Most of the known epilepsy genes have been discovered using a combination of linkage analysis and candidate gene approach. Linkage analysis takes advantage of the numerous genetic polymorphisms that are precisely mapped in our genome. Linkage can be suspected if such a polymorphism cosegregates with the disorder in one large or several smaller families. The distance between the genetic polymorphism and the actual epilepsy gene can than be estimated through the observed recombinations between polymorphism and disorder. Once the recombination rate is (close to) zero, all genes in this chromosomal region can be screened for mutations systematically or some of them can be selected by a candidate gene approach. Ion channels are known to play an important role in neuronal excitability, thus they are obvious candidates for epilepsy genes, a hypothesis that had by now been confirmed by the discovery of several different epilepsy genes. If strong candidate genes exist, it is even possible to use the candidate gene approach directly without performing linkage analysis first.

Functional Studies

Ion channels such as the nAChR provide the possibility to study the effects of mutations found in patients in easily accessible model systems such as *Xenopus* oocytes or HEK cells. Once the mutation is identified in the patients' DNA sample, it can be artificially introduced into a plasmid containing the respective subunit DNA and transcribed. After the injection of the wild-type or mutated mRNA into the experimental cell system, the receptor itself is assembled by the host cell and expressed at the surface – where it can be studied by either whole-cell or single-channel recording techniques. Differences in ion channel properties between wild-type and mutated receptors – such as increased or decreased agonist responses, changes in the duration of opening or closing times, or altered calcium permeability – will then allow a first glimpse at the basic pathogenetic mechanism(s) underlying epilepsy of interest.

Recent Results

The Genes Underlying ADNFLE

CHRNA4 and CHRNB2

Uncovering the genetic basis of ADNFLE took a lot of time, and the story is far from over. To date, mutations in three genes (*CHRNA4*, *CHRNB2*, *CHRNA2*) have been identified in families with nocturnal frontal lobe seizures (**Figure 1**). All three genes encode subunits of the nAChR, which is involved in a wide range of physiological processes and behavioral traits. The first ADNFLE mutation, a

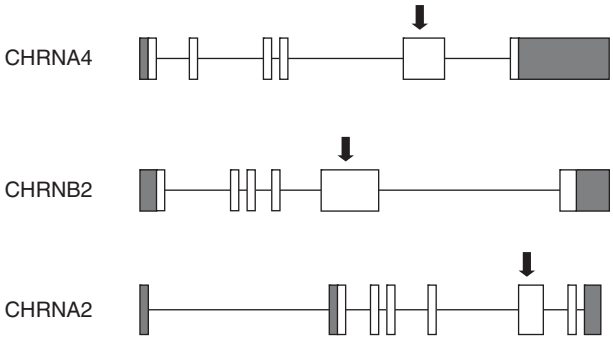

Figure 1 Schematic representation of nAChR subunit genes *CHRNA4*, *CHRNB2*, and *CHRNA2*. The positions of mutations associated with sleep-related epilepsy are indicated by arrows.

S248F amino acid exchange within transmembrane domain II of *CHRNA4*, was identified in 1995. The identification of *CHRNB2* as the second ADNFLE gene was published 6 years later, and so far four mutations have been described for each of these genes. Six of the eight mutations are located within the transmembrane domain II of either *CHRNA4* or *CHRNB2*, and two others were found in transmembrane domain III of *CHRNB2*. All attempts to find mutations in other parts of these genes were unsuccessful, and after more than 12 years of looking hard for such a mutation, nobody really expects to find one anymore (or at least not in association with a clinical phenotype of 'classical' ADNFLE). Why ADNFLE mutations are clustered in this small part of the genes can be explained from a functional point of view as follows: Both the second and the third transmembrane domain contribute to the walls of the ion channel. Thus, it seems that only mutations that have a direct effect on the ion pore are able to cause ADNFLE. One is even tempted to speculate that not all, but only certain, amino acid residues within these transmembrane domains make good candidates for ADNFLE mutations. This speculation is based on the observation that the number of known mutated amino acid residues is rather small, and that some of these amino acids are altered by mutations that occurred independently in unrelated families. The independent occurrence of the same mutation in families from different parts of the world offers the opportunity to study the effects of the genetic and ethnic backgrounds on mutation penetrance and clinical phenotype.

CHRNA2

A third nAChR gene, *CHRNA2*, has been recently reported as mutated in an Italian family with nocturnal seizures that were often accompanied by fear sensations, protruding tongue movements, and nocturnal wandering. Compared with the nAChR subunits *CHRNA4* and *CHRNB2*, much less is known about the expression pattern and functional role of *CHRNA2* in brain. Like *CHRNA4* and *CHRNB2*, *CHRNA2* mRNA has been shown to be ubiquitously expressed in mammalian brain. Highest expression levels were found in thalamus, an expression pattern that is theoretically consistent with a role of *CHRNA2* in epilepsy, since the thalamus is thought to be one of the most important brain structures with respect to epileptogenesis. The Italian family, and the mutation found in its affected members, differ from the earlier described ADNFLE families in some aspects. Fear sensations, choreoathetoid tongue movements, and nocturnal wandering have also been observed in ADNFLE patients, but seemed to occur more frequently in the Italian family. Furthermore, the missense mutation found in this family affects an amino acid residue that, due to its location in transmembrane domain I, is not likely to contribute to the structure of the ion pore. Unlike transmembrane domain II, only one-third of this domain is thought to contribute to the ion pore walls. Transmembrane domain I is linked covalently to the receptors agonist-binding site and is therefore believed to play an important role in the regulation of channel functions. When the *CHRNA2* mutation was first published in 2006, we had already collected a large sample of families with nocturnal frontal lobe epilepsy but no detectable mutations in either *CHRNA4* or *CHRNB2*. Thus, we tried to find mutations in the *CHRNA2* transmembrane regions in our family sample, but without success. Additional families with *CHRNA2* mutations are needed to decide if mutations in this gene are an extremely rare cause of ADNFLE or if these mutations give rise to a sleep-related epilepsy syndrome different from ADNFLE.

Are there Mutation-Specific Associated Features in ADNFLE?

As described earlier, the diagnosis of ADNFLE is not always a straightforward one. Thus, it is not surprising that patients frequently receive other diagnoses such as sleep disorders or a psychiatric diagnosis. It had been previously thought that the psychiatric diagnoses were a 'last resort,' because the epileptic disorder underlying the patient's symptoms had not been recognized. However, there is mounting evidence that the high frequency of psychiatric diagnoses in ADNFLE patients might not be an artifact. Comparison of the clinical phenotypes between ADNFLE families with different nAChR mutations suggests that at least some nAChR mutations not only cause epilepsy but are also associated with additional neurological and psychiatric features or cognitive deficits. A good example supporting this hypothesis is presented by the *CHRNA4* mutations 776ins3 and S252L. The 776ins3 mutation is a 3-bp insertion present in 11 members of a large Norwegian ADNFLE family. At least 6 of the 11 mutation carriers not only had epilepsy but also presented with serious psychiatric problems, mostly schizophrenia, negative symptoms of schizophrenia, severe apathy, or unclassified psychosis. This phenotype suggests that the 776ins3 mutation may be a risk factor for psychiatric

disorders. The S252L amino acid exchange is present in two unrelated families of Korean and Japanese origin, respectively. In both families, the seizures not only were often difficult to control with antiepileptic drugs (many patients required a combination of two or more antiepileptic drugs in order to decrease seizure frequency) but were also associated in most patients with mental retardation and/or behavioral problems. The differences between the two S252L-families, with respect to their geographic origin and their genetic background, strongly suggests that the associated cognitive deficits are caused by the mutation rather than by unrelated genetic or environmental factors.

About the Role of nAChR in Brain

Depending on their subunit composition, the different subtypes of homo- or heteropentameric nAChRs not only vary with respect to their expression patterns in brain but also display different biopharmacological channel properties. The primary nAChR brain subtype is the $\alpha4\beta2$ receptor, which is present in two different stoichiometries: $(\alpha4)_2(\beta2)_3$ or $(\alpha4)_3(\beta2)_2$. The nAChRs contribute to a wide range of brain activities and influence a number of physiological functions. Their binding sites are the targets of natural ligands like acetylcholine, but also of widely used drugs such as nicotine. They play a major role in higher cognitive functions and dysfunctions. In particular, the loss of cortical nAChRs is a neurochemical hallmark of Alzheimer and Parkinson diseases. Most nAChRs are believed to be located presynaptically and have a neuromodulatory role consisting of an enhancement of the release of GABA, glutamate, dopamine, nor epinephrine, serotonin, or acetylcholine. If present at postsynaptic locations, nAChRs have been shown to mediate fast excitatory synaptic transmission. Even an extrasynaptic localization has been demonstrated for nAChRs, although the functional significance of these finding remains unclear. So far, it is not known exactly where the mutated nAChRs involved in ADNFLE pathogenesis are preferentially localized, and by which mechanisms they are able to raise seizure susceptibility in the patient brains. The surprising, and so far not very well understood, observation is that a nAChR subtype that ubiquitously present in brain is able to cause a partial type of epilepsy rather than a generalized one. But as summarized in the following paragraph, recently published experiments with genetically altered mice have given us some insight into the pathomechanisms underlying epileptogenesis in ADNFLE.

ADNFLE Mutations Patch-Clamped

Functional studies with recombinant nAChR receptors carrying different ADNFLE mutations were performed to analyze the similarities and differences in the receptors' biopharmacological profiles. Coexpression of the *CHRNA4* subunit with the S248F mutation and of the wild-type *CHRNA4* subunit in *Xenopus* oocytes or HEK cells were followed by patch-clamp analysis. These experiments showed that acetylcholine-evoked currents of amplitudes comparable to those of wild-type receptors were obtained from receptors containing the mutated subunit, but that the mutation-containing receptor had a higher sensitivity for the natural agonist. Receptors carrying the 776ins3, S252L, or the V287M mutation also displayed increased acetylcholine sensitivity, but to different degrees, than did the S248F mutation. A reduction of calcium permeability was observed for the mutants S248F and 776ins3, but not for the S252L mutation. Taken together, a gain-of-function effect seems to be the main functional feature common to all known ADNFLE mutations. It is tempting to speculate that the particular functional signatures of each mutant contribute to the earlier described observations of associated neurological features in ADNFLE, while the gain-of-function effect might be responsible for the epilepsy phenotype.

What Stories are Mouse and Other Models Telling?

To examine the possible mechanisms underlying ADNFLE pathogenesis, several groups have already engineered mice carrying nAChR mutations. Two mouse strains that harbor either the S252F or the 776ins3 mutation on one of their *CHRNA4* alleles showed abnormal cortical EEG patterns, interictal spiking, and recurrent seizure activity. Furthermore, mice heterozygous for these mutations exhibited a markedly increased sensitivity toward nicotine-induced seizures and (on average) longer seizure durations than their wild-type litter mates. These results confirm that ADNFLE mutations are dominant with respect to the wild-type allele, and that they are able to cause hyperexcitability and spontaneous seizures. The EEG and electrophysiological data obtained from these mouse models were consistent with a model of epileptogenesis in which acetylcholine is one of the regulators of cortical GABAergic transmission. In such a model, the gain-of-function activation of mutant nAChRs would cause increased GABAergic inhibition. In the normal brain, asynchronous firing of pyramidal cells (e.g., in cortical layer II/III) would be synchronized after recovery from inhibition. In the mutant, an increase in inhibition – and therefore in network synchrony – could cause the pathological hypersynchronization (simultaneous firing of too many neurons at once) that gives rise to a seizure (**Figure 2**).

At first glance it might seem surprising that increased inhibition could be the basic mechanism underlying seizure generation. But just imagine that many balloons are held under water and somebody lets them all go up at once.

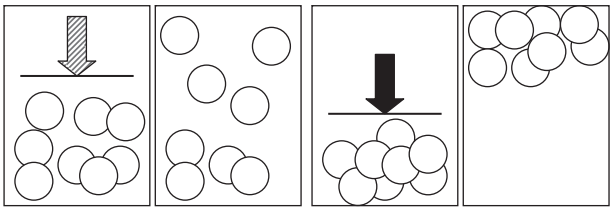

Figure 2 Model of GABAergic inhibition controlled by nAChR activation. Pyramidal cells inhibited by GABAergic interneurons are represented by balloons. Left side: inhibition of neuronal networks; right side, recovery from inhibition; (a) wild type and (b) mutant.

