20 μV. After 10–15 min of multiple MUA recording, the selective $GABA_A$ receptor agonist isoguvacine was briefly applied on the slice (10 μM for 1 min, bath application) to activate $GABA_A$ receptors. In control experiments using whole cell recordings from CA3 pyramidal cells we found that brief bath application of isoguvacine induced a transient chloride-dependent current sensitive to the $GABA_A$ receptor antagonist bicuculline. In extracellular recording, the effect of isoguvacine was associated with transient changes in the frequency of MUA and was completely reversible. We determined the effect of isoguvacine on MUA using a ratio based on the MUA frequency at the peak of the isoguvacine response to the MUA frequency in control. For the purposes of fit, we normalized the effect of isoguvacine by assigning values +1 and −1 for all values >100% (excitation) and <100% (inhibition), respectively.

Recent Results

To study the long-term effects of neonatal seizures on GABA currents, we induced a series of 25 flurothyl seizures in rat pups from postnatal days (P) 0 to 4. Whole-cell patch clamp and extracellular recordings were then made from the CA3 hippocampal pyramidal cells in slice preparations, from 3 to 11 days after the last seizure in flurothyl-treated rats; control rats (no seizures) of comparable age were also examined. We compared sPSCs recorded from pyramidal cells in CA3 in control and flurothyl-treated rats at P8–10 and P15–17. The frequency of sIPSCs in control rats increased significantly over the second and third postnatal weeks (**Figure 1(a)**) ($p < 0.005$). A similar increase in frequency of sIPSCs during this developmental period was also observed in flurothyl-treated rats. As shown in **Figure 1(b)**, on average the amplitude of sIPSCs in control rats also changed with advancing postnatal age ($p < 0.05$). In the flurothyl-treated rats, the amplitude of the sIPSCs did not differ from the control values at P8–10. However, sIPSCs amplitude did not increase during the third postnatal week, and was 27% lower in amplitude than sIPSCs in age-matched control animals. These results show that neonatal seizures are associated with subsequent decreases in GABA currents in the hippocampus.

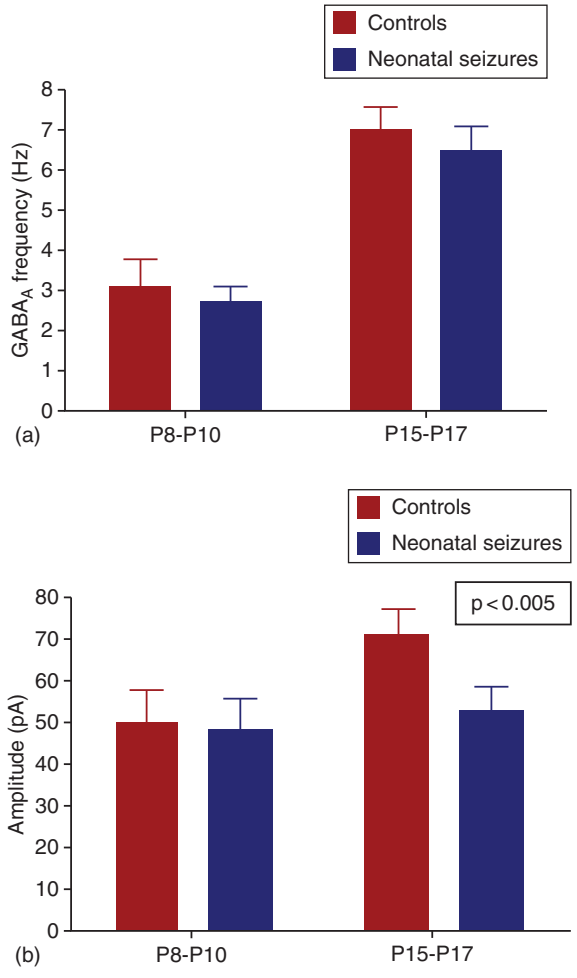

Figure 1 Effect of neonatal flurothyl-induced seizures on GABAergic synaptic transmission in CA3 pyramidal cell at P8–10 and P15–17. (a) GABA(A)-PSCs frequency increased with maturation without a significant difference between the control and flurothyl-treated rats. (b) Amplitude of the GABA(A)-PSCs increased with advancing postnatal age in control rats but not flurothyl-treated rats.

To investigate whether neonatal flurothyl-induced seizures influence excitatory synaptic transmission, recordings were made in the presence of 15 μM bicuculline and at holding potentials −80 and +40 mV to separately detect AMPA and NMDA sEPSCs, respectively. The frequency and amplitude of AMPA and NMDA sEPSCs recorded from control and flurothyl-treated rats increased significantly ($p < 0.05$) and to much the same extent over the second and third postnatal weeks. However, there were no significant differences between AMPA and NMDA sEPSCs amplitudes at any of the ages studied in the control and flurothyl-treated rats. Glutamate neurotransmission does not appear to be permanently altered following neonatal seizures.

In the next series of experiments, we asked whether recurrent neonatal flurothyl-induced seizures affect the developmental excitatory-to-inhibitory switch in the action of GABA. We used non-invasive extracellular recordings of MUA in the CA3 pyramidal cell layer. This method allowed us to record action potentials from tens of neurons in the vicinity of the recording electrode without altering the intracellular chloride concentration. To activate $GABA_A$ receptors, we applied the selective $GABA_A$ receptor agonist isoguvacine (10 μM for 1 min). Day-by-day analysis of the age dependence in the effect of the $GABA_A$ receptor activation, as reflected in MUA frequency, is presented in **Figure 2**; the effect of isoguvacine is presented as a ratio between MUA frequencies at the maximum of the isoguvacine-induced response and during baseline control conditions (prior to isoguvacine application). Age-dependence of the effect of isoguvacine on MUA was approximated with a Boltzman function. A developmental switch in the action of isoguvacine from excitation to inhibition, as determined by the midpoint of the Boltzman fit (i.e., the age at which half of the slices showed an isoguvacine-induced increase in MUA and in the other half showed an isoguvacine-induced decrease in MUA) was estimated to be postnatal day P 13.7 ± 0.3 in control rats and P14.0 ± 0.7 in fluorthyl rats. This difference was not statistically significant, indicating that neonatal seizures did not alter the timing of the switch of GABA from excitation to inhibition.

Down-regulation of GABAergic synaptic transmission by flurothyl-induced seizures can be explained by different mechanisms. Recurrent seizures induced by flurothyl during the neonatal period result in a long-term decrease in the expression of the $GABA_A$-α1 receptor subunit expression.

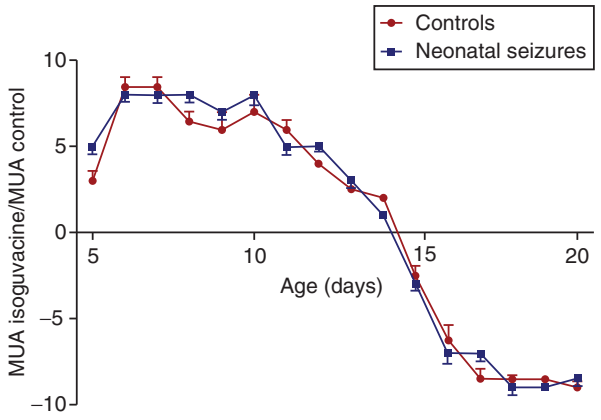

Figure 2 Flurothyl-induced recurrent neonatal seizures in vivo do not affect the developmental switch in the action of GABA from excitatory to inhibitory. Plot of the age dependence in the effect of the GABA(A) agonist isoguvacine on neuronal firing. Each point represents the mean ratio of the multiple unit (MUA) frequency at the peak of isoguvacine effect to the MUA frequency in control conditions. No differences were noted in the control animals and those subjected to recurrent flurothyl seizures.

It has also been shown that increased neuronal activity in hippocampal pyramidal cells in culture increased the percentage of internalized $GABA_A$ receptors. Decreasing of $MgCl_2$ or increasing KCl in the culture medium led to a 30% reduction in mIPSC amplitude. It has been shown that $GABA_A$ receptor endocytosis can last at least several days after low-magnesium treatment of hippocampal cultures, and thus may contribute to a decrease in receptor function and surface expression of $GABA_A$ receptors.

Another possible explanation for the reduction of GABAergic synaptic transmission arises from studies demonstrating a postsynaptic decrease in $GABA_A$ receptor-mediated inhibition secondary to several different metabolic processes. In the low magnesium model of epilepsy, investigators demonstrated that a postsynaptic decrease in $GABA_A$ receptor-mediated inhibition was ATP dependent. It also has been shown that after hypoxia-induced seizures, CA1 pyramidal neurons exhibit a downregulation of $GABA_A$ receptor-mediated inhibition that can be reversed by phosphatase calcineurin inhibitors.

Future Goals

Our study adds further evidence that a seizure during early development alters synaptic function in the developing brain. We propose that the early pathophysiological changes could contribute significantly to the long-term consequences of seizures that occur early in life. Since GABA signaling is important in a wide range of developmental functions, alterations of GABA neurotransmission may have other long-lasting detrimental effects.

Our next major goal is to understand the mechanisms by which neonatal seizures alters inhibitory neurotransmission. The consequences of neonatal seizures appear to be life-long, so that developing the strategies to prevent these long-term changes has major health care implications. Current studies have demonstrated that seizures can alter the functions of brain but the challenge is to determine why such impairment occurs.

Epileptogenesis in Childhood

Introduction

Although 'epilepsy' is referred to as a single disorder, other articles in this encyclopedia highlight that there are many types of epilepsies, involving different neuronal circuits. In addition, these epilepsies are a result of many differing causes and mechanisms. In some instances, the reason for the development of the spontaneous seizures (i.e., epilepsy) relates to abnormal brain structure (malformation) that can be local or generalized. In others, mutations of ion channel genes or of other genes confer a genetic basis of the epilepsy. In still other cases, infection, trauma, and probably also some very long febrile seizures provoke epileptogenesis, the process of epilepsy generation, in a brain that otherwise would not develop epilepsy without this insult. Commonly, the timing of epilepsy onset is during the first decade in humans, even though the responsible mutation, malformation, or other insult may be congenital or occur much earlier in postnatal life. Why do the first seizures that herald the onset of epilepsy occur in infancy and childhood?

Background

Basis of Susceptibility of the Early Postnatal Brain to Seizures

During the first months to years in humans, and the comparable first days and weeks in rodents, several factors coalesce to render the brain, and particularly the limbic circuit, susceptible to the occurrence of single and recurrent seizures. Much of the information about the mechanisms that contribute to this fact has arisen from rodent animal models, and it is therefore important to realize that direct comparison of the developmental stages between human and rodent brain are inexact. For examples, the gestation and postnatal development of rodents are much shorter, and rats reach puberty at ~6 weeks and adulthood at about two months of age. Comparative anatomy suggests that in rats and mice, cortical neuron birth and migration are completed shortly after birth, and brain growth takes place largely within the first 2–3 weeks of life. Particularly considering hippocampal development, a newborn rat pup's developmental stage is comparable to that of a premature baby, a rat at 5–7 days of age has similar development to that of a full-term newborn, and at 3 weeks that of an older child.

During the first postnatal week, excitatory neurotransmitter development and maturation precedes that of inhibition, mainly because activation of the $GABA_A$ receptor by endogenous γ-aminobutyric acid (GABA) produces depolarization. This is a result of the immature state of chloride transporters, resulting in higher intracellular chloride. In addition, expression of certain glutamate receptor subunits 'overshoots' adult levels during the first two postnatal weeks. This combination increases relative excitatory synaptic transmission, promoting hyperexcitability and the susceptibility to seizures.

The unique developmental profile of neurotransmitter expression is accompanied by similar age-specific expression patterns of neuropeptide modulators and intrinsic neuronal ion channels. Like 'classical' neurotransmitters, neuropeptides are released from neurons and can influence the excitability of a neuronal network, acting typically via metabotropic receptors at postsynaptic or presynaptic sites. Inhibitory neuropeptides, including for example neuropeptide y (NPY), are expressed in cortex and hippocampus in humans (and rodents), and reduce network excitability and seizure susceptibility. NPY levels are relatively low in early postnatal hippocampus, which may contribute to the enhanced susceptibility to seizures. In contrast, the excitatory peptide corticotropin-releasing hormone (CRH), and its major receptor, CRFR1, are expressed in developing hippocampus at levels higher than in the adult. This is particularly true during the second postnatal week in the rodents, a developmental epoch characterized by high susceptibility to seizures. CRH increases network excitability by reducing afterhyperpolarizations.

In addition to age-dependent expression patterns of glutamate, GABA, and neuropeptides, and hence in synaptic neurotransmission, developmental expression patterns of ion channels govern age-specific intrinsic properties of neurons, promoting network excitability. Even minor changes in the function of these channels, resulting from mutations or altered expression levels, may promote seizures and epilepsy. For example, mutations in 3 of the 13 known sodium channel genes in mammals (*NaV*1.1, *NaV*1.2, β1) have been associated with epileptic phenotypes, typically arising during infancy or early childhood, and often disappearing later in life. Potassium channels are particularly important during the developmental period when GABA is depolarizing, because they are among the few cellular components that promote repolarization. Indeed, dysfunction of two members of the voltage-gated potassium channels, KCNQ2 and KCNQ3, that carry the

M-current lead to benign familial neonatal convulsions, seizures that occur during the first days and weeks of life, and disappear later. For the Ca^{2+}-channels, age-specific contribution of the CaV2.1-subunit to seizure susceptibility has been delineated in mice. In thalamic neurons of the neonatal mouse, either N- or P/Q-type channels support neurotransmitter release. However, later in life, this function is taken over exclusively by the P/Q-type channels, formed by CaV2.1 subunits, so that dysfunction of these channels provokes seizure vulnerability.

The repertoire of cellular components, including ion channels, transporters, and receptors, that are differentially expressed during development and may influence susceptibility to seizures is constantly enlarging. Recent additions include the chloride transporter NKCC1.

Conceptual and Methodological Considerations

Susceptibility to Seizures Vs. Vulnerability to Epileptogenesis

Although a significant body of information exists that clarifies, or at least is consistent with, the increased likelihood of seizures early in postnatal life, little is known about the basis for the vulnerability to epileptogenesis during this epoch. Indeed, seizure susceptibility is not synonymous with epileptogenesis. An excellent example for this dichotomy involves the consequences of trauma in children and adults. Children are much more likely to experience a seizure in response to even modest trauma, compared with adults. However, the probability of developing posttraumatic epilepsy is at least threefold lower. This example suggests that the developing brain might not be more vulnerable to epileptogenesis compared with that of a mature organism. In this scenario, epileptogenesis might occur more commonly early in life because the incidence of inciting insults, and especially seizures and status epilepticus (SE), is higher. This higher incidence, in turn, is dependent on the factors described earlier.

Age-Specific Epileptogenesis

Epileptogenesis is a term defining a series of complex processes leading to the occurrence of spontaneous seizures. The determinant of epileptogenesis varies widely. The process may arise on an almost purely genetic basis, for example, in the setting of a mutation of a critical gene such as an ion channel. In contrast, environmental input might play a key role in certain epilepsies, such as trauma or stroke. Generally, it is believed that gene–environment interaction underlies the majority of epileptogenic events.

Most of our knowledge of the epileptogenic processes is derived from studies in animals. These have been helpful for both 'genetic' and 'acquired' epilepsies. For example, transgenic mice carrying ion channel mutations, or natural mutations in calcium and other channels, have developed epilepsy, usually around puberty or later. In this case, the effects of the mutation promote seizures, and are typically, but not always, unaccompanied by neuronal death or other anatomical changes. In several animal models, the recurrent spontaneous seizures themselves, i.e., the epilepsy, eventually lead to cell death and often compensatory 'sprouting' of axons of remaining neurons.

Animal models of human epilepsies that do not seem to have strong familial or genetic component, including temporal lobe epilepsy, have often relied on SE as an inciting insult. As described in other chapters, SE leads to loss of neurons in vulnerable brain regions. In the hippocampus, loss of pyramidal cells in areas CA3 and CA1, and loss of neuronal population in the hilus of the dentate gyrus, are typical. The cell loss is classically followed by sprouting of granule cells and other neurons, formation of abnormal circuitry, and – after a latent period – the evolution of spontaneous seizures (i.e., epilepsy). There is considerable evidence that supports the notion that the cell death provoked by the original SE is required for the development of epilepsy.

Recent Results

Seizure-Induced Plasticity May Contribute to Epileptogenesis during Infancy and Childhood

Early in life, however, the story is quite different. In the 1980s it became clear that during the first two weeks of the rodent life, even severe seizures lead to little neuronal death. This finding was originally interpreted to suggest that early postnatal seizures might be benign, and indeed, gross cognitive sequelae as well as epileptogenesis were rare. However, more recently, more refined assessment of cognitive function has suggested that recurrent short seizures or prolonged single seizures might lead to impaired function. Still, the majority of the conventional chemically- and electrically induced SE and prolonged seizures do not seem to result in epileptogenesis.

In recent years, several animal models have shed light on the mechanisms of early-life epileptogenesis. Remarkably, although highly diverse, they provide consistent information. Spontaneous seizures have been reported after early-life experimental prolonged febrile seizures, after tetanus toxin, focal TTX injection, or endothelin-1 injections. In these models, cell death was not prominent and, in contradistinction to the mature brain, does not appear to be required for epileptogenesis. 'Sprouting' and neurogenesis were also not consistently present in the brain of immature rodents that developed epilepsy after these provoking insults. These data suggest that the mechanisms of epileptogenesis during early life require

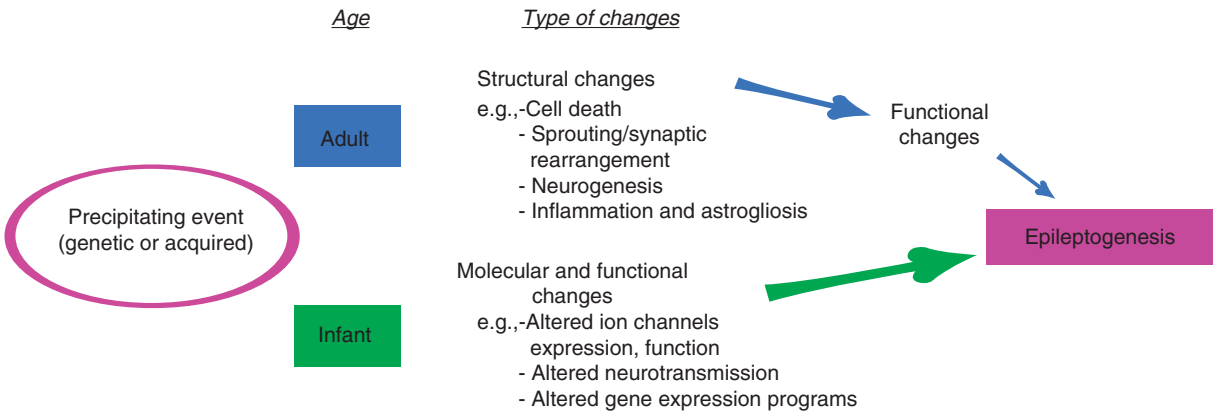

Figure 1 Distinguishing characteristics of epileptogenesis in the mature vs. the immature brain. The schematic shows how an original insult (e.g., genetic mutation of an important gene or severe long seizures) leads to epileptogenesis through different type of processes in immature and adult brain. An adult brain typically requires structural changes such as cell death and sprouting to become epileptic (as best defined in models of acquired epilepsy). In contrast, during childhood, neuroplasticity, often governed by altered programs of gene expression, is a leading mechanism of epileptogenesis.

functional rather than structural changes in neurons and neuronal circuit (Figure 1).

Several candidate mechanisms exist for epileptogenesis without cell death, and generally involve enduring changes in expression programs of key genes. Early-life seizures lead to persistent changes in the expression of several $GABA_A$ receptor subunits, which profoundly alter the properties of the receptors, rendering the brain more conducive to 'runaway excitability.' *N*-methyl-D-aspartate (NMDA)- and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptors are also changed. The expression of intrinsic ion channels, notably the hyperpolarization-activated ion channels, is also changed, leading to currents that increase the probability of rebound depolarization. Other receptors (e.g., the endocannabinoid receptor type 1) are also modulated long-term. The nature of the regulatory factors that are activated by early-life seizures to orchestrate these coordinate alterations of gene expression programs are not yet known. Altered signaling through the cAMP system and the neuronal suppressor NRSF have been found. One theory proposes that, at least in the case of long experimental febrile seizures, induction of endogenous inflammatory mediators and specifically IL-1β leads to altered gene expression via the NF-kB cascade, and endures long-term.

Future Directions

Although much has been learned from these studies and others about the pathways that convert a normal developing brain into an epileptic brain, many questions remain unanswered. For example, following a given insult, such as hypoxia, trauma, or complex febrile seizure, an individual rat or human may or may not develop epilepsy. The ability to predict who will develop epilepsy after an initiating event would be highly beneficial, because it will enable targeting of future interventions to the population at risk. Current and future studies aim to determine genetic and acquired susceptibility to epileptogenesis. In parallel, investigators are attempting to define 'biomarkers' of the epileptogenic process. Molecular arrays, or fingerprints, at mRNA or protein levels are under investigation. In addition, imaging methods (including MRI) are being used to examine whether changes visible in vulnerable brain areas denote regions that are undergoing changes conducive to the development of epilepsy at a later date.

In summary, significant evidence supports the independence of epileptogenesis in childhood from the need for cell death. However, relatively little is known about the nature and basis of the functional neuronal changes (neuroplasticity) that promote the epileptogenic process early in life. Future studies should help clarify these processes and, optimally, predict in advance who will develop epilepsy, and enable intervention and prevention of this disorder.

Hippocampal EEG in the Neonatal Rat: Development of Normal and Pathological Activity

E J Mohns and M S Blumberg, University of Iowa, Iowa City, IA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Children are particularly susceptible to seizures during the first few months of postnatal life. During this period, a clinician may examine a child's background (nonparoxysmal) EEG activity for abnormal patterns that might predict pathological outcomes. In this context, 'abnormal' background EEG patterns (e.g., abnormalities of amplitude and frequency) are defined in relation to 'normal' age-specific patterns, which change continuously across this period as the complexity of the EEG increases.

The most common cause of seizures during the neonatal period is hypoxic–ischemic encephalopathy (HIE). To study the age-dependence of vulnerability to HIE and its associated neurological damage, an animal model was developed by Jensen and her colleagues. This experimental model involves the exposure of neonatal rats to graded global hypoxia in an airtight chamber. Studies utilizing this paradigm have reported age-dependent effects in the developing neocortex and hippocampus, with seizure being most readily induced at approximately postnatal day (P)10. The model therefore appears to capture a period of heightened seizure susceptibility in the neonatal rat that is analogous to that of the human infant. Yet, if the prognostic background EEG correlates of the HIE-like state in rats are to be properly studied, we need to better understand what 'normal' background activity entails.

Recent work in our laboratory has systematically assessed the development of the 'normal' hippocampal EEG across the first three postnatal weeks in unanesthetized rats. In addition, we have correlated the developmental changes in spontaneous activity with the age-dependent emergence of evoked pathological activity. In this article, we describe our findings, with special emphasis on the dramatic changes occurring during the second postnatal week.

Background

In rats, peak susceptibility to hippocampal seizures occurs during the second postnatal week. The increased excitability of the hippocampus during this period appears to be attributable to several factors. One of the more extensively studied of these factors is the ontogenetic shift in intracellular Cl^- concentration, which causes $GABA_A$ receptor activation to transition from having a depolarizing effect to a hyperpolarizing effect on the cell. This shift occurs as the Cl^- accumulating cotransporter NKCC1 is down-regulated, and the Cl^- extruding cotransporter KCC2 is up-regulated. A separate factor thought to contribute to the increased excitability of the neonatal hippocampus is that the effects of the excitatory neurotransmitter glutamate are potentiated by a transient up-regulation of AMPA and NMDA receptors. In addition, electrical coupling between neurons appears to be more abundant during the second

Introduction

Children are particularly susceptible to seizures during the first few months of postnatal life. During this period, a clinician may examine a child's background (nonparoxysmal) EEG activity for abnormal patterns that might predict pathological outcomes. In this context, 'abnormal' background EEG patterns (e.g., abnormalities of amplitude and frequency) are defined in relation to 'normal' age-specific patterns, which change continuously across this period as the complexity of the EEG increases.

The most common cause of seizures during the neonatal period is hypoxic–ischemic encephalopathy (HIE). To study the age-dependence of vulnerability to HIE and its associated neurological damage, an animal model was developed by Jensen and her colleagues. This experimental model involves the exposure of neonatal rats to graded global hypoxia in an airtight chamber. Studies utilizing this paradigm have reported age-dependent effects in the developing neocortex and hippocampus, with seizure being most readily induced at approximately postnatal day (P)10. The model therefore appears to capture a period of heightened seizure susceptibility in the neonatal rat that is analogous to that of the human infant. Yet, if the prognostic background EEG correlates of the HIE-like state in rats are to be properly studied, we need to better understand what 'normal' background activity entails.

Recent work in our laboratory has systematically assessed the development of the 'normal' hippocampal EEG across the first three postnatal weeks in unanesthetized rats. In addition, we have correlated the developmental changes in spontaneous activity with the age-dependent emergence of evoked pathological activity. In this article, we describe our findings, with special emphasis on the dramatic changes occurring during the second postnatal week.

Background

In rats, peak susceptibility to hippocampal seizures occurs during the second postnatal week. The increased excitability of the hippocampus during this period appears to be attributable to several factors. One of the more extensively studied of these factors is the ontogenetic shift in intracellular Cl^- concentration, which causes $GABA_A$ receptor activation to transition from having a depolarizing effect to a hyperpolarizing effect on the cell. This shift occurs as the Cl^- accumulating cotransporter NKCC1 is down-regulated, and the Cl^- extruding cotransporter KCC2 is up-regulated. A separate factor thought to contribute to the increased excitability of the neonatal hippocampus is that the effects of the excitatory neurotransmitter glutamate are potentiated by a transient up-regulation of AMPA and NMDA receptors. In addition, electrical coupling between neurons appears to be more abundant during the second

postnatal week, as the proteins that form gap junctions are transiently up-regulated. Finally, it is during this period that the recurrent collateral branches that interconnect pyramidal cells in the CA3 region reach levels greater than those seen in adulthood, before gradually being refined. Thus, it appears that during the second postnatal week, the hippocampus is characterized by conditions that favor both excitation and population synchrony.

The excitability and synchrony of the adult hippocampus are reflected in the frequency and duration of hippocampal sharp waves (SPWs), large field potential events that reflect a synchronous discharge of neurons in the CA3 network that is then conveyed to the CA1 field via the Schaffer collateral system. Accordingly, the transiently increased tendency of the neonatal hippocampus toward excitability and synchronization should be reflected in the expression of SPWs, and perhaps also their associated high-frequency oscillations. Indeed, there is currently a great amount of interest in the developmental relationship between the emergence of spontaneous physiological high-frequency activity (>40 Hz) and the emergence of the pathological high-frequency oscillations (≥60 Hz) that characterize epileptogenic activity. Although two recent studies have examined neonatal SPWs in vivo, neither study examined subjects during the developmentally important second postnatal week. We therefore sought to determine how age-dependent changes in hippocampal activity relate to the developmental onset and offset of the period of hyperexcitability.

Methods

In our laboratory, we have taken advantage of 16-site linear silicon probes (100-μm vertical separation between recording electrodes; NeuroNexus Technologies, Ann Arbor, MI) to simultaneously monitor the activity of multiple hippocampal layers within the dorsal CA1–dentate gyrus axis. These probes also allow the investigator to distinguish locally generated events and oscillations from passively conducted activity, because the former exhibit polarity reversals across the appropriate layers.

To determine the normal course of postnatal EEG development, the hippocampal activity of unanesthetized rats at P2–18 was monitored. Under isoflurane anesthesia, subjects' heads were secured for electrophysiological recordings by surgically attaching a custom-built, stainless steel apparatus that was designed to attach to the ear-bar and nose-bar holders of a stereotaxic apparatus. This preparation allowed access to the dorsal hippocampus while minimizing movement artifacts. Nuchal and vastus lateralis EMG electrodes were implanted and used to identify behavioral state. Finally, to inhibit movement and calm the subjects, they were wrapped gently in gauze. During recovery, acclimation, and testing, the subjects' body and brain temperatures were maintained at thermoneutrality (35 °C and 37 °C, respectively).

A subset of subjects received intrahippocampal infusions of kainic acid (KA) to assess seizure susceptibility across the first three postnatal weeks. After baseline recording periods, a 30-gauge needle attached to a 10-μl Hamilton syringe was lowered slowly into the contralateral CA1 pyramidale-radiatum region at approximately the same coordinates as the recording electrode. Next, 1 μl of KA (200 ng/μl; dissolved in sterile saline) was manually infused (1 μl per 10 s). After each infusion, hippocampal activity was continuously recorded for 10 min. Each subject received a maximum of 10 infusions (1 infusion per each of ten 10-min recording sessions). The general experimental design that we employed is illustrated in **Figure 1(a)**.

Results

At the earliest age examined (P2), the hippocampal EEG consisted of SPWs and brief bursts of 'slow' gamma (20–50 Hz) rhythms. These two patterns predominated until P6, when we observed the emergence of 'fast' gamma (60–100) rhythms, which were initially observable only as 'tails' of activity following SPWs. At P7, we observed the emergence of the SPW-related 'ripple' (140–200 Hz), as well as dentate spikes. P7 was also the age at which KA infusion was first able to elicit interictal spikes (IISs; **Figure 1(b)** and **1(c)**) and associated pathological high-frequency oscillations (60–200 Hz). Theta activity (4–12 Hz) emerged on P8, coincident with the period of peak susceptibility to KA-induced seizure activity. In general, the amplitude and incidence of all events and oscillations increased across development; the exception was gamma tails, which continued to occur with low probability after their emergence.

As illustrated in **Figure 1(d)**, the sensitivity to KA infusion increased dramatically between P7 and P11, and declined thereafter such that, in most subjects, even 10 infusions of KA were no longer sufficient to evoke seizure activity.

Importantly, we found that in addition to the emergence of ripples and dentate spikes, there were two changes in SPW activity that reflected the onset, as well as duration, of the period of increased seizure susceptibility, between P7 and P11. These included (1) an increase in the occurrence of SPW doublets (that is, two SPWs occurring within a 400-ms window) and (2) a decrease in the duration of SPWs. Our results are summarized in **Figure 2**. Note that the period of greatest seizure susceptibility is predicted by the onset of several EEG patterns, as well as the transient modification of SPWs. The physiological significance of the latter is discussed below.

It was recently suggested that the development of pathological high-frequency oscillations at P6–7 precedes

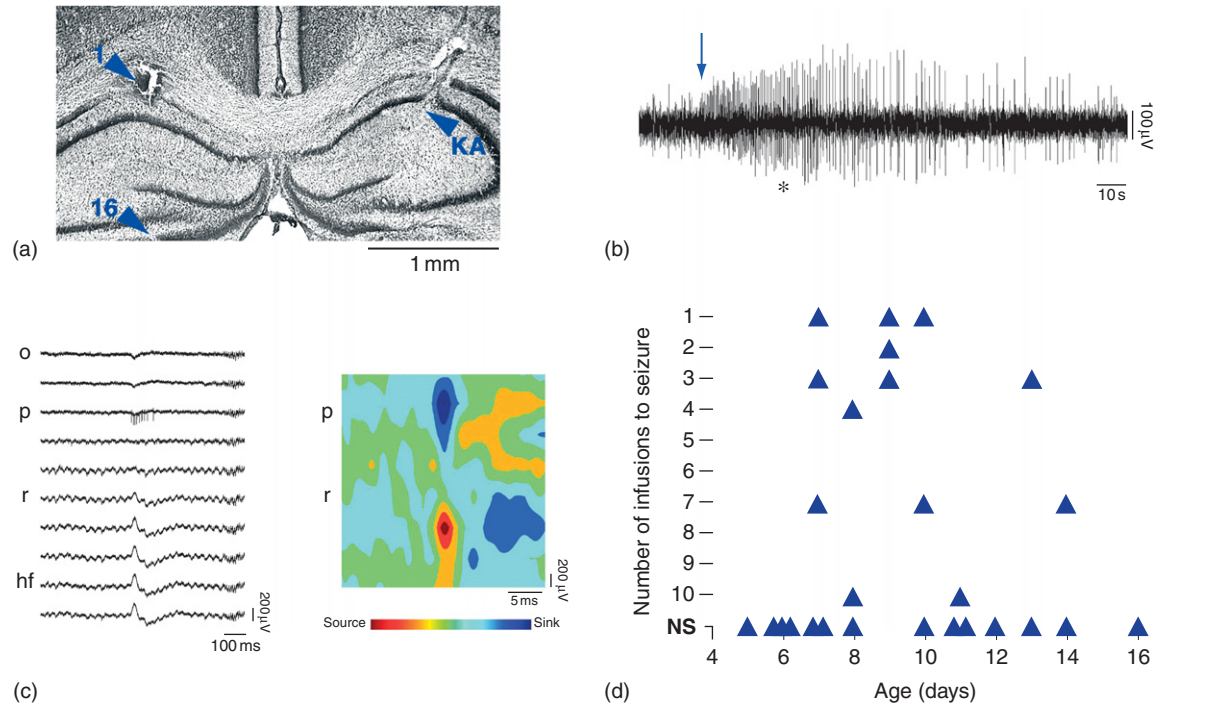

Figure 1 Hippocampal activity following contralateral kainic acid (KA) infusion. (a) Histological section from a P8 subject, illustrating the design of the experiment. In the left hippocampus, a marking lesion indicates the location of the most dorsal recording site (site 1). The most ventral recording site is also indicated (site 16). In the right hippocampus, the location of the KA infusions is indicated by the needle track penetrating CA1. (b) For the subject in (a), this recording illustrates the onset (indicated by arrow) of seizure activity following KA infusion. Asterisk indicates the location of the interictal spike (IIS) presented in greater detail in (c). (c) Left panel: Representative depth profile (wide-band, 1–5000 Hz) of a type 2 IIS, and associated neuronal discharge in stratum pyramidale (p). Right panel: Current source density analysis, derived by averaging across many IISs comprising the interictal episode from which the IIS in the left panel was selected. (d) For each subject, the number of KA infusions required to evoke seizure activity. NS, no seizure activity detected after a maximum of 10 infusions. o, stratum oriens; r, stratum radiatum; hf, hippocampal fissure. Reproduced from Mohns EJ, Karlsson KÆ, and Blumberg MS (2007) Developmental emergence of transient and persistent hippocampal events and oscillations and their association with infant seizure susceptibility. *European Journal of Neuroscience* 26: 2719–2730, with permission from Blackwell.

the development of physiological high-frequency oscillations in the ripple frequency range at approximately P14. While we indeed found that pathological high-frequency oscillations emerge around P7, we also found that physiological high-frequency oscillations in the gamma-frequency range emerge at P6 and in the ripple range as early as P7. Thus, we offer the alternative view that pathological and physiological high-frequency oscillations emerge at approximately the same time.

Gamma-frequency rhythms have been described in head-fixed and freely moving rats as early as P2–5, but it is important to note that these rhythms are unrelated to SPWs, and are of lower frequency (i.e., 20–60 Hz) than the SPW-related high-frequency (60–100 Hz) gamma tails that we have found at P6. These findings reflect an important interaction between subject age and oscillation frequency. Indeed, because high-frequency gamma oscillations are dependent, in part, upon AMPA receptor-mediated excitation, it is noteworthy that the emergence of 60–100-Hz oscillations at P6 is coincident with the up-regulation of AMPA receptors that takes place at this age.

Our study also indicates that the onset and duration of the period of greatest susceptibility to seizure activity are evident in baseline, nonpathological EEG patterns. In particular, this period is characterized by a decrease in the duration of the SPW waveform, and by an increase in the occurrence of SPW doublets. SPW duration in CA1 indicates the degree of synchrony among CA3 pyramidal neurons; a CA1 SPW of shorter duration reflects more rapid recruitment of cells within the CA3 recurrent collateral network, and thus greater network synchrony. Our finding that SPW duration was shortest during the second postnatal week is therefore consistent with the finding that CA3 pyramidal-cell collateralization is greatest during this period. In addition, because seizures are produced by neuronal network hypersynchrony, it is noteworthy that the period of shortest SPW duration was also coincident with the period of greatest seizure susceptibility. It is equally noteworthy that there was an increased rate of SPW doublets during this period; as SPWs occur during periods of reduced cortical and subcortical inhibition, an enhanced rate of occurrence of SPWs and SPW doublets is, in adult

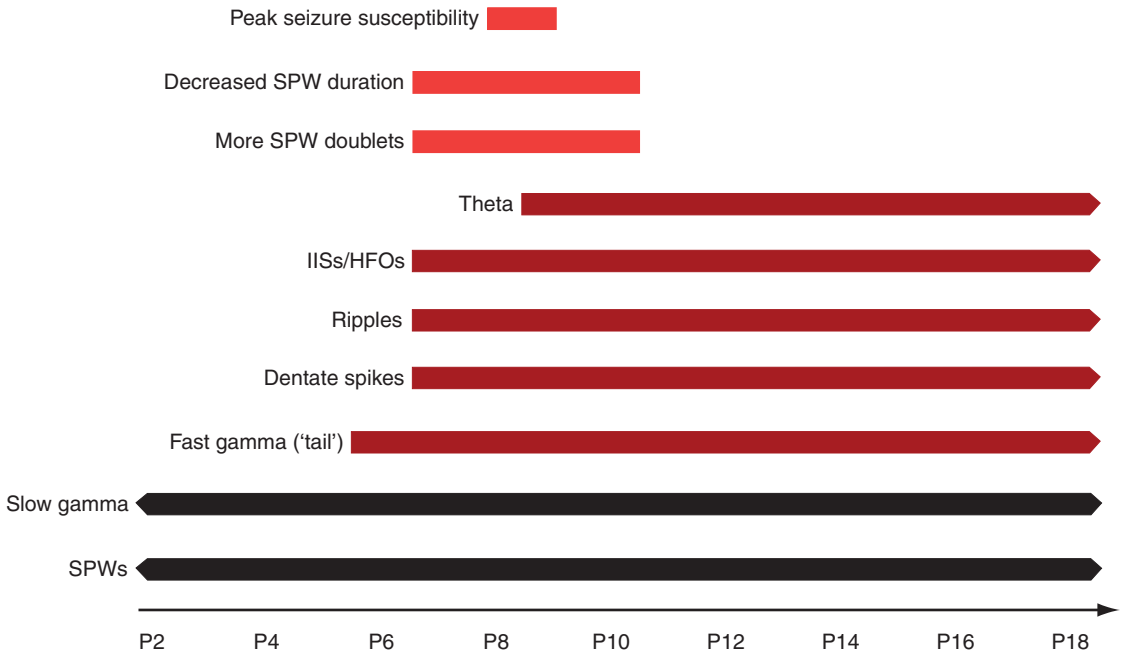

Figure 2 Summary of results. Presented is a schematic illustration of the development of transient and persistent hippocampal events and oscillations. SPWs and slow gamma oscillations (20–50 Hz) occurred at all ages examined. SPW-related fast gamma tails (60–100 Hz) and ripples (140–200 Hz) were first detected at P6 and P7, respectively. Interictal spikes (IISs) and associated pathological high-frequency oscillations (HFOs; 60–200 Hz) were first evoked by kainic-acid (KA) infusion into the contralateral hippocampus at P7. Dentate spikes were also first observed at P7, while theta activity (4–12 Hz) did not emerge until P8. The occurrence of SPW doublets increased, and SPW duration decreased, transiently between P7 and P11. Finally, peak susceptibility to seizure following KA infusion, as indicated by the number of infusions required to evoke seizure activity, occurred at approximately P9. Reproduced from Mohns EJ, Karlsson KÆ, and Blumberg MS (2007) Developmental emergence of transient and persistent hippocampal events and oscillations and their association with infant seizure susceptibility. *European Journal of Neuroscience* 26: 2719–2730, with permission from Blackwell.

rats, thought to reflect a state of increased network excitability.

To test whether the EEG characteristics we had identified did indeed correlate with increased seizure susceptibility, we developed a method for inducing seizure activity in vivo that is based on an in vitro method for induction of epileptogenic mirror foci. This method utilizes the early postnatal development of functional hippocampal commissural projections to induce seizure activity via contralateral KA infusion. Using this experimental preparation, we found that the fewest number of infusions required to produce electrographic seizure activity occurred at approximately P9, with decreased efficacy at younger and older ages. This result indicated that there was, in fact, a strong relationship between the transient SPW-related changes and seizure susceptibility, as illustrated in Figure 2. Figure 2 also illustrates how much the hippocampal EEG increases in complexity during this very brief period.

Our finding that seizure susceptibility reached a peak at P9 in response to KA infusion is consistent with the results of several other experimental models developed to examine neonatal seizure susceptibility. These models include in vivo approaches utilizing hypoxia and hyperthermia to induce seizures, which reveal peak susceptibilities at P10–12 and P8–11, respectively. Our data are also consistent with the high potassium in vitro model of neonatal seizure induction, which reaches peak effectiveness at approximately P11.

Future Goals

One of the primary goals of our ongoing research is to distinguish the epigenetic factors that influence the normal and pathological development of the neonatal brain. We hypothesize that the well-established influence of maternal care on brain development may have a great influence on how prone to seizure a rat will become, particularly during the second postnatal week. Moreover, we believe that the mechanisms underlying postnatal hyperexcitability will be elucidated by further studies addressing the individual and synergistic contributions of recurrent collateral branches, gap junctions, glutamate receptors, $GABA_A$ receptors, and other factors that are developmentally modulated during this period.

The results presented here identify several transient SPW-related events that are characteristic of a period

of increased synchrony and excitability in the neonatal hippocampus. That the period delineated by these events coincides with the down-regulation of NKCC1 and the up-regulation of KCC2 may suggest a mechanistic connection. Specifically, if the shift from GABAergic excitation to inhibition is mediated by an activity-dependent mechanism, then perhaps the increased activity associated with hyperexcitability promotes a self-limiting process by which the infant transitions to a nonhyperexcitable state.

Mechanisms of Epileptogenesis in Models of Pediatric Epilepsy Syndromes Associated with Brain Malformation

Introduction

That malformations of cortical development (MCD) are associated with epilepsy was first reported over 130 years ago. Malformations are primarily associated with severe pediatric seizure disorders and are often resistant to conventional antiepileptic drugs. Driven, in large part, by the advent of sophisticated neuroimaging techniques, MCD-associated seizure disorders are now recognized as a fairly common form of pediatric epilepsy. Indeed, recent clinical estimate indicates that nearly 30% of all epilepsy surgeries involve removal of dysplastic tissue. Consequently, a critical issue facing investigators is to determine mechanisms through which dysplastic tissue can function in a hyperexcitable manner that would, ultimately, contribute to a proepileptic phenotype.

Clinical studies already indicate that (1) malformations are regions of interictal hypometabolism and ictal hypermetabolism, i.e., typical features of epileptogenic foci, (2) malformed brain regions exhibit paroxysmal activity in corticography or synoperative deep electrode recordings, and (3) surgical resection of focal malformations

of increased synchrony and excitability in the neonatal hippocampus. That the period delineated by these events coincides with the down-regulation of NKCC1 and the up-regulation of KCC2 may suggest a mechanistic connection. Specifically, if the shift from GABAergic excitation to inhibition is mediated by an activity-dependent mechanism, then perhaps the increased activity associated with hyperexcitability promotes a self-limiting process by which the infant transitions to a nonhyperexcitable state.

Mechanisms of Epileptogenesis in Models of Pediatric Epilepsy Syndromes Associated with Brain Malformation

S C Baraban, University of California, San Francisco, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

That malformations of cortical development (MCD) are associated with epilepsy was first reported over 130 years ago. Malformations are primarily associated with severe pediatric seizure disorders and are often resistant to conventional antiepileptic drugs. Driven, in large part, by the advent of sophisticated neuroimaging techniques, MCD-associated seizure disorders are now recognized as a fairly common form of pediatric epilepsy. Indeed, recent clinical estimate indicates that nearly 30% of all epilepsy surgeries involve removal of dysplastic tissue. Consequently, a critical issue facing investigators is to determine mechanisms through which dysplastic tissue can function in a hyperexcitable manner that would, ultimately, contribute to a proepileptic phenotype.

Clinical studies already indicate that (1) malformations are regions of interictal hypometabolism and ictal hypermetabolism, i.e., typical features of epileptogenic foci, (2) malformed brain regions exhibit paroxysmal activity in corticography or synoperative deep electrode recordings, and (3) surgical resection of focal malformations

leads, in many cases, to suppression of seizure activity. To further highlight the proepileptogenic nature of MCDs, human dysplastic tissue maintained in vitro was shown to generate ictal-like epileptiform activity when exposed to a common convulsant, 4-aminopyridine (4-AP). From these observations, an experimental interest in how malformed neurons function (and communicate) has emerged. A good starting point for examining how seizures could be generated in malformed tissue is to consider two distinct (but classic) hypotheses, namely, that hyperexcitability is the result of a defect in (1) the intrinsic firing properties of individual neurons or (2) the synaptic properties of a network of neurons – or perhaps both.

Background

At present, a great deal of clinical information is available regarding brain malformations. This information is extremely useful in guiding the development of appropriate animal models. For example, from morphological studies we know that MCDs cover a wide neuropathological spectrum, including patients with subtle (i.e., single aberrant or dysplastic cells) up to severe malformations such as having two separate cortices (i.e., subcortical band heterotopia) or large clusters of dysplastic neurons (i.e., nodular heterotopia). From histological data, we know that MCDs are typically encountered in cortex, but can also be observed as 'tectonic' clusters of pyramidal cells in hippocampal areas CA1 or CA2. Although the precise identity of dysplastic cells is debated, it is often the case that these cells are neurons and not aberrant glia, oligodendrocytes, or astrocytes.

In contrast to our understanding of human MCD anatomy, very little is known about the electrophysiological characteristics of dysplastic tissue. Where sophisticated patch-clamp analysis of tissue derived from surgery was performed, emerging data suggest diverse and, in some cases, clearly hyperexcitable firing properties for subpopulations of cells located within a malformation. Recent single-cell studies further describe (1) N-methyl-D-aspartic acid (NMDA)-mediated currents with decreased Mg^{2+} sensitivity and reduced current density and (2) reduced γ-aminobutyric-acid (GABA)-mediated inhibition onto dysplastic neurons and altered transporter function. Unfortunately, these types of studies are rare, controls are difficult to assign, and this tissue is not always amenable to the wide range of experimental manipulation necessary for testing mechanistic hypotheses.

To address this problem, several animal models have been proposed. Broadly, these animals can be classified as injury-based (e.g., irradiation, teratogen exposure, or freeze-lesion) or genetically-based (e.g., knockout mice, naturally occurring mutants, RNAi knockdown) (**Table 1**).

Table 1 Animal models featuring malformations of cortical development

Rodent model	*Malformation*
Postnatal FL rats	Polymicrogyria
In utero gamma irradiation rats	Nodular heterotopia Loss of lamination Cortical dysplasia Periventricular heterotopia
In utero methylazoxymethanol exposure rats	Nodular heterotopia Loss of lamination Cortical dysplasia Periventricular heterotopia
In utero N,N′-bis(2-chloroethyl)-N-nitrosurea (BCNU) exposure rats	Nodular heterotopia Loss of lamination Cortical dysplasia
In utero cocaine exposure rats	Microdysgenesis
Ihara rats	Microdysgenesis Heterotopia
Ibotenate injection rats	Periventricular heterotopia Band heterotopia
TISH rats	Band heterotopia
SRK	Loss of lamination Cortical dysplasia
RNA interference knockdown of *DCX* in the rat	Band heterotopia
p35 knockout mice	Granule-cell dispersion
Lis1 heterozygote mice	Cortical disorganization Loss of lamination
Otx1 heterozygote mice	Cortical disorganization
MEKK4 knockout mice	Periventricular heterotopia
NXSM and NZB autoimmune mice	Neocortical ectopia
Flathead (fh/fh) mutant mice	Lissencephaly Hydrocephaly
Presenilin-1-deficient mice	Cortical dysplasia
Fukutin-deficient mice	Neocortical ectopia Loss of lamination

MAM, methylazoxymethanol; FL, freeze-lesion; TISH, telencephalic internal structural heterotopia; SRK, shaking rat Kawasaki; *DCX*, *doublecortin*.

In many cases, these animals exhibit robust signs of hyperexcitability and even evidence for spontaneous electrographic seizures in a few examples. It is important to remember that many of these models have been developed or described in the last 10 years, and are not as widely studied as conventional kindling or temporal lobe epilepsy (TLE) animals; thus less information on the phenotypes is available. As these are rodent models with a central nervous system somewhat different from humans, it is not altogether surprising that no single animal model can reproduce the precise anatomical disorganization and behavioral symptoms observed clinically. Fortunately, recapitulation of the entire spectrum of abnormal cells found in human MCDs may be neither an animal model 'short-coming' nor a 'litmus' test requirement. Indeed, it is perhaps unnecessary

to reproduce in an animal model some of the cell types associated with MCDs in human. For example, balloon cells (a hallmark feature of human dysplasia) do not exhibit active firing properties and are likely to be electrically silent nonepileptogenic cells; thus, their absence from animal models should not reduce the usefulness of the model for studying mechanisms underlying epileptic discharge.

Methods

In our laboratory, we have chosen a rodent model with a readily identifiable brain malformation, e.g., prenatal methylazoxymethanol (MAM) exposure. MAM injected into pregnant rats is transported across the placenta into the fetus where it causes DNA methylation and primary damage to newly born cells. MAM-exposed offspring exhibit microencephaly and, if injections occur on embryonic day 15 (E15) in the rat, hippocampal nodular heterotopia with loss of cortical and hippocampal lamination (**Figure 1(a) and 1(b)**). Within the hippocampus, heterotopic neurons exhibit reduced dendritic growth (**Figure 2(a)**), decreased spine density, abnormal connectivity with neocortex, and are hyperinnervated by catecholaminergic fibers. Heterotopic neurons do not express cell-type-specific markers of hippocampal pyramidal or granule cells, but do express a tumor suppressor factor (*Id-2*) normally found in superficial layers of neocortex. White-matter abnormalities and periventricular nodular heterotopia are also present in MAM offspring from single and double prenatal injections, but are highly variable and not as reproducible as the hippocampal heterotopia. The consistent presence of a clear nodule(s) of heterotopic hippocampal cells in MAM animals presents a unique opportunity to identify and study the function, integration, or development of dysplastic neurons.

For most electrophysiological studies, acute hippocampal slices containing heterotopia are prepared from MAM-exposed rats. To efficiently study the intrinsic and synaptic properties of individual neurons within the regions of heterotopia, an infrared differential interference (IR-DIC) video microscopy set-up is commonly used. However, random sampling of neurons in acute slices using a sharp intracellular electrode filled with biocytin (and post hoc analysis of filled neurons) is also possible. Histopathological features of the malformed hippocampus have largely been studied using conventional single- and double-label immunohistochemical protocols. Tract tracing studies have been performed using in vivo injections of biotinylated dextran amine. Analysis of seizure threshold has largely relied on behavioral observation following acute administration of a convulsant (flurothyl, kainic acid, pentylenetetrazole, or kindling) and, in some cases, video-encephalographic (EEG) recording (**Fig. 1(c)**).

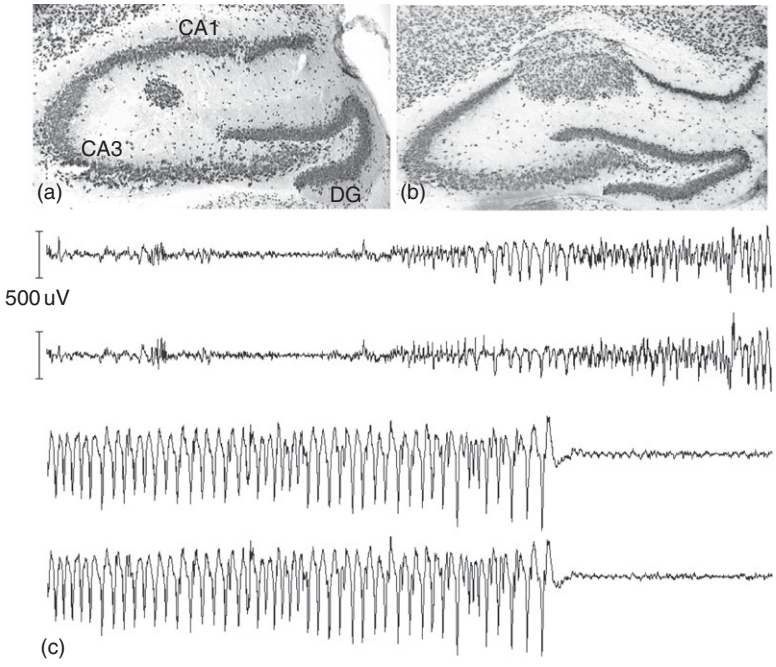

Figure 1 NeuN antibody staining to identify neuronal disorganization in the hippocampus of young adult rats exposed to methylazoxymethanol (MAM) in utero. A small nodule of pyramidal neurons in stratum lacunosum is shown in (a) and a larger cluster of heterotopic neurons disrupting stratum pyramidale (CA1) is shown in (b). Spontaneous seizure episode recorded from an MAM-exposed rat (c).

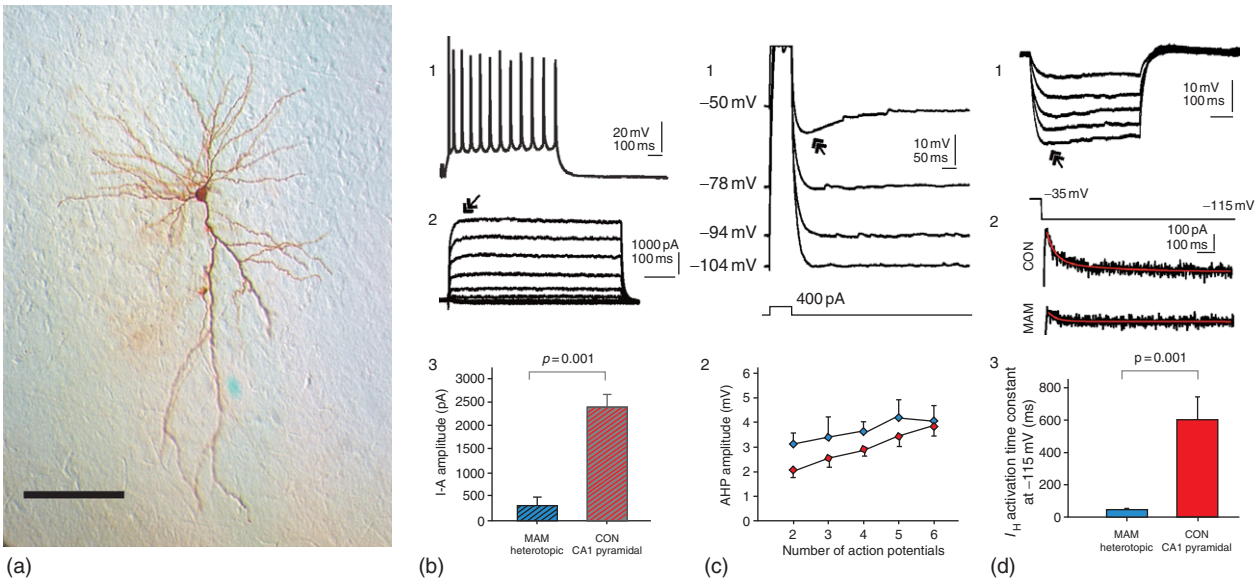

Figure 2 Representative biocytin-filled heterotopic neuron recorded under infrared differential interference (IR-DIC) visualization (a). A current-clamp recording from an identified heterotopic neuron showing increased firing activity (b1); a voltage-clamp recording showing a lack of fast A-type potassium current (arrowhead) is shown for a second heterotopic neuron (b2). A plot comparing the peak amplitude of A-type current for heterotopic ($n = 23$; blue bar) and age-matched normotopic CA1 pyramidal neurons ($n = 17$; red bar) (b3). A current-clamp recording showing spike-train elicited afterhyperpolarizations (AHP, arrowhead) at various holding potentials for a heterotopic neuron. Note the relative absence of an AHP current at more hyperpolarized potentials (c1). A plot comparing peak AHP amplitude following generation of increasing numbers of action potentials for heterotopic ($n = 12$; blue diamonds) and normotopic ($n = 8$; red diamonds) neurons. A current-clamp recording showing membrane sag (arrowhead) at hyperpolarizing step potentials for a heterotopic neuron. Note the relatively small sag current (d1). Voltage-clamp recordings of I_H and a fit of the activation time constant (red line) for age-matched heterotopic (MAM) and normotopic (CON) neurons (d2). A plot of the activation time constant for I_H measured at a step to −115 mV for heterotopic ($n = 7$; blue bar) and normotopic ($n = 7$; red bar) neurons (d3).

Recent Results

Abnormal clusters of pyramidal neurons (heterotopia; Figure 1(a) and 1(b)) first appear postnatally in the hippocampus of rats exposed to MAM in utero. Studying the evolution of hippocampal heterotopia, we noted that disruptions in the development of the embryonic neocortex contribute to this process. For example, marginal zone thickness and an increase in the density of reelin-positive Cajal-Retzius cells within the MZ (and in deeper areas) were observed 24–48 h after embryonic MAM exposure. Interestingly, these defects were associated with decreased chemokine stromal-derived factor-1 (SDF1) expression, and could be 'rescued' in vitro by the addition of this diffusible factor to the culture medium. Increased numbers of reelin-positive cells have also been reported in the tissue from patients with focal cortical dysplasia and cerebral microdysgenesis. Embryonic disruption of radial glial scaffolding noted in MAM-exposed rats (and ferrets) is another mechanism quite likely to contribute to loss of lamination and abnormal cell clustering observed in adult MAM rats. These results suggest that the MAM model may provide valuable insights to the etiology of clinical neuronal migration disorders.

By using in vitro and in vivo manipulations, abnormal clusters of hippocampal pyramidal neurons have consistently been shown to contribute to a hyperexcitable and proepileptic circuit. In these studies MAM animals, or hippocampal slices prepared from these rats, exhibit robust epileptiform activity following exposure to common convulsant manipulations. In nearly all cases, the activity was (1) easier to generate and/or (2) more robust when hippocampal heterotopia was present. Recent in vivo hippocampal recordings showed that afferent activation results in long-latency epileptiform afterdischarge in MAM rats but not in controls; similar results were reported in vitro. Despite these findings, obtained in several different laboratories and using a variety of manipulations, clear evidence for spontaneous seizures has been lacking. Similar to many new animal models of epilepsy, this putative deficiency is probably related more to a lack of good long-term video-EEG monitoring than to the absence of seizure-like activity. We recently addressed this problem in a relatively small sample of adult MAM rats ($n = 11$). Electrographic seizures were observed in two animals (Figure 1(c)). Seizures, classified as Level 3 on the Racine scale, were characterized by a sudden arrest in movement, face twitching, rearing, loss of posture, and hindlimb clonus.

Given the presence of identifiable clusters of dysplastic neurons and convergent evidence indicating hyperexcitability associated with these malformations, the MAM model emerges as a reasonable choice to study seizure generation in a malformed brain. This question is best addressed by considering (1) the intrinsic properties of dysplastic neurons and (2) synaptic communication among dysplastic neurons. Early studies indicated that heterotopic hippocampal neurons display bursts of action potentials in response to intracellular current injection. These findings led to a hypothesis that ion channels mediating these membrane properties were altered in the MAM model. In a series of voltage- and current-clamp studies on visually identified hippocampal heterotopic neurons (**Figure 2(a)**), we uncovered three different aspects of ion channel function that appear abnormal in the context of normotopically placed CA1 pyramidal neurons. First, a fast transient A-type potassium current thought to regulate the processing of synaptic inputs, the amplitude of back propagating action potentials, and action potential firing properties at the soma was nominal or nonexistent in these neurons (**Figure 2(b)**). This reduction in A-type current was associated with markedly reduced expression of Kv4.2 (*Shal*) potassium channel subunits in these neurons. Interestingly, reduced Kv4.2 function was later reported in a rodent model of TLE, and a channel truncation was identified in a patient with TLE, further implicating this current in an epileptogenic process. Second, a Ca^{2+}-activated potassium current responsible for hyperpolarizing the membrane after action potential firing (e.g., afterhyperpolarization, AHP) was found to be diminished in heterotopic neurons (**Figure 2(c)**). AHP currents are thought to play a critical role in preventing abnormal burst firing, and the presence of a robust AHP current can reduce epileptiform discharge. Third, a voltage 'sag' mediated by noninactivating depolarizing current activated upon membrane hyperpolarization (e.g., I_H) is markedly decreased in heterotopic neurons (**Figure 2(d)**). Similar to observations after perinatal seizure-inducing hypoxia and a mouse model of febrile seizures, it is likely that decreased I_H promotes epileptogenesis. Although several hyperexcitable and proepileptic alterations in the membrane properties of heterotopic neurons have been noted, defects in ion channel function for these cells are not global as we could find no evidence for changes in properties related to calcium or sodium channels.

Neurons communicate primarily via glutamate-mediated excitation and GABA-mediated inhibition. Given the severe disorganization of the canonical hippocampal trisynaptic circuit observed in MAM rats, changes in synaptic function are likely. Examination of excitatory neurotransmission in heterotopic hippocampi revealed a low threshold for the generation of abnormal discharge. Using a stimulating electrode or focal glutamate application, heterotopic neurons exhibited a prolonged depolarization with multiple action potentials in current-clamp mode (**Figure 3(a)**) or burst-like excitatory postsynaptic currents in voltage-clamp mode. These responses were blocked by D-2-amino-5-phosphonovaleric acid (D-APV), indicating a role for NMDA-type glutamate receptors. Although we could find no evidence for altered NMDA receptor subunit expression in immunohistochemical studies, single-cell electrophysiology recordings suggest an enhancement of the late NMDA-mediated evoked excitatory postsynaptic current (EPSC) component and reduced sensitivity to ifenprodil (an NR2B subunit antagonist). In contrast, voltage-clamp recordings and focal GABA application did not reveal gross changes in the properties of GABA-mediated synaptic inhibition. However, analysis of inhibitory postsynaptic currents (IPSCs) onto heterotopic neurons revealed a decrease in inhibitory tone consistent with hyperexcitability. We also uncovered a potentially compensatory prolongation of GABA-mediated currents linked to a reduction in GABA reuptake and diffuse expression of the hippocampal GABA transporters, GAT-1 and GAT-3, within the regions of malformation. These inhibitory changes and alterations in GAT expression were confirmed in tissue samples obtained from young adult epilepsy patients undergoing surgery for focal cortical dysplasia. Taken together, these results suggest that synaptic communication is disrupted in the hippocampal formation of rats featuring abnormal clusters of pyramidal neurons.

An additional observation from immunohistochemical studies was a profound reduction in GluR1 expression in and around hippocampal heterotopia. Reduced expression of this alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptor subunit was observed as early as postnatal day 7 and persisted into adulthood. Because GluR1 subunits are essential to the extrasynaptic population of AMPA receptors and could play a critical role in synaptic plasticity, we performed slice electrophysiology studies to analyze long-term potentiation (LTP) in regions of heterotopia. Typical 100-Hz stimulation produced a strong several-fold increase in synaptic response recorded from normotopic CA1 pyramidal neurons, which decays within the next few minutes to a stable enhancement of synaptic transmission, i.e., LTP (**Figure 3(c)**). In contrast, the same stimulation protocol failed to induce LTP in any of the hippocampal heterotopic neurons tested. These findings are consistent with clinical observation of cognitive deficit associated with MCD and recent behavioral studies suggesting working memory deficits in MAM-exposed rats.

Future Directions

A major challenge in understanding epilepsy syndromes associated with MCD is to identify unifying principles of

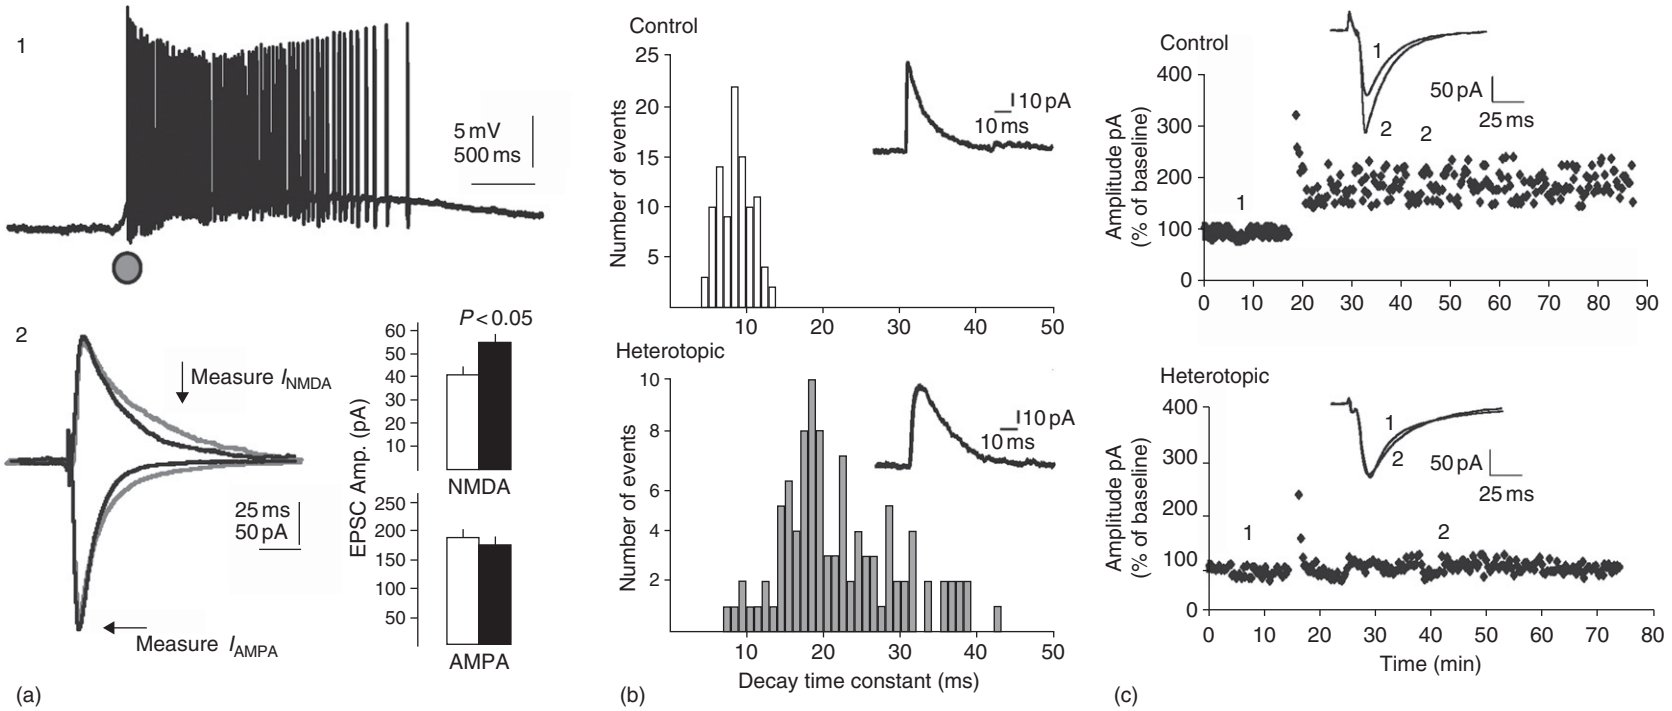

Figure 3 A current-clamp recording from an identified heterotopic neuron showing burst activity in response to focal glutamate application (circle) (a1). Two sets of overlayed evoked EPSCs obtained from normotopic (black traces) and heterotopic (gray) neurons held at −70 mV (to measure I_{NMDA}) and +40 mV (to measure I_{AMPA}) (a2). Plots comparing NMDA and AMPA current components for normotopic ($n = 60$; white bar) and heterotopic ($n = 90$; black) neurons. Representative inhibitory postsynaptic current (IPSC) decay time constant histograms and individual IPSCs (insets) for a normotopic (control CA1) and heterotopic neuron. Note the shift toward longer decay times (b). Absence of LTP onto heterotopic synapses in age-matched recordings (insets) of evoked EPSCs on a heterotopic and normotopic neuron following 100-Hz stimulation (c). Note the enhancement of evoked synaptic activity in control slices.

how seizures are generated in these pathological conditions. From acquired and genetic insults there exists a wide spectrum of MCDs. Although structurally diverse the mechanisms by which abnormal clusters of neurons generate seizure discharge may be similar. From MAM studies, we can predict several defects that directly influence excitability, e.g., loss of A-type potassium current, altered NMDA receptor function, and changes in GABA-mediated inhibition. Whether these defects are specific for this animal model, or universal to all MCD, remains to be systematically evaluated. Should unifying principles emerge from this line of investigation, then appropriate therapeutic treatments targeted to this form of epilepsy can be developed. If not, it is quite likely that each malformation subsyndrome will require individual analysis and syndrome-specific therapy. Animal models mimicking these various forms of MCD epilepsies would be an appropriate starting point for both types of research.

As regards treatment of intractable epilepsies associated with MCD, the MAM model may provide a few starting points. One can imagine designing a viral vector incorporating Kv4.2 potassium channel subunits and then targeting this vector for infection of hippocampal heterotopic neurons. This form of targeted 'gene therapy' would replace a channel shown to be lacking in these cells and could directly lead to restoration of heterotopic cell firing to 'normal' levels. If reduced A-current was a precipitating factor in the reduced seizure thresholds observed in MAM rats, then viral expression of this subunit would 'rescue' this phenotype. Similarly, the MAM model, similar to any rodent model of a human neurological disorder, could also be used for drug screening strategies. In vitro and in vivo testing of conventional antiepileptic drugs indicated that MAM rats, similar to clinical MCD disorders, are resistant to a range of standard antiepileptic drugs. As such, an anticonvulsant drug screening approach utilizing this model could uncover novel compounds effective against epilepsy syndromes associated with brain malformation.

Quantitative and Qualitative Changes of Action of Antiepileptic Drugs in Developing Experimental Animals

P Mareš, Academy of Sciences of the Czech Republic, Prague, Czech Republic

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Approximately 50% of epilepsies start at infancy or childhood. These epilepsies are treated with antiepileptic drugs. Most often, these drugs have been tested preclinically in adult laboratory animals and clinically in trials in adult patients. New antiepileptic drugs (AEDs) are, when first introduced, used for patients older than 12 years. However, after clinicians have some experience with these drugs, they are often introduced into pediatric epileptology by a 'trial-and-error' method. This approach works with many but not all drugs. Therefore, it is important for laboratories to study the action of anticonvulsant drugs (not only of new AEDs but also of those already used in patients) in the immature laboratory animal models.

Background: Mechanisms of Action of AEDs

Many AEDs possess more than one mechanism of action. For example, phenytoin, one of the most frequently studied drugs in the past, exhibits 11 possible actions which might play a role in its anticonvulsant effects. Therefore, the following discussion reflects a considerable oversimplication, but is designed to focus on the main/most important mechanisms of action relevant to seizure activity.

Of the AEDs in current use, there are two primary mechanisms of action: (1) Effects on ion channels and (2) Effects on neurotransmitter systems (mostly on receptors). With respect to the ion channel effects, use-dependent block of voltage-gated sodium channels has been described as a mechanism of action of phenytoin, carbamazepine, oxcarbazepine, lamotrigine, valproate, and zonisamide. Effects on calcium channels have also been described for phenytoin and carbamazepine, and a positive effect on potassium channels for retigabine. Ethosuximide, and to a lesser extent valproate and zonisamide, have specific effects on T-type calcium channels important for generation of the spike-and-wave EEG rhythm.

With respect to effects on neurotransmitter systems, the most common target has been the GABAergic inhibitory system. Potentiation of its action represents the main mechanism of action of phenobarbital, valproate, benzodiazepines, tiagabine, and vigabatrin. In the case of the last three drugs, the drug's effect on GABAergic inhibition represents the only documented mechanism of anticonvulsant action. Drug effects to suppress excitatory neurotransmission has been compromised by serious, unwanted side effects of excitatory amino acid receptor antagonists; therefore, if this action is possessed by an AED, it does not represent the drug's main mechanism of action. Antagonism of the glutamatergic system has been described for topiramate (antagonism of kainate type of glutamate receptors), felbamate (effect on *N*-methyl-D-aspartate receptors), and (perhaps questionably) lamotrigine (decrease of glutamate release).

Some of the newer 'third-generation' AEDs exhibit completely different mechanisms of action – for example, regulation of release of transmitters from presynaptic endings (e.g., levetiracetam's effect on SV2A protein, gabapentin, and pregabalin effects on a subunit of calcium channels).

Methods: Pentylenetetrazol-Induced Motor Seizures in Rats

To assess drug effects in immature animals, we have developed a useful and relatively simple approach. We first elicit convulsions with pentylenetetrazol in four age groups of immature rats and a group of adult animals. Age groups were initially selected according to comparative data on brain development: 7-day-old rats correspond to human premature newborns, 12-day rats correspond to the early postnatal stage, and 18- and 25-day-old rats approximate to late preschool and school-age children, respectively. The subcutaneously administered dose of pentylenetetrazol (100 mg kg^{-1}) is able to induce two different types of seizures in adult rats – a 'minimal' response consisting predominantly of clonic seizures (the minimal Metrazol seizures described in the old literature), and after a longer latency, generalized tonic-clonic seizures. The same pattern is found for 25- and 18-day-old rats. Pentylenetetrazol does not elicit minimal seizures but only GTCS in the two youngest groups.

Results

Action of AEDs on PTZ-Induced Convulsions

AEDs can be divided into four groups according to their action in adult rats: (1) drugs suppressing both minimal

clonic and GTCS; (2) drugs suppressing only GTCS; (3) drugs specifically suppressing the tonic phase of GTCS; and (4) drugs without a reliable effect in this PTZ model. The first group is typically represented by antiepileptics acting through potentiation of GABAergic inhibition: phenobarbital; the benzodiazepines clonazepam, midazolam, clobazam, bretazenil, and flumazenil (a benzodiazepine receptor antagonist with mixed agonist properties); tiagabine; and valproate. In addition, a drug with a different mechanism of action; ethosuximide – also suppresses both minimal and generalized seizures. Nearly all these drugs suppress GTCS at low dose, and only when the higher dose is administered abolish minimal clonic seizures. An exception is tiagabine and another GABA reuptake blocker, NNC-711, which are more active against minimal clonic seizures than against generalized tonic-clonic ones. The second group is represented by primidone (effects examined shortly after administration when conversion to phenobarbital does not play a role), vigabatrin, felbamate, and progabide, which were found to suppress GTCS but left minimal clonic seizures intact. This effect is also characteristic for antagonists of *N*-methyl-D-aspartate type of glutamate receptors. The third group consists of phenytoin, carbamazepine, oxcarbazepine, hydroxycarbamazepine, lamotrigine, topiramate, felbamate, and gabapentin. The sole member of the fourth group is levetiracetam, which is inactive against PTZ-induced convulsions.

The action of AEDs in immature rats is summarized in Table 1.

All the drugs of the first group except tiagabine suppress GTCS in all age groups; tiagabine has an irregular action – suppression of GTCS in 7- and 25-day-old rats, but suppression only of the tonic phase of GTCS in the other two age groups (12 and 18 days). Minimal clonic seizures are invariably suppressed in both 18- and 25-day-old rats by all drugs in this group. Pretreatment with some of these drugs leads, paradoxically, to an appearance of minimal seizures in 7- and 12-day-old animals; this effect is common with phenobarbital and with low doses of bretazenil and flumazenil.

The second group exhibits more variable effects in immature animals. Primidone and progabide are without effect on GTCS in 25-day-old rats; primidone suppresses GTCS in the three younger age groups, whereas progabide is effective only against the tonic phase. Specific suppression of the tonic phase of GTCS is also exhibited by felbamate in all studied age groups. Vigabatrin suppresses the tonic phase in all but 7-day-old rats, in which GTCS are completely abolished. With respect to minimal seizures, only high doses of felbamate are able to suppress them in 18-day-old rats; other drugs are without effect in both 18- and 25-day-old animals. Primidone administration in 7- and 12-day-old rats results in an appearance of minimal seizures.