They would be creating one huge wave instead of many small ripples. The synchronizing effect of GABAergic inhibition and nAChR activation has already been demonstrated in several studies. For example, it has been shown that two pyramidal cells that are connected to a single interneuron synchronize their firing after recovery from inhibition. In the hippocampus, the activation of interneurons by acetylcholine first causes inhibition and than rebound spiking. So far it remains unknown why the increase of inhibition caused by mutated nAChRs only infrequently gives rise to seizures – i.e., what the triggering factors for seizures in ADNFLE patients are. One of these triggering factors is obviously to be found in the regulation of the sleep–wake cycle, since most seizures occur during non-REM sleep. These mechanisms are not easy to investigate in mice heterozygous for the aforementioned nAChR mutations, however, since these animals show nearly continuous abnormal EEG activity that makes it difficult to distinguish between the different sleep phases.

Challenges for the Future

Epilepsies as Channelopathies

In 1995, the year *CHRNA4* was identified as the first epilepsy gene, nobody could have foreseen how tedious the process of identification of additional epilepsy genes would be. Nevertheless, the genes that already have been found demonstrate how important is the role of ion channels in epileptogenesis. A great variety of different ion channels regulates brain excitability and prevents hypersynchronization of neuronal networks. Mutations in any of those ion channels might change the delicate balance between excitatory and inhibitory input, resulting in recurrent firing, hyperexcitability, and finally, seizures. Thus, it should not come as a surprise that one of the most important pathogenetic mechanisms in human epilepsy is based on mutations in various ion channel genes. Our growing knowledge about the genes that can underlie the various types of epilepsies will help future attempts to create a more precise classification of this heterogeneous group of disorders, and might also facilitate the development of new antiepileptic drugs for a more effective treatment of patients. To reach these goals, current research needs to focus not only on the identification of new epilepsy genes and their functional analysis, but also on the equally important task of finding additional mutations in known genes to establish a detailed knowledge of genotype–phenotype relationships.

Introduction

Injuries to the brain, which can stimulate epileptogenesis, typically lead to a variety of changes. One major consequence of brain injury, which is often overlooked, is a change in structure and function of the supporting glial cells. Specifically, astrocytes, a subtype of glial cell, exhibit a hypertrophy of their processes and an altered expression of some of their proteins. When glial cells exhibit these alterations, the process is referred to as reactive astrocytosis. This naming stems from the original belief that these changes represent a response of the glial cell to primary changes occurring in the neuron. However, during the past two decades there has been a revolution in our thinking about the roles of glial cells in the brain. As a result, we are re-examining reactive astrocytosis and asking whether these modified glial cells may in fact regulate neuronal function, and may contribute critically to precipitating seizure disorders.

In this review, much of our attention focuses on the basic biology of astrocytes and how they are involved in a signaling dialog with neurons. However, we also discuss how these signals are altered in the epileptic brain – when astrocytes exhibit reactive astrocytosis, and the possibility that certain actions of some anticonvulsants, as well as the ketogenic diet, may be mediated through the astrocyte to reduce neuronal excitability.

We discuss, for example, the now-accepted concept that astrocytes release chemical transmitters that can change the excitability of the neuron. Astrocytes are known to release transmitters with excitatory actions – glutamate and D-serine. In contrast, by releasing ATP, which is hydrolyzed in the extracellular space to adenosine, astrocytes can exert inhibitory actions on neurons mediated by A1 receptors. Additionally, astrocytes regulate GABAergic synaptic inhibition by providing glutamine to neurons, which acts as a critical precursor for the synthesis of presynaptic GABA. We consider the recent notion that the expression of enzymes essential for adenosine and GABA-mediated inhibition are altered following injury, leading to the potential for reduced inhibition in the brain.

Background – The Tripartite Synapse

Electron micrographs show that many synapses are also associated with a process of the astrocyte. Because presynaptic, postsynaptic, and astrocytic processes are associated with one another, this structure has been termed the Tripartite Synapse. In stratum radiatum of the hippocampus, over 50% of the excitatory synapses are associated with an astrocyte. Clearly, one astrocyte has the potential to regulate numerous synapses. Indeed, in the same region, one astrocyte contacts over 100 000 synapses, and in the cortex it has been estimated that one astrocyte contacts up to 600 different dendrites. Though it has been recognized for many years that astrocytes have privileged access to the synapse, we are only just beginning to understand the diversity of signals released and taken up at these 'tripartite' synapses.

One important role for astrocytes is in the uptake of neuronally released chemical transmitters. Glutamate that is released at excitatory synapses is taken up primarily by astrocytic transporters. Studies in knockout mice lacking one of these transporters, GLT-1, demonstrated that this

glial transporter is responsible for the majority of glutamate clearance; mice lacking this receptor develop spontaneous seizures and hippocampal pathology resembling that of patients with temporal lobe epilepsy (TLE).

Astrocytes express a high density of K^+ channels that are conductive at the resting membrane potential. It is thought that these channels are important to buffer extracellular K^+ thereby preventing excess build up of extracellular K^+ following repetitive neuronal activity.

In addition to clearing K^+ and chemical transmitters, astrocytes can also respond to neurotransmitters with elevations in their internal Ca^{2+} signals. For example, stimulation of whiskers, which evoke neuronal activity in the barrel cortex, also evoke astrocytic Ca^{2+} signals in this brain region. Such Ca^{2+} signals result from the release of Ca^{2+} from internal stores that are triggered by metabotropic receptors, which induce the accumulation of the second messenger IP_3. Astrocytes express receptors for most transmitters that then lead to alterations in the levels of Ca^{2+} as well as other second messengers. Elevation of internal Ca^{2+} can, in turn, lead to the release of chemical transmitters from the astrocyte. In this article we use the term gliotransmitter to identify chemical transmitters released from astrocytes. Astrocytes release glutamate (which acts on neuronal NMDA receptors) and D-serine (which is an endogenous coagonist for the glycine binding site of NMDA receptors). Additionally, astrocytes release ATP, which is hydrolyzed by extracellular ectonucleotidases to adenosine.

Rather than trying to discuss actions of each of these gliotransmitters, we limit our discussion to two areas: First, we provide some examples of the roles of these gliotransmitters in normal physiology; then we contrast these functions with their potential role in the epileptic brain. Reviews concerning gliotransmission have been published recently (see Further Reading).

Methods

Studies of synaptic transmission and astrocytes rely on a combination of techniques that are rooted in electrophysiology and imaging. The study of neurons and synaptic transmission relies on the use of the patch clamp technique, in which glass pipette is used to record the ion currents that flow across the cell membrane. For these recordings, a pipette is filled with a physiological saline solution and is connected to a circuit for the measurement of current. An extremely tight electrical and mechanical seal is formed between the tip of the pipette and the cell membrane, then negative pressure is used to rupture the membrane within the pipette tip and obtain electrical access to the cell interior. The patch clamp methodology allows high fidelity recordings of electrical activity.

For many years, the possible role of astrocytes in brain function was overlooked because they do not exhibit the all-or-none electrical discharge that was believed to be the sine qua non of brain function. However, the development of high-resolution imaging microscopes that could observe changes in the fluorescence of labels provided the initially surprising result that these glial cells exhibit biochemical excitability. Chemically synthesized dyes, the fluorescence of which changes when they bind Ca^{2+}, are loaded into astrocytes. Then a two-photon microscope is used to observe the fluorescence of these dyes within cellular compartments. This approach can be used to image cells in vivo. To perform such studies, mice are immobilized under the microscope and, after making a small hole in the skull, a microscope lens is used to look into the cortex to examine changes in fluorescence. These fluorescence signals are then used to determine changes in free Ca^{2+} concentration.

Results

The Astrocytic Adenosine Cycle

The astrocyte contains the necessary machinery for the tonic control of the extracellular adenosine that acts on A1 receptors – which in turn leads to inhibitory effects in the central nervous system. There is a constant tone of extracellular adenosine that continuously activates A1 receptors, leading to a persistent A1-dependent presynaptic inhibition of excitatory transmitter release. Though this tone is not debated, the predominant source of this purine has only recently been identified. There are at least two potential sources of extracellular adenosine – either through adenosine loss from cells through equilibrative nucleoside transporters (ENTs), or an accumulation resulting from the hydrolysis of ATP that is released from cells. In support of the former is the notion that increased metabolic activity of cells will lead to an accumulation of intracellular adenosine, which will in turn passively result in an extracellular accumulation. However, because the addition of ENT inhibitors leads to elevated levels of extracellular adenosine, this is unlikely to be the predominant pathway of adenosine accumulation under physiological conditions.

Recent studies have shown that selective expression in astrocytes of a SNARE domain of a vesicle protein, which inhibits regulated exocytosis, leads to the loss of the continuous A1 receptor-mediated inhibition of synaptic transmission. This result shows that the source of adenosine that mediates this inhibition is the astrocyte – and that its release (or release of a precursor) is likely to be via an exocytotic pathway (rather than through the loss of adenosine through ENTs). Further studies demonstrated

that the expression of the SNARE domain inhibited ATP release, and that this nucleotide was in turn hydrolyzed to adenosine. Once adenosine accumulates extracellularly, how and where is it metabolized? Adenosine is taken up into the astrocyte by ENTs, where it is metabolized either by adenosine deaminase to inosine, or by an astrocyte-enriched enzyme, adenosine kinase, which phosphorylates adenosine to AMP (which is then subsequently phosphorylated to ADP and ATP). Because adenosine kinase is astrocyte-specific and the source of adenosine controlling A1 receptors is astrocytic, the pathways described above result in an adenosine cycle, in which ATP is released by astrocytes into the extracellular space and converted to adenosine, which is taken up by the astrocyte where it is converted back to ATP.

Although this discussion highlights the importance of astrocytes in the control of extracellular adenosine, it is important to understand that ATP is also released from nerve terminals, and that this ATP can be converted to adenosine. However, recent studies suggest that neuronally derived adenosine is more likely to activate A2A receptors.

Astrocyte-derived adenosine is not merely released at a background rate to exert a continuous adenosine tone. As discussed earlier, astrocytes can respond to neuronal activity, when neurotransmitters activate astrocytic metabotropic receptors. Indeed, stimulation of the Schaffer collateral pathway of the hippocampus induces astrocytic Ca^{2+} elevations, and this metabotropic pathway leads to elevated adenosine accumulation lasting for 5–15 min beyond a brief period (1 s) stimulus train. In the hippocampus, there is a well-documented form of heterosynaptic depression that is mediated by adenosine. Independent studies, using astrocyte-selective molecular genetics and dialysis of a Ca^{2+} chelator directly into the astrocyte, have shown that presynaptic neural activity can induce elevated release of ATP from astrocytes, which after hydrolysis to adenosine causes the A1 receptor-dependent heterosynaptic depression of neighboring unstimulated synapses. Taken together, the results of these studies demonstrate that the astrocytic adenosine cycle exerts a powerful non-GABAergic mechanism of inhibition in the CNS.

Glutamine Synthetase and GABA-Dependent Inhibition

GABA plays an essential role mediating inhibition in the nervous system. As a consequence, GABA receptors have been targets for the development of anticonvulsant drugs. However, the importance of the astrocyte in regulating presynaptic GABA pools has only recently been appreciated. Glutamine synthetase, an astrocyte-enriched enzyme, is responsible for inactivating glutamate through its conversion to glutamine. Glutamine is transported into neurons, where it is converted to glutamate by phosphate-activated glutaminase (PAG); in GABAergic neurons, this glutamate is subsequently converted to GABA by glutamic acid decarboxylase (GAD). Although studies have not been reported using tissue from epileptic subjects, a recent brain slice investigation has identified glutamine synthetase as a key enzyme controlling the functional presynaptic pool of GABA. When glutamine synthetase is chemically inhibited, there is a reduction in the presynaptic pool of GABA, which results in a reduction in the filling of vesicles with this inhibitory transmitter. Importantly, while glutamine synthetase is inhibited by methionine sulfoximine (MSO), addition of exogenous glutamine restores inhibition; pharmacological inhibition of neuronal transporters for glutamine leads to a similar reduction in GABA released. Therefore, on the time scale of minutes, the efficacy of GABAergic synaptic transmission critically requires an astrocytic source of glutamine.

It is self-evident that reduced levels of GABA will impact on the efficacy of neuronal inhibition, but they may also have effects of astrocytic signal transduction – e.g., through metabotropic $GABA_B$ receptors, which are highly expressed in astrocytes (as well as in neurons). Intriguingly, knockout of either $GABA_B$ receptor subunit produces a serve epileptic phenotype, which is lethal in some mouse strains; the relative roles of neuronal and astrocytic $GABA_B$ receptors in this phenotype remain to be explored.