AEDs of the third group abolish the tonic phase of GTCS in all age groups. The exceptions are carbamazepine and oxcarbazepine, which suppress GTCS as a whole in 7- and 12-day-old rat pups, and topiramate, which abolishes the tonic phase of GTCS in 7-day-old animals only. Minimal seizures are left untouched by lamotrigine and topiramate, and suppressed in 18-but not in 25-day-old rats by gabapentin. Carbamazepine pretreatment induces minimal seizures in 7- and 12-day-old rat pups; phenytoin does not have this action in the two youngest groups, but it markedly potentiates these seizures in 18-as well as 25-day-old rats. The potentiation is so marked that it is possible to speak about the 'status' of minimal seizures.

Table 1 Effects of antiepileptic drugs in developing rats

Seizure type	*Generalized tonic-clonic seizures*				*Minimal clonic seizures*			
Age (postnatal day)	P7	P12	P18	P25	P7	P12	P18	P25
Phenobarbital	↓	↓	↓	↓	↑	↑	↓	↓
Primidone	↓	↓	↓	0	↑	↑	0	0
Valproate	↓	↓	↓	↓	0	0	↓	↓
Clonazepam	↓	↓	↓	↓	0	0	↓	↓
Clobazam	↓	↓	↓	↓	0	0	↓	↓
Midazolam	↓	↓	↓	↓	0	0	↓	↓
Bretazenil	↓	↓	↓	↓	↑	↑	↓	↓
Flumazenil	↓	↓	↓	↓	↑	↑	↓	↓
Tiagabine	↓	↓T	↓T	↓	0	0	↓	↓
Vigabatrin	↓	↓T	↓T	↓T	↓	↓	0/↑	0/↑
Felbamate	↓T	↓T	↓T	↓T	0	0	↓	0
Progabide	↓T	↓T	↓T	↓	0	0	0	0/↑
Carbamazepine	↓	↓	↓T	↓T	↑	↑	0	0
Oxcarbazepine	↓	↓	↓T	↓T	0	0	0	0
HydroxyCBZ	↓T	↓T	↓T	↓T	0	0	0	0
Phenytoin	↓T	↓T	↓T	↓T	0	0	mMS status	mMS status
Lamotrigine	↓T	↓T	↓T	↓T	0	0	0	0
Etosuximide	↓	↓	↓	↓	0	0	↓	↓
Topiramate	↓	↓T	↓T	↓T	0	0	0	0
Gabapentin	↓T	↓T	↓T	↓T	0	0	↓	0

There are no data on possible actions of levetiracetam in immature animals; it has not been tested in this context because of its inactivity against pentylenetetrazol-induced convulsions in adult rodents.

Summarizing the action of AEDs in immature rats it is necessary to conclude that the action is quite variable – both quantitative and qualitative changes are possible.

Quantitative Changes of Anticonvulsant Action

There are old data on hexobarbital and phenobarbital action against pentylenetetrazol-induced seizures, demonstrating only quantitative changes of their action. These barbiturates are more potent in immature rodents, not only in their anticonvulsant action but also in their effects on sleep time. Similar effects were demonstrated for the anticonvulsant action of benzodiazepines. A common finding is that there is a longer duration of action (e.g., as seen with benzodiazepines) in 12-day-old rats than in older animals, probably due to an immaturity of catabolic enzymes and possibly other factors playing a role in the elimination of AEDs.

Qualitative Changes of Action

With respect to minimal clonic seizures, the most marked qualitative change is the appearance of minimal clonic seizures in 7- and 12-day-old rat pups; that is, in age groups where pentylenetetrazol is unable to elicit minimal seizures under control conditions. This effect is exhibited by AEDs classified in all three groups (based on their activities in adult rats). The generator of minimal clonic seizures is localized in the basal forebrain, and can be activated by other convulsant drugs (e.g., bicuculline or isonicotinehydrazide) even at very early stages of postnatal life. The mechanisms by which some AEDs (with various mechanisms of action, including potentiation of GABAergic inhibition, and effects on voltage-gated sodium channels) permit pentylenetetrazol to activate the generator of minimal seizures remain to be studied. Marked potentiation of minimal seizures by phenytoin, leading to nearly continuous seizures, is another phenomenon to be explained, as is the difference of effects of felbamate and gabapentin between 18- and 25-day-old rats.

Effects on GTCS appear to be less variable than those on minimal seizures. The relatively common qualitative difference between adult and immature rats is suppression of GTCS in the youngest animals, replaced during development by a specific action against the tonic phase. A lack of effect of primidone and progabide in 25-day-old rats, in contrast to their efficacy in adult as well as younger rats, is still to be explained. The effect may be related to the action of the drug on $GABA_B$ receptors in the case of progabide, but such a mechanism has not been demonstrated for primidone.

Future Directions

Data on the action of AEDs in the model of pentylenetetrazol-induced convulsions in the developing rats do not present a simple picture and indeed give rise to many more new questions than answers. At present, it is impossible to predict the efficacy of AEDs in pediatric neurology from preclinical experiments or from clinical data in mature brain. Even drugs with similar primary mechanisms of action can exhibit different effects in immature laboratory animals (e.g., appearance of minimal clonic seizures in 7- and 12-day-old rats after some, but not all, benzodiazepines). More studies are necessary to elucidate the age-related changes in anticonvulsant action, even in the present model. To predict clinical efficacy of a given drug at a given age, more models must be examined, including a model of complex partial seizures (e.g., hippocampal afterdischarges) and a model of absence seizures (e.g., pharmacologically induced spike-and-wave episodes). All these models give information about anticonvulsant, but unfortunately not about the antiepileptic action of these drugs. To study this antiepileptic phenomena, it is essential to examine drug effects in chronic models of epilepsy.

Seizure-Induced Injury and the Two-Hit Hypothesis

A J Cole, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Repeated or prolonged seizures may result in a striking behavioral syndrome comprised of cognitive decline and selective impairment of declarative memory. This consequence of seizures is a major cause of long-term morbidity in patients with epilepsy and in patients with prolonged or repeated convulsions that occur in the setting of metabolic disturbance. Elegant neuropsychological studies have implicated the hippocampus and related structures in the pathophysiology of this acquired behavioral disorder. Human neuropathological studies and examination of animal models of epilepsy have repeatedly demonstrated evidence of selective neuronal vulnerability in hippocampus and other limbic structures after seizures. Clinical and experimental studies suggest that seizure-induced neuronal injury may lead to altered network properties and the establishment of a chronic epileptic condition. The molecular and biochemical mechanisms of neuronal injury following seizures, and the precise relationship between seizure-induced neuronal injury and subsequent recurrent seizures, remain unclear.

Background

Seizure-Induced Neuronal Injury is Anatomically Selective

An important feature of seizure-induced neuronal injury is its striking anatomic selectivity. Clinical studies have shown that pyramidal cells of the CA1 and CA3 hippocampal regions, as well as hilar neurons, are selectively vulnerable; in contrast CA2, subiculum, and certain peptidergic classes of interneurons are relatively resistant to injury. Dentate granule cells, once thought to be resistant to seizure-induced injury, have more recently been shown to be at least partially vulnerable. Animal models have been variably successful in recapitulating these findings. For example, KA-induced seizures result in injury in CA1 and CA3, but do not appear to affect granule cells, whereas pilocarpine-induced seizures or chronic perforant path stimulation clearly result in both the injury of the Cornu Ammonis and granule cell loss.

Vulnerability to Seizure-Induced Injury is Age-Dependent

Another key characteristic of seizure-induced neuronal injury is its striking age-dependence. Young children and immature rodents (<P21, postnatal day 21), while highly susceptible to seizures, are largely resistant to seizure-induced neuronal injury. While the precise mechanism of age-dependent resistance to injury remains unclear, it is likely that several characteristics of the developing nervous system contribute to it. Maturation of the nervous system involves a series of steps that occur postnatally in the rodent. Neurogenesis is followed by the development of dendrites – a process that peaks at about P15 – and then the elaboration of dendritic spines – which peaks at about P20. Interestingly, it is the appearance of spines that seems to correlate most closely with the development of vulnerability to seizure-induced neuronal injury. All these developmental structural events take place in a changing neurochemical milieu. For example, neurotrophic factors and their receptors, particularly NGF, reach their maximum levels at P15. Subsequent decreases in NGF levels parallel the decline in synapse number that is thought to be mediated by activity-dependent processes. These observations suggest three distinct hypothetical mechanisms that could mediate early-life resistance to activity-dependent neuronal injury: (1) neurons may be protected by an immature dendritic arbor lacking spines; (2) they may be protected by an excess of synapses and arbors; and finally (3) they may be protected by an endogenously generated abundance of trophic or protective factors. In preliminary studies, we have found evidence that the latter mechanism is, at the very least, an important contributor. Another important possibility is that during development, neurons are protected against seizure-induced cell death by a failure of activation, transduction, or execution of cell death programs. As apoptosis is a ubiquitous and normal phenomenon in the CNS during early post-natal life, it is unlikely that the required molecular elements are absent. Rather, we have hypothesized that seizures in the immature brain are either incapable of or inadequate to activate existing apoptotic pathways. Our preliminary observation that seizures lead to an increased abundance of the pro-enzyme procaspase-3, but not its active cleavage product caspase-3, supports this hypothesis.

Methods

Sprague-Dawley rats were designated; K (Kainate (KA) on P15 only), SS (saline on P15 and P45), SK (saline on P15 and KA on P45), KS (KA on P15 and saline on P45), and KK (KA on P15 and P45). On P15, 5–8 rats from each litter were treated with KA (5 mg/kg intraperitoneally

[ip] in phosphate-buffered saline [PBS], pH 7.4). Littermate controls received equal ip volumes of PBS. On P45, animals in the SK and KK groups received KA (15 mg/kg ip), whereas animals in the SS and KS groups received equal volumes of PBS (200–250 mL i.p.). Age-specific doses of KA used in the present study were previously determined to result in 25–40% mortality while inducing seizures in over 60% of animals. On P50, all surviving animals began testing in a modified Morris water maze. Animals were killed on P55 by transcardiac perfusion and brains were processed for histology and for DNA fragmentation assayed by in situ nick translation. We have previously shown that seizure-induced DNA fragmentation is maximal by 48–72 h and remains detectable for 10 days after KA-induced seizures.

Behavioral Observation and Seizure Grading

After KA injections, animals were closely observed and their behavior was recorded for 6 h, as previously described. Latency to the first clinical manifestation of seizure activity was recorded. A seizure severity grade was assigned based on the maximal response achieved, on a scale from 0 to IV as follows: 0, no response; I, wet dog shake (WDS) and/or behavioral arrest; II, WDS, staring, pawing, and clonic jerks; III, WDS, staring, pawing, clonic jerks, rearing, and falling; and IV, continuous grade III seizures for longer than 30 min (status epilepticus).

Behavioral Testing

A modified Morris water maze was used to assess visuospatial learning and memory. A circular steel tank (117 cm diameter) was filled with water to a depth of 25 cm. The water was made opaque by an addition of 100 mL of evaporated milk. On day 1, each rat was placed in the pool for 60 s with no platform present for a "free swim." On days 2–5, rats were trained for 24 trials, 6 trials per day, to locate and escape onto a plexiglass platform (8 × 8 cm) placed 1.5 cm under the water surface. For each rat, while the quadrant in which the platform was located remained constant, the point of immersion into the pool varied in a quasi-random order for the 24 trials. The latency from immersion into the pool to escape onto the platform was recorded.

Detection of DNA Fragmentation by in situ Nick Translation Histochemistry

Animals were killed by transcardiac perfusion with 50 mL of PBS followed by 200 mL of ice-cold 4% paraformaldehyde. Brains were removed, postfixed, and then cryoprotected in 20% sucrose overnight. Fifty-micrometer horizontal sections were cut and processed for in situ nick translation to detect fragmented DNA. Adjacent sections from each animal were stained with cresyl violet to allow assessment of neuronal loss.

Cell Counts

To quantify DNA fragmentation, sections were analyzed by light microscopy using a grid reticule. Counts of positively stained cells in each hippocampal subfield (hilus, CA4, CA3, and CA1) were made from both right and left hippocampii and averaged. A total of 204 hippocampal sections were analyzed from 34 animals (three sections per animal, two hippocampi per section).

Recent Results

Early-Life Seizures Increase Vulnerability to Later Life Seizure-Induced Injury

Considerable evidence suggests that seizures occurring in the immature brain, while not resulting in overt injury, nonetheless, result in a long term change in the nervous system that renders the animal more susceptible to seizure-induced neuronal injury, with associated behavioral deficits, later in life. We have shown that kainic acid (KA)-induced seizures on P15 result in neither immediate (48 h) nor delayed (35 days later, on P50) detectable injury. Animals subjected to KA on P15, however, showed potentiated behavioral (convulsive) responses to KA when re-challenged on P45. Furthermore, these animals showed enhanced cellular injury and striking behavioral abnormalities compared to naïve controls and to animals treated with KA only on P15 or P45.

Similar findings have been reported from other groups using a variety of models. For example, Holmes and colleagues showed that flurothyl seizures early in life potentiated the effects of pilocarpine, KA, and kindling later in life. Baram and colleagues showed that hyperthermic seizures induced on P10–P12 had a similar result. Jensen and colleagues have shown that hypoxia-induced seizures on P10 increase susceptibility to spontaneous and kainate-induced seizures later in life. We have referred to this phenomenon as the "two-hit phenomenon," but perhaps a more descriptive term is that events occurring early in life "prime" the central nervous system, making it especially susceptible to later insults. Notably, the first "hit" need not be epileptic. Previous studies have shown that in rats with a toxin-induced neuronal migration defect, hyperthermia may result in hippocampal injury independent of seizures. Moreover, animals with neuronal migration defects are more susceptible to kainate and kindling, while immature and also as adults. Together with our investigations, these studies suggest that a variety of insults (including but not limited to seizures) during development can increase the susceptibility to seizures in adults and enhance their injurious effect. Of note, some researchers have described a protective effect of mild seizure activity with respect to subsequent seizure-induced injury. It is possible that the severity of the initial

event is critical in determining whether it protects against or predisposes to future injury.

The Mechanism of the Two-Hit Phenomenon is Unknown

The two-hit phenomenon implies that a mechanism exists to transduce brief episodes of paroxysmal activity into long-lasting changes in excitability. Potential underlying mechanisms include, but are not limited to, long-lasting changes in connectivity, cellular phenotype, receptor phenotype, or biochemical milieu – each induced by the early-life event and persisting into adulthood.

In our studies, the detrimental long-term pathologic and behavioral consequences of early KA seizures became evident only when the animals were subjected to another insult later in life. This observation highlights the possibility that early KA seizures alter neuronal connectivity or function, even in the absence of detectable neuronal injury or cell death, in a manner that increases susceptibility to later seizure-induced damage. During normal development, neurons as well as axons and synaptic terminals are overproduced and subsequently eliminated, apparently as a result of a competition between afferents for a limited supply of target-derived substance. In rat CA3 hippocampal pyramidal cells, for example, an exuberant outgrowth of axons takes place by P10, and axon length, number of varicosities, and axon branch points reach up to 225% of mature levels during the second postnatal week. This exaggerated development coincides with the period of enhanced seizure susceptibility. Synaptic activity is critical for the process of refinement of connections between axons and their appropriate targets. It is thus conceivable that a prolonged seizure, via intense synchronized neuronal activation, could have a permanent effect at this critical time of afferent-dependent synaptic remodeling. A precedent for this notion can be found in a study in which continuous infusion of penicillin was used to induce epileptiform activity in the visual cortex of rabbits from P5 through P21. In penicillin-exposed rabbits, visual callosal projections persisted through most of area 17 in a pattern characteristic of neonatal rabbits, rather than being restricted to a narrow zone at the lateral border of area 17 as seen in normal mature animals. These results suggest that epileptic cortical activity stabilized immature callosal projections that are normally eliminated during development. An alternative mechanism has been demonstrated by Jensen and colleagues, who have shown that early life seizures lead to an altered expression of glutamate receptor (GluR2) subunits, resulting in an increased expression of Ca^{2+}-permeable AMPA receptors on hippocampal neurons. In their study, treatment with the AMPA-antagoists NBQX or topiramate reduces or prevents the expression of this two-hit phenomenon.

Endogenous Neuroprotection and the Two Hit Phenomen May Share Common Mechanisms

We have been particularly interested in the hypothesis that early seizures, perhaps by stabilizing immature synaptic connections, result in the persistence of a hyperexcitable neuronal network later in life. Such a process could be the result of paroxysmal seizure-induced trophic factor synthesis occurring in the setting of an already high ambient level of NGF. Numerous studies have demonstrated hat NGF synthesis is increased by seizures, and furthermore that a host of NGF-inducible genes are regulated by seizures in anatomically relevant structures. One might predict that synaptic connectivity would demonstrate increased complexity in this scenario, but evidence to support that notion has not been forthcoming. In fact, Swann and colleagues have shown that under certain circumstances, early seizures appear to result in a simplification of synaptic connectivity with reduced spine number and arborization. It remains unclear just how far this finding can be generalized, and (more importantly) what its effect on subsequent excitability might be. Nonetheless, there is clear evidence that, regardless of its effects on spine complexity, NGF may be protective against seizure-induced neuronal loss and therefore lead to stabilized or persistent neuronal circuits that could mediate the two-hit phenomenon.

To investigate the mechanism of NGF-mediated protection against seizure-induced neuronal injury, we have queried whether the protective effect of NGF is unique or is shared with other neurotrophins. We reasoned that if BDNF and NGF share a neuroprotective property in our models, then that property could not be dependent on specific Trk receptor coupling, but would more likely represent either a pan-Trk effect or a specific effect of NGF mediated through the shared low affinity p^{75ntfr}. In our hands, infusions of BDNF were not protective, nor were bFGF infusions. These results forced us to focus on TrkA or a unique NGF effect mediated through p^{75ntfr}. Because in immunohistochemical studies we could find no significant expression of TrkA (the preferred target for NGF) in adult hippocampus, we chose to focus on the low affinity receptor instead, which is expressed in basal forebrain and in cholinergic terminals projecting to hippocampus.

We initially attempted to test the role of p^{75ntfr} utilizing transgenic mice expressing a defective receptor. Those experiments were unsuccessful for two reasons. First, we had considerable difficulty establishing a breeding program to produce adult animals, mainly due to maternal rejection of the pups. Second, we have found that mice respond to convulsant drugs with an extraordinarily steep dose—response relationship, resulting in either inadequate seizures or early mortality in a high percentage of (often scarce) animals. We, therefore, abandoned these

studies and shifted our attention to animals with an acquired defect in p^{75ntfr}. We chose to by lesion $p^{75ntfr+}$ neurons in immature animals and then looking for a loss of resistance to injury. These studies proved to be fortuitous and dramatic. We found that in animals treated with IgG-192-saporin, a selective immunotoxin that lesions $p^{75ntfr+}$ neurons, an adult pattern of injury resulted from KA-induced seizures on P15. We confirmed that immunotoxin lesions resulted in abolition of $p^{75ntfr+}$ neurons and terminals using both p^{75ntfr} immunohistochemistry and AChE staining. We also saw well preserved cholinergic neurons in these animals in striatum, indicating that the toxin was not lesioning cholinergic neurons indiscriminately. These studies have led us to conclude that high ambient levels of NGF, present during development, serve as an endogenous neuroprotectant.

Conclusions and Directions for Future Research

It will be important to follow up this preliminary observation with two key experiments. First, we must show that NGF levels are indeed high on P15 in our animals. Second, we must go back to the adult animals and show that lesioning $p^{75ntfr+}$-neurons block the neuroprotective effect of NGF against seizure-induced hippocampal injury. If these points can be adequately demonstrated, then we will be in a position to test the hypothesis that the two-hit phenomenon is a maladaptive consequence of an endogenous neuroprotective system mediated by NGF effects on neurons expressing the p^{75ntfr}.

In conclusion, substantial evidence supports the existence of a two-hit phenomenon to which early-life seizures and/or other specific pathological abnormalities confer, and it also supports enhanced susceptibility to later life seizures and their consequences. NGF appears to have an important neuroprotective role, and selective lesions of $p^{75ntfr+}$ neurons confer a unique vulnerability to seizure-induced injury on immature brain. It is tempting to speculate that normal actions of $p^{75ntfr+}$-neurons, perhaps by providing enhanced or persistent direct cholinergic input to the hippocampus, underlie at least part of the two hit phenomenon.

If, in fact, the two-hit hypothesis represents a general mechanism of epileptogenesis, it supports the notion that the development of epilepsy is a multistep processs that occurs in a temporally distributed fashion. If true, it may be possible to intervene at many points during the process of epileptogenesis to effectively prevent the development of the epileptic phenotype. This view of epileptogenesis has obvious ramifications for the development of anti-epileptogenic treatments and the need to treat pre-symptomatic individuals.

Introduction

Marijuana (*Cannabis sativa*) has been used recreationally by human beings for millennia. Historically there also has been interest in possible medicinal or therapeutic applications of *Cannabis*, including its possible effects on seizures in patients with epilepsy. Presumably because it is so widely used and readily available (albeit illegal), *Cannabis* has become an attractive candidate for development as an antiepileptic drug. Anecdotal reports from patients about the effects of *Cannabis* on their epileptic seizures have been mixed: Although some have reported that their seizures are suppressed or 'made better,' others have reported that their seizures become worse. Unfortunately, there have been no publicly accessible controlled laboratory studies of the effects of *Cannabis* or of its major active ingredient, tetrahydrocannabinol (THC), on epileptic activity in humans, although proprietary clinical trials with cannabinoids may be underway. The only controlled study published in any detail examined the effects of a cannabinoid that is supposedly not psychoactive, cannabidiol (CBD), in a group of patients whose epilepsy was resistant to conventional antiepileptic drugs; this study reported that CBD produced significant beneficial effects in a majority of the patients. However, the neural bases of the actions of CBD are unknown, and the observation has apparently not been replicated in the ensuing 27 years. So nearly all of what we know about the potential effects of cannabinoids on seizures has come from studies in animals experiencing various forms of experimentally triggered epileptiform activity.

Background

The availability of pure samples of THC in the 1970s resulted in a spate of studies of the effects of THC and other cannabinoids on seizures in animals. In those studies, researchers triggered convulsions in rats and mice by electroconvulsive shock (ECS) or convulsant drugs, and in epileptic baboons by strobe light; other studies employed the kindling preparation, in which generalized seizures develop gradually in response to intermittent electrical stimulation of forebrain sites. The results were generally disappointing. Although THC exerted anticonvulsant effects against several types of convulsion, these effects were usually at high and toxic doses. THC could delay the progression of kindling, but it was unclear whether this result was due to a genuine prophylactic effect or merely to acute suppression of early-stage seizures. Because of the relatively unimpressive results, and in part because of our lack of knowledge about the biological mechanism of cannabis's actions, research on potential antiepileptic effects had largely ceased by the early 1980s.

Recent Knowledge of Cannabinoid Action

Understanding of the neurobiological basis of cannabis's activity has increased significantly in the past 15 years or so. It is now known that the body contains several different endogenous cannabis-like compounds, the endocannabinoids, which bind to specific receptors. The most thoroughly investigated of the cannabinoid receptors are

the CB1 and CB2 receptors, although other types of CB receptor are probably present. Cloning of CB receptors has led to the development of artificial cannabinoid drugs that either mimic cannabis and activate the receptors (agonists) or bind to the receptors and block the actions of endocannabinoids (antagonists). WIN 55,212-2 and HU210 are examples of potent agonists at CB1 and CB2 receptors, and AM251, AM281, and SR141716A are selective antagonists of CB1 receptors.

One of the important recent discoveries about the action of endocannabinoids in the hippocampus and elsewhere is that they are released from depolarized postsynaptic membranes, and bind in a retrograde fashion with presynaptic CB1 receptors, resulting in decreased release of the neurotransmitter from the presynaptic membrane. Experimentally, endocannabinoids at higher concentrations can suppress release of the excitatory neurotransmitter glutamate; however, much lower concentrations of endocannabinoids suppress release of GABA at inhibitory GABAergic synapses, suggesting that cannabinoid action at inhibitory synapses is more significant functionally. The phenomenon at inhibitory synapses has been referred to as depolarization-induced suppression of inhibition (DSI). When cannabinoids act at CB1 receptors on GABAergic terminals, the consequence of their actions is disinhibition, or increased excitability.

The availability of selective agonists and antagonists for CB receptors has sparked a resurgence of research on the potential antiepileptic effects of cannabinoids. From the forty or so laboratory studies of the effects of synthetic cannabinoids on epileptiform activity published over the last decade, we will focus on experiments from two laboratories that have produced somewhat divergent results. These experiments provide the context for our own research, described subsequently.

A comprehensive series of experiments has recently emerged from De Lorenzo's laboratory at Virginia Commonwealth University, characterizing the effects of cannabinoids on convulsions in several preparations of experimental epilepsy. He and his colleagues have shown that the CB agonist WIN 55,212-1 suppresses convulsions induced by maximal electroshock, as does the endocannabinoid anandamide. These effects are blocked by the antagonist SR141716A, implicating specific action at the CB1 receptor. Furthermore, when administered by itself, the CB antagonist reduces seizure threshold, implicating endocannabinoid tone in the ongoing modulation of seizures. Cannabinoids have similar effects on spontaneous seizures produced by treatment with pilocarpine, and acute pilocarpine-induced seizures are associated with increased concentrations of the endocannabinoid 2-arachidonylglycerol (2AG) and increased expression of the CB1 receptor protein. In another preparation of acquired epilepsy, WIN 55,212-2 abolishes seizure discharge provoked by low Mg^{2+} in primary hippocampal cultures. Because CB antagonists enhance epileptiform activity in cultures treated with low Mg^{2+}, it has been concluded that CB1 receptor-dependent endocannabinoid tone plays an important role in modulating seizures and preventing epileptic status. Collectively these results suggest that endocannabinoids dampen seizure activity, and that cannabinoids might be useful pharmacotherapies in epilepsy.

The results of experiments from Soltesz's laboratory at the University of California, Irvine, with a different preparation of acquired epilepsy, present a somewhat divergent picture. He and his colleagues have found that a single episode of a prolonged febrile convulsion in neonatal rats results in a long-lasting enhancement of cannabinoid-induced suppression of GABA release in the hippocampus – that is, a potentiation of DSI measured at adulthood. The potentiation of endocannabinoid-mediated DSI is associated with increased density of presynaptic CB1 receptors on GABAergic neurons containing cholecystokinin. Thus a sustained epileptiform event early in life results in a persistent proepileptic effect mediated by endocannabinoids. Subsequent research by Soltesz's group has shown that administration of the CB1 antagonist SR141716A during febrile episodes blocks the potentiation of DSI, the upregulation of CB1 receptors, and the enhancement of seizure susceptibility detected later in life. These results are a further demonstration of a long-lasting proepileptic effect established in the hippocampus by the action of endocannabinoids. Note, however, that Soltesz's group observed that, notwithstanding the long-term proepileptic action of endocannabinoids, the CB1 antagonist SR141716A itself produces a proepileptic effect against kainic acid-induced convulsions in neonatal rats, indicative of an acute antiepileptic effect of endocannabinoids. These potentially contradictory results can be reconciled by considering that cannabinoids exert divergent effects over time: The acute or immediate actions of endocannabinoids can be antiepileptic, whereas the chronic or long-term actions of endocannabionids can be proepileptic, presumably as a consequence of the induction of a plastic response such as a long-lasting upregulation of presynaptic CB1 receptors.

Methods

Our own recent research on cannabinoids and seizures was an attempt to extend earlier work on the effects of THC on kindling, a popular preparation of acquired epilepsy. We have been examining the potential antiepileptic effects of the potent and selective CB1/CB2 agonist HU210 and the selective CB1 antagonist AM281 on generalized seizures kindled with stimulation of the

amygdala. The procedure for kindling typically involves application of a 1-s train of electrical stimulation through an implanted electrode once daily until a predetermined endpoint is reached. Standard dependent measures include duration and intensity of the convulsion and duration of the epileptiform afterdischarge (AD) recorded in the EEG. We applied daily kindling stimulation until five generalized stage 5 seizures had been evoked, at which point seizures were well-developed and consistent. We then began drug trials. Rats received intraperitoneal injections of a variety of doses of either HU210 or AM281, at 20 min before each amygdaloid stimulation, one injection daily for 5 consecutive days.

Results

Previous research showed that acute administration of THC produces, at best, weak antiepileptic effects against kindled amygdaloid seizures in rats, cats, and baboons, generally at toxic doses. The same applies to HU210: Figure 1 shows that significant antiepileptic effects occurred only at the highest doses, which were markedly toxic. Furthermore, with chronic administration of HU210, a proepileptic effect emerged at the high doses and even at the more moderate doses (Figure 1). We obtained generally similar results when we examined seizures kindled from the dorsal hippocampus or anterior neocortex in other rats, and with another cannabinoid agonist, WIN 55,212-2. Thus, with clonic forebrain seizures kindled by focal electrical stimulation, we found no evidence of promising antiepileptic effects of cannabinoid agonists, and instead observed a distinct proepileptic effect over time.

We also wanted to determine whether endocannabinoid tone modulates kindled amygdaloid seizures, by examining the effects of a variety of doses of the CB1 antagonist AM281. Figure 2 shows that acute administration of AM281 produced modest, but at some doses significant, proepileptic effects on amygdaloid AD duration, whereas it was without effect on the accompanying behavioral seizures (data not shown). Note that proepileptic effects of the agonist HU210 emerged only with chronic administration, whereas no additional effects were seen with chronic administration of the antagonist (Figure 2). These results are generally consistent with the view that endocannabinoid tone dampens acute susceptibility to kindled seizure

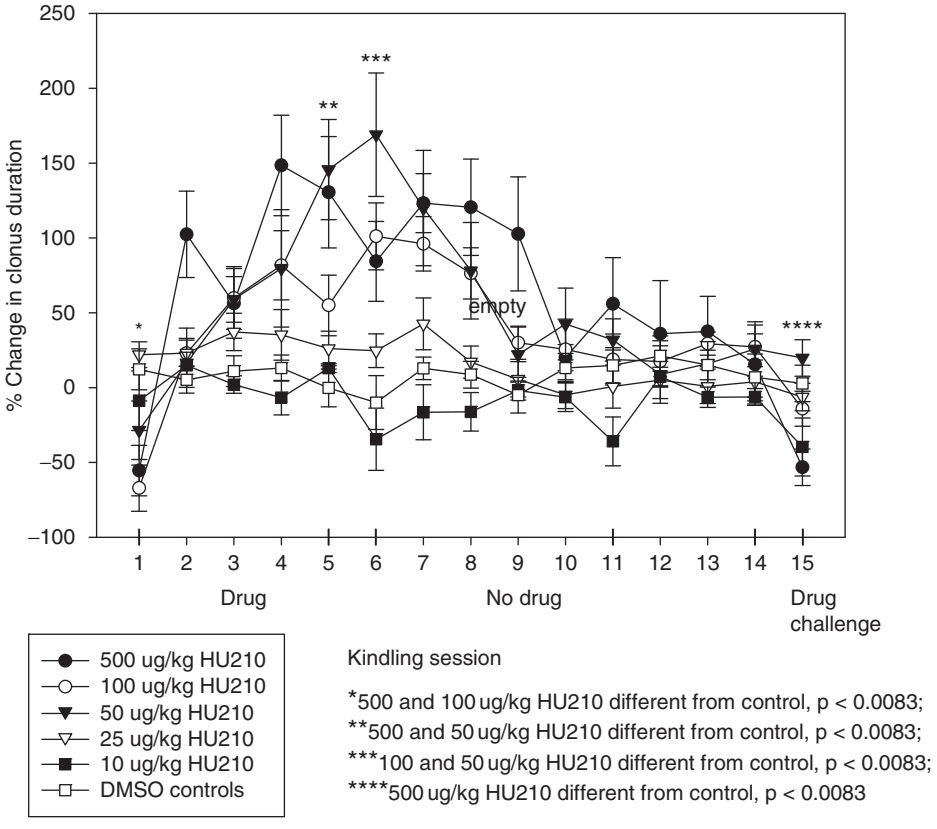

Figure 1 Dose-related effects of acute and chronic administration of the cannabinoid agonist HU210 on kindled generalized seizures, expressed as percentage change in duration of clonus.

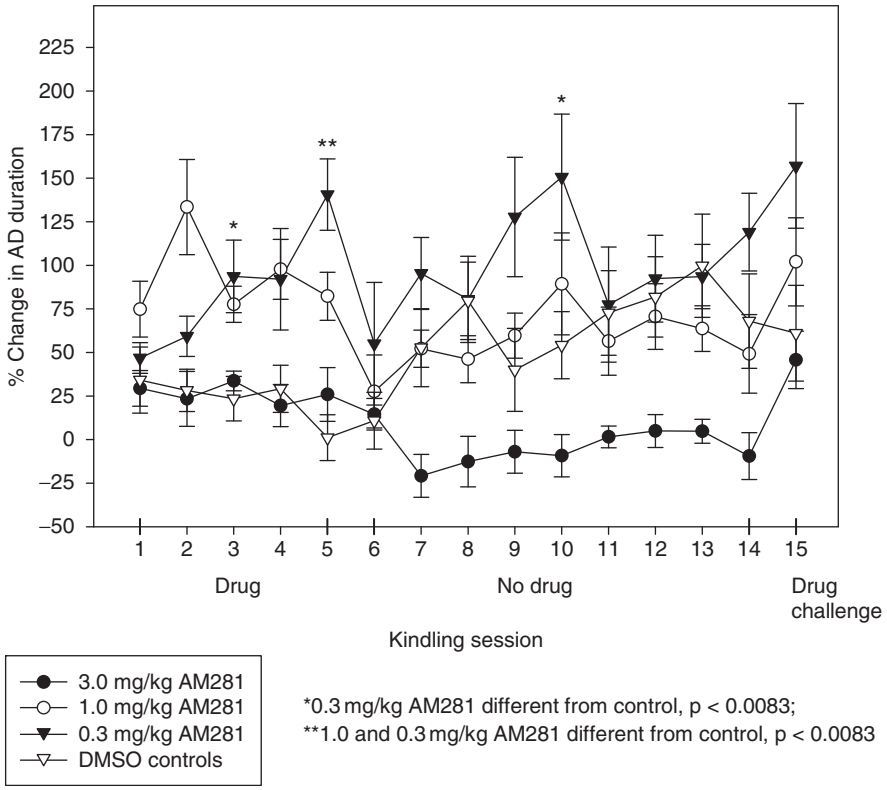

Figure 2 Dose-related effects of acute and chronic administration of the cannabinoid antagonist AM281 on kindled generalized seizures, expressed as percentage change in duration of AD.

discharge, measured electrographically but not behaviorally. In an attempt to determine whether the acute antiepileptic effect of HU210 is due to action at the CB1 receptor, we treated some rats with a cocktail of HU210 and a high dose of AM281 ($3\,mg\,kg^{-1}$) that by itself had no effect on kindled seizures (Figure 2). We found that the antagonist blocked the antiepileptic effect of a high dose of agonist (Figure 3), thereby implicating the CB1 receptor in the acute antiepileptic action of HU210. Surprisingly, however, the antagonist had no effect on the emergence of the proepileptic effect consequent to repeated administration of the agonist. This result suggests that the proepileptic effects of HU210 are produced at a site other than the CB1 receptor.

An important feature of kindling is that one can determine the effects of drug treatment during kindling itself, to test for effects on epileptogenesis. Figure 4(a) shows that amygdaloid kindling was markedly accelerated by treatment with moderate doses of the agonist HU210, whereas Figure 4(b) shows that the antagonist AM281 had no effect on the rate of kindling. Thus chronic administration of a selective cannabinoid agonist potentiates both kindled seizures and epileptogenesis itself.

Our results are generally compatible with Soltesz's findings that a severe febrile episode produces a lasting increase in seizure susceptibility dependent on a proepileptic effect of endocannabinoids. Our data diverge from De Lorenzo's findings that acute administration of cannabinoids suppresses a variety of seizure types. Why do our results point to a proepileptic effect of CB agonists against kindling and kindled seizures, whereas other research points to antiepileptic effects? One possibility is that antiepileptic effects are observed against convulsions induced in the normal brain, whereas proepileptic effects are seen against acquired epilepsies, as in kindling or febrile-induced susceptibility. This explanation is unlikely, however, given that CB agonists exert antiepileptic effects against other models of acquired epilepsy, such as the pilocarpine preparation. Or perhaps cannabinoids suppress tonic (brainstem) seizures but not clonic (forebrain) seizures, such as those triggered by amygdaloid kindling. However, we have determined that the tonic seizures associated with brainstem kindling are unaffected by an injection of HU210, arguing against this explanation.

A third possibility is, as discussed earlier, that acute and chronic administration of cannabinoids evoke different mechanisms. To determine whether the acute–chronic dimension is critical, we have compared the effects of acute and chronic administration of HU210 in rats challenged with a dose of pentylenetetrazol (PTZ) that

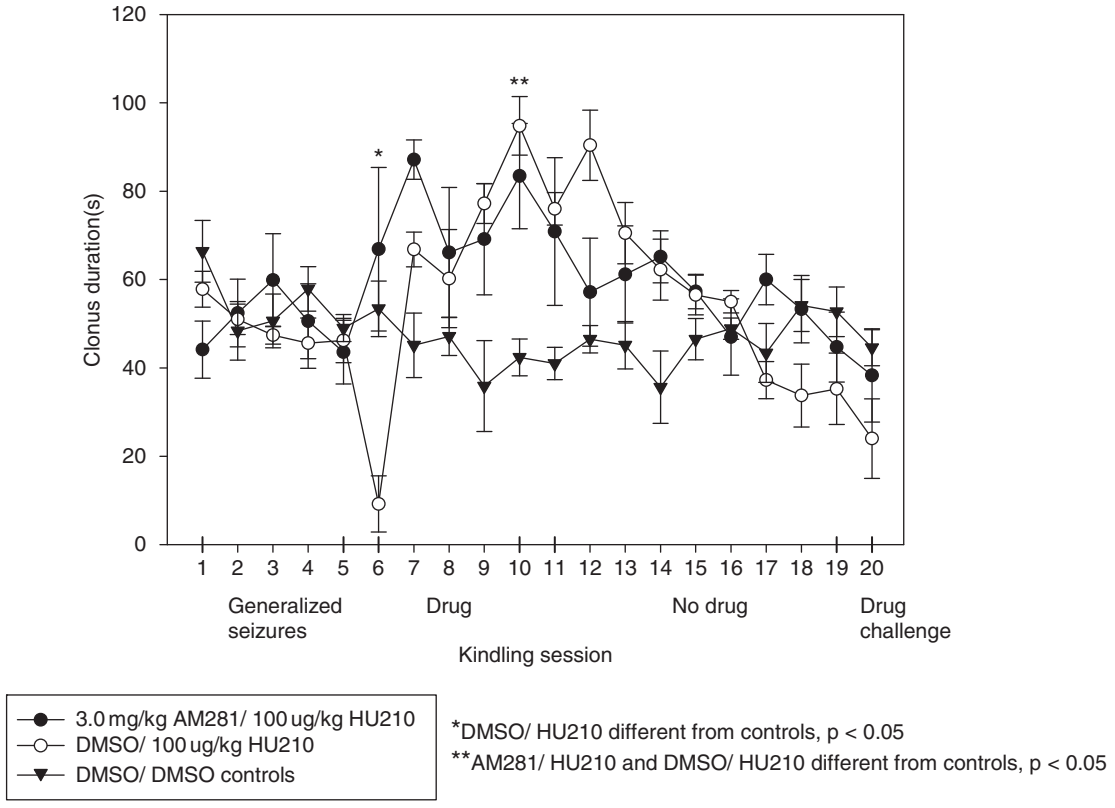

Figure 3 Effects of HU210 on generalized kindled seizures after pretreatment with AM281, expressed as percentage change in duration of clonus.