Reactive Astrocytosis Disrupts the Adenosine and Glutamine Cycles

Given the importance of the astrocyte for controlling inhibition mediated by A1 receptors and by GABA, it becomes important to determine whether the adenosine and glutamine cycles are impaired in brains of epileptic patients. In patients with medial temporal lobe epilepsy, astrocytes become reactive and there is a dramatic loss of neurons in area CA1. In such sclerotic tissue, the expression of glutamine synthetase is dramatically reduced. Whether this reduction is a consequence of the neuronal loss, or whether initial reductions in glutamine synthetase led to reduced GABAergic inhibition which triggered neuronal demise, is not known. However, this observation highlights the potential importance of glutamine synthetase in epileptogenesis, and identifies a potential therapeutic site of intervention for restoration of GABAergic inhibition.

In addition to glutamine, the astrocytic adenosine cycle is impaired in tissue isolated from rodents exhibiting spontaneous recurrent seizures. Following status epilepticus,

the astrocytic expression of adenosine kinase is enhanced. The consequence for the A1-dependent inhibition is dramatic. Because adenosine kinase phosphorylates cytosolic adenosine, enhanced adenosine kinase expression leads to the depletion of intracellular adenosine, and as a consequence there is an increased gradient for extracellular adenosine to enter the astrocyte. Therefore, elevated adenosine kinase results in reduced extracellular adenosine and reduces the tonic inhibition of excitatory synaptic transmission mediated by presynaptic A1 receptors.

Because reactive astrocytosis occurs within days of an initial brain injury (and continues during the period of epileptogenesis), it is tempting to propose that alterations in enzyme expression within reactive astrocytes lead to reduced GABAergic and adenosine-dependent inhibition in the brain, and that the reduction in these forms of inhibition contributes to the chain of events that results in the reorganization of structure and function that supports the generation of seizures.

Astrocytes Excite Neurons – A Basis for the Modulation of Epilepsy?

Some of the first demonstrations that astrocytes release glutamate showed that this glutamate can act on NMDA receptors, and that the affected neurons can generate slow depolarizations similar in form to paroxysmal depolarizing shifts (PDS). Given the importance of the PDS to the generation of epileptiform activity, it has been proposed that excitatory glutamate-mediated signaling from astrocytes may underlie pathological events in the nervous system, including the generation of epileptiform activity.

In order to discuss the relevance of astrocyte-mediated neuronal excitation by glutamate, it is necessary to recount some of the supporting evidence for the presence of this important pathway in the nervous system. Initially in cell culture studies, astrocytic Ca^{2+} signals were shown to lead to delayed neuronal Ca^{2+} elevations that were shown to be mediated by the release of glutamate from the astrocyte. Subsequent studies have shown that Ca^{2+} is the causal stimulus for the release of glutamate. There are numerous pathways that have been shown capable of releasing glutamate from astrocytes, including release through hemi-channels, P2X receptors, and via exocytotic vesicular release of transmitter.

When glutamate is released from astrocytes, it can have several actions on neurons, including the regulation of NMDA receptor function, the control of neuronal excitability, and the modulation of synaptic transmission. A provocative study provided evidence supporting the idea that by releasing glutamate, astrocytes are able to trigger epileptiform events. Support is provided by the independent demonstration that astrocytic glutamate release can cause PDS-like depolarizations. Because of a lack of astrocyte-selective tools, it is experimentally challenging to directly test this hypothesis. However, since astrocytic glutamate predominantly signals through NMDA receptors, pharmacological studies indicate that this glial glutamate is not necessary for ictal epileptiform activity – although it is possible that ictal activity is modulated by a glial source of glutamate. Further support for an astrocytic contribution to epilepsy-related events is provided by the observation that selective chemical inhibition of astrocytic Ca^{2+} signals in vivo leads to a protection of neurons from the delayed neuronal death that follows status epilepticus. We await tools that allow the selective inhibition of astrocytic Ca^{2+} signals and/or the release of glutamate from these glial cells, to test the importance of glial modulation of neuronal excitability in epilepsy.

Directions for Future Research – Could treatments be Targeted through the Astrocyte?

Astrocytes offer the potential for an entirely new set of molecular targets for the development of therapeutics for a variety of disorders, including epilepsy. Perhaps some of the existing anticonvulsants do act through glia. In support of this possibility is the observation that valproate, gabapentin, and phenytoin all reduced astrocytic Ca^{2+} signals in vivo during epileptiform activity, and that when astrocytic Ca^{2+} signals are directly stimulated (using focal application of ATP), these same anticonvulsants reduced this glial Ca^{2+} signal.

In recent years, the ketogenic diet has won increasing clinical acceptance for the management of seizures in patients whose seizures are refractory to antiepileptic drugs, or, in whom pharmacologic intervention has evoked unacceptable side effects. This regimen entails the administration of 80–90% of calories as fat (with the remainder derived primarily from protein). Most patients demonstrate ketosis (3–5 mmol l^{-1}; normal 0.1–0.3 mmol l^{-1}) within a few days of diet initiation. Many patients enjoy an attenuation of seizure frequency and severity, and they do not suffer the obtundation that typifies the response to most medications. The precise mechanism for the therapeutic response is not known with certainty, and it is probable that ketosis evokes multiple changes in brain biochemistry, physiology, and gene expression. Several laboratories have noted alterations of brain glutamate handling in response to ketosis. For example, ketosis appears to favor flux through the glutamine synthetase pathway, thereby enabling more efficient

'detoxification' of glutamate and providing GABAergic neurons with an abundant supply of glutamine, a favored precursor to GABA via the glutamate decarboxylase pathway. Indeed, GABA concentration is increased in the cerebrospinal fluid of patients who receive the ketogenic diet.

Adenosine is considered an endogenous anticonvulsant. However, given the variety of systemic actions of A1 agonists, as well as the soporific effects of A1 receptor activation, it is not feasible to use such compounds as anticonvulsants. However, given that novel receptors have now been identified in astrocytes, it may become feasible to activate glial signaling pathways with novel drugs in order to induce the glia-dependent accumulation of adenosine in select regions of the brain, and either prevent epileptogenesis or inhibit seizures in the epileptic brain.

Glial-Mediated Mechanisms of Epileptogenesis in Tuberous Sclerosis

L H Zeng, D H Gutmann, and M Wong, Washington University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy is among the most common neurological disorders, affecting about 1% of people, and is associated with significant morbidity and mortality. Since only a limited number of patients with epilepsy are candidates for surgical therapy, the majority of epilepsy patients are treated with antiepileptic drugs (AEDs), which are primarily designed to suppress seizures by directly controlling excitability of neurons. Unfortunately, seizure control is poor in about one-third of epileptic patients; seizures in these patients are refractory to currently available AEDs. To develop more effective therapies for epilepsy with potential novel mechanisms of action, it is important to better understand the basic cellular and molecular mechanisms underlying epileptogenesis.

Glial Modulation of Excitability via Glutamate and GABA Transporters

A Schousboe, University of Copenhagen, Copenhagen, Denmark
H S White, University of Utah, Salt Lake City, UT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Fine tuning of glutamatergic excitatory and GABAergic inhibitory neurotransmission is a prerequisite for optimal, normal functioning of the central nervous system (CNS). Termination of the transmission processes mediated by glutamate and GABA is controlled by a number of high-affinity transporters for these amino acids, transporters that are expressed in both neurons and astrocytes. The latter cell type has a major role in this fine-tuning process. Any disturbance in glial transporter function will lead to an imbalance in the equilibrium between excitation and inhibition, leading to seizure activity and epileptic episodes.

Disinhibition, resulting from altered GABAergic neurotransmission, has been associated with a number of neurological disorders, including epilepsy, migraine headaches, chronic pain, anxiety, and sleep disorders. Abnormal excitatory neurotransmission, resulting from excessive synaptic glutamate levels, has been associated with a number of neurodegenerative disorders, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease, Huntington's disease, Parkinson's disease, and neuronal damage associated with cerebral ischemia. In addition to a role in these and other neurodegenerative disorders, alterations in glutamate transporters also contribute to the development of seizures and epilepsy. Thus, efforts to regulate the function and trafficking of GABA and glutamate transporters will likely have important implications for the treatment of a number of these neurological disorders and diseases. Ongoing efforts to gain a greater understanding of the factors that control their cellular expression, function, and regulation at the cellular and network level are critical, and will play important roles in the development of a new class of therapeutics for a number of devastating neurological conditions. Indeed, a number of antiepileptic drugs exert their action by modulating these transport processes.

Background

Characteristics and Nomenclature of Glutamate and GABA Transporters

Cloning strategies have led to the identification of five high-affinity glutamate transporters, the operation of which depends on an intact membrane potential as well as a transmembrane sodium gradient. The prevalent cellular localization of the individual transporters is summarized

in Table 1. Quantitative immunogold analysis has provided evidence that the majority of the transport capacity resides in astrocytes, a conclusion confirming that of classical studies of the kinetics of glutamate uptake in neurons and astrocytes. The determination of the presence and functional importance of a presynaptic neuronal glutamate transporter has been somewhat elusive, but it appears likely that such a process does play a functional role. It is, however, clear that the ability of astrocytes to keep the extracellular glutamate concentration in the low micromolar range is of fundamental importance for the optimization of glutamatergic activity. Malfunction of this process will lead to, e.g., seizure activity, excitotoxic neuronal damage, and cell death.

In analogy to the glutamate transporters, cloning efforts have revealed the existence of four GABA transporters, one of which is highly homologous to the transporter for the osmolyte, betaine. The nomenclature and cellular localization of these transporters in rat and mouse brains are summarized in Table 2. It is unfortunate and confusing that nomenclature has developed such that rat GAT-2 and GAT-3 correspond to the mouse GAT3 and GAT4, respectively. Like the glutamate transporters, GABA transport is sodium dependent; in addition, these transporters exhibit chloride dependency. In contrast to the glutamate transporters, it appears that the major sites for GABA transport are expressed in GABAergic nerve endings. Nevertheless, astrocytic GABA transport plays an important role for the function of GABAergic neurotransmission, since astrocytic GABA uptake will reduce the amount of GABA available for recycling into the presynaptic nerve endings for subsequent transport into the vesicular GABA pool. It is now recognized that this balance between neuronal and astrocytic GABA transport plays a significant role in the prevention of seizure activity.

Pharmacological Characteristics of Glutamate and GABA Transporters

Throughout several decades, the pharmacological properties of glutamate transport have been extensively studied. Table 3 provides examples of the most commonly used pharmacological tools to investigate glutamate transporter function. The most important development in this regard has been the identification of DL-threo-β-benzyloxyaspartic acid (TBOA), which, in contrast to all other inhibitors, does not act as a transporter substrate. Thus, it is possible to block glutamate uptake without generating release of glutamate by heteroexchange. Studies with TBOA have unequivocally shown that an intact glutamate transport system is imperative for the prevention of excitotoxic neuronal damage, and that inhibition of glutamate transport will generate seizure activity.

Similarly, a vast number of studies have been devoted to investigating the pharmacological properties of GABA transporters. Table 4 provides a summary of GABA analogs that have been identified as inhibitors of the cloned GABA transporters, and that inhibit GABA transport into neurons and astrocytes. The identification of pharmacological tools that differentially affect neuronal and astrocytic GABA transport has led to the notion that inhibitors of astrocytic GABA transport may be of interest as anticonvulsant agents (see the following sections). This view is based on the idea that astrocytic GABA uptake may result in a drain of GABA from the neurotransmitter pool. Moreover, the development of subtype selective GABA transport (GAT) inhibitors should facilitate functional studies of these transporters and provide insights that may be of value for the development of antiepileptic drugs – e.g., with mechanisms of action analogous to that of tiagabine, which selectively inhibits GAT1.

The methods employed in the studies described in the remainder of this overview are described in detail in the primary literature referenced at the end of this chapter. Please refer to these for an in-depth description of the methods employed in the summarized studies in the following sections.

Methods

The techniques and methods, used to develop and characterize pharmacological agents that may selectively inhibit glutamate or GABA transporters, have been previously described and can be found in the citations included in Further Reading section.