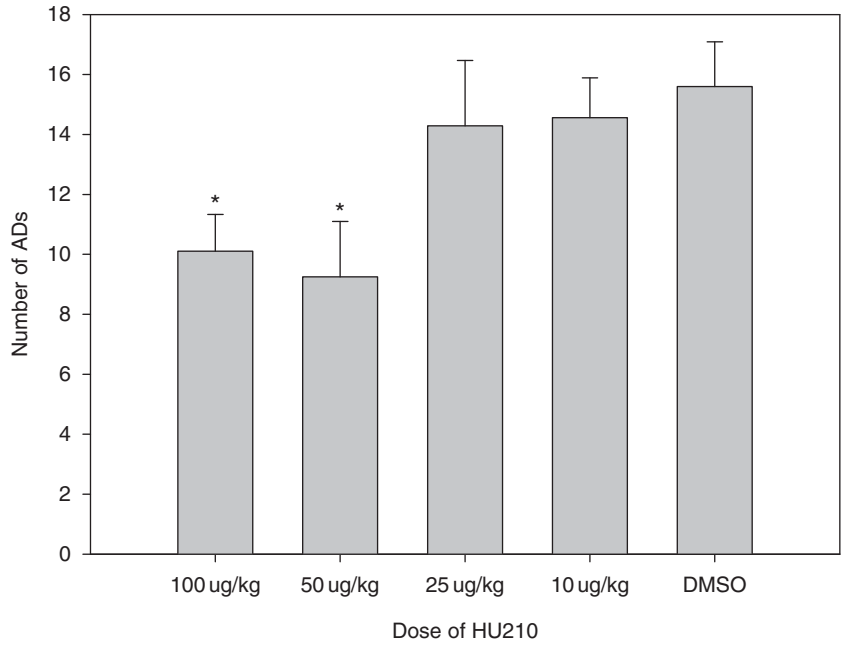
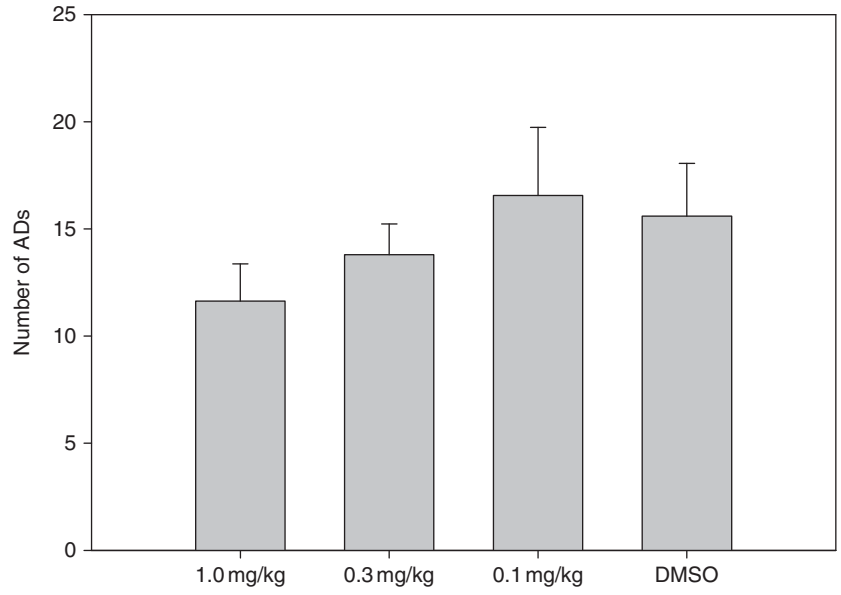


produces recurrent clonic convulsions. Rats in the chronic group received five injections of 100 $\mu g\,kg^{-1}$ of HU210, one each day, with the final injection followed 20 min later by a subcutaneous injection of PTZ at 65 $mg\,kg^{-1}$. Rats in the acute group received only a single injection of HU210, followed by challenge with PTZ. Chronic treatment with HU210 resulted in more intense convulsions as compared to controls – a proepileptic effect – whereas acute treatment with HU210 resulted in less intense convulsions as compared to controls – an antiepileptic effect.

Thus current data from two different preparations of acquired epilepsy support the interpretation that proepileptic effects of cannabinoids are a function of chronic administration of the drug. Note that some previous studies uncovered proepileptic effects of cannabinoids in particular preparations of experimental epilepsy. What is novel about our findings, however, is that the proepileptic effects against kindling and kindled seizures emerge after repeated injections. Presumably, chronic administration triggers a plastic process that exacerbates epileptogenesis and kindled seizures, analogous to the increased density of presynaptic CB1 receptors seen following a sustained febrile episode early in life. It is unlikely that increased density of CB1 receptors underlies the proepileptic effect, however, given that coadministration of the antagonist failed to block it. In contrast, administration of the antagonist did block the weak antiepileptic effect against kindled seizures we observed after acute administration, and this effect may reflect suppression of epileptiform activity in principal cells (e.g., pyramidal neurons in the hippocampus) as a consequence of CB1 receptor activation.



Future Goals

Numerous additional issues remain to be explored. For one, there is no published information about the pharmacokinetics of CB agonists such as HU210 and WIN 55,212-2. It is conceivable that the drugs accumulate with chronic injections at relatively short interinjection intervals, as in our experiments, and the molecular consequences and proepileptic effects of chronic injections may in part be due to failure to clear the drug, resulting in drug accumulation. It also remains to be determined whether chronic injections of HU210 in adulthood result in upregulation of CB1 receptors, as does a single febrile episode in infancy. If upregulation does occur, is it restricted to the hippocampal formation, or is it more widely distributed?

It is certainly conceivable that hyperexcitability induced in the hippocampus by chronic cannabinoid

(a) *100 and 50 ug/kg HU210 different from control, $p < 0.05$

(b)

Figure 4 (a) Dose-related effects of HU210 on the rate of kindling the first generalized stage 5 seizure, expressed as number of ADs to generalization. (b) Dose-related effects of AM281 on the rate of kindling the first generalized stage 5 seizure, expressed as number of ADs to generalization.

administration could accelerate kindling and exacerbate kindled seizures. However, if upregulation of CB1 receptors is not responsible for the proepileptic effect, as suggested by the failure of coadministration of the antagonist to block the effect, other potential mechanisms will have to be investigated. One possibility is that repeated administration of the exogenous agonist prevents the endocannabinoids from binding to the CB1 receptor, resulting in atypical actions at other CB receptors.

Whatever the final explanation for these results, it is clear that caution needs to be exercised in considering pharmacotherapy with cannabinoids. The effects of cannabinoid agonists are different in different preparations of experimental epilepsy, and, unexpectedly, chronic

administration of agonists can exacerbate seizures. These facts raise serious questions about the potential usefulness of cannabinoid drugs in treatment of epilepsy.

Introduction – The Possible Implication of Dynorphin A and N/OFQ in Epilepsy

One new therapeutic approach to the epilepsies may be based on the pharmacological modulation of neuropeptide transmitters. In many nerve terminals, neuropeptides coexist and are coreleased with classic small molecule transmitters in a frequency-dependent manner. Neuropeptide release appears to require burst discharge or high frequency activity – that is, events characteristic of epileptiform activity and seizures. Under these conditions, released neuropeptides may act as auxiliary messengers, modulating the efficacy of the principal neurotransmitter and the excitability of the tissue. Indeed, a large body of data supports the view that neuropeptides are involved in seizure mechanisms. Taken together, experimental results have shown that (1) seizures specifically and differentially influence the biosynthesis and release of neuropeptides in various brain areas and (2) neuropeptides exert region- and cell-specific complex effects on seizure expression.

Among the neuropeptides, endogenous opioids have been proposed to play a prominent role in epilepsy. The endogenous opioids are grouped in four systems, based on the existence of four genes coding for four peptide precursors and of four receptor types. The four precursors (pre-proenkephalin, pre-proopiomelanocortin, pre-prodynorphin, and pre-proN/OFQ) can generate many biologically active peptides: [met]enkephalin, [leu]enkephalin, β-endorphin, α-neo-dynorphin, dynorphin A (Dyn A), dynorphin B, nociceptin/orphanin FQ (N/OFQ). This article will focus on dynorphin A and N/OFQ.

Dynorphin A

Electrophysiological, biochemical, pharmacological, and clinical data strongly support the hypothesis that the dynorphinergic system is involved in specific types of seizures. Evidence for this association is particularly strong for complex partial (limbic) seizures – that is, those seizures characteristic of temporal lobe epilepsy.

administration of agonists can exacerbate seizures. These facts raise serious questions about the potential usefulness of cannabinoid drugs in treatment of epilepsy.

Introduction – The Possible Implication of Dynorphin A and N/OFQ in Epilepsy

One new therapeutic approach to the epilepsies may be based on the pharmacological modulation of neuropeptide transmitters. In many nerve terminals, neuropeptides coexist and are coreleased with classic small molecule transmitters in a frequency-dependent manner. Neuropeptide release appears to require burst discharge or high frequency activity – that is, events characteristic of epileptiform activity and seizures. Under these conditions, released neuropeptides may act as auxiliary messengers, modulating the efficacy of the principal neurotransmitter and the excitability of the tissue. Indeed, a large body of data supports the view that neuropeptides are involved in seizure mechanisms. Taken together, experimental results have shown that (1) seizures specifically and differentially influence the biosynthesis and release of neuropeptides in various brain areas and (2) neuropeptides exert region- and cell-specific complex effects on seizure expression.

Among the neuropeptides, endogenous opioids have been proposed to play a prominent role in epilepsy. The endogenous opioids are grouped in four systems, based on the existence of four genes coding for four peptide precursors and of four receptor types. The four precursors (pre-proenkephalin, pre-proopiomelanocortin, pre-prodynorphin, and pre-proN/OFQ) can generate many biologically active peptides: [met]enkephalin, [leu]enkephalin, β-endorphin, α-neo-dynorphin, dynorphin A (Dyn A), dynorphin B, nociceptin/orphanin FQ (N/OFQ). This article will focus on dynorphin A and N/OFQ.

Dynorphin A

Electrophysiological, biochemical, pharmacological, and clinical data strongly support the hypothesis that the dynorphinergic system is involved in specific types of seizures. Evidence for this association is particularly strong for complex partial (limbic) seizures – that is, those seizures characteristic of temporal lobe epilepsy.

In synthesis, the available data suggest that (1) dynorphin is highly expressed in various parts of the limbic system, and particularly in the granule cells of the hippocampus; (2) dynorphin is released in the hippocampus (and in other brain areas) during limbic seizures; (3) released dynorphin inhibits excitatory neurotransmission at multiple synapses in the hippocampus via activation of κ opioid receptors; (4) κ opioid receptor agonists are highly effective in blocking experimental limbic seizures; (5) virus-induced encephalitis causes loss of dynorphin in the hippocampus and epileptic responses that are prevented by κ receptor agonists; and (6) decreased prodynorphin promoter activity increases risk for temporal lobe epilepsy in humans.

Data on generalized tonic–clonic seizures are less straightforward. Dynorphin release appears to occur after electroconvulsive shock seizures, and κ agonists exert a clear anticonvulsant effect in this model. However, inconclusive biochemical data and the lack of κ agonist efficacy in other generalized tonic–clonic seizure models argue against the key involvement of dynorphin in this seizure type. Involvement of dynorphin in generalized absence seizures appears unlikely. Given the presumed origin of absence seizures in alterations of the thalamocortical circuit, and the low representation of dynorphin in the thalamus, this conclusion may not be surprising.

In summary, it appears that dynorphin plays a role as an endogenous anticonvulsant in complex partial seizures and in some cases of tonic–clonic seizures, but not in generalized absence.

N/OFQ

N/OFQ may also be involved in seizure control. The genes encoding the N/OFQ precursor and the NOP receptor are constitutively expressed in forebrain areas thought to be implicated in limbic seizures, such as the dentate granule cell region of hippocampus, as well as in other areas possibly involved in the generation of other seizure types. As detailed below, however, the role specifically played by N/OFQ is still unclear.

Background

Biosynthesis

Only one prodynorphin and one proN/OFQ gene have been reported in man and rodents. The prodynorphin mRNA codes for the biologically inactive peptide precursor pre-prodynorphin, which is posttranslationally processed to generate several functional peptides, including dynorphin A, α-neo-endorphin, dynorphin A 1–32, dynorphin B 1–13 and dynorphin A 1–8. The proN/OFQ mRNA codes for the precursor pre-proN/OFQ, which can also generate multiple functional peptides, including N/OFQ and nocistatin.

Dynorphin A and N/OFQ are both 17 amino acid peptides and share high sequence similarity. However, they belong to clearly distinct systems, based both on biological features (different precursors and receptors, above) and pharmacological properties (different agonists and antagonists, below).

Distribution and Regulation

Cells expressing prodynorphin mRNA in the CNS are found in several regions. The expression is high in the hypothalamus, nucleus accumbens, caudate–putamen, hippocampus, cerebral cortex and spinal cord. In the hippocampus, prodynorphin-derived peptides are synthesized in the granule cells of the dentate gyrus and then transported not only to the axon terminals in the hilus and CA3, but also to the granule cell dendrites.

In the forebrain, proN/OFQ mRNA and N/OFQ peptide levels are prominent in the neocortex, in the reticular nucleus of the thalamus, in the central and medial nucleus of the amygdala, and (at lower levels) in the dentate gyrus of the hippocampus.

Receptors

Four opioid receptor types, μ (MOP), δ (DOP), κ (KOP), and NOP, have been identified, each with distinct distributions and functions.

Dynorphin A shows a relatively high selectivity for the κ opioid receptor, although it can also bind to all other opioid receptor types. Kappa sites are dense in areas that may be directly implicated in some forms of epilepsy, like the cerebral cortex, the hippocampus, the ventromedial part of the caudate–putamen, and some hypothalamic nuclei. In the hippocampus, κ receptors are observed in the pyramidal cell layer and, with lower density, in the granular and molecular layers of the dentate gyrus. Based on different agonist and antagonist sensitivities, the existence of κ receptor subtypes (κ1, κ2, κ3) has been suggested; however, at present there is no molecular basis to support this hypothesis. Like the other opioid receptors, the κ receptors are members of the seven-transmembrane G-protein-coupled receptor family. Activation of κ receptors can cause inhibition of adenylate cyclase, opening of K^+ channels and/or closure of Ca^{2+} channels, with inhibition of transmitter release and of action potential discharge. Pharmacologically, the cloned κ receptor shows high affinity for dynorphin A, for the agonists U69593 and U50488, and for the antagonist nor-binalthorphimine.

N/OFQ shows a relatively high selectivity for the NOP receptor. The NOP receptor, originally cloned using molecular screening methods based on opioid receptor gene sequences, shares a high sequence similarity with κ opioid receptors. Relatively high constitutive NOP receptor levels are found in areas critical for

epilepsies, like the cortex (neo-, entorhinal, and piriform cortex), the hippocampal formation (mainly dentate gyrus and CA3 pyramidal cells), the amygdala (mainly medial and basal nucleus), and various nuclei of the thalamus and of the hypothalamus. The NOP receptor is coupled to the Gi/Go protein-mediated transductions system. Similar to the case with activation of κ receptors, activation of NOP receptors can cause inhibition of adenylate cyclase, activation of K^+ conductances, and/or closure of voltage-sensitive Ca^{2+} channels. These effects can lead to the inhibition of the release of various neurotransmitters and to a reduction in the neuronal firing rate. Pharmacologically, NOP shows high affinity for N/OFQ, for the agonists Ro646198 and UFP102, and for the antagonists J-113397 and UFP101. The NOP receptor can be antagonized by only high concentrations of naloxone.

Effects

Cellular effects

Dynorphin is an inhibitor of excitatory neurotransmission. This effect has been well characterized in the hippocampus where dynorphin is contained in the mossy fibers (the axons originating from the dentate gyrus granule cells) and released together with glutamate. The high frequency stimulation of granule cells causes a transient heterosynaptic inhibition of neighboring glutamatergic mossy fibers, as well as retrograde inhibition of perforant path terminals in the dentate gyrus. These effects are mediated by the release of dynorphin from granule cell axon terminals and dendrites. That release activates κ opioid receptors located presynaptically at the perforant path-granule cell synapse, and both pre- and postsynaptically at the mossy fiber-CA3 synapse. Studies on granule cells of the guinea pig dentate gyrus demonstrated release of the prodynorphin-derived peptides from dendrites as well as from axon terminals. There is evidence that L-type calcium channels mediate dynorphin release from dendrites, whereas the N-type calcium channels control release from axon terminals. Thus, a single cell type can release dynorphin from two different cellular domains (axonal and dendritic) using different release mechanisms.

N/OFQ exerts inhibitory effects on neurotransmitter release, with relevant differences in efficiency depending on the 'target' neurotransmitter and the brain area. Relevant to the epilepsies, N/OFQ inhibits norepinephrine, serotonin and perhaps glutamate release in the cortex, while it does not appear to affect acetylcholine and GABA release. In the hippocampus, N/OFQ inhibits norepinephrine release and excitatory neurotransmission; in the amygdala, it inhibits GABA and glutamate release; and in the thalamus, N/OFQ decreases firing rate in a subset on neurons, but increases it in another subset. These heterogeneous cellular effects underly complex (and sometimes paradoxical) effects at the integrated (intact animal) level.

Behavioral effects

Dynorphin has been proposed to be involved in a range of functions, including nociception, mood, motor activity, and response to injury. N/OFQ may also exert a variety of functions, including modulation of nociception, of locomotor activity, of stress responses and anxiety, and of learning and memory.

Methods

In an attempt to provide some insight into the possible involvement of N/OFQ in seizures and epilepsy, we have investigated the adaptive changes taking place in the N/OFQ-NOP system in epilepsy models, and assessed the functional (pro- or antiseizure) consequences of these changes by using an integrated, pharmacological, and genetic approach. We first analyzed changes in proN/OFQ and NOP mRNA levels (using Northern blot and in situ hybridization), and in receptor binding following acute, kainate-evoked limbic seizures. Second, we studied kainate seizure-evoked N/OFQ release in critical brain areas, namely the hippocampus and the thalamus, using in vivo microdialysis. Third, we evaluated the severity of kainate seizures in mice treated with a NOP receptor antagonist, J-113397, and in mice made N/OFQ-deficient by targeted disruption of the proN/OFQ gene. Fourth, we evaluated amygdala kindling development in N/OFQ-deficient mice.

Recent Data

Alterations in the N/OFQ–NOP System in Response to Seizures

We have studied proN/OFQ gene expression following limbic seizures. Northern analysis revealed increased proN/OFQ mRNA levels in the thalamus (but not in the hippocampus) 3–24 h after kainate administration, with maximal effect (twofold increase over basal levels) at 6 h. In situ hybridization revealed that kainate evokes a dramatic (fourfold) increase in proN/OFQ mRNA levels in the thalamic reticular nucleus and in the medial nucleus of the amygdala. In contrast, NOP mRNA levels were found to decrease within the first 3 h after kainate in many areas, including the amygdala, hippocampus, thalamus, and cortex. Within 3–4 days, NOP receptor density also decreased in the same areas. Thus, the N/OFQ–NOP system appears to undergo adaptive changes following seizures.

One interpretation of these data is that N/OFQ is released during seizures and causes downregulation of NOP receptors and activation of N/OFQ biosynthesis. Therefore, we developed and characterized a microdialysis approach for measuring N/OFQ release in freely moving, awake animals, and used it to study kainate seizure-evoked N/OFQ release in the hippocampus and in the thalamus.

Under basal, unstimulated conditions, more than half of the N/OFQ output was Ca^{2+}-dependent and TTX-sensitive, indicating that it depends on action potential propagation. The Ca^{2+}-independent and TTX-insensitive component of N/OFQ output may be generated by N/OFQ leakage due to the damage produced by the implantation of the microdialysis probe. N/OFQ efflux was greatly increased by depolarization. High K^+ caused a threefold increase in N/OFQ efflux both in the hippocampus and thalamus. Stimulus-evoked release was totally Ca^{2+}-dependent and TTX-sensitive, suggesting a neuronal origin. Importantly, all of these characteristics of N/OFQ release were essentially identical to those reported for other neuropeptides under similar experimental conditions.

The mechanism of N/OFQ release has not been studied yet. However, in analogy with other neuropeptides, it is most likely frequency-dependent, requiring neuronal burst discharge or high frequency activity. Indeed, kainate-induced status epilepticus caused a robust, but transient, increase in N/OFQ efflux in the rat hippocampus and thalamus. This phenomenon displayed several interesting characteristics. First, consistent with the increase of proN/OFQ gene expression, the increase in N/OFQ release began in coincidence with the start of status epilepticus (i.e., approximately 90 min after kainate injection), whereas no significant changes were observed while the animals were experiencing the self-limiting, low-grade seizures that precede status. Although it is tempting to speculate that only prolonged seizures can evoke N/OFQ release, it is also plausible that the technique employed is not sufficiently sensitive to detect less dramatic, fleeting changes.

Second, this early increase in N/OFQ release was transient. It began to decline within 90–120 min, and eventually returned to baseline levels. This decline may depend upon depletion of N/OFQ-containing vesicles in the nerve terminals. Increased release of neuropeptides does prompt new synthesis in the soma and transport along the axons to restore appropriate levels in the nerve terminals, but these events are time-dependent. Indeed, arrival of newly synthesized N/OFQ in the terminals coincided with a second, late increase in its release.

Third, N/OFQ release was not increased compared to prekainate levels on the following day, when animals display only low grade seizures. This observation indicates that N/OFQ release depends on occurrence of generalized seizures. Interestingly, all these characteristics strikingly overlap those reported by others for kainate seizure-induced opioid peptide release in the hippocampus.

Based on these data, we propose the following cascade of events. First, seizures cause N/OFQ release, reducing its levels in the nerve terminals and stimulating new synthesis within the releasing neurons themselves. In turn, released N/OFQ causes downregulation of the NOP receptor. Consistent with this proposal is the chronological sequence of events in the hippocampus and in the thalamus: following kainate administration, peak increase in N/OFQ release occurs at 3 h, peak proN/OFQ mRNA at 6 h (which may cause the late increase in N/OFQ release), decreased NOP mRNA levels in the first day, and decreased NOP receptor density in 3–4 days (consistent with a reported opioid receptor turnover time of 3–4 days in vivo). Furthermore, receptor desensitization and/or internalization may occur at earlier time-points.

Physiopathological Implications

As stated above, the role of released N/OFQ in seizure expression is still uncertain. Initially, the possible involvement of N/OFQ in seizures and epilepsy has been studied by release and electrophysiological studies, which provided information about the basic effects of N/OFQ in the modulation of excitability. As described, N/OFQ exerts inhibitory effects at a cellular level and inhibits the release of excitatory and inhibitory neurotransmitters, with relevant differences in efficiency depending on the neurotransmitter and the brain area under study. It is difficult to speculate about pro- or antiseizure effects of the peptide on this basis, because the net effect of N/OFQ will probably depend on the circuitry involved in the generation or amplification of the specific type of seizure.

Another approach to the problem has been the use of NOP agonists. This approach has given conflicting, inconclusive results. In one study, an N/OFQ analog produced pro-epileptic effects, but these were blocked by naloxone (thus, they were not NOP-mediated); in other studies, intracerebroventricularly injected N/OFQ attenuated bicuculline-, NMDA-, and penicillin-induced seizures and retarded kindling development, but did not attenuate electrical shock and fully kindled seizures.

Finally, by using a combined pharmacological and genetic approach, we have found converging evidence for a proseizure effect of endogenous N/OFQ. Mice treated with the NOP receptor antagonist J-113397 displayed reduced susceptibility to kainate-induced seizures (i.e., significant reduction of behavioral seizure scores). In keeping with these observations, N/OFQ knock-out mice were less susceptible to kainate seizures compared with their wild-type littermates; lethality was reduced, latency to generalized seizure onset prolonged, and behavioral seizure scores decreased. Intracerebroventricular administration of N/OFQ prevented reduced susceptibility to kainate seizures in N/OFQ knock-out mice. We have also found that N/OFQ deficient mice are more resistant to kindling development than their wild-type littermates.

Future Goals

Further investigation is required to characterize the involvement of the N/OFQ-NOP system in epilepsy. Taken together with the other reports, our data suggest

that the role of N/OFQ during seizures is complex, with different effects in different seizure and epilepsy types. Therefore, a careful examination of the precise indications of drugs affecting the N/OFQ-NOP system in the different epilepsy types is warranted. To perform this experimental examination, however, it will be essential to improve the pharmacological tools that are currently available. In particular, there is still a need for highly selective and specific, potent, nonpeptidic NOP receptor agonists and antagonists.

The experimental analysis of the dynorphin involvement in epilepsy is much more advanced. As summarized above, the available experimental evidence convincingly support the view that dynorphin plays a role as an endogenous anticonvulsant in complex partial seizures and in some cases of tonic–clonic seizures, but not in generalized absence. This pattern of effects should coincide with the antiseizure spectrum of selective κ agonists. Although κ agonists have undergone clinical evaluation, primarily for the treatment of pain or of heroin addiction, studies on their effects in epileptic patients have not been performed. Of course, several factors may be expected to limit the use of pharmacological agents acting through the dynorphin system, including psychotropic side effects (dysphoric or psychotic episodes) and nonspecific actions that may lead to hyperexcitability. Furthermore, prolonged treatments with κ agonists may cause receptor downregulation, with attenuation or loss of the clinical effects. Nonetheless, consideration of these obstacles should not discourage investigators from attempting a progress toward clinical testing of such drugs in patients resistant to the currently available antiepileptic agents.

Introduction

The endogenous opioid and cannabinoid systems, while entirely separate and distinct at cellular and molecular levels, share many remarkable similarities. They both represent systems in which endogenous neuromodulators act on the same receptors that are also activated by plant-derived agents. Both classes of receptors are G-protein coupled and, for the most part, located on presynaptic nerve terminals, where their activation reduces transmitter

that the role of N/OFQ during seizures is complex, with different effects in different seizure and epilepsy types. Therefore, a careful examination of the precise indications of drugs affecting the N/OFQ-NOP system in the different epilepsy types is warranted. To perform this experimental examination, however, it will be essential to improve the pharmacological tools that are currently available. In particular, there is still a need for highly selective and specific, potent, nonpeptidic NOP receptor agonists and antagonists.

The experimental analysis of the dynorphin involvement in epilepsy is much more advanced. Introduction

The endogenous opioid and cannabinoid systems, while entirely separate and distinct at cellular and molecular levels, share many remarkable similarities. They both represent systems in which endogenous neuromodulators act on the same receptors that are also activated by plant-derived agents. Both classes of receptors are G-protein coupled and, for the most part, located on presynaptic nerve terminals, where their activation reduces transmitter

release. In the hippocampal CA1 region, the receptors are mainly found on inhibitory interneuron terminals. Enkephalin, endorphin, and dynorphin are examples of endogenous opioid receptor agonists. Extracts of the opium poppy yield the exogenous agonists morphine and codeine, whereas heroin is a synthetic morphine derivative. Anandamide and 2-arachidonyl glycerol (2-AG) are the major endogenous cannabinoids (endocannabinoids), and in the brain they act on the same receptor at which the derivative of the cannabis plants, Δ^9-tetrahydrocannabinol (THC), is a ligand. In both systems the exogenous and endogenous ligands have powerful psychoactive properties.

Opioids and cannabinoids play many behavioral roles. For example, they both modulate reward behaviors, analgesia, and hypothermia. However, while morphine is a highly addictive drug (causing a broad and well-defined spectrum of dependencies and withdrawal symptoms), cannabis products are generally nonaddictive, although a susceptible subgroup of users may develop a psychological dependency on them. Besides dependence, opiate use also leads to tolerance, prompting the use of higher doses and the risk of fatal outcomes, whereas cannabis use does not lead to tolerance. Opiates often induce vomiting, while cannabinoids are antiemetics.

Background

Endogenous Opioid and Cannabinoid Systems-Basic Properties

As suggested earlier, while opioids and cannabinoid systems share some similarities, they differ in several ways. In terms of basic properties, endogenous opioids are peptides that are derived from larger, dedicated proprecursor proteins. In the CA1 region of hippocampus, the principal endogenous opioid is enkephalin, although in other parts of hippocampus dynorphin is present at high levels. Opioids are generally packaged in secretory vesicles in presynaptic terminals, and are released into the synaptic cleft by conventional mechanisms of synaptic transmission. Opioids are soluble in water, and once released diffuse to their postsynaptic receptors. Interneurons are probably the primary source of enkephalin in CA1, although some extrinsic fibers are also weakly immunoreactive for enkephalin. In CA1, endogenous opioids can be released by stimulation of axonal fibers in stratum lacunosum-moleculare in CA1. Opioid receptors have numerous subtypes (perhaps as many as 16), with the mu opioid receptor (MOR) being the most prominent in the hippocampus and other parts of the brain. Different OR subtypes have selective ligand requirements and are distinguishable pharmacologically. Notably, dynorphin is present in dentate granule cells, and can be released when the cells are stimulated vigorously; details of its packaging and release mechanisms in this system are still lacking. Once released from the postsynaptic granule cells, dynorphin acts as a retrograde messenger and activates kappa-opioid receptors that are present on the excitatory perforant path terminals.

Endogenous cannabinoids are small lipid fatty acid derivatives of arachidonic acid, and are only weakly water-soluble. 2-AG and anandamide, which are derived directly by enzymatic action on common molecular components of the cellular plasma membrane: diacylglycerol in the case of 2-AG, and *n*-arachidonyl–phosphatidyl ethanolamine in the case of anandamide. Anandamide was the first identified endocannabinoid, however, a growing consensus is that 2-AG is probably the major endocannabinoid in most of the brain, and we will focus on 2-AG in this discussion. Production of 2-AG is thought to proceed via two enzymatic steps, activation of phospholipase C, which produces diacyglycerol, and activation of diacylglycerol lipase. The product of diacylglycerol cleavage by diacylglycerol lipase is 2-AG. 2-AG is synthesized and released from postsynaptic target neurons either by a large increase in postsynaptic $[Ca^{2+}]_i$, or activation of G-coupled neurotransmitter receptors (GPCRs) (group I mGluRs, and M1/M3 mAChRs, in the hippocampus), or the combination of a small increase in $[Ca^{2+}]_i$ combined with GPCR activation. Present technologies do not allow the rapid experimental distinction between the synthesis and release steps in cellular studies, and the term 'mobilization' is sometimes used to encompass both. Endocannabinoids can be mobilized when synaptic excitation causes a sufficient rise in $[Ca^{2+}]_i$ to occur in the pyramidal cells. The actual change in $[Ca^{2+}]_i$ required for endocannabinoid synthesis and release depends on the particular stimuli and the time course of the stimulation. If a rise in $[Ca^{2+}]_i$ is the only stimulus, then $[Ca^{2+}]_i$ must be in excess of 10 μM; however, if a GPCR is activated at the same time, then much lower levels of $[Ca^{2+}]_i$, (on the order of 1 μM) are sufficient. The time course of the stimulation is also critical. Even submicromolar levels of $[Ca^{2+}]_i$ can be effective if prolonged for many minutes. Endocannabinoids are not packaged in vesicles, and they are lipophilic. Since they are produced in a membrane environment, it is not clear how readily they will simply diffuse into the largely aqueous environment of the synaptic cleft. Hence, the precise molecular mechanism of their release is presently not understood; it could involve unknown mechanisms, such as transporters or chaperone molecules, rather than simple diffusion.

Thus far, only one type of neuronal cannabinoid receptor has been extensively described in the brain, CB1R; a splice variant, CB1aR, seems functionally indistinguishable from CB1R, and the peripheral cannabinoid receptor, CB2R, may be present on certain microglia. Everywhere else, CB1R predominates. Currently, CB1R is considered the most abundant G-protein coupled receptor in the brain. There are effective CB1R antagonists, SR141716A (also called 'rimonabant'), and AM-251, that

permit pharmacological dissection of the system. It should be born in mind that the antagonists most widely used are not neutral antagonists; they are 'inverse agonists' that have effects all their own on the CB1R, even in the absence of a CB1R agonist. Moreover, neither rimonabant nor AM-251 are perfectly selective and do affect other receptors. Rimonabant is also an antagonist at the transient receptor potential (TRP) channel called V1 (or VR1).

Recent evidence for a third kind of cannabinoid receptor, GPR55, has appeared. GPR55 is richly expressed in brain, including hippocampus, and once detailed studies appear, it will certainly force reevaluation of the roles of endocannabinoids. GPR55 reacts with a number of cannabinoid ligands, but in general its pharmacological properties are very different from those of CB1R; e.g., a well established antagonist/inverse agonist at CB1R, AM251, may be an agonist at GPR55. No physiological roles for GPR55 in the brain have yet been identified.

Several lines of CB1R knockout mice have been developed, including some in which the deletion of CB1R has been targeted to specific cells groups in the brain. To avoid the limitations inherent in constitutive knockouts as well as the complexities of the pharmacological antagonists, a comprehensive strategy for investigating endocannabinoid actions would involve using both antagonists and confirming results with a CB1R knockout mouse. An alternative is to inject a Cre-loaded virus into a restricted brain region of a CB1R-'floxed' mouse. In virally transfected cells, the Cre induces CB1R deletion. Local inducible CB1R removal thus avoids some of the problems inherent in either constitutive knockouts or pharmacological approaches.

At the subcellular level, activation of opioid and cannabinoid receptors inhibit adenylyl cyclase, inhibit voltage-gated calcium channels, and increase the activation of voltage-gated potassium channels – all of which lead to a reduction in the amount of neurotransmitter released from presynaptic terminals. Indeed, one of the most important similarities between endogenous opioids and cannabinoids is that their receptors are often located on presynaptic nerve terminals and mediate presynaptic inhibition.

Localization of MORs and CB1Rs

Interneurons

Perisomatic, 'basket cell' synapses are thought to be the most important for regulating pyramidal cell somatic action potentials, and thereby strongly influence axonal conduction and synaptic output. Dendritic synapses are probably the most important for dendritic integration and the regulation of the intrinsic dendritic excitatory properties, rather than network activity. CB1Rs are present on a major class of interneurons that target both somatic and dendritic regions. These cells selectively colocalize the neuropeptide, cholecystokinin (CCK), with GABA.

The other major class of basket cell contains parvalbumin (PV) but not CCK, in addition to GABA. PV immunoreactivity is reduced in the hippocampus of some patients with temporal lobe epilepsy as well as in animal epilepsy models. This reduction may be associated with the neuronal loss that is seen in some cases of epilepsy, even though few studies have shown an actual correlation. A reduction in the expression of PV, even without a decrease in the number of interneurons, could have an effect on the properties of those interneurons, since PV is a calcium buffer and its downregulation will certainly affect the normal properties of those cells. Human studies find fewer changes in PV immunoreactivity than those reported in animal studies, where PV immunoreactive cell loss is extensive. The subiculum of a small group of epileptic patients was reported to have a marked reduction in PV cell density, whereas in CA1 the PV cell number increased. In mouse models, 2 months after the induction of seizures, the percentage of interneurons expressing PV and P/Q type calcium channels increased, suggesting that the switch to a PV and P/Q expressing interneuron could be neuroprotective.

Cellular and subcellular localization of MOR and CB1R

Both MORs and CB1Rs are mainly located on inhibitory, GABAergic interneurons in the hippocampus. In the CA1 region, there are several classes of GABAergic inhibitory interneurons having distinct morphological and electrophysiological characteristics. As indicated earlier, two prominent and mutually exclusive classes express either the calcium-binding protein, PV, or the neuropeptide, CCK, in addition to the GABA-synthesizing enzyme, glutamic acid decarboxylase. PV and CCK interneurons are considered basket cells that mainly innervate principal cell somata and proximal dendrites, thus providing perisomatic inhibition.

In the CA1 region, CB1Rs are densely packed on the terminals and preterminal axons of CCK-expressing interneurons. This localization is almost exclusive; few other interneurons express CB1R, and in particular, PV cells do not express any. Although initial immunohistochemical studies reported finding no CB1R on glutamatergic fibers in CA1, this view has been revised as recent pharmacological and immunohistochemical studies demonstrate their presence on excitatory fibers, albeit at a much lower density (perhaps 30-fold lower) than on the inhibitory axons. Interestingly, PV-cells express high levels of MOR, and CCK cells reportedly express none. Unlike the comparatively restricted distribution of CB1Rs, however, the distribution of MORs is broader and encompasses, in addition to the PV cells, a heterogeneous group of interneurons found in all the laminae of CA1. These other interneuron types express vasoactive intestinal peptide, somatostatin, or calretinin in addition to GABA. The PV interneurons target pyramidal cells, but the other

MOR-expressing interneurons generally target other interneurons, suggesting complex circuit effects may result from MOR stimulation. Whether or not the nonPV, MOR-expressing interneurons directly target PV cells is not clear. Given these results, a diffuse form of paracrine signaling from the enkephalin-containing interneurons to PV cells, rather than conventional synaptic transmission, seems possible. Similarly, in dentate gyrus, kappa opioid receptors are present on glutamatergic perforant path fibers. Stimulation in the CA1 region induces a kappa-opioid receptor-dependent enhancement of long-term depression (LTD) of glutamate fibers in s. radiatum, suggesting an association of this opioid receptor subtype on s. radiatum excitatory axons.