Results

Glutamate Transporters

As discussed earlier, extracellular levels of glutamate are maintained at relatively low levels by the presence of high-affinity, high-capacity transporters localized on neurons and glial. The strategic location of various glutamate transporters on neurons and glia functions to

Table 1 Nomenclature and principal cellular localization of glutamate transporters

	Transporter subtype				
Systematic name	EAAT-1	EAAT-2	EAAT-3	EAAT-4	EAAT-5
Original name	GLAST	GLT-1	EAAC-1	EAAT-4	EAAT-5
Brain area location	Cerebellum	Cortex	Uniformly	Cerebellum	Retina
Cellular location	Glia	Glia	Neurons	Purkinje cells	–

prevent neuronal cell death as a result of overactivation of excitatory neurotransmitter receptors. To date, the numerous attempts to reduce excitatory neurotransmission by blocking postsynaptic glutamate neurotransmitter receptors have not been highly successful in identifying clinically effective neuroprotective therapies. Recently, investigators have been evaluating two other equally attractive options for regulating extracellular glutamate levels: blocking glutamate release and/or enhancing glutamate uptake. A number of different anticonvulsant drugs that display sodium channel blocking properties (e.g., phenytoin, carbamazepine, and lamotrigine) have been observed to reduce glutamate release by blocking depolarization of the presynaptic terminal. It is not clear whether this effect of sodium channel blockers is solely responsible for their anticonvulsant action, as this class of drugs has been shown to have other effects that limit seizure spread from the seizure focus.

In contrast to the efforts to prevent glutamate release, several different approaches have been employed (with varying levels of success) to test the hypothesis that increasing glutamate transport – from the extracellular to the intracellular compartment – will result in a therapeutic effect. These experimental approaches include efforts to study (1) transgenic mice that overexpress glutamate transporters, (2) pharmacological upregulation of transporters, and (3) use of viral vectors to increase expression of glutamate transporters in various cell types. The results from these studies have been encouraging, and suggest that the presence of increased transporter function can lead to reduced cell death and less severe seizures. For example, in the double transgenic mouse model created from crossing an ALS mouse model with a mouse overexpressing EAAT2, animals are able to maintain their grip strength longer than in the ALS model, and display delayed motor neuron loss and a slightly greater lifespan than the nonoverexpressing ALS mutant. Moreover, overexpression of EAAT2 results in reduced seizure severity and improved neuronal survival following status epilepticus (induced by either kainic acid or pilocarpine). A number of antiepileptic drugs have been found to increase glutamate transporter expression. For example, zonisamide has been reported to increase EAAC1 protein levels in the hippocampus and cortex in the $FeCl_3$-induced seizure model. This effect, coupled with a reduction in GAT1 GABA transporter levels, may contribute to the anticonvulsant action of this broad-spectrum anticonvulsant drug. In addition, topiramate has been shown to increase GLT-1 protein levels in cocultures of rat astrocytes and neurons; this result may explain the ability of this anticonvulsant to decrease elevated glutamate levels in the spontaneously epileptic rat, as well as cerebrospinal fluid glutamate levels in human traumatic brain injury.

Table 2 Nomenclature and principal cellular localization of GABA transporters from rat and mouse brain

Nomenclature and cell localization				
Species/cell type				
Rat brain	GAT-1	BGT-1	GAT-2	GAT-3
Mouse brain	GAT1	GAT2	GAT3	GAT4
Neurons	+++	+	+	+
Astrocytes	+	++	++	+++

Number of '+' indicates relative expression levels.

In addition to these anticonvulsant drugs, treatment with ceftriazone (a member of the β-lactam class of antibiotics) leads to increased expression of GLT-1 transporters and glutamate uptake (for review, see Sheldon and Robinson in Further Reading). This effect of ceftriaxone is of particular interest because it results in a marked and significant disease-modifying effect in models of ALS. For example, ceftriaxone promotes neuronal survival in vitro in a model of motor neuron degeneration, and increases survival and decreases loss of muscle strength in vivo in a mouse model of ALS. Moreover, EAAT2 overexpressing HEK cells appear to protect cultured motor neurons from glutamate-mediated toxicity. It is also of interest to note that a similar treatment protocol with ceftriaxone increased the seizure threshold for generalized clonic and generalized clonic–tonic seizures induced by the chemoconvulsant pentylenetetrazol in two separate mouse strains, albeit strain, sex, and age differences were observed (Jelenkovic *et al.*, 2008). Unfortunately, the authors of the manuscript did not confirm the presence of upregulated glutamate transporter protein, and any final interpretation of their results, as it relates to an improved removal of extracellular glutamate, will necessarily have to await additional confirmation. In addition to epilepsy and ALS, overexpression of glutamate transporters has been found to be neuroprotective in various in vitro and in vivo models of ischemia.

These few examples clearly exemplify the promise underlying this novel strategy to improve the treatment options for a number of devastating neurological disorders. However, it is important to note that every word of promise usually comes with a word of caution; i.e., the upregulation or overexpression of glutamate transporters could negatively affect the outcome under conditions of energy failure. For example, glutamate transporters can operate in reverse direction, and thereby cause an increased release of glutamate, under conditions of energy depletion. As such, their reversal during acute energy failure could contribute to increased neuronal death. Nonetheless, manipulation of glutamate transporter function is an important and exciting new approach to the treatment of neurological disorders that warrants further investigation.

GABA

As mentioned earlier, compounds that selectively block GABA uptake have been demonstrated to possess anticonvulsant activity in both animals and humans. The most successful example of this strategy is the GAT1-selective inhibitor, tiagabine. Tiagabine emerged from a mechanistic-based drug discovery program at Novo Nordisk to identify orally active anticonvulsant derivatives of nipecotic acid. Tiagabine is currently utilized for the add-on treatment of partial seizures in both children and adults. Unfortunately, tiagabine use is not without significant adverse events when used in high doses. These include agitation, sedation, and psychotic-like episodes in patients predisposed to psychiatric illness. As discussed earlier, tiagabine is a selective inhibitor of GAT1, which is preferentially localized on neurons as opposed to astrocytes. Whether or not the adverse effect profile of tiagabine is related to its selective inhibition of GAT1 is an issue that has yet to be resolved, but the possibility has led to the suggestion that inhibitors of non-GAT1 GABA transporters may afford some benefit over that of tiagabine and other GAT1-selective inhibitors. Interestingly, a number of nonselective GABA transport inhibitors have been experimentally demonstrated to possess anticonvulsant activity. Of these, one particular molecule – EF1502 (*N*-[4,4-bis(3-methyl-2-thienyl)-3-butenyl]-4-(methylamino)-4,5,6,7-tetrahydrobenzo[*d*]isoxazol-3-ol, which is substituted with the tiagabine side chain – displays significant inhibitory effects on both GAT1 and GAT2 transporters. Combination isobolographic studies conducted with EF1502 and tiagabine demonstrated that inhibition of GAT2 by EF1502 contributes to the potent and broad-spectrum anticonvulsant profile of systemically administered EF1502 in rodent seizure and epilepsy models. Moreover, the combination of EF1502 with tiagabine did not increase the behavioral toxicity of either drug alone. This latter finding suggests that inhibitors of the GAT2 transporter may offer some advantage over pure GAT1-selective inhibitors. The extrasynaptic location of non-GAT1 transporters, coupled with the pharmacological activity of EF1502, demonstrates the important role of extrasynaptic GABA transporters in controlling neuronal function.

Future Directions

Recent advances in our understanding of the expression pattern of neuronal and glial glutamate and GABA transporters have suggested that these transporters play an important role in a number of neurological and psychiatric disorders. The ability to increase the expression of glutamate transporters with a broad-series of β-lactam antibiotics represents an interesting and novel finding and has broad implications for the treatment of ALS, epilepsy, and other CNS disorders.

The fact that the non-GAT1 transporters located on glial and extrasynaptic membranes play a functional role in the control of neuronal excitability demonstrates that these transporters are potentially important targets for future drug design. Moreover, it is also important to note that the development of selective inhibitors of glial GABA uptake could one day play an important role in enhancing extrasynaptic GABA-mediated inhibition.

The successful translation of ongoing efforts to better understand the factors that control the regulation and expression of glutamate and GABA transporters will depend heavily on the design and synthesis of selective

agents that target these transporters, and the willingness of investigators, drug companies, and funding agencies to invest in the clinical trials that will ultimately determine the utility of this approach for the treatment of epilepsy and other neurological disorders.

Peritumoral Epilepsy

S A Lyons and H Sontheimer, University of Alabama at Birmingham, Birmingham, AL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Each year ~100 000 patients are newly diagnosed with tumors in the central nervous system (CNS) in the United States. According to data from the Central Brain Tumor Registry of the United States (CBTRUS), ~18 500 of these are considered primary brain tumors, i.e., arising initially in the brain; interestingly, the vast majority are of glial origin. These glial-derived tumors are collectively called gliomas and include oligodendrogliomas, astrocytomas, and glioblastomas. These tumors share a number of genetic alterations with other cancers, but also differ in some important aspects. These differences include, for example, their inability to spread via hematogenous routes and their physical containment within the bony cavity of the brain. Biological adaptations that allow gliomas to develop with these constraints may, in part, contribute to the high likelihood with which these cancers produce seizures in patients. Although most brain tumors, including metastatic tumors, can produce seizures, the causal relationship between tumor biology and peritumoral seizures is best understood in glial-derived tumors, which are the principle topic of this article.

Background

Gliomas and Epilepsy

Gliomas arise de novo within the CNS. Although they are generally believed to derive from glial cells or their progenitor cells, their etiology is still in question. Some gliomas are considered benign and can be treated, but the majority of gliomas form aggressive and highly malignant tumors that are largely unresponsive to treatment. Surgical resection is typically unsuccessful as tumor cells tend to invade the normal brain parenchyema diffusely and create satellite tumors. Upon resection of the main tumor, regrowth typically occurs within just a few months. Unfortunately, chemotherapy provides only limited benefit to patients, in part because the blood–brain barrier makes effective delivery difficult and in part also because gliomas tend to be quite resistant to commonly-used chemotherapeutic drugs. Consequently, the outlook for patients with malignant gliomas remains dismal, with average patient survival of less than one year even with all currently available treatments.

In 30–50% of patients, the diagnosis of a primary brain tumor is preceded by epileptic seizures. This percentage

'detoxification' of glutamate and providing GABAergic neurons with an abundant supply of glutamine, a favored precursor to GABA via the glutamate decarboxylase pathway. Indeed, GABA concentration is increased in the cerebrospinal fluid of patients who receive the ketogenic diet.

Adenosine is considered an endogenous anticonvulsant. However, given the variety of systemic actions of A1 agonists, as well as the soporific effects of A1 receptor activation, it is not feasible to use such compounds as anticonvulsants. However, given that novel receptors have now been identified in astrocytes, it may become feasible to activate glial signaling pathways with novel drugs in order to induce the glia-dependent accumulation of adenosine in select regions of the brain, and either prevent epileptogenesis or inhibit seizures in the epileptic brain.

Glial-Mediated Mechanisms of Epileptogenesis in Tuberous Sclerosis

L H Zeng, D H Gutmann, and M Wong, Washington University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy is among the most common neurological disorders, affecting about 1% of people, and is associated with significant morbidity and mortality. Since only a limited number of patients with epilepsy are candidates for surgical therapy, the majority of epilepsy patients are treated with antiepileptic drugs (AEDs), which are primarily designed to suppress seizures by directly controlling excitability of neurons. Unfortunately, seizure control is poor in about one-third of epileptic patients; seizures in these patients are refractory to currently available AEDs. To develop more effective therapies for epilepsy with potential novel mechanisms of action, it is important to better understand the basic cellular and molecular mechanisms underlying epileptogenesis.

Traditionally, glia have been viewed as playing secondary supportive roles in the brain, and have received relatively little attention in contributing to proposed mechanisms of epileptogenesis. However, in recent years, accumulating evidence has suggested that glial cells have more fundamental roles in modulating and participating in neuronal and synaptic physiology, and can directly influence epileptogenesis. Astrocytes, in particular, have been shown to be involved in the reuptake of synaptically-released neurotransmitters and in the regulation of extracellular ion concentrations. Functions that were previously thought to be exclusively carried out by neurons, such as the release of local chemical signals, have also been reported for glial cells ('gliotransmitters'). In addition, although glia cannot generate typical action potentials, they possess numerous neurotransmitter receptors and ion channels, and have their own mechanisms of expressing excitability in the form of calcium waves, which can spread between astrocytes to trigger the release of gliotransmitters. Given this previously underappreciated diversity of glial functions in controlling neuronal physiology and excitability, it is now critical to reexamine the potentially important roles that glia may play in the pathophysiology of epilepsy.

Tuberous sclerosis complex (TSC) is one of the most common genetic causes of epilepsy, affecting ~1 in 6000 individuals worldwide. TSC is an autosomal dominant disorder, which results from a germline mutation in either the *TSC1* or *TSC2* gene. As the protein products of these two genes, hamartin and tuberin, are regulators of cell growth and proliferation, TSC involves hamartoma or tumor growth in multiple organ systems. Neurological involvement, including epilepsy, mental retardation, and autism, usually represent the most significant health concerns affecting patients with TSC. Epilepsy occurs in at least 80% of TSC patients, and typically involves multiple seizure types, including infantile spasms, which are often refractory to currently available AEDs and surgical treatments. Pathologic examination of the brains from affected individuals frequently reveals the presence of dysplastic areas or hamartomas (tubers), which positively correlate with the severity of cerebral dysfunction and seizures and are often identified as sites of epileptic foci in TSC brains. Tubers consist of focal regions containing increased numbers of astrocytes as well as 'giant cells,' which exhibit features of both neurons and glia. The observation that patients with TSC develop nonneoplastic tubers with abnormal glial features, as well as neoplastic growths composed of glia (subependymal giant-cell astrocytomas, SEGAs), suggests that brain dysfunction in TSC – including epilepsy – might result in part from primary defects in astrocyte function. In this regard, an improved understanding of the role of astrocytes in epileptogenesis in TSC may be important for developing more effective treatments for epilepsy in TSC patients.

Background

A number of recent studies have begun to investigate potential glial-mediated mechanisms of epileptogenesis. Because glial abnormalities may not only promote epileptogenesis, but also may result from seizures ('astrogliosis'), it can be challenging to demonstrate a clear cause (versus effect) role for astrocytes in epilepsy. A number of approaches have been utilized for identifying pathophysiological alterations of glia that might be responsible for, or contribute to, the initiation of seizures. One approach has involved studying glia cells in human brain tissue resected from patients with epilepsy, including patients with TSC. However, information from human tissue studies is often limited, because they almost always involve patients with chronic intractable epilepsy who are taking multiple AEDs. As a result, it is difficult to determine whether the glial abnormalities observed in such studies are a primary cause of the epilepsy or are secondary to other factors, such as the long-standing effects of AED treatment or seizure activity itself.

Clinically-relevant small-animal models offer an alternative approach to more directly elucidate the role of glia in epileptogenesis in TSC. The Eker rat, which harbors a spontaneous heterozygous *Tsc2* gene mutation, was initially described almost 50 years ago and has probably been the most commonly-used animal model of TSC. However, while the Eker rat is an excellent model for other features of TSC, such as renal disease, the brain is only modestly affected. In this regard, Eker rats exhibit relatively mild neuropathological abnormalities and do not appear to develop spontaneous epilepsy, limiting their utility for studying mechanisms underlying epileptogenesis. Conventional knockout mice with homozygous *Tsc1* or *Tsc2* gene inactivation die in midembryogenesis, and mice heterozygous for *Tsc1* or *Tsc2* gene inactivation develop tumors in other organs, but exhibit minimal neurological phenotypes. Since conventional *Tsc* knockout mice have limited utility for studying epilepsy, we and others have developed conditional knockout mice, in which *Tsc* gene inactivation is targeted to specific cell types within the brain. Given the prominent glial abnormalities observed in brain specimens from TSC patients, we generated conditional knockout mice with inactivation of the *Tsc1* gene primarily in glia ($Tsc1^{GFAP}$CKO mice). These mice develop spontaneous recurrent seizures and represent a very attractive model for investigating the role of astrocytes in epileptogenesis in TSC.

Methods

$Tsc1^{flox/flox}$-GFAP-Cre ($Tsc1^{GFAP}$CKO) mice were generated in our laboratories using Cre-LoxP methodology. To inactivate *Tsc1* gene expression in glial fibrillary acidic

protein (GFAP)-positive cells (glia), we developed GFAP-Cre mice in which Cre-recombinase was expressed under the control of a human GFAP promoter. These GFAP-Cre mice were crossed with *Tsc1*$^{flox/flox}$ mice containing LoxP sites targeted to the *Tsc1* gene (**Figure 1(a)**). Characterization of these mice with LacZ transgene expression, Cre-recombinase staining, and Cre reporter mice indicates that Cre recombination first occurs around embryonic day

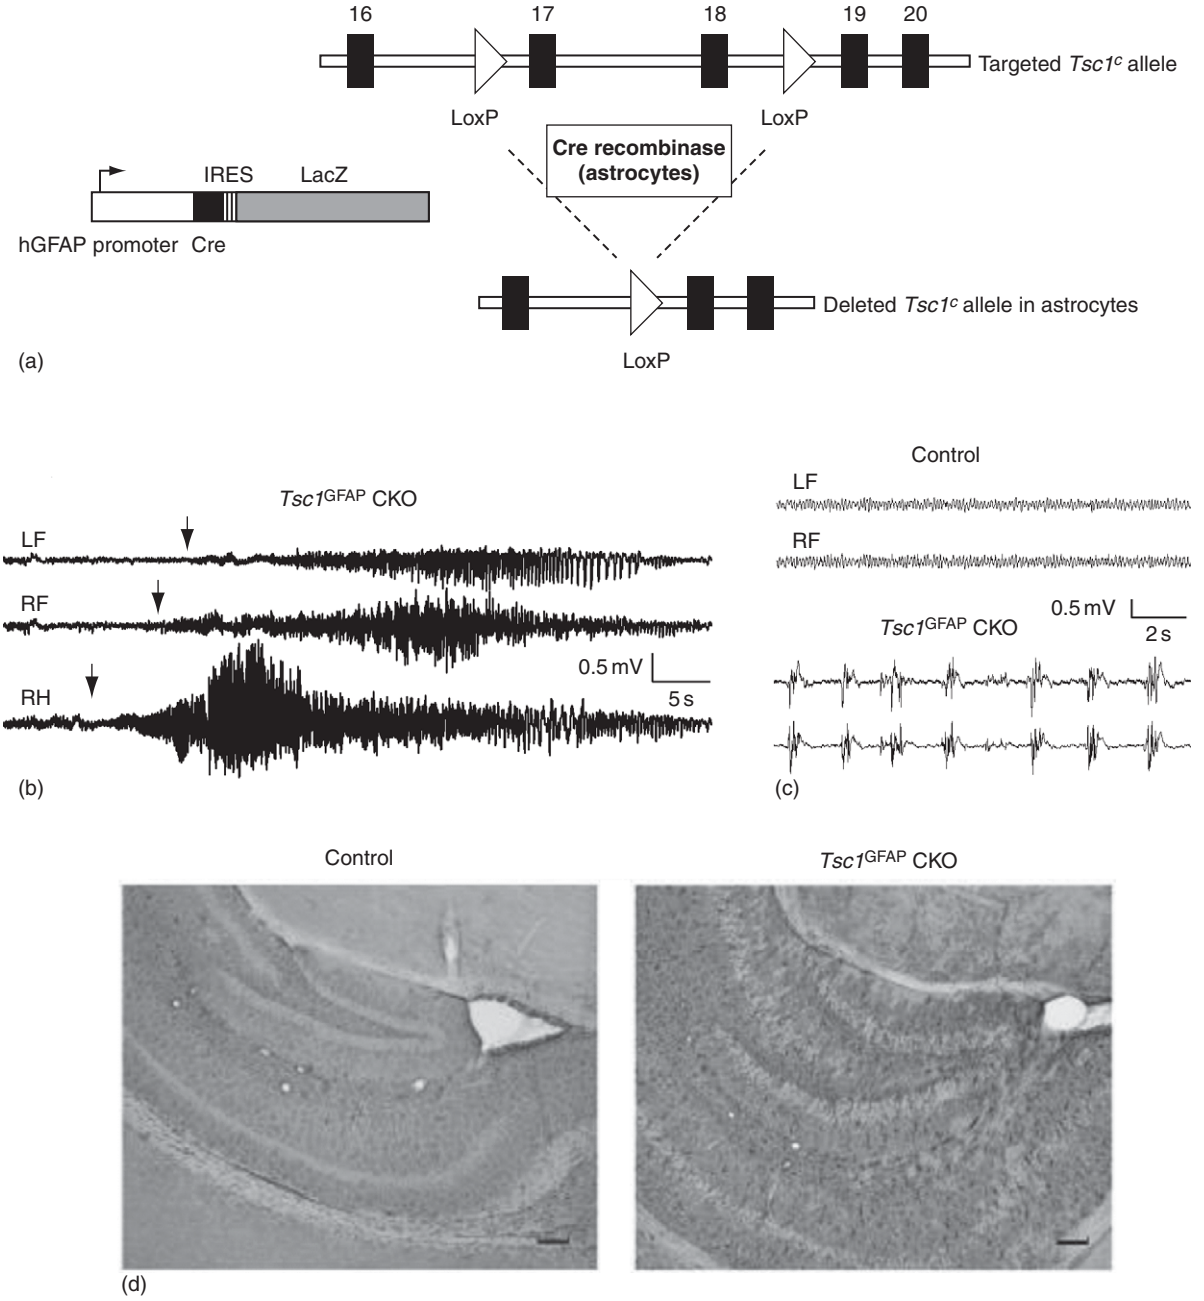

Figure 1 *Tsc1*^{GFAP}CKO mice exhibit progressive seizures and astrocyte proliferation. (a) Schematic diagram of the deletion of *Tsc1* exons 17 and 18 in glia mediated by the GFAP-Cre transgene. Arrowheads indicate the LoxP sequences. (b) Ictal EEG pattern of a typical seizure in *Tsc1*^{GFAP}CKO mice. Seizure onset began in the hippocampus before spreading to cortical surface electrodes. Arrows denote EEG seizure onset in each electrode. LF, left frontal; RF, right frontal; RH, right hippocampus. (c) Interictal EEG baseline in control and *Tsc1*^{GFAP}CKO mice. Control mice show a normal theta rhythm. *Tsc1*^{GFAP} CKO mouse typically develop a burst-suppression pattern with age. (d) Progressive astrocyte proliferation in *Tsc1*^{GFAP}CKO mice at 6 weeks of age compared with a control mouse, as assayed by GFAP staining. Magnification is the same for both images (scale bar = 200 μm). Adapted from Uhlmann EJ, Wong M, Baldwin, *et al*. (2002) Astrocyte-specific TSC1 conditional knockout mice exhibit abnormal neuronal organization and seizures. *Annals of Neurology* 52: 285–296, with permission.

14.5 in GFAP + cells in the developing brain. *Tsc1*$^{flox/+}$-GFAP-Cre and *Tsc1*$^{flox/flox}$ mice have been found to have no abnormal phenotype and are used as controls for most experiments.

A range of electrophysiological recording methods have been used to characterize the seizures developing in *Tsc1*^{GFAP}CKO mice. Video-EEG monitoring has been used to record seizures as well as interictal EEG abnormalities. Epidural screw electrodes were surgically implanted under isoflurane anesthesia and secured with dental cement for long-term video-EEG recordings. EEG data were recorded with standard AC amplifiers and saved digitally, along with simultaneous video data. Extracellular and whole-cell recordings from hippocampal or cortical brain slices have been performed to characterize synaptic and neuronal physiology, as well as astrocyte physiology, using standard techniques. DIC-IR optics was used to assist with obtaining whole-cell patch-clamp recordings from directly identified neurons and astrocytes in slices. For more detailed pharmacological studies, patch-clamp recording have also been performed on cultured cells.

Tsc1^{GFAP}CKO mouse brains have also been used for histology and Western blot analysis. Histological studies have included traditional Nissl or hematoxylin and eosin staining as well as immunohistochemistry for a variety of molecular markers, such as cell death indicators (TUNEL, caspase-3, Fluoro-Jade), neurotransmitter receptors, transporters, and ion channels, and intracellular signaling molecules. Similarly, Western blot analysis for the expression of a variety of proteins has been performed using standard techniques.

Recent Results

The behavioral phenotype of *Tsc1*^{GFAP}CKO mice has been well characterized. From birth to at least one month, *Tsc1*^{GFAP}CKO mice are indistinguishable from control littermates in both appearance and behavior. However, after the first month, *Tsc1*^{GFAP}CKO mice become less active and tend to assume a retracted posture. The most prominent phenotypic feature of *Tsc1*^{GFAP}CKO mice is the development of epileptic seizures, which appear to start around 1 month of age. Seizures are initially rare, but become progressively more frequent with age, eventually leading to death at about 3 months. In developmental video-EEG studies, no seizures were recorded at 4 weeks of age in about two-thirds of mice, and the seizures were clinically subtle with a seizure frequency of 1.0 ± 0.6 seizures per day. By 9 weeks, all mice had clinically-obvious seizures and the average seizure frequency increased significantly to 9.5 ± 3.5 seizures per day. On video analysis, most seizures were characterized by a brief period of tonic stiffening of the trunk or extremities without loss of upright posture, followed by rearing and forelimb clonus, resembling limbic seizures of rodents. On EEG, most seizures appeared to have simultaneous onset in both hemispheres. However, some seizures that were recorded using hippocampal depth electrodes showed earlier onset in the hippocampus compared with the neocortex, indicating that some seizures may originate focally in the hippocampus (**Figure 1(b)**). Correlating with the increased seizure frequency as a function of age, the interictal EEG was normal at 4 weeks, but then developed progressive loss of normal background rhythms and increasing epileptiform spikes, culminating in a burst-suppression pattern by 9 weeks of age (**Figure 1(c)**). All *Tsc1*^{GFAP}CKO mice died, by 3–4 months of age, within the context of having frequent seizures. In addition to the obvious seizure phenotype, detailed behavioral testing at ~1 month of age also showed significant cognitive deficits in hippocampal-dependent learning tasks, such as water maze spatial learning and conditioned fear paradigms.