Methods

We have made electrophysiological recordings from single neurons in the rat acute brain slice preparation. The slices, which are continuously bathed in an oxygenated, physiological salt-solution, are 400 μm thick and contain microcircuits of excitatory and inhibitory neurons that remain substantially intact. The preparation is especially convenient for pharmacological investigations, as drugs can be applied to bath solution in known concentrations where they affect the entire surface of all cells. We typically study tissue from young adult (5–7 week-old) male rats, to avoid the variability that can be induced by hormonal variations in females. Nevertheless, this introduces the danger that our results may not apply straightforwardly to females. Our recordings are made by impaling neurons with high resistance ('sharp') or with whole cell patch electrodes. Each technique has advantages and disadvantages: sharp electrodes permit stable, long-term recordings (>2 h) to be made routinely, however they lack the ability to control the intracellular membrane potential, or measure transmembrane currents, and cannot be used to detect the smallest synaptic signals. Synaptic neuronal activity was recorded as changes in membrane potential. As we are interested in studying the inhibitory circuits in the hippocampus, we blocked excitatory inputs to pyramidal cells by adding ionotropic glutmatergic receptor blockers into the bath solution. Inhibitory synapses were stimulated by extracellular electrodes placed into the vicinity of the inhibitory interneurons. Inhibitory postsynaptic potentials were recorded from the principal cells of the hippocampus, the pyramidal cells.

Results

Cellular Studies

Opioids suppress inhibitory postsynaptic potentials (IPSPs)

Adding morphine or synthetic MOR agonists to hippocampal brain slices causes large hyperexcitable interictal spike responses (involving numerous pyramidal cells) that spread easily throughout the cell population. This response was at first considered paradoxical, because MORs are present only at a relatively low density in the hippocampus. The apparent discrepancy was reconciled by the finding that hippocampal MORs are strategically located on interneurons, where their activation reduces $GABA_A$-mediated IPSPs. The resulting disinhibition has several major consequences: (1) Excitatory synaptic potentials that are normally shaped and truncated by GABAergic inhibition grow in size and express NMDA-dependent components; (2) Cells within a given circuit communicate readily and directly in ways that are ordinarily suppressed by GABA. This effect is especially significant in regions of high interconnectivity among principal cells, such as the CA3 region, where powerful and self-sustaining recurrent excitatory loops are normally prevented by inhibition. Recurrent activity within the loops is a major factor in spreading epileptic activity to downstream target areas – e.g., the CA1 region; (3) Finally, intrinsic burst potentials are generated. The apparently disproportionate proconvulsant actions of MOR agonists can therefore be attributed to the localization of MORs on interneuron terminals and the disinhibitory effects of their activation on pyramidal cell firing.

Opioids regulate excitatory postsynaptic potentials (EPSPs) indirectly

Recent optical studies, using voltage-sensitive dyes, have revealed that the magnitudes of excitatory synaptic potentials are also under the control of MORs. This influence is a result of opioid modulation of dendritic inhibitory synapses, however, and not a direct influence on the excitatory fibers, since the presence of $GABA_A$ receptor antagonists completely occludes the MOR-mediated effect. While the ability of MORs to regulate $GABA_B$-mediated responses was initially discounted, it now appears that MOR-regulation of $GABA_B$ inhibition of glutamate responses also occurs. Finally, exposure to morphine in vivo can produce persistent loss of GABAergic synapses in the midbrain, and resultant long-term changes in ratio of AMPA–NMDA receptor mediated currents. Since some of these effects were obtained with a single exposure to morphine, it may be that imbalances in the opiate system have deeper and more far-reaching consequences than expected.

Depolarization-induced suppression of inhibition (DSI) by endocannabinoids

A train of action potentials, or a large transient depolarization such as associated with a burst potential, in a postsynaptic pyramidal cell can cause a temporary reduction in the amplitudes of inhibitory postsynaptic potentials experienced by that cell. The decrease in inhibition has been termed DSI. In principle, several mechanisms could account for DSI. One class of mechanisms would be

confined to the postsynaptic cell – for example, a decrease in GABA receptor sensitivity or other alteration that decreased the ability of the GABA receptor to change the cell's membrane potential. Another class of mechanisms would involve presynaptic effects, such as a change in calcium influx into the presynaptic nerve terminals that reduces their ability to release GABA. However, since the decrease in inhibition is triggered by the postsynaptic cell, the presynaptic mechanisms would involve the generation of a signal in the postsynaptic cell that would then travel to the presynaptic receptors – in effect a retrograde signaling process. Although at first retrograde signaling seemed to be the less likely explanation, in fact many experiments done by dozens of laboratories have convincingly shown that DSI is mediated by such a retrograde signal process. Moreover, it is now clear that the retrograde signal is an endocannabinoid.

Short-term activation of presynaptic CB1R is caused when the postsynaptic pyramidal cell experiences a sufficiently large bolus of calcium (generally initiated by depolarization) to synthesize and release endocannabinoids as described earlier. DSI transiently reduces GABA release by blocking the N-type Ca^{2+} channels that serve as the primary stimulators of transmitter release from the CB1R-expressing interneurons. This process reduces the inhibition received by the endocannabinoid-releasing cell for a period that lasts tens of seconds in vitro, and probably on the order of seconds in vivo. An especially important aspect of endocannabinoid signaling is that the endocannabinoid molecules are lipids that cannot diffuse great distances in the mainly aqueous extracellular medium. Moreover, they are rapidly taken up and degraded by efficient mechanisms. It is likely that they can act no more than a micron or so from their source cell, except under extraordinary circumstances in which they are produced in large quantity or the uptake and catabolic systems are inactivated. Thus, endocannabinoids are quintessentially local signals; an endocannabinoid-sourcing cell affects its own inputs, but probably not those of even its closest neighbors. DSI in one cell does not induce DSI in the nearby cell in the hippocampus.

During the resultant transient period of DSI, a cell is free to respond much more vigorously to incoming excitatory synaptic inputs than its still-inhibited neighbors, even if all cells receive the same degree of excitation. A weak train of stimuli, one that is normally subthreshold for induction of long-term potentiation (LTP), becomes capable of inducing LTP if it occurs during the DSI period. Most importantly, simultaneous field potential recordings show that the stimuli that induce LTP in the single cell during DSI do not produce LTP in the population, confirming that LTP induction in the single cell can be attributed to local, endocannabinoid-mediated disinhibition. In this case, while the endocannabinoid effects themselves are short-lasting, the indirect consequence of endocannabinoid action is persistent.

Prolonged CB1R activation can directly induce LTD of inhibitory synapses (iLTD)

If mGluR-dependent endocannabinoid mobilization is prolonged for several minutes, there is a long-lasting form of synaptic depression (iLTD). iLTD underlies the E–S type of long-term potentiation, whereby a given sized EPSP (E) has an increased likelihood of triggering an action potential (spike – S) in a pyramidal cell. Endocannabinoid-mediated iLTD requires minutes-long activation of presynaptic CB1R, subsequent activation of protein kinase A, and the presynaptic protein, RIM 1α, indicating the existence of at least two pathways downstream of CB1R within the presynaptic terminal that inhibit transmitter release. iLTD induction represents a direct effect of long-lasting CB1R activation. Nevertheless, DSI and iLTD heighten neuronal excitability by facilitating LTP induction indirectly.

Interactions Between Opioids and Cannabinoids

Behavioral studies

As noted earlier, the opioid and cannabinoid systems are distinct molecular and cellular entities, with their respective receptors largely located on nonoverlapping cell groups. The output from individual CCK interneurons is not affected by MOR agonists in paired recording. Nevertheless, the two systems clearly interact; cannabinoid- and opiate-mediated actions are intertwined. In behavioral experiments (i.e., place preference and self-administration experiments), opiate antagonists can disrupt a learned behavior induced by cannabinoid agonists or vice versa. Mice genetically altered to lack CB1Rs have a markedly decreased preference for heroin rewards, while normal mice rapidly acquire and maintain strong behavioral responding for heroin. There is ample evidence for cross-talk between the systems in seizure-related phenomena as well. CB1R antagonists can oppose the anticonvulsant actions of morphine, and naltrexone (MOR antagonist) opposes the anticonvulsant effects of CB1R agonists. In contrast, the high-dose proconvulsant MOR effects are also antagonized by CB1R antagonists, underscoring the complexity of the opioid effects on seizures. Since both anticonvulsant and proconvulsant actions of MOR are opposed by CB1R, it appears unlikely that there is a unitary cellular mechanism by which CB1R and MOR actions interact.

Cellular studies

There is some evidence for direct molecular interactions between MORs and CB1Rs. They could heterodimerize, for example, although this seems to contradict immunohistochemical and electrophysiological data indicating that the receptors are on different interneurons. In general, the physiological relevance of heterodimerization has not been well-established.

Assuming that heterodimerization is not a factor in the cannabinoid or opioid responses in the hippocampus, it is a matter of great interest to learn if, or how, the two systems might interact at the cellular or network levels. We have begun to test some predictions (based on a simple model) that opioids and endocannabinoids regulate distinct groups of interneurons that act independently and synapse in parallel on pyramidal cells. This model implies that the pyramidal cell is the junction point for their interactions. Both $GABA_A$- and $GABA_B$-receptor mediated IPSPs shape hippocampal network activity. To rule out network level interactions, an efficient method for activating either class of interneuron in isolation is required. Selective, global elimination of CCK- or PV-cell-mediated inhibition is possible because of their reliance on distinct types of voltage-gated Ca^{2+} channels to release GABA. A great deal of prior evidence shows that the large evoked and spontaneous IPSPs are made by somatic or perisomatic synapses – that is, by basket cells or axo-axonic cells. The PV and CCK cells constitute the overwhelming majority of these cells. Hence, large IPSPs occurring in the presence of agatoxin probably issue mainly from the CCK cells, and large IPSPs occurring in the presence of conotoxin probably issue mainly from PV cells.

$GABA_B$ activation is generally anticonvulsant in animal models, whereas blocking the $GABA_B$ receptors or the $GABA_A$ receptors can exacerbate epileptiform activity in some cases. In view of the roles of $GABA_A$ and $GABA_B$ receptors in epilepsy, it is important to unravel the ability of opioid and cannabinoid receptors to suppress these responses. We wanted especially to test the hypothesis that both receptors would suppress the same GABA responses.

Exogenous MOR and CB1R agonists suppressed $GABA_A$ responses, but only MOR agonists affected both $GABA_A$ and $GABA_B$ responses. We concluded that CB1Rs are not present on the interneurons that produce $GABA_B$ responses. If CB1Rs and MORs interact on the same interneurons, these would have to be the interneurons that produced exclusively $GABA_A$ responses. CB1Rs reduced $GABA_A$ IPSPs in the short and long term (**Figure 1(a)**), but not $GABA_B$ responses (**Figure 1(b)**). Since epileptiform activity that is induced by a variety of convulsants (including $GABA_A$ antagonists) is exacerbated by blocking $GABA_B$ receptors, the aforementioned result offers new insights into how opiates may affect some cases of epilepsy. Knowing which cells are the source of the postsynaptic $GABA_B$ IPSPs, or whether all interneurons are potentially a source, would provide important information about how $GABA_B$ responses can act as anticonvulsants in some animal models.

By using neurotoxins that selectively block GABA release from certain classes of interneurons, we ruled out any substantial overlap between MORs and CB1Rs on the same interneurons. There was no evidence for mutual occlusion between the effects of the selective agonists of the receptors. However, as noted earlier, CB1Rs induce

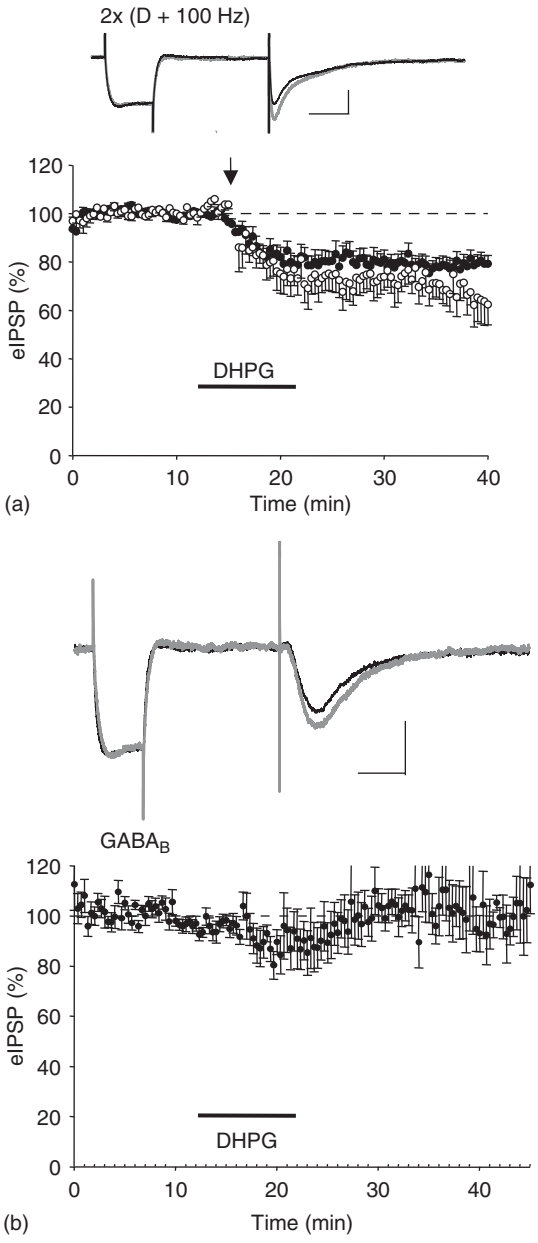

Figure 1 iLTD of $GABA_A$ but not $GABA_B$ IPSPs. (a) Top, Representative trace of an eIPSP before (gray trace) and 20 min after (black trace) synaptic stimulation (2× 100 Hz train, 20 s apart). Calibrations for the traces are: *x*-axis, 2 mV; *y*-axis, 200 ms. Graph: A 10-min DHPG application (black circles, $n = 27$) reduced the amplitude of an eIPSP for more than 30 min (iLTD). Synaptic stimulation (white circles, $n = 6$) also induced robust iLTD. (b) Endogenous cannabinoids mobilized by DHPG do not affect the $GABA_B$ response. A representative $GABA_B$ isolated in bicuculline 20 mM before (black trace) and 20 min after (gray trace) a 10 min application of 50 mM DHPG. Calibrations for the traces are: *x*-axis, 1 mV; *y*-axis, 200 ms. There is no change in the amplitude of the bicuculline (20 μM) – isolated $GABA_B$ response after a 10 min application of DHPG 50 μM ($n = 7$). Modified from Lafourcade CA and Alger BE (2008) Distinctions among GABA(A) and GABA (B) responses revealed by calcium channel antagonists, cannabinoids, opioids, and synaptic plasticity in rat hippocampus. *Psychopharmacology (Berlin)* 198(4): 539–549.

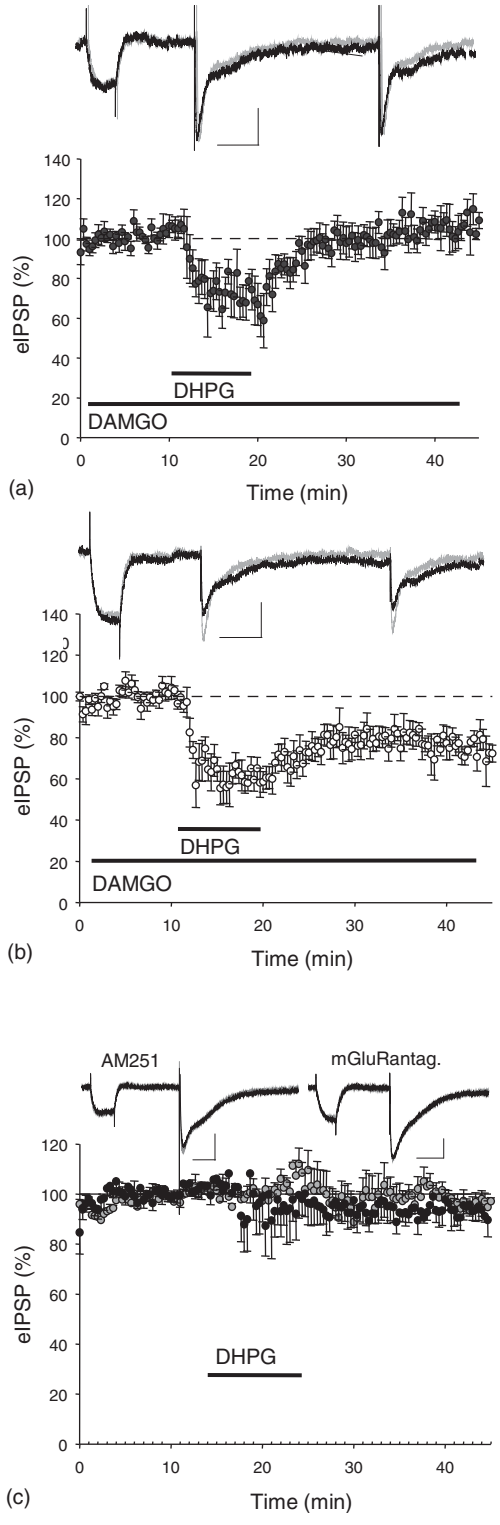

Figure 2 DAMGO prevents or reduces DHPG-induced iLTD induction. (a) Representative trace of a pair of eIPSPs, elicted at a 50 ms interval, before (gray trace) and 20 min after (black trace) DHPG 50 μM application. Pooled data ($n = 6$) of cells that did not show DHPG-induced iLTD in the presence of DAMGO. (b) Representative trace of a pair of eIPSP as in (a), before (gray trace) and 20 min after (black trace) DHPG 50 μM application. Pooled data of cells ($n = 7$) that did show decreased DHPG-induced iLTD in the presence of DAMGO. Dotted lines in (a) and (b) show estimated level of iLTD expected if MOR-expressing and CB1R-expressing cells did not interact. (c) Antagonists of CB1R or mGluR block iLTD. (a) Representative traces of eIPSPs before (gray trace) and 20 min after (black trace) DHPG 50 μM application in the presence of AM251, 3 μM (left), or group I mGluR antagonists (LY 367385, 100 μM, plus MPEP, 5 μM (right). Calib: 2 mV, 200 ms for all traces. iLTD induction by a 10 min DHPG 50 μM application is blocked by AM 251, 3 μM (black circles, $n = 4$) and by LY367385 100 μM plus MPEP 5 μM (gray circles, $n = 4$). Modified from Lafourcade CA and Alger BE (2008) Distinctions among GABA(A) and GABA (B) responses revealed by calcium channel antagonists, cannabinoids, opioids, and synaptic plasticity in rat hippocampus. *Psychopharmacology (Berlin)* 198(4): 539–549.

both short-term (DSI) and long-term (iLTD) responses. Different intracellular cascades mediate the different mechanisms. We did observe that in a sizeable fraction of cases, prior activation of MORs abolished the long-term effects of CB1R activation on inhibitory transmission (Figure 2). Since there was no overt short-term interaction, we infer that intracellular biochemical cascades responsible for the long-term effect could be altered by MOR activation. Unlike the short-term (i.e., DSI) suppression of transmission caused by CB1R activation (mainly transient downregulation of the N-type presynaptic calcium channel), iLTD involves inhibition of the cAMP-dependent protein kinase A pathway that affects vesicle release. The mechanisms of CB1R-induced iLTD are clearly localized in the presynaptic nerve terminals of the affected cells. Accordingly, the data imply a convergence of actions on the same interneurons. Only the CCK cells express CB1Rs, so a subset of these cells must be susceptible to MOR activation. Interference between MOR action and CB1R-induced iLTD is unlikely to take place at the level of the pyramidal cell, because DAMGO did not prevent the pyramidal cell from mobilizing endocannabinoids, as shown by the persistence of the short-term IPSP suppression mediated by mGluRs. Important future tasks will be to determine the identity of the subset of affected interneurons, and the molecular mechanisms of MOR interference with long-lasting CB1R effects. Figure 3 shows a simple summary diagram of these proposed interactions.

Epileptic Seizures and Neuroprotection

Opioids and cannabinoids – convulsant or anticonvulsant?

With regard to epileptic activity, opioids present a confusing picture. In general, they act as anticonvulsants, although both pro and anticonvulsant actions have been reported. Key variables include receptor subtype, agonist dose, and perhaps seizure model. For instance, in the pentylenetrazole model, opiates are anticonvulsant at low doses and proconvulsant at high doses. The

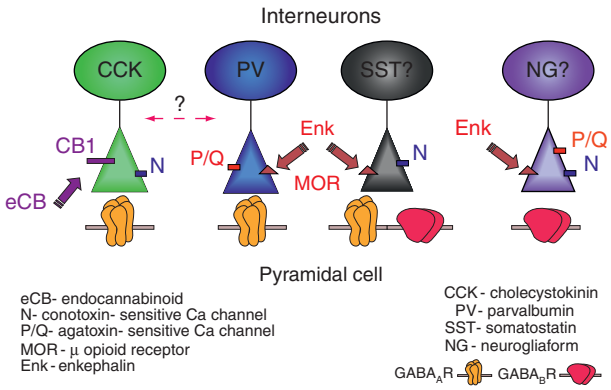

Figure 3 Schematic summary of proposed associations of hippocampal interneurons and MORs and CB1Rs. The diagram is meant to give a flavor for the characteristics of interneurons, and is not intended to be complete. Four major subtypes of interneurons are shown at synapses composed of GABA receptors; the basic properties of CCK and PV cells are widely agreed on, the somatostatin (SST) and neurogliaform (NG) cells less so. There is no direct evidence that the NG cells are the source of $GABA_B$ IPSPs, but they may well be a source. The SST cells express MORs, and may release via N-type channels; there are certainly other cell types with these characteristics. Not shown are electrical junctions: it is thought that CCK cells couple to each other, and PV cells couple to each other, in this way. CB1Rs are shown exclusively on CCK cells, but our recent data points to a minor component on another cell type, perhaps the PV cells. The large question mark and arrow between the PV and CCK cells suggest a possible interaction between them that would explain the unexpected ability of the P/Q channel antagonist, and the MOR agonist, to interfere markedly with CB1R-mediated iLTD.

cerebrospinal fluid of rats exposed to experimentally-induced seizures contains a substance that acts as an anticonvulsant when injected into a separate group of rats, and this anticonvulsant effect is antagonized by naloxone, implying that it is an endogenous opioid of some kind. Several laboratories report changes in the expression of opioid receptors or their endogenous agonists after the occurrence of seizures. These changes could be suppressed by kappa opioid peptides, whereas delta opioid peptides promoted status epilepticus.

Exogenous cannabinoids are generally found to be anticonvulsants, and indeed, this was one of their first documented medicinal uses in humans. Animal studies corroborate this picture, but have provided new insights and puzzles. In a maximal electroshock model of epilepsy, anandamide (administered i.p.) is anticonvulsant, and its effects are abolished by the CB1R antagonist SR141716. In a pilocarpine model, both THC and the synthetic agonist, WIN55212–2, injected i.p., prevented spontaneous seizures, supporting the idea that exogenous CB1R agonists are anticonvulsants. Likewise, CB1R antagonists appear to be proconvulsant. However, endogenous cannabinoids may act differently; as discussed later, some evidence suggests that endogenous cannabinoids have proconvulsant actions.

The precise regulation of the endocannabinoid system may determine whether cannabinoids enhance or diminish the occurrence of seizures. The exogenous application of cannabinoids could, in principle, have proconvulsant effects by inhibiting GABAergic interneurons, causing a concomitant increase in excitatory activity throughout the hippocampus. Nevertheless, cannabis use is not widely associated with epileptogenic effects, despite the prominent localization of CB1R on inhibitory nerve terminals in hippocampus and neocortex. A likely explanation for this observation is that CB1Rs are not indiscriminately located on all inhibitory nerve terminals, but only on those of a subgroup of the basket- and dendrite-targeting cells. This group of cells also expresses CCK. This group comprises a relative minority of all inhibitory synapses – probably ~20% in the hippocampus. Disrupting inhibition from these cells can alter neuronal network activity, but in ways that do not inevitably lead to seizures. As discussed below, CB1Rs present on excitatory nerve terminals, albeit at a low density, can play key roles in epilepsy.

Seizures affect endocannabinoids

Not only do endocannabinoids affect seizure activity, but seizures also directly affect the endocannabinoid system. CB1R receptor expression increases after pilocarpine-induced status epilepticus and kainate-induced seizures, and are accompanied by rapid postsynaptic increases in anandamide production in the hippocampus. Febrile seizures are observed in about 3% of young children, and about one-third of them are of prolonged duration (10–20 min). Prolonged febrile seizures during childhood are associated with an increased risk in developing temporal lobe epilepsy in adulthood. An animal model of febrile seizures has also been developed. In these rats, CA1 pyramidal cells are hyperexcitable and show rhythmic epileptiform discharges. Interestingly, febrile seizures also induce long-term changes in the endocannabinoid system. DSI is enhanced in rat hippocampal CA1 pyramidal cells following a single episode of prolonged febrile seizures during early development. Pharmacological and biochemical experiments have revealed that an increase in CB1R receptor number, rather than increased endocannabinoid mobilization, was the most likely cause. Responses to direct application of a synthetic CB1R agonist were enhanced, and Western blot analysis confirmed that CB1R protein expression was increased. In contrast, measurements of anandamide and 2-AG, revealed that their levels were not altered. As noted, a low density of CB1R does exist on excitatory hippocampal nerve terminals, it is present in high concentrations on CCK interneuron terminals, suggesting that a major effect of increased CB1R expression is a decrease in inhibition.

In a model of the febrile seizures, tetanic stimulation of Schaffer collateral synapses causes an activity-dependent

long-term DSI potentiation. Activation of AMPA/kainate receptors, metabotropic glutamate receptors, and CB1Rs are all required to induce the endocannabinoid plasticity. Mutual occlusion between febrile seizures and the synaptically-induced plasticity of the system suggest that these processes share common mechanisms of induction. The therapeutic implications for epilepsy treatment are complex: activation of CB1Rs is expected to be anticonvulsant, but could cause a long-term upregulation of CB1Rs on GABAergic terminals. Although endocannabinoid-mediated inhibition may not be strongly proconvulsant in some settings (because of the relatively small fraction of inhibitory synapses affected, see earlier sections), it could contribute in others. In contrast, therapeutic antagonism of CB1R during a seizure might transiently increase excitability in the short term, but prevent the upregulation of CB1R, and thus be beneficial in the long term.

Neuroprotection

Cell death may cause, or be caused by, prolonged seizures. A common mechanism of cell death is excitotoxicity resulting from excessive stimulation of glutamate receptors. In an in vivo model, application of the glutamate analog kainic acid to the cortex causes seizures that give rise to large-scale cell death. Although cell death is fairly widespread across cortical areas, the presence of endocannabinoids limits the extent of seizure-induced excitotoxic damage, and thereby acts as a neuroprotectant in this model. This conclusion follows from observations that kainic acid-induced cell death is greatly exacerbated in CB1R KO mice. It seems that interruption of the normal workings of the endocannabinoid system enables the excitotoxic effects to spread to a much wider area than usual. Endocannabinoid-induced neuroprotection is brought about by the ability of this system to limit the further release of glutamate that is triggered by the kainic acid seizure. Release of glutamate initiates a deleterious positive feedback loop, whereby depolarization and calcium-influx triggered by glutamate release causes more glutamate release, etc. Endocannabinoids break the cycle by inhibiting glutamate release. CB1Rs are present on glutamate axons and terminals, although at such a low level their presence was initially overlooked both anatomically and functionally. The levels of endocannabinoids that are released by physiological neuronal activity are insufficient to interfere with normal glutamate transmission. However, the much higher levels of endocannabinoid release associated with massive glutamate release and neuronal depolarization does effectively oppose further glutamate release. Release of glutamate, followed by metabotropic glutamate-induced endocannabinoid release from the pyramidal cells, could be sufficient to activate vast numbers of glutamate-associated CB1Rs. Hence, even though the system is not absolutely effective in preventing all neuronal cell death, it can limit the extent of the damage.

Targeted deletions of CB1R on specific cell populations reveal that CB1Rs on presynaptic glutamatergic nerve terminals in the forebrain and hippocampal hilus are most important for endocannabinoid-mediated neuroprotection. The system-wide, seizure-induced production of endocannabinoids can affect all CB1Rs, on inhibitory as well as excitatory terminals. It might be imagined that by inhibiting GABA release, and thereby limiting inhibition, activation of CB1R on the inhibitory cells would increase the extent of the excitotoxicity. This result does not occur, presumably because CB1R affects only a fraction (perhaps 10%–20%) of all inhibitory terminals – which even though individually powerful, are still in the minority. Continued functioning of the remainder of the inhibitory synapses may contribute some degree of neuroprotection. The distribution of CB1R on glutamatergic terminals is apparently much wider, perhaps encompassing the terminals of all of the major excitatory synaptic inputs to CA1, and accounting for up to half of all of the CB1R in the hippocampus. Thus, the net result of the endocannabinoid inhibition of both GABA and glutamate release would be neuroprotective.

Upregulation of opioid receptors occurs after seizures, and special attention has been given to the protective properties of the endogenous neuropeptide dynorphin in both animal models and human studies. The latter has not been without controversy, however. Initial findings showing correlations between epilepsy and the reported polymorphism of distinctive opiate genes (such as the promoter for the dynorphin gene or the MOR subunit gene) remain controversial. Since dynorphin can activate (with different affinities) the three main opiate receptors (mu, delta, and kappa), and arguably even NMDA receptors, more detailed studies are needed to understand the mechanisms underlying its role in epileptic conditions. New evidence from animal models does support a role for prodynorphin-derived peptides as anticonvulsants, almost exclusively through their activation of kappa opioid receptors. Further work will be needed to determine if such a role has been conserved in humans. MOR mRNA expression is downregulated by global ischemia (an insult that leads to the death of CA1 cells in the hippocampus), whereas intracerebroventricular injection of naloxone in vivo is neuroprotective. Similarly, MOR blockade is protective in models of hypoxia/ischemia, which seems to suggest that the decrease in MOR expression (and therefore the ensuing decrease in excitability) may be an important defense mechanism utilized by neurons.

Conclusions and Future Directions

Functional interactions between the opioid and cannabinoid systems, both of which independently modulate seizures, present a new, albeit challenging, target for pharmacological epilepsy therapies.

Several models have been proposed to explain opioid–cannabinoid interactions throughout the CNS, including shared downstream molecular targets, stimulation of opioid release by cannabinoids, ordopamine-mediated interactions. In hippocampus, immunohistochemical studies have indicated that MORs and CB1Rs are localized on distinct populations of cells. Nevertheless, our studies clearly show interactions between MOR and CB1R effects. These interactions may be subtle, and are centered on long-term regulation of synaptic inhibition. Their potential significance, however, suggests that further investigation of the mutual influence between opioids and cannabinoid systems on inhibition in the hippocampus will pay dividends.

Despite the widespread use of marihuana and heroin, and the increasing amount of research dedicated to understanding these systems, their relevance in some diseases is still controversial and many times confusing. The complexity of the opiate and cannabinoid systems, added to the fact that some diseases (like epilepsy) can have multiple etiologies, contributes to the difficulties researchers face when trying to understand the role that these drugs of abuse play in such diseases. A better understanding of how cannabioids and opioids are regulated, as well as what cells are susceptible to them in control and under epileptic conditions, would help us understand the importance each of these players has in such situations. This goal will certainly not be easily attained, as there are a considerable number of different types of interneurons in the hippocampus, as well as many types of opiate receptors and possibly more than one type of cannabinoid receptor. Understanding how these interneurons maintain normal hippocampal activity, what disrupts that regulation – and what roles are played by opioid or cannabinoid receptors in normal and disease processes – may prove crucial to our developing new approaches to prevent seizures. Such insight may also help us determine to what extent the treatment with exogenous cannabinoids may be useful to alleviate or prevent some of the symptoms associated with these pathologies.

Lastly, the strict regulations scientists face when conducting clinical trials with these drugs of abuse makes it harder to collect sufficient data to reach more robust conclusions. Making it easier for scientists to conduct more clinical trials is of vital importance to reach a faster understanding on the role of commonly-used drugs of abuse on the origin and/or maintenance of epilepsy, as well as on their ability to counteract some of its symptoms.

Galanin Modulation of Epileptogenicity

Introduction

Initial experimental evidence implicating galanin in the regulation of seizure activity came a decade after the discovery of the peptide (by Tatemoto and colleagues in 1983). In 1992, galanin was shown to suppress kindled seizures in rats upon its intrahippocampal administration. A year later, in vitro study suggested that galanin inhibits seizure activity via presynaptic inhibition of glutamate release from hippocampal neurons. Since then, with progress in our understanding of the physiology, biochemistry, and pharmacology of galanin and its receptors, data have accumulated regarding the involvement of galanin in epileptic processes. To further research on this topic, new animal models have been developed, including galanin knockout mice, galanin receptor knockout mice, and animals with focal overexpression of the peptide in limbic structures.

Background

Galanin is a 29 (30 in humans) amino acid neuroendocrine peptide, originally isolated from porcine intestine. Galanin has been identified in many species, including rodents and primates. The peptide modulates a variety of physiological processes and is widely distributed in both central and peripheral nervous systems, as well as in the endocrine system and the gut. Galanin modulates the release of gonadotropic hormone, prolactin, insulin, glucagon, growth hormone, and somatostatin and affects behaviors related to these hormones (for example, appetite, digestion, and sexual behavior).

In the brain, galanin is colocalized with, and modulates both pre and postsynaptic action of other peptides (somatostatin, neuropeptide Y, dynorphin, vasoactive intestinal peptide, substance P) and of classic neurotransmitters (acetylcholine, dopamine, serotonin, norepinephrine, glutamate). The peptide has several central effects, and has been shown to be involved in the regulation of satiety, nociception, mood, learning, and memory.

In the hippocampus, no galanin-containing neurons have been identified; galanin is localized exclusively in the axonal projections originating from the medial septum and locus coeruleus (**Figure 1(a)** and **1(b)**).

Galanin exerts its physiological effects via the activation of one of the three types of receptors, GalR1, GalR2, or GalR3. The first two types are abundantly expressed in the brain, particularly in the hippocampus. Like for many other neuropeptides, intracellular signaling cascades downstream from galanin receptors are multiple, and include inhibition of adenylate cyclase; opening ATP-sensitive K^+ channels (KATP); activation of G-protein coupled inwardly rectifying potassium channels (GIRK); inhibition of L-type and N-type Ca^{2+} channels; stimulation of inositol phospholipids turnover; stimulating or inhibiting Ca^{2+} mobilization; and activating MAP kinase.

Among these multiple effects of galanin, several are likely to be involved in the inhibition of seizure activity. One plausible scenario explaining how galanin might inhibit seizures was described in experiments showing that galanin inhibited depolarization-induced glutamate release from hippocampal slices. This action was prevented by coapplication of glybenclamide, a blocker of K_{ATP}. These results implied that in the hippocampus, galanin opens K_{ATP} channels, which in turn leads to membrane hyperpolarization and eventually to the inhibition of glutamate release from presynaptic terminals.

Methods

Studies of modulatory effects of galanin on experimental seizures have employed several animal models of epilepsy, such as kindling induced by electrical stimulation of the hippocampus; systemic injection of picrotoxin; status epilepticus induced by electrical stimulation of perforant path, by kainic acid, or pilocarpine; and acute chemoconvulsant-induced seizures (e.g., pentylenenetrazole). Biological activity of galanin receptor ligands has been evaluated upon their focal (intrahippocampal) or systemic administration. Functional state of galanin peptide and receptors in the epileptic brain has been studied using immunohistochemistry, quantitative polymerase chain reaction, and tissue binding of radioactive galanin receptor ligands. Manipulations with brain galaninergic signaling involved generation of transgenic mice, including galanin and/or galanin receptor knockouts and animals with upregulation, as well as local delivery of viral vectors carrying galanin gene.

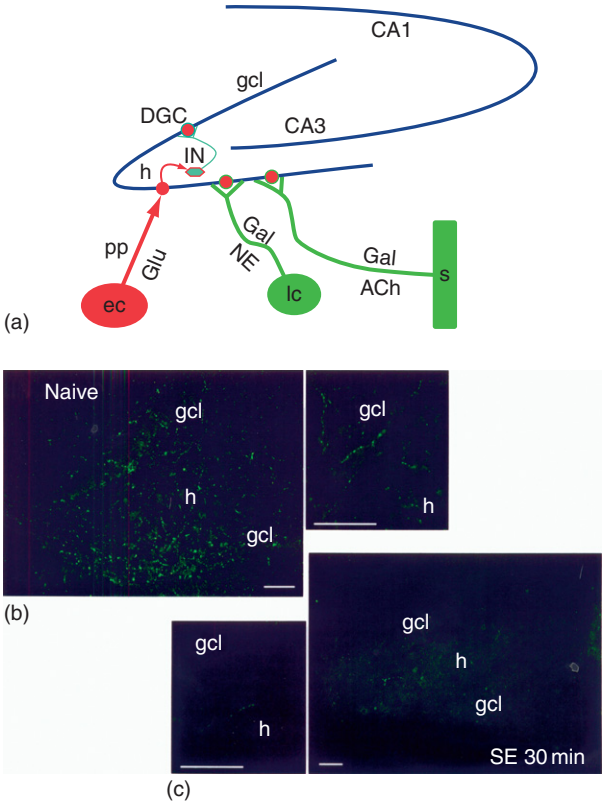

Figure 1 *Galaninergic innervation of the rat hippocampus under normal and seizure conditions*. (a) Anatomical substrate of anticonvulsant effects of galanin in the hippocampus. Dentate granule cells (DGC) (red circles in the granule cell layer) receive excitatory glutamatergic input from entorhinal cortex in a form of perforant path. In hilus DGC excite GABAergic interneurons, which in turn inhibit DGC. At the same time, dentate gyrus receives galaninergic innervation, which comes with noradrenergic fibers from locus coeruleus and cholinergic fibers from septum/diagonal band complex. Abbreviations: ec – entorhinal cortex; pp – perforant path; gcl – granule cell layer; h – hilus; lc – locus coeruleus; s –septum/diagonal band; DGC – dentate granule cells; IN – interneuron; Glu – glutamate; Gal – galanin; NE – norepinephrine; ACh – acetylcholine. Excitatory projections are shown by red and inhibitory-by green lines. (b) Galanin immunoreactivity in naïve rat dentate gyrus. Abbreviations: gcl – granule cell layer; h – hilus. Scale bar: 50 μm. (c) Perforant path stimulation-induced seizures lead to rapid depletion of galanin in the dentate gyrus. Immunohistochemical galanin labeling in the animal 30 min after the end of perforant path stimulation. Note the depletion of the peptide from galanin-positive fibers. Results

Effects of Exogenous Galanin Receptor Ligands on Seizures

The first report of anticonvulsant effects of galanin came from the experiments involving kindling induced by chemoconvulsant picrotoxin. Investigators showed that central administration of galanin (1–29) (which activated both types of brain galanin receptors) inhibited kindled seizures, and that the hippocampus played the key role in mediating anticonvulsant effects of the peptide. Subsequent studies revealed that intrahippocampal administration of galanin exerted strong antiepileptic effects under conditions of status epilepticus induced (in rats) by electrical stimulation of the perforant path. Similarly, intrahippocampal administration of a GalR2 preferential agonist, galanin fragment (2–11), protected against status epilepticus, particularly during its late phase. This finding was particularly significant, since it is known that the late phase of status epilepticus is resistant to many conventional antiepileptic drugs. At the same time, galanin receptor blockers facilitated the progression of status epilepticus-associated seizure activity.