Consistent with the role of *Tsc1* as a negative growth regulator, histopathological examination of brains from *Tsc1*^{GFAP}CKO mice (using hematoxylin and eosin staining) revealed a striking, diffuse increase in size in all areas of the brain, which was first apparent at about 1 month of age and progressively increased with age. Immunohistochemical staining with GFAP showed a robust increase in astrocytes, which correlated with the increase in brain size (**Figure 1(d)**). By 6 weeks of age, the increase in GFAP-immunoreactive cells was approximately five-fold greater than control littermates. Immunofluorescence with a marker for proliferating cells was also increased in *Tsc1*^{GFAP}CKO brains, indicating the existence of increased astrocyte proliferation (as opposed to reactive astrocytosis). Intriguingly, development of increased astroglial proliferation roughly correlated with the onset of spontaneous seizures. No cortical tubers or gross abnormalities of neocortical lamination were observed. However, there was evidence of neuronal disorganization, particularly in hippocampus, where there was marked dispersion of pyramidal neurons in the stratum pyramidale, especially in CA3 and CA4.

Given the robust, progressive seizure phenotype and corresponding histological changes primarily in astrocytes in *Tsc1*^{GFAP}CKO mice, we next explored the potential mechanisms by which an astrocyte defect might predispose to neuronal hyperexcitability and seizures (**Figure 2**). As astrocytes play an important role in regulating extracellular glutamate homeostasis, we initially focused on the hypothesis that impaired glutamate transport by astrocytes may result in elevated extracellular glutamate concentrations, predisposing to neuronal hyperexcitability, excitotoxic cell death, and seizures. Expression of GLT-1 and GLAST, two astrocyte-specific

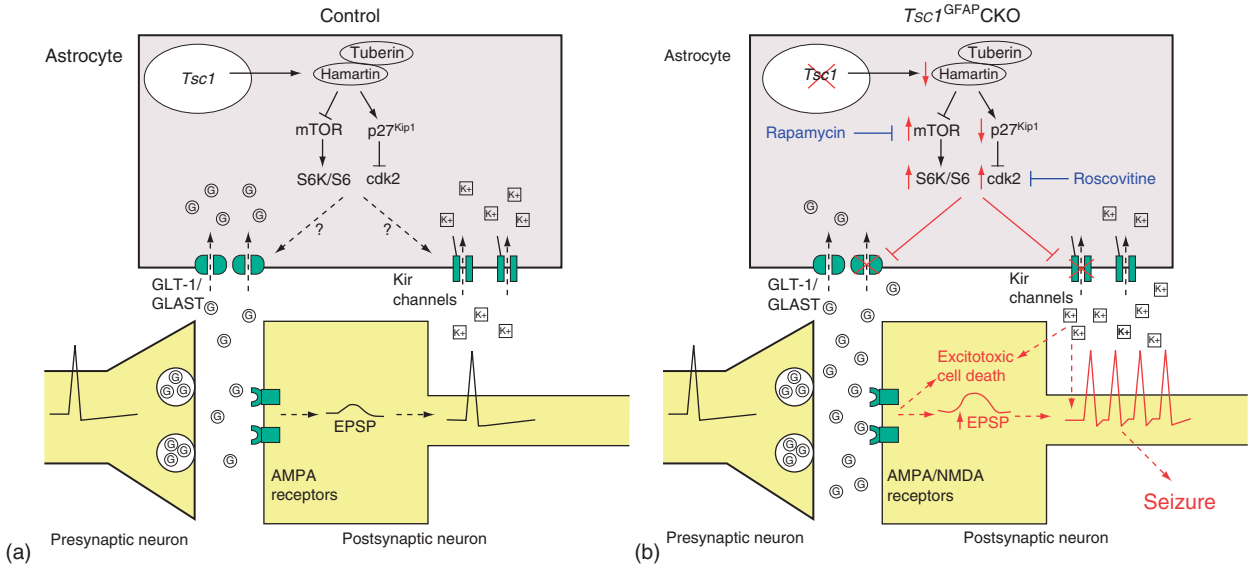

Figure 2 Putative mechanisms of epileptogenesis in *Tsc1*^{GFAP}CKO mice. (a) In control mice, astrocytes closely regulate extracellular glutamate and potassium homeostasis and prevent excessive excitation of neurons by these substances. Glutamate released by neurons during synaptic transmission is taken up by specific astrocyte glutamate transporters, GLT-1 and GLAST. Extracellular potassium that accumulates during neuronal activity is absorbed by astrocytes through potassium channels, such as inward-rectifying potassium (Kir) channels. The role of the *Tsc* genes in regulating these transporters and channels under normal conditions is unknown, but there is some evidence that hamartin and tuberin may have modulatory effects via mTOR/S6K or p27/cdk2 pathways. (b) In *Tsc1*^{GFAP}CKO mice, the expression and function of astrocyte glutamate transporters and Kir channels are reduced, leading to excessive accumulation of extracellular glutamate and potassium. The abnormal glutamate and potassium homeostasis may cause excessive excitation of neurons, as well as predispose to excitotoxic cell death, both of which may promote epileptogenesis and seizures. Preliminary evidence indicates that inactivation of the *Tsc1* gene in *Tsc1*^{GFAP}CKO mice may cause down-regulation of astrocyte glutamate transporters and potassium channels via hyperactivation of the mTOR/S6K and cdk2 pathways. The drugs, rapamycin and roscovitine, have potential therapeutic benefit in TSC by inhibiting the mTOR and cdk2 pathways, respectively. G, glutamate, $K+$, potassium ions.

glutamate transporters, was dramatically decreased in *Tsc1*^{GFAP}CKO mice, both in whole brains and in cultured astrocytes. GLT-1 expression was primarily reduced in the forebrain in *Tsc1*^{GFAP}CKO mice, whereas GLAST expression was decreased most markedly in cerebellum, its primary site of expression, and to a lesser degree in the neocortex. Whole-cell recordings from astrocytes in hippocampal slices and in culture from *Tsc1*^{GFAP}CKO mice also showed a functional decrease in glutamate transporter currents. Thus, *Tsc1*^{GFAP}CKO mice display impaired expression and function of astrocyte glutamate transporters, which could predispose to excessive extracellular glutamate levels. In support of this idea, recent in vivo microdialysis studies demonstrated elevated extracellular glutamate levels in *Tsc1*^{GFAP}CKO mice. Furthermore, the *Tsc1*^{GFAP}CKO mice also exhibit abnormal neuronal death in the neocortex and hippocampus, which likely results from elevated glutamate levels. Importantly, these abnormalities in glutamate homeostasis were observed in mice less than 1 month of age, which precedes seizure onset. Thus, defective glial regulation of extracellular glutamate could represent a primary mechanism promoting epileptogenesis in *Tsc1*^{GFAP}CKO mice.

In addition to regulation of glutamate homeostasis, a related hypothesis for a glial-mediated mechanism of epileptogenesis involves control of extracellular potassium by astrocytes. Astrocytes contain specific potassium channels and pumps that prevent the excessive accumulation of potassium in the extracellular space. Abnormal potassium handling by astrocytes could lead to neuronal hyperexcitability and seizures. In astrocytes, inward-rectifying potassium (Kir) channels are particularly efficient at removing extracellular potassium. Similar to the reduction of glutamate transporters, we found that Kir currents were significantly reduced in both cultured astrocytes and hippocampal slices from *Tsc1*^{GFAP}CKO mice. In addition, expression of the Kir channel protein subunits Kir2.1 and Kir6.1, but not Kir4.1, was decreased in *Tsc1*^{GFAP}CKO astrocytes. This impaired Kir channel function likely predisposes to increased neuronal excitability, since exposing hippocampal slices to a high potassium-containing solution induced epileptiform discharges more readily in tissue from *Tsc1*^{GFAP}CKO mice than in slices from control mice.

While abnormalities in astrocytic neurotransmitter transporters and ion channels may contribute to

epileptogenesis in *Tsc1*^{GFAP}CKO mice, the molecular pathways by which *Tsc1* gene inactivation leads to alterations in these transporters and channels is unknown. Previous studies from numerous laboratories have demonstrated that the *TSC* gene products, tuberin and hamartin, are involved in regulating intracellular signaling pathways that control cell growth and proliferation by activating the mammalian target of rapamycin (mTOR)/S6 kinase (S6K) pathway. Furthermore, *Tsc*-deficient cells have decreased expression of the cyclin-dependent protein kinase (CDK) inhibitor, p27^{kip1}. We have confirmed that similar abnormalities occur in these signaling pathways in *Tsc1*^{GFAP}CKO mice. In cultured astrocytes derived from *Tsc1*^{GFAP}CKO mice, the expression of p27^{kip1} is significantly decreased compared with the expression in astrocytes from control littermates. In addition, *Tsc1*^{GFAP} CKO astrocytes demonstrate constitutive hyperactivation of the mTOR/S6K pathway, as reflected by an increase in phospho-S6K expression.

The relationship of these intracellular signaling pathway alterations to the abnormalities observed in glutamate and potassium homeostasis and neuronal excitability is only beginning to be elucidated. In recent work, we found that the decreased Kir currents in *Tsc1*^{GFAP}CKO astrocytes were reversed by roscovitine, a CDK2 inhibitor, and by retinoic acid, which increases p27^{kip1} levels, suggesting that the decreased p27^{kip1} expression in *Tsc1*^{GFAP}CKO astrocytes may mediate the effects on potassium channels. Recent studies indicate that rapamycin, an inhibitor of the mTOR pathway, can block the hyperactivation of the S6K/S6 pathway and the decreased glutamate transporter expression observed in *Tsc1*^{GFAP}CKO mice in vivo, as well as prevent the development of seizures. These results demonstrate the importance of the mTOR pathway in mediating the neurological phenotype in *Tsc1*^{GFAP}CKO mice, and have exciting potential therapeutic implications for neurological symptoms in human TSC.

Future Goals

As summarized in **Figure 2**, the work accomplished to date strongly implicates a number of mechanisms in astrocytes that may cause or contribute to epileptogenesis in *Tsc1*^{GFAP}CKO mice, as well as identifies potential novel therapeutic targets for treating epilepsy in TSC. In particular, defects in astrocyte regulation of glutamate and potassium homeostasis represent logical mechanisms for promoting neuronal excitability, neurotoxicity, and seizures in these mice. However, more work is required to definitively establish whether these constitute primary, causative mechanisms of epileptogenesis or simply represent secondary effects. The use of detailed pharmacological or genetic techniques to reverse the observed cellular and molecular abnormalities may provide stronger evidence for a primary etiologic role of these defects in the neurological phenotypes of *Tsc1*^{GFAP}CKO mice. A number of other mechanisms involving astrocytes or glial–neuronal interactions might also be critical for epileptogenesis but are yet to be explored in this model. Among these still unexplored issues are the role of different glial cell subtypes, gliotransmitters, calcium waves in astrocytes, spatial buffering properties of glia networks via gap junctions, and glial–vascular coupling affecting blood–brain barrier function.

The various cellular and molecular abnormalities identified in the *Tsc1*^{GFAP}CKO mice have tremendous potential for identifying novel, rational therapeutic strategies for treating the neurological manifestations of TSC. As mentioned earlier, recent data in the *Tsc1*^{GFAP}CKO mice suggest that inhibitors of the mTOR pathway might represent promising treatments for seizures in TSC. Clinical trials of rapamycin have already been initiated for kidney tumors, as well as astrocytomas in TSC, but the effect of rapamycin on epilepsy in humans has not yet been explored. In addition, drugs already in clinical development for other diseases that modulate the CDK-p27^{kip1} pathway, such as roscovitine, have not been considered as therapies for TSC. Finally, relevant to the abnormalities in glutamate transporters in the *Tsc1*^{GFAP}CKO mice, a comprehensive screen of over a thousand FDA-approved drugs has identified several drugs that specifically increase the expression of the astrocyte glutamate transporter, GLT-1. Among these drugs, the commonly-used antibiotic, ceftriaxone, showed a dramatic effect in elevating GLT-1 expression, and prolonging the survival of a mouse model of amyotrophic lateral sclerosis. Future studies in the *Tsc1*^{GFAP}CKO mice may provide evidence for the efficacy of other mTOR inhibitors, roscovitine and ceftriaxone for treating TSC-related epilepsy, and would support their testing in clinical trials for epilepsy in TSC patients.