The role of galanin receptor subtypes, and related downstream signaling cascades, in mediating antiepileptic effects of the peptide was explored in detail using the kindling model of epileptogenesis. In these studies, a preferential GalR1 blocker, synthetic peptide M617, delayed but did not block the acquisition of hippocampal kindling in rats. The anticonvulsant effect of this GalR1 agonist depended on an intracellular pathway involving G_i protein, since the effect was abolished in the presence of G_i protein inhibitor pertussis toxin (PTX); further, GIRK were implicated, since the effect was reversed by a selective GIRK blocker tertiapin Q (**Figure 2**). Interestingly, activation of hippocampal GalR2 may exert either anticonvulsant effects (which are coupled to G_i, but are GIRK-independent) or promote seizures in a manner that depends on $G_{q/11}$ protein (the effect of the peptide was abolished in the presence of $G_{q/11}$ protein blocker [D-Arg1,D-Trp5,7,9,Leu11]-substance P) and further downstream on the mobilization of intracellular Ca^{2+} (as the effect was sensitive to dantrolene, an agent which inhibits the release of intracellular Ca^{2+} from endoplasmic reticulum, **Figure 2**). Additional experiments revealed that a preferential blocker of GalR2, the synthetic peptide M817, abolished anticonvulsant effects of low-frequency electrical stimulation of perforant path on the severity of kindled seizures. These experiments led to the proposal of a sequence of galanin-regulated pathways that may modulate the evolution of the epileptic state (**Figure 2**).

Seizures Themselves Modify the Expression of Galanin and Galanin Receptors in the Brain

Experimental studies involving status epilepticus in rodents have shown changes of galanin expression in the hippocampus following seizures. Profound depletion of galanin in the axonal hippocampal projections, originating both from locus coeruleus and from medial septum, was reported as early as 30 min after the onset of electrically-induced status epilepticus in rats (**Figure 1(b)** and **1(c)**). Reduced expression of galanin was observed as late as 1 week after the insult, and was suggested to be a contributory factor in the progression of both status

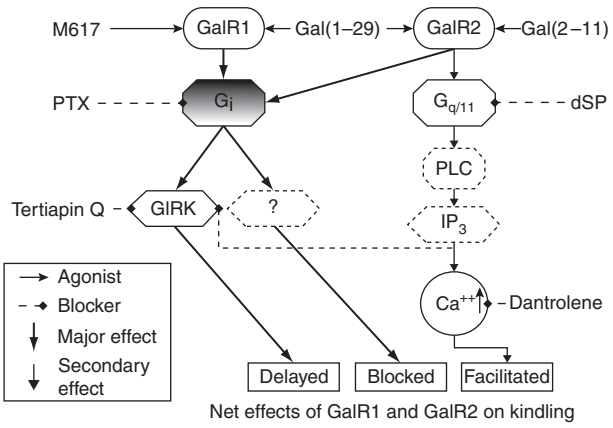

Figure 2 *Proposed mechanisms of antiepileptic action of hippocampal GalR1 and GalR2 under conditions of kindling model of epilepsy, based on the in vivo pharmacological analysis.* Activation of hippocampal GalR1 by both a nonselective agonist galanin (1–29) and by a selective agonist M617 inhibited kindling. These effects were abolished by pretreatment with PTX, an inhibitor of G_i protein, or by pretreatment with Tertiapin Q, a selective blocker of G-protein coupled inwardly rectifying potassium channels (GIRK). Inhibition of Glutamate (Glu) release from hippocampal neurons due to GIRK-induced membrane hyperpolarization is indicated as a likely end-effect of the activation of GalR1. Activation of hippocampal GalR2 using galanin (2–11) (which acts at GalR2) also exerted antiepileptic effect. However, unlike GalR1, the effect of GalR2 activation was not simply abolished by PTX: the inhibition of G_i protein inversed the effect of GalR2 agonist from anticonvulsant to proconvulsant. The latter action of GalR2 was prevented when $G_{q/11}$ protein was blocked by [D-Arg1,D-Trp5,7,9,Leu11]-substance P (dSP). Activation of phospholipase C (PLC), inositol triphosphate accumulation (IP_3) and mobilization of intracellular Ca^{2+} are indicated as plausible downstream signaling. The latter was confirmed experimentally, as the facilitation of seizures by GalR2 agonist was abolished in the presence of dantrolene, which inhibits the release of Ca^{2+} from endoplasmic reticulum. Finally, the fact that inhibition of G_i abolished anticonvulsant effect of GalR2 agonist in Tertiapin Q-independent manner suggests the presence of antiepileptic pathway downstream from GalR which is coupled to G_i, but is independent on GIRK.

epilepticus and of subsequent chronic epilepsy. Concurrently with the depletion of the peptide from the axonal pool, de novo galanin expression was reported in the inhibitory interneurons of hilus of the dentate gyrus after status epilepticus both in rats and in mice. The physiological significance of the latter phenomenon remains unclear, although it has been suggested to represent a compensatory mechanism in response to the fatigue of galaninergic innervation of the hippocampus.

While status epilepticus compromised the expression of galanin in the hippocampus, it did not affect the expression of GalR1. At the same time, the expression of GalR2 decreased by 30% as compared with control values.

In conclusion, seizure activity leads to the depletion of galanin in the hippocampus; given the effects of exogenously applied peptide, this depletion may exacerbate epileptic process. Together with complete (GalR1) or partial (GalR2) preservation of targets for action of galanin in epileptic hippocampus, the discussed findings justify the utility of prospective galanin-based antiepileptic drugs (see later text).

Genetic Manipulations with Galanin and its Receptors Modify Seizure Phenotype

The first direct evidence that endogenous galanin is capable of counteracting seizure activity came from the experiments involving mutant animals. In the status epilepticus model, mice with the functional disruption of the galanin gene showed a greater predisposition to seizures than their wild type littermates (as reflected in a shorter time to induce seizures as well as in greater severity of the convulsions in response to hippocampal stimulation). In contrast, mice that overexpressed galanin in the brain (under control of a dopamine beta hydroxylase promoter, since galanin is colocalized with norepinephrine) showed enhanced resistance to seizure induction. Additional in vitro studies revealed that hippocampal slices obtained from galanin knockout mice exhibited significantly higher glutamate release upon K^+-induced depolarization, while hippocampal slices from galanin-overexpressing animals showed virtually no glutamate release in response to the same procedure. These observations confirmed the earlier suggestion that galanin exerts anticonvulsant effect through presynaptic inhibition of glutamate release.

Overexpression of galanin with the transgene under control of a promoter (platelet-derived growth factor B) which does not confine the overexpression to neuronal populations with a certain neurotransmitter profile, inhibited the progression of kindled seizures, and increased afterdischarge threshold upon hippocampal stimulation. These data, too, are consistent with an antikindling action of galanin.

The development of galanin receptor knockout mice afforded further understanding of the role of galanin receptor subtypes in epileptogenesis. For example, 25% of GalR1 knockout mice exhibited spontaneous seizures. Furthermore, epileptic animals showed a cascade of changes in the expression of other several neuropeptides, which was similar to the pattern of changes observed in models of limbic epilepsy. Furthermore, spontaneously seizing GalR1 knockout mice exhibited reduced frequency of miniature inhibitory postsynaptic currents (mIPSCs) in hippocampal CA1 pyramidal neurons, thus implicating impaired synaptic inhibition in the seizure phenotype. Moreover, the subpopulation of GalR1 knockout animals that did not show spontaneous seizures developed more severe and longerlasting seizure activity, and more profound seizure-induced hippocampal neuronal injury (compared with controls), under conditions of pilocarpine – and perforant path stimulation – induced status epilepticus.

In contrast, GalR2 knockout mice exhibited neither spontaneous seizure phenotype nor enhanced susceptibility in response to convulsions induced by chemoconvulsants. However, given the pharmacological studies discussed earlier, the absence of the enhanced predisposition to seizures in GalR2 knockout animals does not mean that this receptor is not involved in the regulation of seizure activity. Rather, the 'normal' phenotype suggests that the elimination of GalR2 is compensated through the activation of other regulatory factors. This possibility has been supported by the finding that GalR2 mice showed no other physiological deficits (including normal sensory function, feeding behavior, reproduction, mood, learning, and memory) although other lines of research have shown that these activities are modulated by GalR2. Indeed, the lack of phenotypic alterations in transgenic animals – due to the redundancy or compensation – is not uncommon; this is a drawback of the transgenic approach, but can be addressed using an experimental approach discussed later.

Focal Over Expression of Galanin in the Brain Suppresses Seizures

An elegant approach further exploring the anticonvulsant role of galanin was applied in the studies that used an adeno-associated viral (AAV) vector, carrying the galanin gene, to transfect neurons in vivo. A coding sequence of the galanin gene was cloned and inserted into the AAV vector, which also contained fibronectin secretory signal sequence (FIB), to ensure not only expression but also active secretion of galanin into the extracellular space. In vivo injection of AAV-FIB-galanin vector into the inferior colliculus of the rat significantly attenuated seizures induced by focal electrical stimulation of this brain area. In contrast, administration of AAV-galanin vector which led to the overexpression of galanin – but not to the increased secretion of the peptide – had no anticonvulsant effects. Later, investigators showed that the administration of AAV-FIB-galanin into the pirifirm cortex attenuated seizures induced by kainic acid. The necessity of active secretion of galanin from peptide-expressing neurons for achieving the inhibition of seizures was addressed in different set of experiments; these studies showed that simple overexpression of galanin – induced by AAV-Neuron Specific Enolase (NSE)-galanin vector inserted into rat dentate gyrus neurons – was sufficient for mitigating the severity of convulsions induced by intrahippocampal administration of kainate. This latter result suggested that the secretion of galanin, which was presumably induced by seizures from neurons expressing galanin de novo, was sufficient to inhibit focal epileptic activity.

A philosophically similar approach was applied to examining the role of galanin receptors in epilepsy. Peptide nucleic acid (PNA) antisense, was used to downregulate GalR2 in the hippocampus in vivo. PNA is a DNA or RNA mimic, which binds to DNA or RNA in complementary antiparallel fashion, thus inhibiting transcription or translation. PNA which was targeted at mRNA encoding GalR2 reduced the expression of the latter receptor in the hippocampus by 50% after 1 week of focal administration. This downregulation of hippocampal GalR2 expression dramatically increased both the severity and the duration of status epilepticus induced by hippocampal stimulation.

Depending on the Site of Action, Galanin may be Either Anti or ProConvulsant

In addition to its direct action on hippocampal receptors, galanin is capable of modulating limbic seizures through interaction with outside neuronal populations that project to the hippocampus. The interaction between galanin and serotonin (5-HT) in dorsal raphe is a good example of how its external (to hippocampus) modifier function can alter hippocampal activity and limbic seizures. 5-HT possesses antiepileptic properties in the hippocampus via the activation of 5-HT_{1A} receptors. In dorsal raphe, a major source of serotonergic innervation of the hippocampus, local activation of GalR1 augmented the severity of limbic seizures both in rats and in mice, and concurrently reduced serotonin concentration both in dorsal raphe and in the hippocampus. In contrast, local dorsal raphe activation of GalR2 (using a preferential GalR2 agonist), reduced the severity of seizures in both rats and mice, and increased serotonin concentration in both hippocampus and dorsal raphe. Injection of native galanin molecule (which does not discriminate between GalR1 and GalR2) into the dorsal raphe of GalR1 knockout mice produced anticonvulsant effects, thus corroborating the anticonvulsant profile of GalR2 in dorsal raphe.

Finally, systemic depletion of 5-HT in the brain, which was achieved via the administration of a 5-HT-selective neurotoxin (para-chloroamphetamine), eliminated both proconvulsant effects of GalR1 and anticonvulsant effects of GalR2.

These experiments emphasize the importance of the site of action of galanin, and of the neurotransmitter system subject to the modulatory effects of the galanin peptide, in the regulating of seizure activity.

Future Research

Conclusions

Several lines of evidence support the notion that galanin acts as an endogenous anticonvulsant peptide: (1) Exogenous central administration of GalR agonists inhibits seizures, while GalR blockers facilitate epileptic activity;

(2) Compromised galaninergic innervation of the hippocampus parallels the evolution of epileptic state; (3) Transgenic animals which lack either galanin, or its receptor GalR1, exhibit enhance susceptibility to seizures, or even have spontaneous seizure phenotype; (4) Focal overexpression of galanin in limbic structures using virus vector technique mitigates seizure activity, while focal knockdown of galanin receptors (GalR2) in the hippocampus promotes seizures. Antiepileptic properties of galanin, along with the advance of medicinal chemistry, open the opportunity for the development of novel type of antiepileptic drugs, which suppress seizures through the activation of galanin receptors.

A Prospect for Galanin-Based Antiepileptic Drugs

Anticonvulsant effects of galanin, as well as its physiological activity in other neurological disorders (e.g., impairments in memory, mood, and appetite), make it an attractive target for therapeutic interventions. However, native galanin, not unlike other peptides, is a poor candidate for a therapeutic agent owing to its low bioavailability, particularly because of it degradation by peptidases and low permeability through the blood–brain barrier.

The first successful attempt in overcoming this drawback was accomplished using a Combinatorial approach – synthesis of a small nonpeptide molecule with physicochemical, biochemical, and pharmacological properties resembling those of galanin. Screening of the galanin sequence established Trp-2, Asn-5, Tyr-9 as a 'pharmacophore' – that is, an amino acid sequence primarily responsible for the physiological effects of the whole peptide molecule. On the basis of this finding, the first nonpeptide low molecular weight GalR agonist, galnon, was synthesized. This compound exhibited equal affinity towards GalR1 and GalR2, penetrated the blood–brain barrier, and showed potent anticonvulsant effects upon systemic administration in both rats and mice. The next generation of nonpeptide galanin agonists included galmic, with preferred action toward GalR1 over GalR2; this compound was also effective in inhibiting seizures in rodents upon systemic administration.

However, both galnon and galmic suffered the same shortcoming – particularly, they had only moderate to low affinity towards galanin receptors. This drawback prompted the search for alternative strategies for the development of galanin-based antiepileptic drugs. Such efforts led to the synthesis of NAX-5055, a rationally designed analog of truncated galanin neuropeptide that contains lipo-amino acid and basic residues at the C-terminus. The compound was shown to be active after systemic administration and under conditions of several seizure models, including kindling epileptogenesis.

The development of galanin-based antiepileptic drugs is still in its nascent stage. The ongoing research has been focusing on balancing reasonable affinity of such compounds towards galanin receptors with their biological availability (i.e., preservation of anticonvulsant efficacy upon systemic administration), evaluation and mitigation of possible side effects (for example inhibition of the activity of pancreatic beta-cells), and synthesis of ligands with selective affinity towards galanin receptor subtypes.

Participation of Opioid Peptides in Epilepsy

Introduction

Opioid peptides are endogenous substances that exhibit the pharmacological properties of morphine. Morphine (named after Morpheous, the Greek god of dreams) is an alkaloid analgesic, isolated as one of the components of opium, the infamous product of the poppy, *Papaver somniferum.*

The opioid peptides are involved in physiological actions such as motor behavior, feeding, drinking, analgesia, immune responses, memory, and in the regulation of gastrointestinal, cardiovascular, neuronendocrine, and cognitive functions. They are also implicated in the mechanisms of pain, addiction, tolerance, dependence, stress, depression, and mental illness. Current evidence supports the view that when normal regulatory processes are disrupted, endogenous opioid peptides may play a significant role in the etiology or elaboration of seizure phenomena, and may contribute to neurological deficits encountered in association with epilepsy. Opioid peptides are also involved in neurological disorders such as Alzheimer's disease and Huntington's disease.

Background

Classification and Localization

In the early 1970s, two pentapeptides with opiate-like activity were extracted from porcine brain and characterized. These peptides differed only in the C-terminal amino acid, and named met-enkephalin (Tyr–Gly–Gly–Phe–Met) and leu-enkephalin (Tyr–Gly–Gly–Phe–Leu). At present, three major branches of the opioid peptide greater family are known: the proopiomelanocortin-derived peptides (adrenocorticotrophic hormone, β-lipoprotein, β-endorphin, melanocyte-stimulating hormones, and corticotrophin-like intermediate lobe peptide), the proenkephalin-derived peptides (met-enkephalin, leu-enkephalin, peptide F, amidorphin, met-enkephalin–Arg–Gly–Leu, peptide E, met-enkephalin–Arg–Phe, etc.), and the prodynorphin-derived peptides (neoendorphins and dynorphins). Immunoreactivity corresponding to the different opioid peptides is widely distributed throughout the brain and spinal cord, the highest concentrations being in the hypothalamus, anterior pituitary, reticular formation, caudate, hippocampus, amygdala, periaqueductal gray, substantia nigra, and neocortex.

Although endogenous opioid peptides have been known for many years, initial attempts to label the opioid receptors biochemically were without success. In 1973, three laboratories (Pert and Snyder, Terenius *et al.*, and Simon *et al.*) reported the biochemical demonstration of opioid binding sites using ^{3}H-labeled naloxone, dihydromorphine, or etorphine. For the most part, these initial studies were labeling mu binding sites, since ^{3}H-naloxone and ^{3}H-dihydromorphine are relatively mu selective, whereas ^{3}H-etorphine labels a variety of subtypes in addition to mu. In 1976, Martin and coworkers found different pharmacological profiles for a series of opiate alkaloids and suggested the existence of three types of opiate receptors: 'mu' for morphine, 'kappa' for ketocyclazocine, and 'sigma' for *N*-alylnormetazocine (SKF 10047). Thereafter, in 1977, Kosterlitz's group postulated the presence of a distinct opioid receptor termed 'delta.' The mu receptor is operationally defined as the high-affinity site at which morphine-like opioids produce analgesia and other classical opioid effects. The delta receptor is operationally defined as the receptor (found in peripheral tissues such as vas deferens as well as central nervous system) that exhibits a high affinity for the naturally occurring enkephalins. The kappa receptor is the receptor at which opioids produce analgesia and is highly selective for dynorphins. Opioid concentrations in the low nanomolar range are needed to obtain favorable ratios of specific-to-nonspecific binding.

Phylogenetically, opioid binding sites have been reported in the nervous system of a wide range of species, including insects and mollusks. In the mammalian central nervous system, the existence of opioid receptors is found within neuronal and glial cell membranes, and no significant specific opioid binding is detected in white matter. High levels of opioid receptor binding are detected in the brain areas associated with the limbic system. The importance of the hippocampal formation in learning and memory mechanisms and the role of this region in certain forms of epilepsy have greatly stimulated the analysis of opioid peptides' effects in this structure. Activation of mu and delta opioid receptors induces excitatory effects on the activity of pyramidal neurons via disinhibitory mechanisms involving GABAergic interneurons. In contrast, activation of kappa opioid receptors induces inhibitory effects on perforant path-granule cell excitatory neurotransmission and synaptic plasticity in the hippocampal dentate gyrus.

Effects of Opioid Agonists and Antagonists on Seizure Activity

Reports dating back to the nineteenth century indicate that opium may induce proconvulsant and anticonvulsant

effects. Modern studies indicate that opioid peptides may induce excitation or inhibition, depending on the route of administration and the type of seizure or the experimental model evaluated.

That the endogenous opioids may play a role in epilepsy was considered after it was demonstrated that the intracerebroventricular (i.c.v.) administration of met-enkephalin, leu-enkephalin, morphine, or β-endorphin in normal animals produces a prolonged immobile, stuporous state with intermittent sudden twitches and 'wet-dog shakes'. These behaviors are accompanied by abnormal electroencephalographic activity consisting of brief episodes of rapidly repetitive spikes evolving into slower high-amplitude sharp waves. Both the pathological behavioral signs and the abnormal electrographic patterns are reversed by naloxone, a competitive antagonist for mu, delta, and kappa receptors. Similarly, the injection of morphine facilitates the status epilepticus induced by pilocarpine, an effect blocked by naloxone.

The administration of opioid agonists produces anticonvulsant effects on generalized seizures induced by fluorothyl (pentazocine or meperidine, i.c.v.), estricnine (morphine, i.c.v.), and electroshock (morphine, β-endorphin, DADL, i.c.v.). The opioid peptides modify the seizure activity in natural models of epilepsy. In gerbils, the systemic administration of naloxone enhances, whereas β-endorphin (i.c.v.) or morphine (s.c.) decreases the severity of seizures. The i.c.v. injection of morphine, met-enkephalin, or β-endorphine augments the latency to myoclonus in the photosensitive baboon *Papio papio*. In fully kindled rats, the i.c.v. administration of mu, but not delta, agonists of opioid peptides reduces the intensity of generalized seizures. In contrast, the antagonist naloxone facilitates the development of the kindling. During the postictal period (after generalized seizures induced by kindling), the administration of opioid agonists enhances the refractoriness for subsequent seizures whereas naloxone blocks this effect.

Blockade of delta receptors prevents the establishment of seizure activity in a model of self-sustaining status epilepticus, while their activation facilitates its development. In contrast, activation of mu receptors does not modify seizure activity in that experimental model. Activation of kappa receptors is highly effective in suppressing seizure activity in animal models of epilepsy, and it plays an inhibitory influence in the induction and maintenance of status epilepticus.

Effects of Seizure Activity on Endogenous Opioid Peptides

Evidence from both humans and experimental models supports the view that endogenous opioids are activated as a consequence of the seizure activity. In 1979, Frenk and collaborators suggested that endogenous opioid peptides are released after convulsive seizures, and this induction has inhibitory effects and enhances refractoriness for subsequent seizures during the postictal depression period. In 1981, Vindrola and Fernandez-Guardiola reported that the cerebral tissue levels of enkephalins are modified by electrical kindling model, an effect that depends on the seizure rate and the peptide evaluated; for example, leu-enkephalin increases progressively through the kindling process, whereas met-enkephalin levels augment only after several generalized seizures are produced. At present, several studies support the view that the opioid peptides, their precursors, and their receptors are modified as a consequence of seizure activity in human brain and experimental models, as described below.

Opioid Peptides in Patients with Epilepsy

Opioid peptides are released as a consequence of seizure activity in the human brain. This notion is supported by the increased content of leu-enkephalin, but not of met-enkephalin or β-endorphins, in the cerebrospinal fluid of patients with partial and generalized seizures. This effect is not caused by antiepileptic drugs or because of structural pathological changes. A diffuse release of cerebral opioids, as evidence by displacement of ^{11}C-diprenorphine binding, has been seen in the association cortex after repeated absence seizures and in parieto-temporo-occipital cortex during reading-induced seizures. These findings suggest that opioid-like substances are released as a consequence of seizures.

The opioid receptor distribution is modified in the epileptic focus and the surrounding areas involved in seizure propagation, a situation that depends on the type of epilepsy. In patients with mesial temporal lobe epilepsy (MTLE), positron emission tomography (PET) with specific opiate receptor ligands has revealed a regionally specific increase of opioid receptor availability in the temporal pole and fusiform gyrus ipsilateral to the seizure focus immediately after spontaneous seizures, with a gradual return to basal levels during the interictal period. Interictally, amygdala from patients with MTLE presents reduced mu binding that could be due to epilepsy-induced volume changes of this brain area. In the hippocampus of patients with temporal lobe epilepsy (TLE) induced by tumors or not associated with neuronal loss, the highest density of kappa opioid receptors is found in CA1 and subiculum, whereas hippocampi from patients with MTLE show significant reduction of kappa receptors in CA1. Interictal PET with specific opiate receptor ligands has also revealed increases in both mu and delta opioid receptors in neocortex overlying limbic structures. Augmented mu receptor binding is confined to the middle aspect of the inferior temporal cortex, whereas increased binding of delta receptors is found in the mid-inferior temporal cortex and the anterior aspect of the middle and superior temporal cortex. The interictal enhanced opioid

receptor binding in the neocortex of patients with MTLE has been suggested as a compensatory mechanism that prevents the spread of seizure activity originating in the limbic structures.

In contrast with MTLE, neocortical epileptic tissue surgically obtained from patients with pharmacoresistant TLE show increased cholinergic receptors and no significant changes in opioid receptors, whereas the surrounding cortical areas are characterized by decreased mu and delta opioid receptors. These results indicate an increased excitatory influence in the neocortical epileptic focus (high cholinergic receptor density), but decreased inhibitory neurotransmission in the area of seizure propagation (low opioid receptor binding in the surrounding cortex). In patients with childhood and juvenile absence epilepsy, PET studies revealed an acute reduction in ^{11}C-diprenorphine binding (which binds with similar affinities to the mu, delta and kappa opioid receptors) in association areas of neocortex, but not in other brain areas. This set of results suggests that the reduced opioid receptor binding in the neocortex of patients with TLE and the absence of seizures may facilitate the spreading of epileptic activity (Figure 1).

Recent Results

Kindling and Opioid Peptides

Kindling is an experimental model of epileptogenesis consisting of a progressive development of behavioral and electrographic changes that culminate in generalized tonic–clonic seizures. This process involves functional and structural changes similar to those detected in human TLE. A significant enhancement of leu- and met-enkephalin tissue levels and their precursor proenkephalin in the amygdala complex is detected during electrical kindling. Partial seizures induced by kindling augment met-enkephalin release in the basolateral nucleus, but generalized seizures are associated with a significant decrease in opioid release in this brain area. It is possible that the augmented extracellular levels of opioid peptides after partial seizures prevent seizure propagation from amygdala to other brain structures. The observation that the amygdala fails to respond to electrical stimulation with increased opioid peptide release after the fully kindled state is achieved suggests a facilitation of seizure spread and a reduction in arrest mechanisms in this brain area. It is interesting to note that although the amygdala complex displays significant alterations in opioid tissue levels and release during the kindling process, it does not show mu receptor binding alterations.

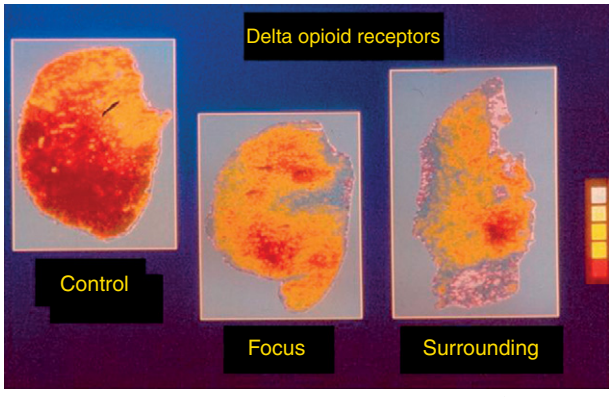

Figure 1 Distribution of mu receptors labeled with [^{3}H]DAMGO in cortex of a control subject, and neocortical epileptic foci and surrounding area obtained from a patient with pharmacoresistant epilepsy. Notice the reduced binding in the surrounding cortex. Structures with high MO receptor binding appear as black and red areas, whereas blue areas delineate structures with low receptor binding.

Striatonigral circuitry has been shown to be involved in the control of seizure activity. In the caudate–putamen, no significant changes have been found in opioid peptide tissue levels, their precursors, or their release during amygdala kindling. However, this region shows an enhanced mu receptor binding after partial and generalized seizures that might be associated with supersensitivity to endogenous peptides released from cells in other brain areas after seizures.

The frontal lobes have an important role in the propagation of complex partial seizures and they participate in the stability of generalized seizures. Cerebral cortex shows elevations of proenkephalin mRNA and met-enkephalin-like immunoreactivity during the early and late kindling stages. Cortex also presents a late (beginning at 2 h) and prolonged (up to 24 h) decrease in both prodynorphin mRNA and dynorphin A immunoreactivity after kindled seizures. Frontal cortex demonstrates increased mu receptor binding after partial and generalized seizures induced by kindling. However, augmentation of opioid peptide release is only evident in this brain area when animals become epileptic and present generalized seizures. In temporal cortex, enhanced release of opioid peptides is only detected after generalized seizures, whereas mu receptor binding is augmented during the early kindling stages and decreased long-term after the last generalized seizure. The enhanced opioid peptide release in frontal and temporal cortices detected immediately after generalized seizures in the epileptic brain may underlie postictal seizure suppression as well as some behavioral disturbances noticed during the postictal and interictal periods.

In hippocampus, expression of proenkephalin mRNA and tissue levels of derived peptides are enhanced throughout the course of amygdala kindling development, persisting in the fully kindled state. Prodynorphin mRNA levels transiently increase (1 h) after kindled seizures, and return to baseline by 2 h, whereas dynorphin A levels are slightly decreased at 1 h, but increase twofold at 2 h and return to baseline by 6 h. Hippocampus presents increased

leu-enkephalin and dynorphin release immediately after partial and generalized seizures induced by amygdala kindling stimulation. This brain area presents a rapid and sustained increase of met-enkephalin-like immunoreactivity, but there is no evidence for met-enkephalin release after kindling seizures – although release of this peptide, in addition to leu-enkephalin and dynorphins, is evoked by high-potassium stimulation. This result can be interpreted in two ways: First, if the leu-enkephalin released originates in proenkephalin-containing neurons, then it is possible that met- and leu-enkephalins derived from the proenkephalin precursor are differentially released by amygdala kindling stimulation. Second, it is possible that the leu-enkephalin released after kindling stimulation is derived from prodynorphin localized in mossy fibers (production of leu-enkephalin by dynorphinergic neurons has been demonstrated).

Brain structures in which no significant receptor binding alterations are observed during early kindling stages (entorhinal cortex) and 24 h after the last generalized kindling seizure (substantia nigra) show enhanced tissue levels of opioid peptides and their precursors during the kindling process. These regional discordances suggest that the regulation of opioid peptide synthesis and release, and regulation of opioid receptor binding, depend on independent processes. The lack of correspondence of these events in restricted anatomical structures suggest that opioid peptides released in one brain region may induce changes in distant receptor (e.g., via transport in cerebrospinal fluid).

These data (see Table 1) demonstrate a constellation of alterations in several opioid peptide systems with distinct spatiotemporal patterns, particularly in regions known to be important in kindling and epilepsy. The mismatch between changes in the tissue content and release is probably because they are regulated by separate mechanisms.

Table 1 Changes in opioid peptides during the kindling process

Kainic Acid and Opioid Peptides

Kainic acid (KA) is an analog of the excitatory amino acid transmitter glutamate. It is a potent excitatory compound that produces important neurotoxic actions. The systemic or intracerebral administration of KA initially induces status epilepticus, which is followed by long-term changes such as spontaneous seizures and progressive neuronal damage, primarily in the hippocampus. These changes closely resemble the pathology associated with TLE in humans. Particularly because of these long-term effects, KA injections in animals have been considered an experimental model of MTLE.

Hippocampal proenkephalin and prodynorphin mRNA levels are elevated during the KA-induced status epilepticus and return to basal levels by 48 h after treatment. In contrast, KA causes a transient decrease in hippocampal tissue content of met-enkephalin and dynorphins, both during and following status epilepticus (3–6 h after KA administration). Subsequently (1–4 days after KA), increased immunoreactive met- and leu-enkephalin levels in the hippocampus are detected, sometimes proceeded by an initial decrease a few hours after seizure onset.

During the KA-induced status epilepticus, there is a strong but transient, increase of leu-enkephalin, met-enkephalin, and dynorphin release in the hippocampus. These changes are prominent only during status epilepticus. Several days after status epilepticus, the hippocampal opioid peptide release is decreased (relative to control animals) in basal conditions but evoked by K^+ stimulation. Interestingly, tissue content in basal conditions is augmented, suggesting that the mechanisms of release are altered. It is probable that the depleted tissue content and enhanced biosynthesis of prodynorphin- and proenkephalin-derived peptides, observed short-term after KA, result from their enhanced release during status epilepticus. In contrast, the reduced extracellular opioid peptide levels detected long-term after KA could be associated with status epilepticus-induced hippocampal damage or high enzymatic activity involved in degrading opioid peptides.

In contrast to amygdala kindling, during which met-enkephalin is not released in hippocampus (see earlier), KA-induced status epilepticus augments the extracellular levels of this peptide in this brain area. This observation suggests that hippocampal proenkephalin- and prodynorphin-derived peptides may be differentially released in the two experimental models of epilepsy. However, several days after the ictal event both KA and kindling model share similar effects – i.e., decreased hippocampal opioid peptide release.

Concerning opioid receptors, the autoradiography approach does not reveal mu receptor changes 24 h after KA-induced status epilepticus in hippocampus, amygdala, or other regions of limbic cortex – structures that present intense seizure activity and neuronal damage. In contrast, some brain areas such as neocortex and substantia nigra – which do not show significant metabolic alterations during status epilepticus, but do present with edema, perivascular hemorrhages, and progressive necrosis – demonstrate enhanced mu receptors 24 h after KA. The increment of mu receptors in these specific brain areas may be involved in effects produced by short periods of hypoxia or ischemia.

Pharmacological experiments indicate that mu but not delta opioid receptor stimulation intensifies KA-induced neurotoxicity in rat hippocampus. It is possible that the enhanced mu receptor binding detected in amygdala and hippocampus 40 days after status epilepticus is involved in the neuronal necrosis detected in these brain areas of adult rats surviving long-term after KA (**Figure 2**).

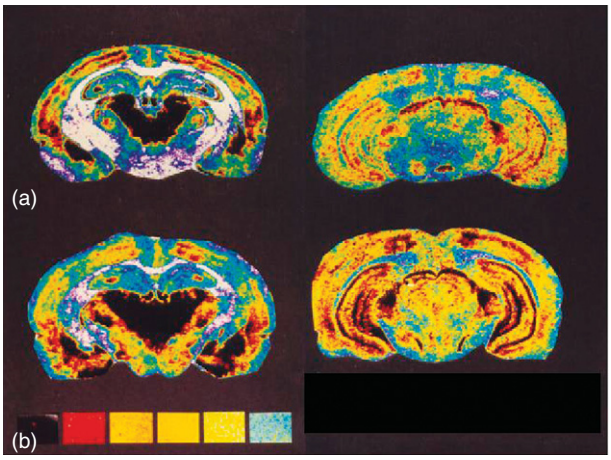

Figure 2 Distribution of mu receptors labeled with [^{3}H]DAMGO in coronal sections of adult rats at the level of amygdala and dorsal hippocampus (left) and substantia nigra, central gray and ventral hippocampus (right). In comparison with the sections of a control rat (a), the sections of an animal sacrificed 40 days after KA-induced status epilepticus (b) shows high receptor binding in amygdala, ventral hippocampus, and substantia nigra. Notations as in **Figure 1**.

Does a Single Seizure Activate Opioid Peptide System?

An important issue to be considered is whether a single subconvulsant stimulation is able to modify the opioid peptides in a normal brain. The application of a single kindling electrical stimulation in amygdala of naive animals enhances opioid release in amygdala and hippocampus and increases proenkephalin gene expression in olfactory tubercle, ventral striatum, arcuate nucleus, and ventral hippocampus. In normal rats, a subconvulsant amount of pentylenetetrazol (PTZ, 30 mg/kg, i.p.), an antagonist of $GABA_A$ receptors, induces significant changes in opioid peptide system. Thirty minutes after its administration, animals show an enhanced analgesic response, an effect associated with increased opioid peptide release in amygdala. Twenty-four hours after PTZ injection, there is reduced mu and delta receptor number in cortex and amygdalae, whereas the steady-state proenkephalin mRNA levels in hippocampus, amygdala, and piriform cortex is augmented. If PTZ enhances the extracellular levels of opioid peptides, they may lead to opioid receptor internalization and their subsequent degradation. This idea is supported by data indicating that the administration of opiates induces rapid internalization of opioid receptors. The possible functional effect of reduced opioid receptors following the administration of subconvulsant amounts of PTZ may be associated with subsequent decreased sensitivity to the inhibitory effects of opioid peptides, leading to progressive enhanced seizure susceptibility, thus facilitating the epileptogenesis (**Figure 3**).

It is not clear whether the increase in the steady-state proenkephalin mRNA levels is due to an accelerated transcription or due to reduced degradation. However, the elevated biosynthetic capacity reflected by the increased proenkephalin mRNA level 24 h after PTZ administration would tend to replenish losses from the enkephalin pool due to their significant release following PTZ.

From this set of data, it is clear that a single subconvulsant stimulation is able to modify the opioid peptide system, a situation that may result relevant to the epileptogenic process.

Antiepileptogenesis and Opioid Receptors

Spiny rats of the genus *Proechimys* (Family, Echimydae; Suborder, *Hystricomorpha*) are mammals inhabiting the ground of moist neotropical forests in Central and South America. These nocturnal terrestrial rodents have a high population density in their habitat; they do not dig burrows, and they move around rather sluggishly within a small home range. *Proechimys guyannensis*, the common Brazilian name of which is casiragua, has received some attention as natural host of infectious agents. This animal has also been of interest because of its remarkable genome size, which is the highest recorded so far in mammals and which harbors several repetitive DNA families.

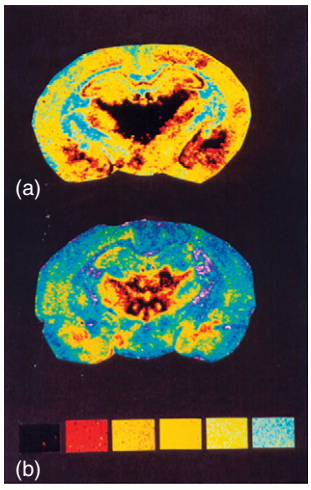

Figure 3 Distribution of mu receptors labeled with [^{3}H]DAMGO in coronal sections of adult rats at the level of amygdala and dorsal hippocampus. In comparison with the section of a control rat (a), the section of an animal sacrificed 24 h after the systemic administration of a subconvulsant amount of pentylenetetrazol (b) shows low receptor binding in several brain areas. Notations as in Figure 1.

Proechimys guyannensis shows a striking resistance to several different paradigms of experimental epilepsy. Indeed, these animals present a high sensitivity to the acute effects of pilocarpine and KA injections, but they do not develop long-lasting status epilepticus or spontaneous seizures (up to 120 days postinjection). When compared with Wistar rats, most of *P. guyannensis* animals show a higher mean afterdischarge threshold and their afterdischarge duration is longer from stages 1–4 of kindling, but not statistically different in stage 5. These observations have led to the view that there must be some factors preventing the afterdischarges from gaining access to structures related to the motor organization of the epileptic seizure.

An interesting aspect demonstrated by *P. guyannensis* is that during kindling stages 4 or 5, these animals present an initial behavior similar to that observed in catalepsy syndrome induced by opiates. Under normal conditions (and compared with Wistar rats), the *P. guyannensis* brain shows lower delta receptor binding in cingulated cortex, olfactory tubercle, thalamus, and substantia nigra, and greater binding in CA1 field of hippocampus. In contrast, mu binding is enhanced (frontal, piriform and temporal cortices, medial amygdala, dentate gyrus, and periacueductal gray) or reduced (cingulated cortex, olfactory tubercle, thalamus, basolateral amygdala, CA1-3, and substantia nigra). This pattern of mu receptor binding is similar to that detected in the brain of kindled rats during the interictal period. It is possible that the high mu receptor binding detected in specific brain areas of the *Proechimys* rodents may underlie the catalepsy-like behavior and lower kindling progression, as well as the extreme sensitivity of these animals to the acute effects of pilocarpine and KA injections.

The different organization of inhibitory and modulatory systems that *Proechimys* brain presents may represent a useful tool for the investigation of the role of opioid peptides on postictal and interictal seizure refractoriness and protection against epileptogenesis.

Postictal and Interictal Effects of Endogenous Opioid Peptides

Endogenous opiates are among the neurotransmitters and neuromodulators that have been implicated in ictal termination and in the enhanced refractoriness to subsequent seizures during the postictal (after seizure) and interictal (between seizures) periods. Indeed, the activation of endogenous opioid peptides by electroconvulsive seizures is able to curtail the epileptogenesis process induced by kindling. Opioid peptides have also been implicated in some of the behavioral disturbances – such as rigidity, analgesia, and immobility – observed during the postictal period, as well as interictal enhanced locomotion. In hippocampus, opioid peptides are involved in the memory disturbances and reduced responses to pain detected during the postictal period.

Cerebral metabolic alterations after kindled seizures match with postictal and interictal behavioral disturbances. Immediately following the end of a fully kindled seizure (0 time postictal), decreased metabolism is detected in caudate–putamen and pyriform cortex, whereas enhanced metabolism is found in the hippocampus and substantia nigra. During the interictal period (28 days after the last kindled seizures) rats with bilateral epileptic foci present forebrain metabolic rates significantly lower than those in controls or kindled rats with unilateral focus. All of these metabolic disturbances are reversed by naloxone administered immediately before seizure induction, suggesting that the postictal and interictal metabolic alterations are opioid mediated. It is possible that once kindled seizure activity is established, specific brain areas may respond to electrical stimulation with enhanced activation of opioid peptides followed by metabolic changes in areas with high opioid receptor binding.

Disruption in 'emotional tone' associated with anger, aggression, and depression are characteristics often attributed to interictal behavior in TLE. Endogenous opioids represent natural 'euphoragens' and their release may explain the beneficial effect of electroconvulsive shock treatment on clinical depression, whereas their reduction during the postictal and interictal periods is associated in certain behavioral deficits. Postictal explosive motor behaviors in epileptic animals have been suggested as a result of an opioid withdrawal effect. Indeed, these behaviors are enhanced by pretreatment with naloxone.

One hypothesis to explain some interictal disturbances is that recurrent seizures cause a chronic exposure to atypically high extracellular levels of the endogenous opioids, with a subsequent physiological dependence on

these neuropeptides. Interictal behaviors may therefore be viewed as 'withdrawal responses' – i.e., when seizures do not occur. Other explanation is that during the interictal state, basal extracellular opioid peptide levels in hippocampus are decreased, rather than increased, suggesting that kindling induces a progressive hypoactivity of opioid peptide systems in this brain area that may be a causal factor in producing an increase in local excitability and epileptogenesis (**Figure 4**).

Future Goals

Epilepsy results of a shift in the excitation and inhibition balance and opioid peptides may have an important moderating influence. Knowledge of the pro- or anticonvulsant effects of the opioid peptides has potentially important implications for the progressive nature of epilepsy, with respect to both epileptogenesis and the development of postictal and interictal behaviors. Much work is needed to develop and test new opiate drugs that might be effective in treating epilepsy and its consequences. Studies using selective agonists and antagonists, antisense oligonucleotides, or animals lacking opioid receptors could be useful to investigate future strategies for the treatment of epilepsy. Careful screening of opiate agonists and antagonists will be therefore necessary before the antiepileptic efficacy is pursued in man.

Importantly, epilepsy appears to induce a progressive hypoactivity of opioid peptide systems that may lead to higher susceptibility to subsequent seizures and postictal and interictal behavioral disturbances. We therefore should perhaps pursue new strategies to activate these depressed endogenous opioids. Deep brain stimulation, used as a therapy for intractable chronic pain and Parkinson's disease, has been associated with enhanced opioid peptide release. Thus, we might expect deep brain stimulation to restrict epileptic activity by the activation of endogenous opioid peptides. However, additional studies are needed to support the idea that the activation of endogenous opioids might be appropriate for the therapy of certain forms of epilepsy.

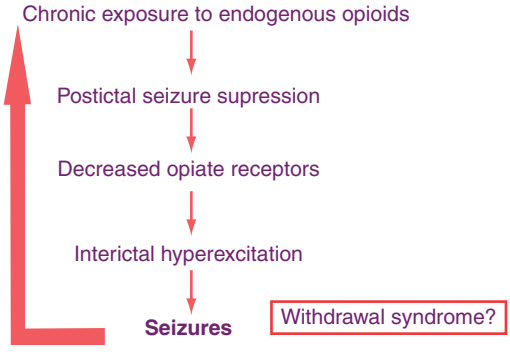

Figure 4 Diagram showing the hypothesis of a withdrawal syndrome that may result from chronic exposure to endogenous opioids released as a consequence of repetitive seizures.

Finally, the analysis of the brains of models of resistance to epilepsy, such as *P. guyannensis*, is a useful approach for the investigation of the substrates underlying the protection against seizure genesis and epileptogenesis, and to determine how the opioid peptides are involved in the circuits associated with a natural seizure resistance condition.

Introduction

Prenatal opiate exposure can be damaging to humans, leading to deficits in cognition and increased seizure susceptibility in exposed children. Animal models have shed light on the wide array of neurobehavioral systems that may be affected in prenatally opiate-exposed offsprings. Maternal opiate abuse may affect the systems in the central nervous system (CNS) that are developing in the fetus during drug exposure.

Morphine is an opioid receptor agonist that binds with varying affinity to all three major opioid receptors: μ, δ and κ. Receptors for opioids, gonadal steroids, catecholamines, γ-aminobutyric acid (GABA), and excitatory amino acids (EAA) are present during the second half of gestation in the rat. Morphine exposure during this phase of development has several long-term effects on adult progeny, including alterations in the expression of opioid peptides and their receptors as well as alterations in normal synaptic transmission in opioid peptide-containing afferents. Studies of these changes suggest that limited exposure to opiates during fetal development may produce long-lasting, perhaps permanent alterations in normal opioidergic function in the brain. One such alteration in normal opioidergic function may be an increase in seizure susceptibility.

Seizures are defined as sudden alterations of electrical activity in the brain, sufficient in magnitude to alter motor or sensory function, behavior, or consciousness. The incidence of seizures is age-related, and influenced by gonadal steroids in both humans and animals. In humans, the incidence of seizure is highest during the first few years of life. In rats, the occurrence of seizures in response to convulsant agents increases during the second and third postnatal weeks and then decreases – between postnatal days (PND) 30–35 – just prior to puberty.

Background

Opioid Systems Involved in Seizures

Acute or chronic administration of opiate drugs either potentiates seizures or induces seizure protection, depending on the dose and route of drug administration and the type of seizure. In humans, high doses of opiates potentiate focal as well as generalized seizures. Intravenous administration of morphine in newborns elicits neonatal seizures. Infusion of morphine into the cerebrospinal fluid induces seizures in adults. A sudden cessation of opiate intake, after an extended period of abuse may also induce seizure-like activity, manifesting in symptoms such as tremors, hyperactivity, twitching, and myoclonic jerks.

In rats, systemic administration of low doses of opioid receptor agonists such as morphine, fentanyl, pentazocine, and meperidine generally induces seizure protection. However, morphine and fentanyl seem to have biphasic effects on seizures: low doses increase seizure thresholds and thus reduce seizure susceptibility, while high doses reduce seizure thresholds (increase seizure susceptibility) in several seizure models. Morphine administered in high doses increases the number of focal seizure episodes, the duration of post-seizure akinesis, and the incidence of generalized clonic seizures in the picrotoxin model of epileptic seizures. Additionally, high morphine doses given intrathecally elicit myoclonic seizures, and these seizures are not reversed by the opiate antagonist

Introduction

Prenatal opiate exposure can be damaging to humans, leading to deficits in cognition and increased seizure susceptibility in exposed children. Animal models have shed light on the wide array of neurobehavioral systems that may be affected in prenatally opiate-exposed offsprings. Maternal opiate abuse may affect the systems in the central nervous system (CNS) that are developing in the fetus during drug exposure.

Morphine is an opioid receptor agonist that binds with varying affinity to all three major opioid receptors: μ, δ and κ. Receptors for opioids, gonadal steroids, catecholamines, γ-aminobutyric acid (GABA), and excitatory amino acids (EAA) are present during the second half of gestation in the rat. Morphine exposure during this phase of development has several long-term effects on adult progeny, including alterations in the expression of opioid peptides and their receptors as well as alterations in normal synaptic transmission in opioid peptide-containing afferents. Studies of these changes suggest that limited exposure to opiates during fetal development may produce long-lasting, perhaps permanent alterations in normal opioidergic function in the brain. One such alteration in normal opioidergic function may be an increase in seizure susceptibility.

Seizures are defined as sudden alterations of electrical activity in the brain, sufficient in magnitude to alter motor or sensory function, behavior, or consciousness. The incidence of seizures is age-related, and influenced by gonadal steroids in both humans and animals. In humans, the incidence of seizure is highest during the first few years of life. In rats, the occurrence of seizures in response to convulsant agents increases during the second and third postnatal weeks and then decreases – between postnatal days (PND) 30–35 – just prior to puberty.

Background

Opioid Systems Involved in Seizures

Acute or chronic administration of opiate drugs either potentiates seizures or induces seizure protection, depending on the dose and route of drug administration and the type of seizure. In humans, high doses of opiates potentiate focal as well as generalized seizures. Intravenous administration of morphine in newborns elicits neonatal seizures. Infusion of morphine into the cerebrospinal fluid induces seizures in adults. A sudden cessation of opiate intake, after an extended period of abuse may also induce seizure-like activity, manifesting in symptoms such as tremors, hyperactivity, twitching, and myoclonic jerks.

In rats, systemic administration of low doses of opioid receptor agonists such as morphine, fentanyl, pentazocine, and meperidine generally induces seizure protection. However, morphine and fentanyl seem to have biphasic effects on seizures: low doses increase seizure thresholds and thus reduce seizure susceptibility, while high doses reduce seizure thresholds (increase seizure susceptibility) in several seizure models. Morphine administered in high doses increases the number of focal seizure episodes, the duration of post-seizure akinesis, and the incidence of generalized clonic seizures in the picrotoxin model of epileptic seizures. Additionally, high morphine doses given intrathecally elicit myoclonic seizures, and these seizures are not reversed by the opiate antagonist

naloxone. Repeated administration of low doses of morphine decreases seizure thresholds, thereby potentiating seizures. Intracerebral administration of endorphin, met-enkephalin and morphine potentiates kindling seizures in adult rats. Moreover, both μ- and δ-opioid receptor agonists elicit seizures in rats as young as 1 day old.

Brain Structures Involved in Seizures

The limbic system, and specifically the hippocampus, is one of the brain regions involved in the effects of opiates on seizure susceptibility. The endogenous opioid peptides, enkephalins and dynorphins, have differential effects on hippocampal excitation. The proenkephalin-derived opioid peptides, which preferentially bind μ- and δ-opioid receptors, generally have excitatory effects in the hippocampus that may result in seizure activity. Enkephalins block GABA release from inhibitory interneurons, resulting in disinhibition. Enkephalins may also excite neurons directly by closing potassium (K^+) channels or by augmenting *N*-methyl-D-aspartate (NMDA) receptor-mediated responses.

The prodynorphin-derived opioid peptides, which bind to κ-opioid receptors, primarily have inhibitory actions in the dentate gyrus (DG) and CA3 subfield of the hippocampus. They inhibit glutamate release from presynaptic terminals. However, they also potentiate a voltage-dependent K^+ current (the M-current) via κ receptors, and may have non-opioid receptor-mediated effects on the NMDA receptor.

Aside from the hippocampus (and limbic system in general) playing a significant role in seizure initiation, several other brain structures may also influence seizure genesis and spread, including substantia nigra (SN), superior colliculus (SC), and subthalamic nucleus (STN) – which inhibits the spread of epileptic seizures in the rat brain and therefore control seizure propagation. All of these seizure-controlling structures are functionally connected via neuronal pathways, influenced by the inhibitory GABA and EAA neurotransmitter systems.

Because opioid peptides and receptors are widely distributed in the brain, exogenous opiates such as morphine may affect not only the hippocampus but also other seizure-controlling brain structures including SN, SC, and STN. There are studies showing that intrathecal administration of morphine induces convulsive activity in rats. Microinfusion of morphine into the SN pars reticulata, for example, increases seizure susceptibility to pilocarpine-induced seizures, and this effect can be blocked by the opiate antagonist, naloxone. In contrast, in maximal electroshock-induced seizures, intra-nigral application of the μ-opioid agonist [d-Ala^2]-Met-enkephalin decreases seizure susceptibility, while κ-opioid agonist, dynorphin A 1–17 amide, has no effects. The finding that μ but not κ-opioid receptor agonists administered into the SN alters seizure susceptibility suggests that the μ-opioid receptor activation may be responsible for the opioid effects in the SN. The differential effects of μ-opioid receptor agonists in the SN, as described earlier, suggest that the effects of μ receptor agonists might be seizure model-dependent.

Methodological Approaches

Seizure Models

Many experimental seizure models have been developed in animals. Most models currently employed are based on the acute administration of convulsant drugs to living animals or in vitro preparations, and therefore involve mostly nonspontaneous seizures. Animal seizures are classified as partial or generalized. Partial seizures are limited to a part of one cerebral hemisphere, and generalized seizures involve both hemispheres. These models can be further subdivided into electrical, chemical, and genetic seizures, depending on how the seizure is induced. Electrical and chemical seizure models have the advantage of providing full control over seizure precipitation, but, in most cases they induce nonspontaneous seizures.

Epileptic seizures usually originate from an imbalance between neural excitation and inhibition. To resolve such imbalance, a suppression of neural excitation or potentiation of neural inhibition is necessary. Neural excitation and neural inhibition are mediated in large part by EAAs such as glutamate and aspartate, and by inhibitory amino acids such as GABA. Interestingly, both EAA and GABA systems can be affected by morphine. As indicated previously, morphine administration induces either anticonvulsant or proconvulsant effects depending on its dose. Whether exposure of the developing brain to morphine during gestation, as a result of maternal drug abuse, has long-term effects on seizure susceptibility or generation is yet to be established. Both opioid receptor agonists and antagonists administered systemically affect seizure susceptibility in several seizure models.

Seizure Models in our Studies

In all our studies, the injection protocol for prenatal morphine exposure followed the procedures developed in our original work in 1985. Pregnant dams were injected with 5–10 mg per kg morphine or physiological saline twice daily on gestation days 11–18, and were then left undisturbed until delivery of pups on gestation day 22. The timing of morphine injection was chosen to evaluate whether this drug affects the development of μ-opioid receptors in the offspring; the critical period for the appearance of μ-opioid receptors is gestation day 14–15 in rats.

After birth, on PND 1, pups were cross-fostered, and left undisturbed until weaning, at which time they were

housed individually. They were tested for seizure susceptibility with different convulsant agents before and after puberty (PND 25 and PND 38, respectively), and in young adulthood (PND 60–80). The effect of prenatal morphine exposure on seizure susceptibility was examined in both male and female rats. Some males and all females were gonadectomized (GNX) and the effects of gonadal hormones were assessed. Specifically, the involvement of ovarian hormones in females was examined in most of our experiments; estrogen and progesterone were replaced, alone or in combination, to elucidate their effects on seizure susceptibility.

Table 1 Seizure susceptibility in adult prenatally morphine-exposed male rats

Recent Results

Effects of Prenatal Morphine Exposure on EAA- and GABA-mediated Seizure Susceptibility

EAA system

Low magnesium-induced epileptiform discharges. Epileptiform activities were evoked in entorhinal cortex (EC)-hippocampal slices of male and female rats, by removing magnesium from the perfusion solution, which unblocks the NMDA subtype of glutamate receptors. The latency to onset of seizure-like events and recurrent status were assessed to investigate whether prenatal morphine exposure alters NMDA-dependent epileptiform discharges in morphine-exposed male and female rats.

NMDA-induced seizures. NMDA-induced seizures were examined by administering several doses of NMDA (150, 175, 200, 225, and 250 mg per kg) to adult male and female rats, exposed prenatally to morphine. The incidence and latency to onset of stereotypy and clonic-tonic seizures were noted. The stereotypy involved sigmoidal tail movements (tail-twisting), caudal biting, and enhanced rearing activity associated with orientation, jumping, and running. The NMDA administration was lethal in some cases.

Kainic acid-induced seizures. Kainic acid-induced seizures were assessed in adult male and female rats to several doses (10, 15 or 20 mg per kg) of KA, in order to examine non-NMDA receptor mediated EAA-induced seizures. Kainic acid-induced wet-dog shakes (WDS), scratching, washing, and clonic seizures were recorded during one hour after kainic acid administration. The incidence and latency to onset of WDS and clonic seizures were evaluated.

The results of the EAA-mediated seizure studies demonstrate (Table 1) that prenatal morphine exposure increases seizure susceptibility in seizure models associated with NMDA receptor activation, but do not affect seizure susceptibility in non-NMDA receptor-associated models. Specifically, in slices in which low magnesium induces epileptiform discharges, morphine-exposed males have reduced latencies to onset of initial seizure activity and recurrent status; male rats also show a decreased latency to NMDA-induced seizures (at 200 mg per kg). In contrast, prenatal morphine exposure has no effects on kainic acid-induced clonic seizures in adult male rats. These data suggest that there are differences in the sensitivity of NMDA and non-NMDA receptors to prenatal morphine exposure in different brain regions, especially in different subdivisions of the hippocampus. While the highest concentration of the NMDA receptors is in the CA1 region of the hippocampus, the highest concentration of the KA receptors is in the CA3 region. The results of our experiments suggest that prenatal morphine exposure affects differently the cross-talk between opioids and different subtypes of glutamate receptors, or has different influences on the CA1 and CA3 region of the hippocampus.

GABA system

Flurothyl-induced seizures. Flurothyl is a convulsant ether that is thought to affect GABA receptors. The effects of prenatal morphine exposure on flurothyl-induced seizures were tested in male rats prior to puberty on PND 25, after puberty on PND 38, and in young adulthood at PND 60–70. Animals were exposed to flurothyl at a constant flow rate ($30\,\mu l\,min^{-1}$) in an air-tight chamber until tonic–clonic seizures occurred. Flurothyl produces two types of seizures that occur sequentially: clonic seizures occur first, and tonic–clonic seizures follow.

Bicuculline-induced seizures. Bicuculline is a $GABA_A$ receptor antagonist, which induces clonic and tonic-clonic seizures after systemic administration. The effect of prenatal morphine exposure was examined in bicuculline-induced seizures at PND 25, 38 and 60–70 in male rats. Bicuculline seizures have two distinct phases, clonic and tonic-clonic components, each of which originates from separate morphological substrates in the brain. Clonic seizures are characterized by a rapid contraction and relaxation of the muscles of the head and forelimbs. Tonic-clonic seizures usually begin with wild running followed by a tensing of the muscles (tonus) and then a long-lasting clonus, which may end in death. Loss of the righting reflex is observed during tonic-clonic seizures. The latencies to

onset of both clonic and tonic-clonic seizures, as well as the incidences of each, were examined.

Our work on GABA-mediated seizures demonstrates that prenatal morphine exposure alters susceptibility to flurothyl and bicuculline in an age-dependent manner. Prenatal morphine exposure increases seizure susceptibility in males at PND 25, whereas decreases it at PND 38 in both seizure models. In gonadally intact adult male rats (Table 1), seizure susceptibility is decreased in prenatally morphine-exposed animals after administration of flurothyl and bicuculline, while this decrease is not apparent in adult GNX male rats. It seems, therefore that the presence or absence of male gonadal hormones plays a role in modulating the effects of prenatal morphine exposure on seizures induced by chemicals (flurothyl and bicuculline) affecting the GABA system. The effect of prenatal morphine exposure on bicuculline seizure susceptibility switches from proconvulsant at prepubertal ages to anticonvulsant at older ages. This switch in the effect of prenatal morphine exposure supports the clinical data showing that puberty is a critical period for seizure susceptibility. Seizures may start, end, or change their character during puberty. Our data suggest that the effect of prenatal morphine exposure on seizures may be affected by the level of androgens in young male rats. Further, the opioid receptor antagonist naloxone is able to block the bicuculline-induced seizures in prenatally morphine-exposed, gonadally intact male rats; that is, prenatal morphine exposure increases the latency to onset of tonic-clonic seizures in saline-but not in naloxone-injected males. These results demonstrate that prenatal morphine exposure induces long-term, perhaps permanent alterations in the opioid system interacting with GABA-mediated seizures.

Effects of Gonadal Hormones on EAA- and GABA-mediated Seizures in Prenatally Morphine-exposed Animals

Studies show that changes in ovarian hormone levels (especially estrogens) play an important role in increasing seizure susceptibility in women. Susceptibility to seizures in human females varies at times of hormonal changes, such as throughout the menstrual cycle and during puberty and menopause. In several basic research studies, the effects of ovarian hormones on seizure susceptibility have also been investigated in GNX female rats. While estrogen generally increases seizure susceptibility in GNX female rats, progesterone decreases it. There are, however, other studies showing 'protective' effects of estrogen against seizures. The mechanism(s) of ovarian hormone actions on seizure susceptibility is not yet established.

We investigated the effects of ovarian hormones on seizures induced by pharmacological agents influencing both NMDA and non-NMDA systems in prenatally morphine-exposed adult female rats. Our work demonstrates that in the low magnesium slice model, the development of epileptiform activities or seizure-like events are not affected by hormonal conditions in brain slices from control females, while they are suppressed in brain slices from prenatally morphine-exposed, estrogen-replaced GNX females. Additionally, in NMDA-induced seizures, estrogen replacement in GNX females has mostly anticonvulsant effects in both control and prenatally morphine-exposed females. In contrast, estrogen has proconvulsant effects in both prenatally morphine-exposed and control females in kainic acid-induced seizures. Thus, it is likely that the effect of estrogen on seizures is differently associated with NMDA and non-NMDA systems of female rats.

Our hormone studies on GABA-mediated seizures show that prenatal morphine exposure alters seizure susceptibility of female rats in age- and ovarian hormone-specific manner. In adult female rats, prenatal morphine exposure has anticonvulsant effects in estrogen-treated GNX females in both flurothyl- and bicuculline-induced seizures. However, prenatal morphine exposure increases seizure susceptibility to flurothyl-induced seizures at PND 15, decreases seizure susceptibility tested just prior to puberty at PND 25, and has no effects on seizures at PND 38 (after puberty). In bicuculline-induced seizures, prenatal morphine exposure does not affect seizure susceptibility at PND 25 or 38. These results suggest that there is an estrogen-opiate interaction in GABA-mediated seizures.

Other Changes in the Opioid Systems of Morphine-exposed Animals that Might Account for Changes in Seizure Susceptibility

Proenkephalin and prodynorphin mRNA

Using the *in situ* hybridization technique, we explored the alterations in proenkephalin and prodynorphin mRNA in the hippocampus of prenatally morphine-exposed males (Table 2). The results demonstrate that prenatal morphine exposure down-regulates proenkephalin mRNA and met-enkephalin peptide levels in the DG of the

Table 2 Levels of opioid peptides mRNA in adult prenatally morphine-exposed male rats

pENK = proenkephalin, pDYN = prodynorphin, DG = dentate gyrus.

hippocampus. In the DG, the changes in opioid peptides could reflect levels within the DG cells themselves or in the afferent terminals from other structures since: (1) Proenkephalin-but not prodynorphin-derived peptides are present in the axons of the lateral perforant path, which project from the lateral entorhinal cortex (EC) and innervate the DG. (2) Interneurons in the dentate hilus contain proenkephalin-but not prodynorphin-derived peptides. (3) Opioid peptides (both proenkephalin- and prodynorphin-derived) in the DG are found in the granule cells themselves. Granule cells may release opioid peptides in the DG from dendrites or mossy fiber collaterals. The changes in opioid peptides seen after prenatal morphine exposure is certainly due (at least in part) to alterations in the granule cells, since that explanation is consistent with the *in situ* hybridization findings showing changes in proenkephalin and prodynorphin mRNA levels in granule cells. To conclusively address the source of changes in opioid peptides, the cell bodies in EC should also be examine with *in situ* hybridization.

Proenkephalin- and prodynorphin-derived peptides are present and detectable in DG, CA3, and CA1 subfields of the hippocampus. In the CA3, a decrease is found following prenatal morphine exposure in the levels of three of the prodynorphin-derived peptides dynorphin A (1–8), dynorphin β, and α-neoendorphin. The low levels of these peptides may be due to chronic changes in opioid processing, which could cause increased peptide degradation. An alternative explanation is that there may be increased peptide release in the CA3 of prenatally morphine-exposed males.

It should be noted that alterations in opioid peptide mRNA in some brain regions correlate with changes in only some but not all of the peptide products of that mRNA. It is known that post-translational processing within a particular cell can vary with conditions over time, depending on a wide variety of regulatory events. There is evidence that there are regional and species differences in processing which yield varied products. The purpose of these variations may be to alter receptor subtype selectivity (different peptide end products have varying selectivity for opioid receptors). Peptide processing can be modified by cell activity.

Opioid receptors

Mu-opioid receptor binding is upregulated in dendritic strata of the DG (Table 3) in morphine-exposed males, possibly to compensate for the decreased level of met-enkephalin in this region. An increase in μ-opioid receptor binding has been found in the inner molecular layer of the upper blade of the DG, which receives afferents from Layers IV-VI of the medial EC. Most μ-opioid receptors in the molecular layers of the DG are localized in interneurons that contain GABA immunoreactivity. Therefore, it is likely that the increased μ-opioid receptor levels in the inner molecular layer of the DG of prenatally morphine-exposed males have a net disinhibitory effect.

Table 3 Mu-opioid receptor binding density in adult prenatally morphine exposed male rats

Brain areas	*Morphine effect*
CA1	↑
CA2	↑
CA3	↑
DG	↑

Arrows signify an increase (↑) induced by prenatal morphine exposure in the measured parameter compared with prenatally saline-exposed controls.
DG = dentate gyrus.

The increase in μ-opioid receptor binding in stratum lucidum of CA3, the area of mossy fibers projection, is another interesting finding. Although prodynorphin-derived peptides are the best known endogenous ligands for the κ-opioid receptor, they also bind to μ-opioid receptors with reasonable affinity. Therefore, it is possible that the μ-opioid receptors are upregulated to compensate for the decreased availability of prodynorphin-derived peptides, which can serve as ligands for μ-opioid receptors.

In CA1 and CA2, as in CA3 (Table 3), the increase in μ-opioid receptor binding indicates that the hippocampal circuit may be more excitable in prenatally morphine-exposed males. Endogenous enkephalin-derived peptides, which may serve as ligands for the μ-opioid receptors in that region, are present in these subfields in the temporoammonic tract from the EC, as well as in interneurons. Mu-opioid receptors are disinhibitory in CA1, and therefore higher μ-opioid receptor levels in morphine-exposed animals may indicate a more excitable CA1.

Conclusion and Future Directions

Prenatal exposure to morphine alters susceptibility to seizures. Decreases in the excitatory proenkephalin-derived peptides and increases in the inhibitory prodynorphin-derived peptides would be expected to decrease hippocampal excitation. These findings are consistent with the results of our seizure study using flurothyl and bicuculline as chemoconvulsants, which showed an increased latency to seizure onset. Although these seizures are not likely to begin in the hippocampal formation, the clonic component of seizures propagates through the limbic system and may be modulated by the hippocampal formation.

The opioid peptide findings in the DG are also consistent with our studies showing plasticity changes in the DG of prenatally morphine-exposed male rats. At perforant

path-DG synapses, prenatally morphine-exposed males show long-term depression (LTD) while controls do not. It is possible that the decreased levels of proenkephalin-derived peptides do not allow for sufficient activation of μ-opioid receptors to induce long-term potentiation, and therefore result in the expression of LTD. Similarly, if the increased levels of prodynorphin-derived peptides are released and neurotransmitter release from perforant path terminals are inhibited, they may induce LTD.

Together, our seizure studies show that prenatal morphine exposure has long-term effects on the endogenous opioid system in exposed offsprings, and these effects endure through adulthood. While the exact nature of changes underlying the modification in seizure susceptibility following prenatal morphine exposure remains unclear, our work raises many important questions about the role of opioids in brain development, and as such may have far reaching implications.

Prenatal exposure to morphine alters susceptibility to seizures that emerge from different morphological neural substrates in the brain. Clonic seizures originate from the forebrain, and tonic-clonic seizures arise from the brainstem. How does prenatal morphine exposure target different brain regions and different systems within the CNS during development? As noted earlier, gestational drug exposure affects those neurotransmitter and neuromodulator systems that are developing during drug exposure. Some of the CNS systems that might be affected include catecholamines, opioids, GABA, and EAAs. During CNS development, neurotransmitters are thought to act as signals to facilitate or inhibit neural growth and synaptogenesis. Because opiates inhibit neural growth and development, fetal exposure to exogenous opiates could interfere with neuronal growth such that these neurons may respond inappropriately to neurotrophic signals.

Prenatal morphine exposure clearly induces long-term, perhaps permanent alterations in several CNS systems. These alterations are evident long after the opiate exposure is discontinued, and therefore cannot be attributed to tremor, hyperactivity, twitching, myoclonic jerks, or seizure-like activities associated with acute opiate withdrawal. Thus, our studies are the first to show long-term effects of prenatal morphine exposure on adult male and female seizure susceptibility. Although, similar consequences are reported in clinical studies of children born to women who abuse opiates during pregnancy, no studies have been conducted in adolescents or in young adults.

If morphine exposure in early life alters developmental events, morphine may somehow be mistaken for endogenous opioids in the regulatory pathways, thereby leading to alterations in the biological profile of the organism. An excess of opioids such as heroin, morphine, or methadone, as a result of maternal abuse, may alter growth by acting like the overexpression of trophic factors controlling growth. This possibility could well provide valuable insight into the mechanisms of how opioids can exert detrimental influences on the developing organism, and may hold a key for prophylactic measures or provide insight for treatment.

Introduction

Status epilepticus (SE) is a condition defined as epileptic seizures that last more than 30 min, without full recovery of consciousness between seizures. SE frequently causes neuronal damage and has a 27% mortality in adults. It is estimated to affect 150 000 people per year in the United States.

Animal models of SE have shown several features that may explain the poor outcome of that acute syndrome. Seizures tend to become self-sustaining and independent of their original cause. They also become pharmacoresistant to standard anticonvulsant drugs. Associated with SE, there is a great increase in glycolytic rates in limbic system structures such as the hippocampus, amygdala, and pyriform cortex. In an animal model of SE, the neuronal damage follows this metabolic pattern, and is associated with hippocampal damage and subsequent chronic epilepsy. Within seconds to minutes of SE onset, the ratio of excitatory to inhibitory receptors increases via receptor trafficking. Internalization into clathrin-coated pits leads to a reduction in the number of available synaptic $GABA_A$ receptors, which causes strong (but partial) pharmacoresistance to GABAergic anticonvulsants. At the same time, subunits of glutamate ionotropic receptors move in the opposite direction, and the number of synaptic NMDA and AMPA receptors increases significantly.

Within minutes to hours, many plastic changes occur to neuropeptides, including tachykinins. Some of those changes are maladaptive, with an increase in proconvulsant neuropeptides and a decrease in inhibitory neuropeptides, thereby raising the excitability of the limbic system. In the hippocampus of rats with SSSE, there is a reduction of inhibitory peptides like dynorphin, galanin, somatostatin, and neuropeptide Y. In the same models, there is an increase in the expression of proconvulsant tachykinins, substance P and neurokinin B. These changes may be a factor in causing and/or maintaining the shift from stimulus-dependent seizures to self-sustaining seizures.

Background

Tachykinins and their receptors

Tachykinins are one of the largest known peptide families. From low invertebrates to prochordates and vertebrates, many tachykinins are highly conserved. Classically thought of as a type of neuropeptide, tachykinins are located throughout the peripheral and central nervous system and even in nonneural tissue. Most tachykinins end at the C-terminal with the sequence Phe–Tyr/Ile–Gly–Leu–Met–NH_2. Though current research has suggested many novel human tachykinins and receptors, only seven have thus far been identified (**Table 1**), including substance P (SP), neurokinin A (NKA), neurokinin B (NKB), endokinin A, endokinin B, endokinin C, and endokinin D (EKA-D).

The three genes responsible for encoding the mammalian tachykinins are named preprotachykinin 1 (TAC1), preprotachykinin 3 (TAC3), and preprotachykinin 4 (TAC4). TAC1 contains transcripts for both SP and NKA. Its expression occurs in all human tissues except the placenta. Alternate splicing allows for α, β, γ, and δTAC1 variants. The α and δTAC1 variants code for SP only, whereas β and γTAC1 code for SP along with NKA. While the expression of α and δTAC1 is widespread in

Table 1 Amino acid sequences of mammalian tachykinins

Species	*Tachykinin*	*Sequence*
Mammals	Substance P	Arg-Pro-Lys-Pro-Gln-Gln-***Phe***-Phe-***Gly-Leu***-Met.NH2
Mammals	Neurokinin A	His-Lys-Thr-Asp-Ser-***Phe***-Val-***Gly-Leu***-Met.NH2
Mammals	Neurokinin B	Asp-Met-His-Asp-Phe-***Phe***-Val-***Gly-Leu***-Met.NH2
Rat/mouse	Hemokinin-1	Arg-Ser-Arg-Thr-Arg-Gln-***Phe***-Tyr-***Gly-Leu***-Met.NH2
Human	Hemokinin-1	Thr-Gly-Lys-Ala-Ser-Gln-***Phe***-Phe-***Gly-Leu***-Met.NH2
Human	Endokinin C	Lys-Lys-Ala-Tyr-Gln-Leu-Glu-His-Thr-***Phe***-Gln-***Gly-Leu***-Leu.NH2
Human	Endokinin D	Val-Gly-Ala-Tyr-Gln-Leu-Glu-His-Thr-***Phe***-Gln-***Gly-Leu***-Leu.NH2

The three residues common to all tachykinins are shown in bold and italic.
The N-terminally extended forms of NKA (neuropeptide K and neuropeptide g) and of human HK-1 (endokinins A and B) are not shown.
Reproduced from Pennefather JN, Lecci A, Candenas ML, Patak E, Pinto FM and Maggi CA (2004) Tachykinins and tachykinin receptors: A growing family. *Life Sciences* 74(2): 1445–1463.

the central nervous system, β and γTAC1 expression is more common peripherally.

TAC3, which encodes NKB, is expressed in the central nervous system and some peripheral tissues, including the placenta. Although there are two splice variants (α and βTAC3), they only differ in an untranslated region and both express NKB.

TAC4 is unique in that its gene product varies across species. In mice and rats, TAC4 encodes for hemokinin-1 (HK1), whereas in humans it encodes for endokinins A-D. In humans, TAC4 has four splice variants – α, β, γ, and δTAC4. EKA and C are encoded by αTAC4, EKB is encoded by all four splice variants, and EKD is encoded by βTAC4. EKC and EKD do not contain the classical tachykinin C-terminal motif. Instead of ending in FXGLM-NH_2, EKC/D have the sequence FQGLL-NH_2. EK peptides are expressed in all human peripheral tissues including the placenta, but are not strongly expressed in the brain.

There are currently three identified mammalian tachykinin receptors called NK_1, NK_2, and NK_3. Encoded by TACR1, TACR2, and TACR3, respectively, they are structurally homologous G-protein coupled receptors and have a common mechanism of action through the breakdown of phosphoinositol. Although all tachykinins are agonists for all three receptors, they have different affinities for each receptor (**Table 2**). For example, SP and the EK peptides have the strongest affinity for NK_1. It was previously thought that SP was the strongest activator of NK_1, but SP-like endokinins (EKA/B) have a very similar potency for NK_1. Also this receptor is found in several tissues that express only EKA/B. Therefore, EKA/B are thought of as peripheral endocrine/paracrine agonists of the NK_1 receptor. NKA has the highest affinity for NK_2, and NKB has the highest affinity for NK_3.