Glial Modulation of Excitability via Glutamate and GABA Transporters

Introduction

Fine tuning of glutamatergic excitatory and GABAergic inhibitory neurotransmission is a prerequisite for optimal, normal functioning of the central nervous system (CNS). Termination of the transmission processes mediated by glutamate and GABA is controlled by a number of high-affinity transporters for these amino acids, transporters that are expressed in both neurons and astrocytes. The latter cell type has a major role in this fine-tuning process. Any disturbance in glial transporter function will lead to an imbalance in the equilibrium between excitation and inhibition, leading to seizure activity and epileptic episodes.

Disinhibition, resulting from altered GABAergic neurotransmission, has been associated with a number of neurological disorders, including epilepsy, migraine headaches, chronic pain, anxiety, and sleep disorders. Abnormal excitatory neurotransmission, resulting from excessive synaptic glutamate levels, has been associated with a number of neurodegenerative disorders, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease, Huntington's disease, Parkinson's disease, and neuronal damage associated with cerebral ischemia. In addition to a role in these and other neurodegenerative disorders, alterations in glutamate transporters also contribute to the development of seizures and epilepsy. Thus, efforts to regulate the function and trafficking of GABA and glutamate transporters will likely have important implications for the treatment of a number of these neurological disorders and diseases. Ongoing efforts to gain a greater understanding of the factors that control their cellular expression, function, and regulation at the cellular and network level are critical, and will play important roles in the development of a new class of therapeutics for a number of devastating neurological conditions. Indeed, a number of antiepileptic drugs exert their action by modulating these transport processes.

Background

Characteristics and Nomenclature of Glutamate and GABA Transporters

Cloning strategies have led to the identification of five high-affinity glutamate transporters, the operation of which depends on an intact membrane potential as well as a transmembrane sodium gradient. The prevalent cellular localization of the individual transporters is summarized

agents that target these transporters, and the willingness of investigators, drug companies, and funding agencies to invest in the clinical trials that will ultimately determine the utility of this approach for the treatment of epilepsy and other neurological disorders.

Peritumoral Epilepsy

S A Lyons and H Sontheimer, University of Alabama at Birmingham, Birmingham, AL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Each year ~100 000 patients are newly diagnosed with tumors in the central nervous system (CNS) in the United States. According to data from the Central Brain Tumor Registry of the United States (CBTRUS), ~18 500 of these are considered primary brain tumors, i.e., arising initially in the brain; interestingly, the vast majority are of glial origin. These glial-derived tumors are collectively called gliomas and include oligodendrogliomas, astrocytomas, and glioblastomas. These tumors share a number of genetic alterations with other cancers, but also differ in some important aspects. These differences include, for example, their inability to spread via hematogenous routes and their physical containment within the bony cavity of the brain. Biological adaptations that allow gliomas to develop with these constraints may, in part, contribute to the high likelihood with which these cancers produce seizures in patients. Although most brain tumors, including metastatic tumors, can produce seizures, the causal relationship between tumor biology and peritumoral seizures is best understood in glial-derived tumors, which are the principle topic of this article.

Background

Gliomas and Epilepsy

Gliomas arise de novo within the CNS. Although they are generally believed to derive from glial cells or their progenitor cells, their etiology is still in question. Some gliomas are considered benign and can be treated, but the majority of gliomas form aggressive and highly malignant tumors that are largely unresponsive to treatment. Surgical resection is typically unsuccessful as tumor cells tend to invade the normal brain parenchyema diffusely and create satellite tumors. Upon resection of the main tumor, regrowth typically occurs within just a few months. Unfortunately, chemotherapy provides only limited benefit to patients, in part because the blood–brain barrier makes effective delivery difficult and in part also because gliomas tend to be quite resistant to commonly-used chemotherapeutic drugs. Consequently, the outlook for patients with malignant gliomas remains dismal, with average patient survival of less than one year even with all currently available treatments.

In 30–50% of patients, the diagnosis of a primary brain tumor is preceded by epileptic seizures. This percentage

is even greater in low-grade astrocytomas, where close to 75% of patients present with seizures. Interestingly, it is the otherwise benign, low-grade pilocytic astrocytomas that are particularly prone to cause peritumoral seizures, and quite frequently the seizures necessitate surgery more than the growth of the tissue per se. This situation is particularly the case in children, where astrocytomas constitute the leading solid cancer yet often carrying a relatively good prognosis. In many patients, the seizures generated by the tumor are largely refractory to normal antiepileptic medication, most likely because the biology of the underlying seizures is different from other forms of epilepsy.

Although the co-appearance of seizures and brain tumors has been recognized for some time, little effort has been expended to understand the biological interdependence of these phenomena. Indeed, it had been a common assumption that the growing tumor compresses the surrounding brain tissue and that seizures result primarily from mechanical effects on neighboring tissue. This notion has been challenged by several recent studies that examined the effect of gliomas on the peritumoral brain more directly. These studies provide a more logical framework to explain peritumoral seizures, and offer new opportunities to treat the disease and the associated seizures.

Seizures and Glutamate

As extensively discussed in other articles in this encyclopedia and in the published literature, seizures result from an imbalance of excitatory and inhibitory neurotransmission in brain. It is commonly accepted that an increase in excitatory neurotransmission is sufficient to drive seizure initiation, and experimental application of glutamate or other excitatory amino-acid receptor agonists can produce seizures. Glutamate is the principle excitatory neurotransmitter in the brain and its binding to postsynaptic neuronal glutamate receptors mediates fast signal transmission. Its excitatory activity is typically opposed by GABAergic inhibition. However, in various disease conditions this excitation–inhibition balance fails. Most notably, under conditions of energy failure, glutamate release can increase substantially, thereby causing a sustained activation of glutamate receptors. Importantly, under such conditions, the otherwise controlled and modest increases in intracellular [Ca^{2+}] through NMDA receptors become more sustained and massive, thus overwhelming intracellular Ca^{2+}-regulatory processes, ultimately leading to Ca^{2+}-mediated cell death. This process, termed 'excitotoxicity' many years ago, is now believed to be a final common death pathway in numerous diseases ranging from acute trauma and ischemic stroke to progressive neurological conditions such as amyotropic lateral sclerosis (ALS) or Alzheimer's disease.

Because of the vulnerability of the brain to excessive glutamate, several Na^{+}-dependent transport systems for glutamate have evolved that maintain extracellular glutamate at very low micromolar levels. These are primarily expressed on nonmalignant astrocytes. The neuroprotective role that these astrocytic transporters play are evident from studies in knockout mice, showing neurodegeneration and lethal epilepsy in animals that have lost functional astrocytic glutamate transporters. Interestingly, these 'neuroprotective' astrocytic glutamate transporters are not at all functional in astrocytic tumors, which therefore cannot participate in glutamate homeostasis. Much to the converse, these tumor cells actually release glutamate into the peritumoral space, contributing to excitotoxic death of peritumoral neurons, probably allowing the tumor to expand into the vacated space (**Figure 1**).

Methods

Glutamate and cystine transport uptake and assays: To study the transport of amino acids such as glutamate and cystine, we used routine radiotracer studies in which cells are pretreated with a defined ratio or concentration of radiolabeled amino acids (i.e., ^{35}S-cystine and ^{3}H-glutamate or ^{3}H-aspartate), which are also transported by the excitatory amino-acid transporter (EAAT) family of glutamate transporters. The rate of release or uptake can then be determined after defined time periods. Experiments performed in the presence or absence of extracellular Na^{+} allow us to isolate the Na^{+}-dependent component of glutamate release. Furthermore, sister cultures can be treated with defined inhibitors such as S-4CPG or sulfasalazine. We also used a commercial bioluminescence assay kit to measure glutamate release from gliomas, and two fluorescent assay kits to determine glutathione (GSH) production in cell culture; these approaches allow us to quantitatively determine GSH levels (over several days) in the presence and absence of system x_c^- inhibitors.

To examine the effects of system x_c^- inhibitors on tumor growth in vivo, 0.5-mil human glioma cells were concentrated and stereotactically injected into the cranium of anesthetized, severe immune-compromised mice. Following a 30-day period of growth, animals were sacrificed and tumor volumes determined by quantitative histological examination, allowing a direct comparison of treated to untreated animals.

To better understand the mechanism of glioma invasion and the potential contribution of system x_c^--mediated glutamate release, we used Transwell migration assays in which cells are challenged to transverse a barrier membrane with 8-μm pores. The bottom of the filters are coated with the chemoattractant vitronectin.

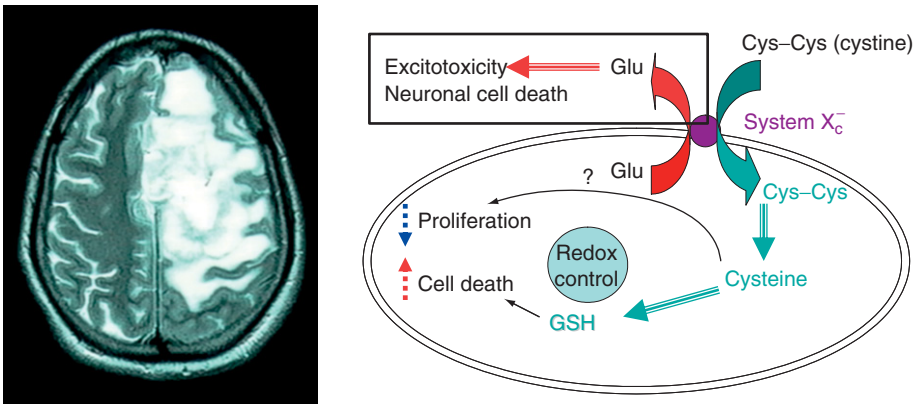

Figure 1 Gliomas destroy normal brain as they grow: Glial-derived tumors are limited in their physical growth space by the cranium. To grow, they must destroy normal brain tissue to vacate room for their own growth. They do so by releasing glutamate, which occurs as an obligatory byproduct of cystine uptake through system x_c^-. The latter serves as precursor for the synthesis of the antioxidant glutathione (GSH). System x_c^- is the primary transport system for the import of cystine into glioma cells, and hence tumor growth is dependent on the continued supply of cystine via this pathway. The released glutamate triggers peritumoral seizures and causes excitotoxic neuronal cell death in peritumoral regions. The illustrated brain is a MRI scan from a patient who suffered a high-grade malignant glioma occupying a large part of the brain.

To study Ca^{2+} signaling in migratory cells, we used standard Fura-2 fluorescence imaging, which allows the investigator to monitor spontaneous or induced changes in intracellular calcium after loading cells with Fura-2 AM dye.

Recent Results

Glutamate Release from Tumor Cells

As illustrated in Figure 2(a), even in culture, glioma cells release up to 500 μM of glutamate over a 12-h period. In contrast, nonmalignant astrocytes remove glutamate from the medium rather than secrete it. Astrocytes use the GLT-1 glutamate transporter for the uptake of glutamate, which, as further discussed below, is not expressed in gliomas (Figure 2(b)). When hippocampal neurons are placed in the vicinity of glioma cells, neurons undergo NMDA receptor-mediated excitotoxic cell death (Figure 2(c)). Moreover, when rat C6 glioma cells are implanted into the brains of host animals, tumors only grow when the implanted C6 cells are capable of releasing glutamate – but not in cell lines deficient of glutamate release. Hence, glioma growth in situ and in vivo appears to require the release of glutamate from the tumor. In all likelihood, the released glutamate is used to kill peritumoral brain tissue in order to vacate room for the tumor expansion. Of note, gliomas are the only cancers that grow in a confined space and hence are physically limited in their ability to grow. The release of glutamate and its excitotoxic action on surrounding brain tissue represent a biological adaptation that may be uniquely suited to the needs of these CNS tumors.

Of note, several studies have now independently demonstrated that glutamate is elevated in the vicinity of tumors in both animal models and in patients suffering from glioblastoma or oligodendrogliomas. This principal finding that glioma tumors release glutamate in vivo is firmly supported by experimental data. These findings also suggest that glutamate released from gliomas would overactivate peritumoral neurons through a continued release of glutamate. This glutamate-mediated excitation, of course, explains the initiation and localization of seizures to peritumoral regions of the brain. However, one would expect that a need to vacate brain tissue through an excitotoxic, possibly seizure-initiating, pathway would be most prominent in very advanced stages of the disease. To the contrary, it is the lower grade tumors that are more likely to present with seizures.