Tachykinins are located in a multitude of sites (**Figures 1** and **2**). In the CNS, these peptides are found in posterior pituitary gland, thalamic nuclei, substancia nigra, periaqueductal gray, locus coeruleus, the caudate nucleus, globus pallidus, septum, hypothalamus, medulla oblongata, nucleus accumbens, olfactory bulb, cerebral cortex, superior colliculus, reticular formation, and both dorsal and ventral horns of the spinal cord.

In the PNS, tachykinins are located in enteric neurons of the gut, respiratory tract, blood vessels, urinary system, skin, and immune system. In nonneuronal tissue, these proteins are in blood and carcinoid tumors.

Physiological Roles of Tachykinins

Because tachykinins and their receptors are so widespread, they play a role in a spectrum of activities. These versatile peptides are involved in hypotension, tachycardia, intestinal motility, biliary secretions, pancreatic secretions, tone of airway musculature, bladder tone and motility, pain, and inflammation when injected peripherally.

Cardiovascular effects

Tachykinins cause a reduction in blood pressure in humans. For example, when a multireceptor tachykinin agonist eledoisin is rapidly injected intravenously, blood pressure drops, spinal fluid pressure rises, respiration rate increases, and skin vasodilates. Also, after SP injection, diastolic blood pressure falls significantly. Tachykinins, like SP and physalaemin (an NK_1 agonist), cause tachycardia when injected intravenously. They also cause increased cardiac output and myocardial contractile force.

Gastrointestinal effects

SP, eledoisin, and physalaemin all cause stimulation of intestinal motility. These contractile, excitatory responses are detected in all parts of the gut and all layers of muscle. When eledoisin is injected subcutaneously in dogs, it causes vomiting, abundant salivation, ejection of watery stools containing mucus and blood, and violent tenesmus. When dogs are injected with physalaemin, bile flow increases only because of gall bladder contraction. In fact, this NK_1 agonist causes decreased bile flow in the hepatic duct. Also, physalaemin causes increased exocrine secretions of the pancreas in dogs.

Table 2 Agonists and Antagonists at tachykinin receptors

Respiratory system effects

Tachykinins also play a role in the airway systems, namely the muscular tone of the trachea and bronchi. In humans, SP causes increased airway resistance at low doses and bronchodilation at high doses.

Pain and inflammatory effects

The tachykinin substance P is highly linked to nociception. Once the skin is lesioned, high levels of potassium are released by vessels, thereby depolarizing free nerve endings and increasing their rate of action potentials. These activated nerves release substance P, which triggers an inflammatory response by dilating neighboring blood vessels. Dilated vessels induce edema, mast cell release, and histamine activation. Histamines then sensitize the free nerve endings to cause increased nociception. SP is involved in inflammatory disease as well; in diseased tissue, there are abnormal levels of SP, SP-nerve fibers, and NK_1 receptors. NK_1 receptor antagonists have been shown to be beneficial in animal models of inflammatory disease. In rodent models, SP is produced not only by neuronal tissue, but also by inflammatory cells like macrophages, lymphocytes, eosinophils, and dendridic cells. SP causes enhanced release of cytokines, histamine, and arachidonic acid derivatives. These inflammatory mediators promote leukocyte proliferation, thereby magnifying the inflammatory response.

Other effects

Bladder contraction is augmented significantly with exogenous endokinins at extraphysiological levels.

CNS effects

When injected into various regions of the CNS, tachykinins are associated with hypotension, bradycardia, increased gastric acid secretion, increase of respiratory volume, inhibition of colonic propulsion, increased sexual behavior, aggressive behavior, increased learning, improved memory, and anxiety. It has even been shown that SP can cross the blood–brain barrier (BBB) (in both the apical-to-basolateral (AP-BL)

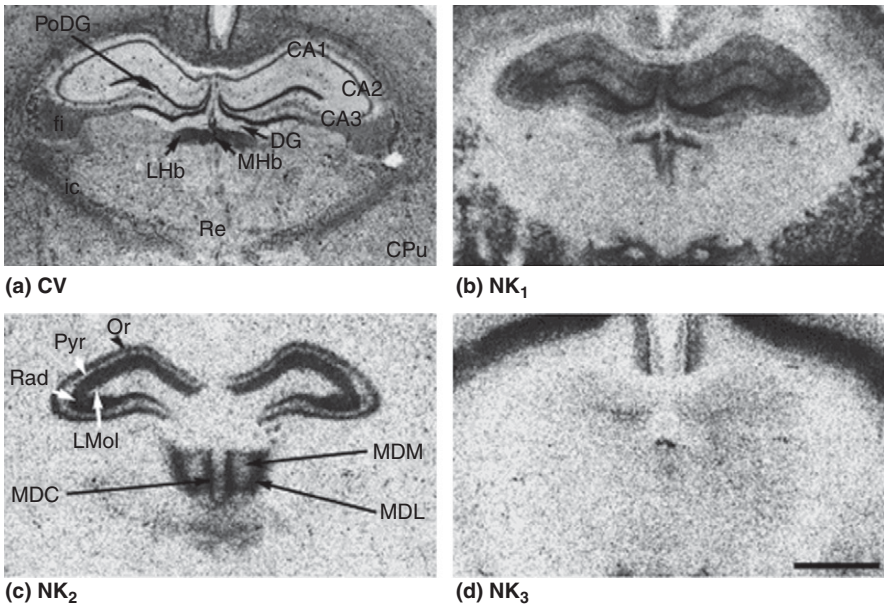

Figure 2 Comparison of the localization of NK_1, NK_2 and NK_3 binding sites at the dorsal hippocampal and thalamic level (incubation conditions are reported in **Figure 1**). Scale bar: 2 mm. Adapted from Saffroy M, Torrens Y, Glowinski J, Beaujouan JC (2003) Autoradiographic distribution of tachykinin NK2 binding sites in the rat brain: comparison with NK1 and NK3 binding sites. *Neuroscience* 116(3): 761–773, with permission from Neuroscience Journal.

and basolateral-to-apical (BL-AP) directions) altering both brain function and behavior. The evidence of an active transport pathway, the decreased permeation with endocytic inhibitors, and the 10–20 min lag time suggest a transcytotic mechanism of transport. The pathway involves endocytosis at the apical end of the BBB and exocytosis at the basolateral side. Pro9 SP, a high-affinity NK_1 substrate, inhibits the transport of SP, indicated that the NK_1 receptor is involved in the transport of SP across the BBB. Knowledge regarding the mechanism of transport of tachykinins across the BBB can be used to design future pharmacological agents.

Pathological Roles of Tachykinins

At abnormal levels, tachykinins are linked with diseases like schizophrenia, Alzheimer's disease, Huntington's disease, and epilepsy. When levels of TAC1 mRNA in the amygdala were examined in schizophrenic subjects, it was found that the SP system of the amygdala was altered; in the basal, lateral, and accessory basal amygdaloid nuclei, there was a significant reduction of TAC1 mRNA. In Alzheimer's disease, SP immunoreactivity is diminished; levels of TAC1 mRNA are lower in the basal nuclei of the stria terminalis and medial preoptic area than in controls. And in Huntington's chorea, SP fibers in the substantia nigra are greatly affected, perhaps contributing to many of the symptoms of this disease such as choreiform movements and dementia.

Altered levels of tachykinins are also associated with epilepsy – the focus of the rest of this review.

Methods

A description of the methods used in most of our studies can be found in the article by Liu and collaborators in the *Proceedings of the National Academy of Sciences* (1999) (see Further Reading section).

Results

Substance P and SE

Substance P is normally present in low concentrations in the rat hippocampus, specifically in the CA2–CA3 junction and in the subiculum; there are no SP fibers in the dentate gyrus in control rats. In contrast, in rats with SSSE, the levels of SP-immunoreactivity (ir) showed a dramatic increase (**Figure 3**). In the dentate gyrus, SP-ir was found to increase 30-fold, in CA1 13-fold, and in CA3 35-fold. In situ hybridization of TAC1 mRNA revealed a significant increase in TAC1 mRNA in CA1, CA3, dentate gyrus, and hippocampal mossy fibers.

The effect of SP has also been examined on the induction of SSSE. In control rats, it took 30 min of perforant path stimulation (PPS) to induce stage 4–5 seizures and SSSE; the seizure activity continued for 24 h (i.e., past the end of the PPS period). Seven minutes of PPS caused only stimulus-dependent seizures that stopped as soon as the PPS was stopped. When SP was injected into the hippocampus, seven minutes of PPS was sufficient to trigger

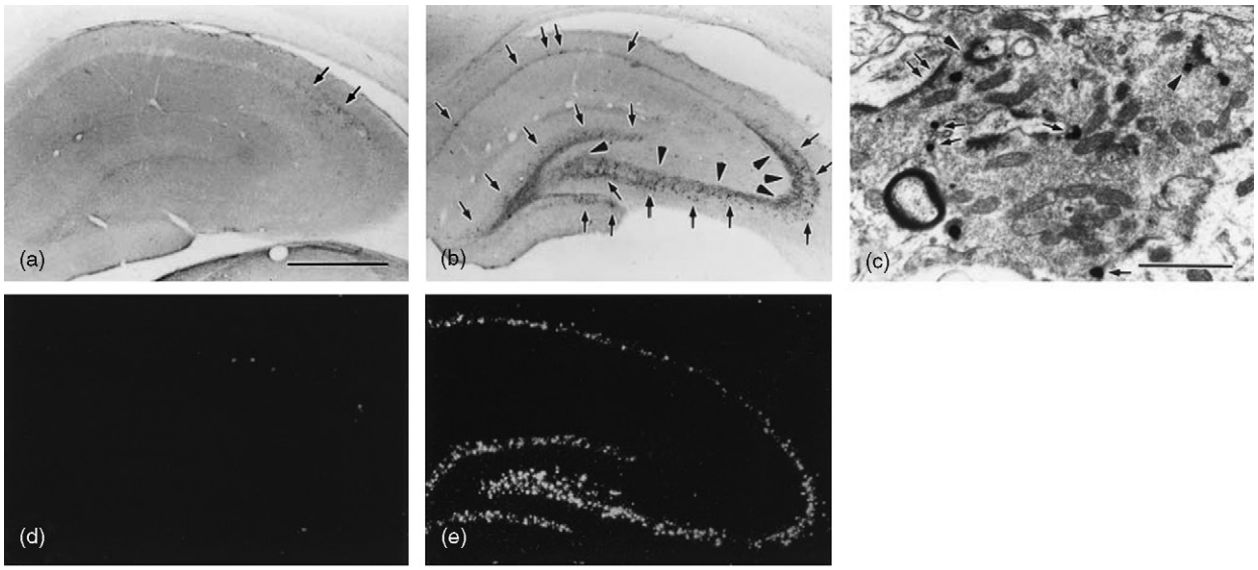

Figure 3 Seizure-induced neurochemical changes in the hippocampus. In the control hippocampus (a), some SP-ir fibers are seen at the junction of CA2 and CA3, and a few SP-ir cells are present in the stratum oriens of CA1 andCA2 (arrows). Twenty-four hours after 30-min PPS (b), there is a dramatic increase in SP-ir cell bodies in CA3, CA1, in the granule cell layer (arrows), and in mossy fibers (arrowheads). (c) Electron micrograph of a typical mossy terminal in CA3 was obtained from a rat killed 24 h after 30-min PPS. The SP-immunoreactive immunogold particles in the mossy fiber terminal are located at a presynaptic density (arrowheads) and in extrasynaptic areas along the internal face (arrows) of the terminal membrane. Asymmetric synapses on the dendrites of CA3 pyramidal neurons (double arrows) are typical features of excitatory connections. (d, e) PPT-A mRNA expression in the hippocampus. In the control hippocampus (d), a few PPT-A mRNA-positive neurons are scattered in the stratum oriens of CA1, CA2, and CA3. Very few PPT-A mRNA-positive cells are present in the pyramids of Ammon's horn. Three hours after 30-min PPS (e), a dramatic increase in PPT-A mRNA is observed in the dentate granule cell layer and in all pyramidal cell layers. (Bars 5 200 mm in a, b, d, and e, 1 mm in c). Adapted from Liu *et al*. (1999) Substance P is expressed in hippocampal principal neurons during status epilepticus plays a critical role in the maintainance of status epilepticus. *Proceedings of the National Academy of Sciences* 96: 5286–5291.

SSSE. The SSSE in the control rats (after 30 min PPS) and in the SP-injected rats (after 7 min PPS) led to severe neuronal loss throughout CA1 and CA3 pyramidal cell layers, a distribution of damage resembles neuronal loss seen in human epilepsy. In both control rats and SP-injected rats, the SP antagonists spantide II and RP-67 580 blocked initiation of SE and SE-induced hippocampal damage, and terminated anticonvulsant resistant SSSE. These antagonists prevented the development of SE when injected before PPS and reduced seizure duration when administered after the end of PPS.

Another study revealed that TAC1 knockout (KO) mice show a resistance in developing SE when injected with kainic acid. When control rats were compared with KO rats, the KO rats exhibited shorter, less intense seizures. It took longer for seizures to commence and recovery was more rapid. Also, in TAC1$^{-/-}$ rats, there was less hippocampal damage. This result suggests a strong proconvulsant role of SP and the TAC1 gene.

SP's proconvulsant nature is thought to be a result of its ability to cause increased presynaptic glutamate release. In hippocampal slices perfused with SP for 5 min, there was a threefold increase in glutamate concentration, an effect that may increase the limbic system's excitability and therefore increases seizure susceptibility. This finding in hippocampus is consistent with the demonstration that SP causes glutamate release in spinal cord.

Neurokinin B and SE

Normally NKB is present throughout all interneurons of the hippocampal formation, especially in large hilar neurons of the dentate gyrus. There are also many NKB-positive cells in CA1 pyramidal layer and faint staining of NKB immunoreactivity in CA3 terminal field of mossy fibers. Our preliminary results show that NKB injection into hippocampus causes severe seizures, and that NKB antagonists block SSSE induced by perforant path stimulation.

Kainic acid-induced (KA) seizures caused a significant cell loss in CA3 and hilus, and extrahippocampal damage in the amygdala, pyriform cortex, and thalamus. KA-induced seizures were also associated with an increase of NKB-ir in mossy fibers, CA3, and the dentate gyrus at days 10–60 after injection. During this same period, there was an enhanced expression of TAC3 mRNA in granule cells and hilar interneurons. Two to ten days after the intraperitoneal injection of KA, the CA1 pyramidal cell layer showed an increase of TAC3 mRNA that dropped to control levels by 60 days. Interestingly, pentylenetetrazole-kindled (PTZ) seizures caused no cell loss, but also were

associated with increases in NKB-ir and TAC3 mRNA hybridization.

NKB works through similar mechanisms as SP. Not only does it enhance glutamate release presynaptically, it also potentiates glutamate actions postsynaptically. These actions can boost excitability in the limbic system, which (like the effects of SP) may contribute to increased seizure susceptibility.

SP in Human Epilepsy

SP facilitates epileptic activity of the principal cells of the hippocampus, but can also reduce seizure activity, presumably by activating SP receptor (NK1R)-expressing interneurons. A study of the CA1 region in autopsied human brains in which no pathology was found showed, in a subpopulation, colocalization of NK1R-immunoreactivity with calbindin (but little or no colocalization with parvalbumin, calretinin, cholecystokinin or somatostatin) in multipolar interneurons with smooth dendrites, that these interneurons may participate in dendritic inhibition. In hippocampi which were surgically ablated for intractable epilepsy, these cells survived but were morphologically altered. In sclerotic hippocampi from epileptic patients, the number of NK1R-immunoreactive interneurons was reduced, but their dendritic arborization was greatly increased, with intense branching and frequent beading, suggesting intense reactive changes (**Figure 4**). Other studies have shown a loss of SP-IR interneurons in the hilus, but an increase in stratum moleculare, and sprouting of SP-IR projections from the supramamillary nucleus. The functional significance of those changes remains open to various interpretations.

Conclusions and Directions for Future Research

Tachykinins are important excitatory neuropeptides that not only have physiological functions, but also play key roles in disease states of the gut, respiratory system, and the brain. Expressed in all human tissues, tachykinins are involved in a plethora of mechanisms. From the treatment of schizophrenia to inflammatory disease, the pharmacologic potential of tachykinin receptor agonists and antagonists is increasing. The pharmacology of the older tachykinins (substance P and the neurokinins) and their receptors are already fairly well developed. However, the characterization of the newer agonists and antagonists is in its infancy, and the future may bring a host of novel applications. For example, tachykinin antagonists should be considered for the treatment of pharmacoresistant epilepsy and SE, in the treatment of inflammation and blood – brain barrier breakdown, and in pain syndromes. Through a better understanding of the roles of tachykinins and their receptors in epilepsy (and other illnesses), more effective therapies can be designed.

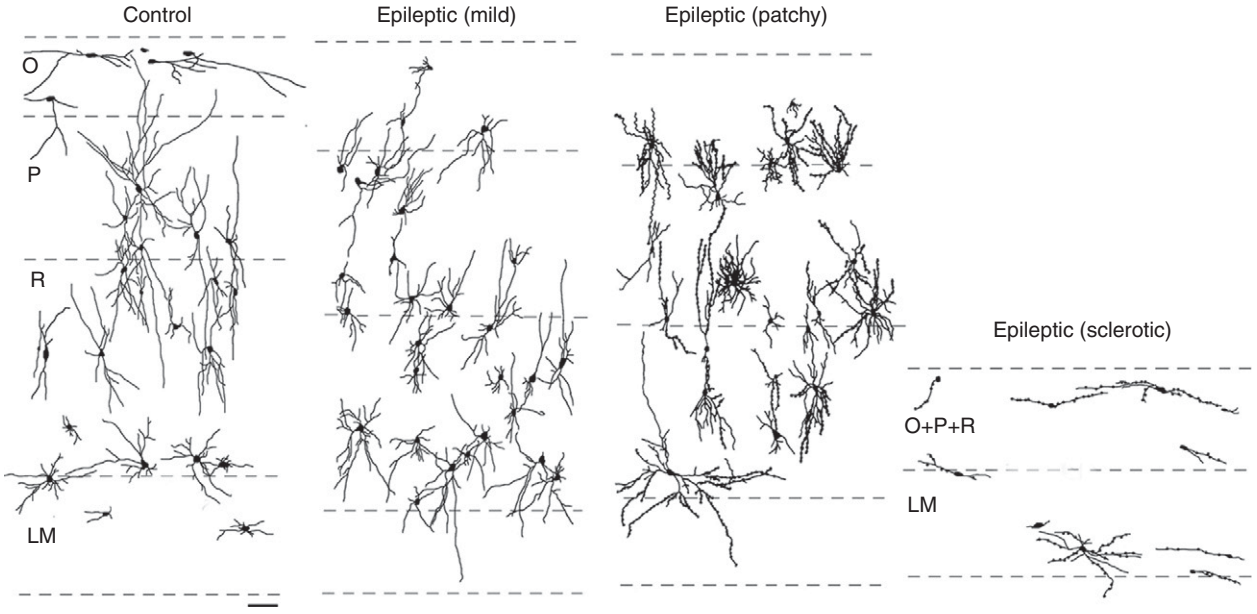

Figure 4 Camera lucida drawings from the CA1 region show changes in the distribution and morphology of the SPR-immunoreactive interneurons. In the non-sclerotic cases (mild and patchy) the number and distribution of positive cells are unchanged, but their morphology is considerably altered, the dendrites have more branches and become beaded. In the sclerotic samples the number of cells is decreased and most of them have only a few distorted dendrites. Scale bar_0.1 mm. Reproduced from Toth K, Wittner L, Urban Z, *et al*. (2007) Morphology and synaptic input of substance P receptor-immunoreactive interneurons in control and epileptic human hippocampus. *Neuroscience* 144: 495–508, with permission from Neuroscience Journal.

Introduction

The majority of patients with epilepsy have a good prognosis and their seizures are well controlled by a single antiepileptic drug (AED), but up to 40% develop refractory epilepsy, especially those with partial seizures. Patients with persistent seizures despite treatment with an adequate AED at maximum tolerated doses have only a 10–15% chance of complete seizure control with alternate AEDs; i.e., the resistance to the initial AED extends to various other

Introduction

The majority of patients with epilepsy have a good prognosis and their seizures are well controlled by a single antiepileptic drug (AED), but up to 40% develop refractory epilepsy, especially those with partial seizures. Patients with persistent seizures despite treatment with an adequate AED at maximum tolerated doses have only a 10–15% chance of complete seizure control with alternate AEDs; i.e., the resistance to the initial AED extends to various other

AEDs. Animal models of epilepsy that simulate this multidrug type of resistance are important to uncovering the specific mechanisms of AED resistance in epilepsy, and to developing new and more effective therapies. Thus, the identification and characterization of one or more model systems that would predict efficacy in the AED-resistant patient population would be a valuable asset for any AED discovery program.

Pharmacoresistance in animal models, based on human experience, can be minimally defined as persistent seizure activity that does not respond, or responds poorly, to monotherapy at tolerable doses with at least two current AEDs. An animal model for pharmacoresistant epilepsy should have good parallels to human forms of AED-resistant epilepsy. The goal should be to develop animal models that reflect the most common forms of pharmacoresistance in humans. Thus, most researches involved in model development concentrated on animal models for a common form of human drug-resistant epilepsy, the temporal lobe epilepsy (TLE) or limbic epilepsy syndrome.

Background and Methodologies

There are different approaches to developing animal models of drug-resistant epilepsy (**Figure 1**). One is to use models of seizures or epilepsy that per se are resistant to antiepileptic effects of AEDs. An example is the 6-Hz psychomotor seizure model in mice, which can be viewed as a potential screen for therapy-resistant epilepsy. In this model, which is used in the early drug identification studies by the Antiepileptic Drug Development (ADD) program at the University of Utah, electrical stimulation by low-frequency (6 Hz) rectangular pulses of 0.2-ms duration, delivered through corneal electrodes for 3 s, induces seizures that are reminiscent of 'psychomotor seizures' occurring in human limbic epilepsy. At 22 mA, the convulsant current in 97% of the mice tested (CC_{97}), all AEDs (phenytoin, lamotrigine, ethosuximide, levetiracetam, valproate) examined in this model block the seizures, demonstrating that the model does not discriminate between clinical classes of AEDs at this current. However, when the current is increased to twice the CC_{97} (i.e., 44 mA), most AEDs loose their efficacy, and only levetiracetam and valproate provide complete protection against the 6-Hz seizures (**Figure 1**). Based on these observations, it was suggested that the 6-Hz stimulation may provide a useful and rather inexpensive model of therapy-resistant limbic seizures.

Another, much more labor-intensive and expensive approach is the use of chronic epilepsy models such as kindling (**Figure 1**). In the kindling model of TLE, repeated excitatory stimuli induce partial and, later, secondarily generalized seizures that increase in length and severity with continued stimulation. In the amygdala-kindling model in rats, in which kindling is produced by repeated electrical stimulation of the amygdala, exposure to low doses of lamotrigine during kindling development leads to a reduced subsequent anticonvulsant response to the drug in fully kindled animals. The same observation was reported for kindling with pentylenetetrazole. Lamotrigine-refractory kindled rats are also resistant to

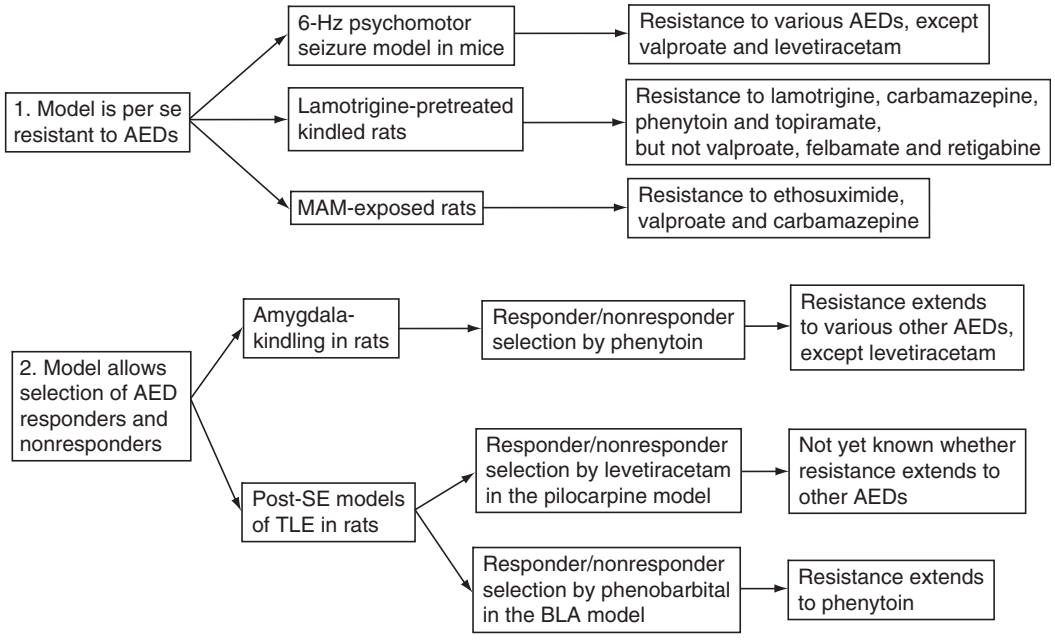

Figure 1 Experimental approaches used in the development of animal models of drug-resistant epilepsy.

carbamazepine, phenytoin, and topiramate, but not valproate, felbamate, and retigabine. It was suggested that lamotrigine-resistant kindled rats may serve as a model of drug-refractory epilepsy. In view of the fact that loss of efficacy (tolerance) develops upon prolonged exposure to several AEDs, including lamotrigine, the loss of efficacy of several AEDs in lamotrigine-resistant rats could be a consequence of cross-tolerance between lamotrigine and AEDs that act, at least in part, by the same mechanism – i.e., modulation of voltage-dependent sodium channels. Whereas cross-tolerance between AEDs acting by similar mechanisms has been demonstrated previously in animal models such as kindling, it is not clear whether cross-tolerance plays a role in AED resistance in patients with epilepsy.

In human patients, seizure activity associated with cortical dysplasia is often resistant to commonly used AEDs. In rats, exposure to treatment with the antimitotic agent methylazoxymethanol acetate (MAM) in utero produces a neuronal migration disorder similar to the cortical dysplasias seen in human brain. In such MAM-exposed rats, seizures induced by either kainate or the cholesterol biosynthesis inhibitor AY-9944 are refractory to valproate, ethosuximide, or carbamazepine (**Figure 1**). Thus, these rats seem to provide a two-hit model of refractory seizures.

An alternative approach to develop animal models of drug-resistant epilepsy is the treatment of large groups of kindled or epileptic rats with AEDs, with subsequent selection of subgroups of animals that either respond or do not respond to this treatment (**Figure 1**). An animal model of epilepsy allowing selection of subgroups of animals with drug-refractory and drug-responsive seizures could be a valuable tool to study why and how seizures become intractable, and to develop more effective treatment strategies. Two models that allow such subgroup selection are described in the following paragraphs.

Results

Phenytoin-Resistant Kindled Rats

We became interested in developing such an animal model almost 20 years ago, leading to the discovery of phenytoin-resistant subgroups of amygdala-kindled Wistar rats (**Figure 1**). By repeated testing of the anticonvulsant effect of phenytoin in large groups of rats of the Wistar outbred strain, we found that the individual response of fully kindled rats to phenytoin differs; i.e, that kindled seizures in some animals consistently respond whereas kindled seizures in others never respond to phenytoin. In recent years, we have repeated the selection of phenytoin responders and nonresponders in kindled Wistar rats several times, using either phenytoin or its prodrug fosphenytoin for selection. Average data from more than 200 rats show a consistent anticonvulsant response to phenytoin in only about 20% of the animals, no anticonvulsant response in another 20%, and a variable response in the remaining 60%. Based on our data, we suggest that the three subgroups of amygdala-kindled rats model three different clinical scenarios. The nonresponder subgroup models drug-refractory patients with TLE in whom AED treatment does not significantly reduce seizure frequency. The variable responder group models patients in whom AED treatment reduces seizure frequency but does not achieve complete control of seizures. The responder subgroup models patients who achieve complete control of seizures during AED treatment.

Following the identification of phenytoin-resistant kindled Wistar rats, most clinically available AEDs were tested in such animals. Except the novel drug levetiracetam, all examined AEDs were significantly less efficacious or not efficacious at all in phenytoin-nonresponders compared to phenytoin responders, demonstrating that the phenytoin resistance of a subgroup of kindled Wistar rats extends to various other old and new AEDs. This result reflects the clinical situation in patients with TLE, because most patients who are refractory to one AED are also resistant to other AEDs, including newly developed drugs.

Subsequent studies showed that the different response to phenytoin of the responder and nonresponder subgroups is not due to differences in the location of the kindling electrode in the amygdala, difference in kindling rate or severity of kindled seizures, drug pharmacokinetics, seasonal variations in drug response, or the sex of the animals. Furthermore, adverse effects of phenytoin were the same in responders and nonresponders, indicating that resistance is restricted to the anticonvulsant effect of this drug.

In the search for mechanisms of resistance in phenytoin-nonresponders, several differences between responders and nonresponders were found (**Figure 2**). Breeding studies with phenytoin responders and nonresponders suggested that the ability to respond or not to respond to phenytoin is genetically determined, although it does not follow a simple scheme of inheritance. The involvement of genetic factors in the different drug sensitivity in responders and nonresponders was substantiated by a study in which we tested phenytoin in various outbred and inbred rat strains. Besides genetics, another possible explanation for development of different pharmacosensitivity in kindled rats would be the kindling process itself. Epileptic patients may initially respond to an AED, but this effect may be lost with increasing duration of the disease – i.e., when epilepsy becomes chronic. To address the influence of kindling on the anticonvulsant response to phenytoin, we tested phenytoin's anticonvulsant effect before and after kindling in the same rats. Following kindling, rats were repeatedly tested with phenytoin to

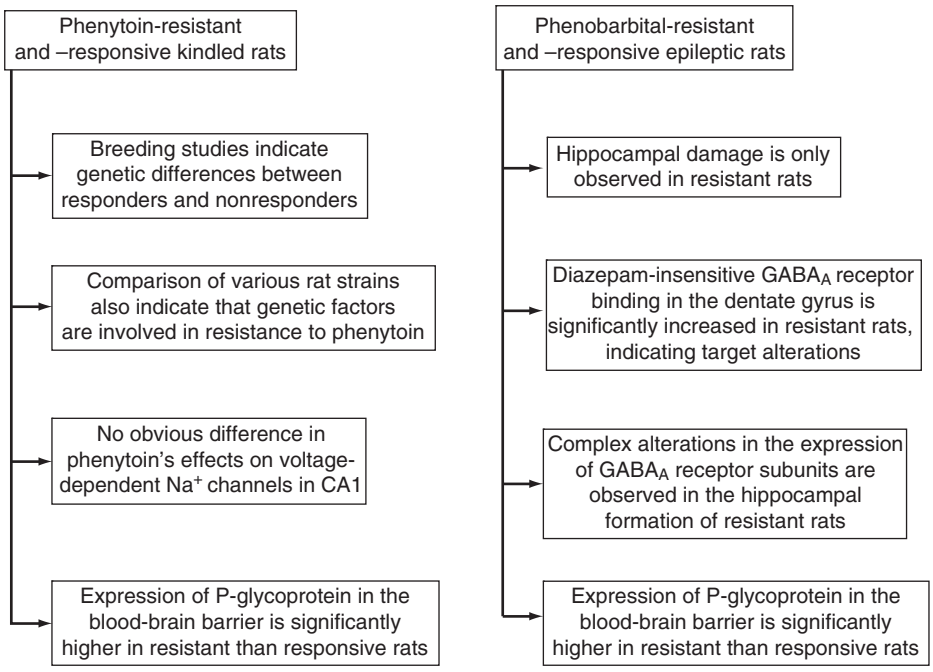

Figure 2 Differences between AED-responders and AED-nonresponders in animal models of drug-resistant epilepsy.

allow subgroup selection. This study indicated that kindled phenytoin-nonresponders become nonresponders, at least in part, through the kindling process – i.e., through the kindling-induced brain alterations. In view of the results of our breeding studies, the genetic background of an individual rat seems to determine whether it becomes a responder or nonresponder by kindling-induced limbic epileptogenesis.

With respect to kindling-induced brain alterations that could determine whether a rat becomes a responder or nonresponder to an AED such as phenytoin, we concentrated on three possibilities. One is that the brain target of phenytoin, i.e., voltage-dependent sodium channels, exhibits a reduced sensitivity to phenytoin in nonresponders. However, in kindled rats with in vivo resistance to the anticonvulsant effect of phenytoin (phenytoin-nonresponders), in vitro modulation of sodium currents by phenytoin in hippocampal CA1 neurons did not differ from respective data obtained in phenytoin responders; that is, phenytoin resistance was not associated with any obvious change in the modulation of sodium currents by this drug.

Apart from target changes, an alternative explanation of the AED resistance in phenytoin-nonresponders is upregulation of drug efflux transporters such as P-glycoprotein (Pgp) in the blood–brain barrier. Such upregulation of Pgp has been determined in resected brain tissue of patients with intractable epilepsy. Because phenytoin and several other AEDs are substrates of Pgp, regionally restricted overexpression of Pgp in the blood–brain barrier is likely to reduce concentrations of AEDs at their brain targets, leading to AED-resistance. In phenytoin-nonresponders, we found significantly increased expression of Pgp in brain capillary endothelial cells in the kindled focus (the amygdala) compared to phenytoin-responders, strongly indicating that Pgp may be involved in pharmacoresistance in this model.

The breeding studies and experiments in various rat strains described above strongly indicated that genetic factors are involved in the inter-individual differences in the efficacy of AEDs in the amygdala-kindling model. Such genetic factors could also explain the increased expression of Pgp in the kindled amygdala of phenytoin-nonresponders – e.g., by assuming a polymorphism affecting the promoter region of the Pgp gene (*Mdr1a*), which governs the expression of Pgp in the blood–brain barrier in rats. However, sequencing of the *Mdr1a* gene coding sequence revealed no general differences in phenytoin responders and nonresponders.

As a further approach for identification of genes that may encode key proteins involved in molecular mechanisms underlying phenytoin resistance in the kindling model, gene expression profiling by microarrays was used. Using the Affymetrix oligonucleotide microarray, we have surveyed the expression levels of more than 26 000 genes and ESTs in responders and nonresponders. About 50 genes were differentially expressed in the two groups of kindled rats. Currently, real-time quantitative

PCR (QPCR) is being used to confirm the data from the microarrays.

Compared to models in which seizures are resistant to AEDs in all animals, a major advantage of the phenytoin-resistant kindled rat model is that it allows the investigator to directly compare AED-refractory and AED-responsive rats from the same strain, which is an important benefit for studies on mechanisms of pharmacoresistance. Other groups have started to use this model in the search for further differences between AED-resistant and AED-responsive rats. Even though the model is very time- and labor-intensive, it does not require any continuous EEG/video monitoring of seizures, because seizures are induced at will. However, animal models of chronic epilepsy with spontaneous recurrent seizures have, of course, greater parallels with human epilepsies than the kindling model.

Post-Status Epilepticus Models of TLE

Stimulated by the findings in the kindling model, we started studying whether pharmacoresistant rats can also be selected from TLE models with spontaneous recurrent seizures. In post-status epilepticus (post-SE) models of TLE, a chemically or electrically induced SE is followed, after a latent period, by spontaneous recurrent seizures. This group of models is often considered to have the greatest parallels with human TLE, but until recently only few studies examined the pharmacological responsiveness of the spontaneous seizures in these models. One obvious reason is that drug efficacy testing in rats with spontaneous recurrent seizures is technically difficult, expensive, and time-consuming, because AEDs have to be administered over a prolonged period and rats have to be recorded continuously by video/EEG monitoring during this period for the occurrence of seizures, to allow comparison of seizure frequency during treatment with seizure frequency in control periods.

In the pilocarpine model of TLE in Wistar rats, prolonged administration of levetiracetam via osmotic minipumps resulted in a large inter-individual variation in drug response. About 40% of the epileptic rats were responders with complete or almost complete control of spontaneous seizures, another 40% were nonresponders, and the remaining rats could not clearly be included in either group because of variation between pre- and post-drug control seizure frequency.

Prompted by these promising data from the pilocarpine model, we investigated whether responders and non-responders also occur in another post-SE model of TLE. In this model, SE is induced by prolonged electrical stimulation of the basolateral amygdala (BLA), which leads to development of spontaneous recurrent seizures in >90% of the animals. Prolonged treatment of epileptic Sprague–Dawley rats with phenobarbital, at maximal tolerated doses, results in two subgroups – responders and nonresponders. In two independent studies in 11 and 15 epileptic rats, 36% and 40% of the rats were resistant to treatment with phenobarbital, demonstrating the reproducibility of this model. When the phenobarbital-resistant rats were subsequently treated with phenytoin, 83% of these rats were also resistant to the latter drug (**Figure 1**), thus fulfilling the minimum requirements for a model of drug-resistant epilepsy described above. Plasma drug levels and adverse effects of phenobarbital and phenytoin were comparable in responders and nonresponders, demonstrating that the resistance is restricted to the anticonvulsant effect of these AEDs. The severity or duration of the initial brain insult (the SE) did not differ between responders and nonresponders, indicating that the different AED response in the two subgroups is genetically determined.

In the search for mechanisms of resistance in phenobarbital-nonresponders, several differences between responders and nonresponders were found (**Figure 2**). Although most rats develop epilepsy with spontaneous recurrent seizures after SE induced by sustained electrical stimulation of the BLA, hippocampal damage with neurodegeneration in CA1, CA3, and dentate hilus occurs in only a subgroup of these epileptic rats, strongly indicating that such hippocampal damage is not critically involved in epileptogenesis. When hippocampal damage was compared in phenobarbital-responders and-nonresponders, only the nonresponders exhibited such damage, supporting the clinical notion that hippocampal sclerosis is often associated with AED resistance. Autoradiographic imaging of diazepam-sensitive and diazepam-insensitive $GABA_A$ receptor binding in the hippocampal formation showed a significant shift to enhanced diazepam-insensitive binding in the dentate gyrus of nonresponders, suggesting functional alterations in $GABA_A$ receptors. This finding was supported by recent immunohistochemical analyses of $GABA_A$ receptor subunit expression in responders and nonresponders. Phenobarbital-resistant epileptic rats exhibited complex alterations in $GABA_A$ receptor subunits in hippocampus and dentate gyrus, which certainly alter the efficacy of AEDs that act via modulation of $GABA_A$ receptors.