Glutamate Transporters in Gliomas

A natural next step in examining the glioma glutamate release was a search for the release pathway, as this pathway could be therapeutically important. An obvious candidate was one of the five members of the EAAT family, two of which – EAAT1 and EAAT2 – are highly expressed in nonmalignant astrocytes. These transporters typically take up glutamate using the inwardly-directed transmembrane Na^+-gradient, but have been shown to reverse direction under conditions of energy failure and have been suggested to contribute to glutamate release and excitotoxicity in ischemia. Quite surprisingly, however, functional EAAT transporters are absent in gliomas (Figure 2(b)); as a consequence, Na^+-dependent glutamate transport is negligible. This result illustrated in Figure 3, which shows Western blots from patient tissue sections probed for the principal glial glutamate transporter, EAAT2 – prominent in nonmalignant brain but absent in all gliomas (Figure 3(a)). In these cancers,

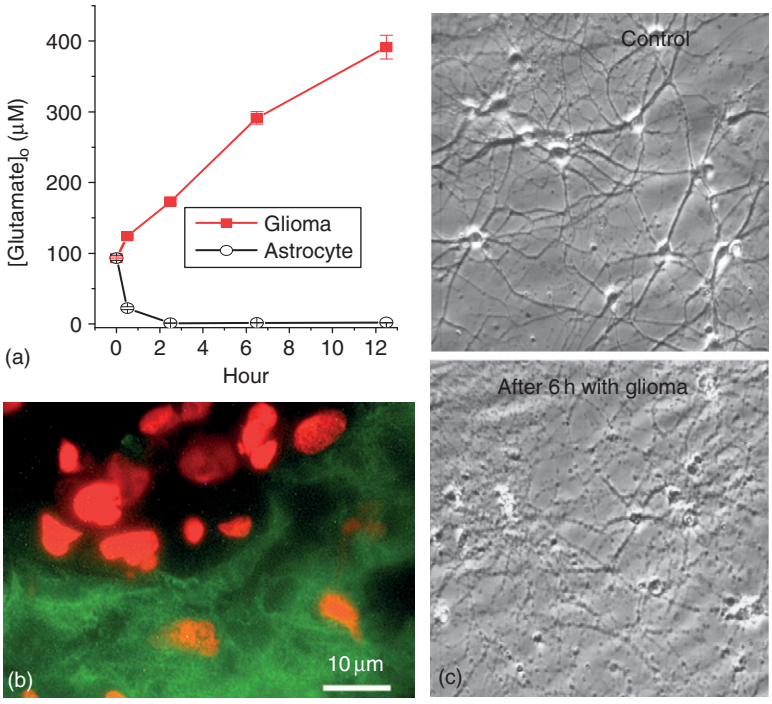

Figure 2 Gliomas release Glutamate. (a) Glioma cells release glutamate as determined by sampling medium in a 70-cc flask measuring bioluminescence as a function of time. By contrast, nonmalignant astrocytes remove glutamate when challenged with 100 mM at the start. (b) Gliomas in vivo do not express the GLT-1 glutamate transporter (green), while the surrounding astrocytes do as shown by immunocytochemistry. The GLT-1 staining demarcates the tumor boundaries. Red staining is propridium iodine to label cell nuclei. (c) Time-lapse video microscopy shows pronounced neuronal cell death when hippocampal neurons are placed in the vicinity of glioma cells yet without touching them (sandwich culture). Reproduced from Ye ZC, Rothstein JD, and Sontheimer H (1999) Compromised glutamate transport in human glioma cells: Reduction-mislocalization of sodium-dependent glutamate transporters and enhanced activity of cystine–glutamate exchange. *Journal of Neuroscience* 19: 10767–10777.

glutamate release was dependent on the presence of extracellular cystine and was competitively inhibited by extracellular glutamate. These characteristics are signature features of another transport system for glutamate called 'system x_c^-.' This abundant but relatively poorly investigated electroneutral amino-acid transporter transports cystine into the cell in exchange for glutamate release. System x_c^- is a heterodimeric protein complex consisting of a catalytic light chain (xCT) that confers substrate specificity and a regulatory heavy chain (4F2hc). The latter is a cell-surface glycoprotein (previously known as CD98) that is essential for membrane localization of the transporter; only the heteromultimeric protein complex functions as an amino-acid transporter. The light chain that confers the transport of cystine has recently been cloned and shown to belong to the 12-transmembrane domain amino-acid transporter proteins. The catalytic subunit can exist in two splice variants (hxCTa and hxCTb), both of which are up-regulated following oxidative stress. As shown in **Figure 3(b and c)**, both regulatory and catalytic subunits of this transporter are highly expressed in human glioma cell lines and glioma biopsies from patients.

In most cell types, system x_c^- serves as one of multiple pathways through which cells satisfy their demand for intracellular cysteine (the reduced form of cystine), which is required for the biosynthesis of many proteins and the intracellular reducing agent GSH (discussed in more detail below). System x_c^- accounts for the major route of cystine uptake into immature cortical neurons but not mature neurons or astrocytes, and appears to play a role in cystine transport in early oligodendrocyte precursor cells. Neurons and glial cells employ at least two other pathways to meet their cysteine needs, namely the γ-glutamyl cycle and the EAAT family of Na^+-dependent transporters that can also transport cysteine. It has recently been demonstrated that over 85% of the neuronal demand for cysteine in cultured neurons is mediated by the Na^+-dependent uptake of cysteine via the EAAT-2 and EAAT-3 transporters, with little contribution of system x_c^- in these neurons. Gliomas, in contrast, rely almost exclusively on system x_c^- activity for this process.

System x_c Function in Gliomas

The main function of the cystine–glutamate exchanger (system x_c^-) is to supply cells with the essential amino acid cystine, which is an important biosynthetic precursor molecule. Once taken up, cystine is readily reduced to cysteine, one of the principle building blocks for the ubiquitous tri-peptide GSH (L-γ-glutamyl-L-cysteinylglycine), which

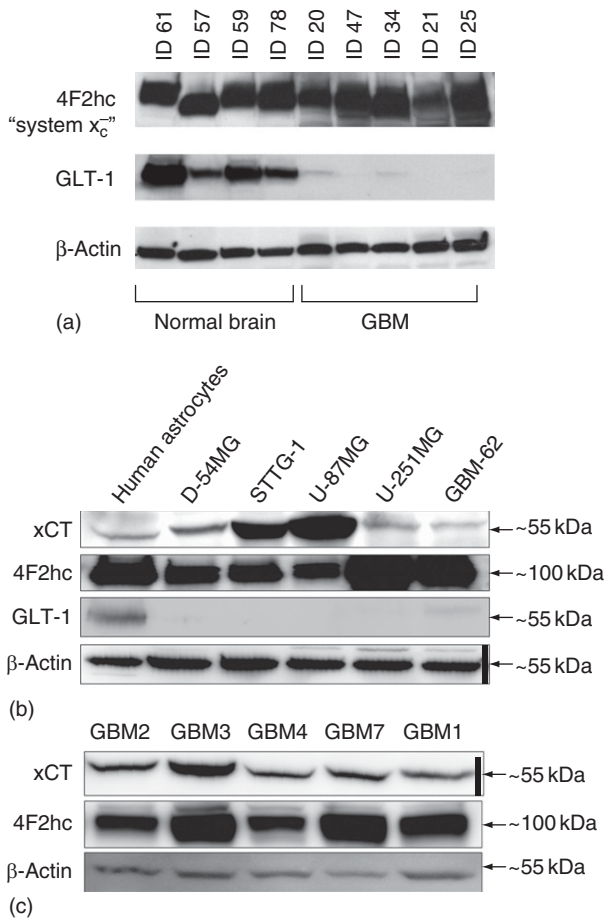

Figure 3 Glutamate transporters in gliomas. (a) The GLT-1 or EAAT2 Na^+-dependent glutamate transporter is highly expressed in normal brain but absent in all glioma biopsies examined by Western blot expression. Five representative glioma biopsies and four nonmalignant brain biopsies are shown. (b) Five glioma cell lines and five acute glioma biopsies (c) highly express the catalytic (xCT) and regulatory (4F2hc) subunit of the system x_c^- cystine–glutamate exchanger. is formed from glutamate, cysteine, and glycine. GSH is present in almost all tissues and serves as an intracellular thiol-disulphide redox system. It scavenges peroxides and prevents oxidation of –SH groups by reactive oxygen species (ROS).

GSH has been called the guardian of the cells' redox status, as its primary role is to defend cells against endogenously produced ROS. These ROS include hydroxyl radicals ($^{\cdot}OH$), superoxide anion (O_2^-), nitric oxide (NO), and hydrogen peroxide (H_2O_2). Some of these ROS are inevitable and constant by-products of oxidative metabolism and mitochondrial function. ROS species are all short lived and highly reactive. They can cause lipid peroxidation as well as oxidation of DNA and proteins, and hence can cause significant cell damage if uncontrolled. Under normal conditions, this damage is prevented by the activity of GSH peroxidase, an enzyme that creates a disulphur bond between two GSH molecules to form oxidized GSH (GSSG). ROS production is notably enhanced in rapidly growing cancer cells, including gliomas, and it is thought that these cancer cells use GSH to scavenge ROS. To meet the need for continuous GSH biosynthesis, gliomas require significant cellular uptake of cystine or cysteine, the latter being rate limiting for the production of GSH.

The resistance of certain cancers, including gliomas, to chemo- and radiation therapy has also been linked to the cells' GSH status. First, members of the GSH-S-transferase (GST) superfamily of enzymes catalyze the conjugation of GSH with numerous compounds often referred to as xenobiotics. Such xenobiotics include chemotherapeutic drugs and environmental toxins. These GSH conjugates are converted to mercapturic acids for excretion. A second role for GSH in this context pertains to the inactivation of ROS species produced specifically by ionizing radiation. Hydroxyl free radicals ($^{\cdot}OH$) are a prominent product of ionizing radiation and have been shown to be responsible to a large degree for the DNA degradation and protein peroxidation observed in cells exposed to radiation. Again, GSH serves to protect cells from hydroxyl radicals under such conditions; indeed, cells deficient in GSH show enhanced sensitivity to attack by such ROS. Hence, the vulnerability of gliomas and other cancers to both chemo- and radiation therapy can be enhanced by depriving cells of GSH, which, in gliomas, appears possible through the inhibition of system x_c^- function (as further discussed below).

It should be noted that system x_c^--mediated glutamate release has recently also been discussed as a possible contributor to extracellular glutamate in normal brain function. However, in situ hybridization and PCR studies suggest that, in the normal brain, system x_c^- is primarily expressed in the meninges and periventricular organs, with only very low expression levels in neurons and glia throughout the brain. Nevertheless, owing to its regulation by oxidative stress, system x_c^- expression may become a factor under certain disease conditions. Indeed, CNS inflammation, virally-induced encephalopathy, and periventricular leukomalacia may invoke the release of glutamate through system x_c^-. In addition, the very small basal levels of nonsynaptic glutamate may be regulated by system x_c^-. In most normal brain cells – including nonmalignant glial cells – any system x_c^--mediated glutamate that is released will be immediately taken back into the cells via the Na^+-dependent EAAT family of transporters. However, one of the major differences between gliomas and nonmalignant brain cells is the loss of functional EAAT glutamate transporters from the membrane. Combined with up-regulation of system x_c^-, this loss leads to a situation where cystine uptake causes the net

release of significant amounts of glutamate (as demonstrated in vitro and in vivo). In other words, glutamate release from gliomas appears to be an obligatory byproduct of cystine uptake, as illustrated in the schema in **Figure 1**. Hence the resulting over-activation and seizure activity of peritumoral neurons appears to also be a byproduct of a unique biology of these tumors. This condition would predict that inhibition of glutamate release from gliomas via system x_c^- would be highly beneficial. On the one hand, it should limit GSH synthesis by gliomas, and on the other hand it should stifle glutamate excitotoxicity and seizures. Both results would be expected to curtail the growth of these cancers.

Preclinical Studies Using Pharmacological Inhibition of System x_c to Inhibit Glutamate Release

The activity of system x_c^- can be inhibited by a number of related drugs that also affect metabotropic glutamate receptors. Of these, S-4-carboxyphenylglycine (S-4-CPG) has proven to have the greatest affinity, and in culture models, causes almost complete inhibition at ~100 μM. Their secondary action on mGLUR receptors, however, limits their use in animal studies. This difficulty was overcome with the discovery that sulfasalazine, a drug that is clinically used to treat Crohn's disease, also effectively inhibits system x_c^- activity. As shown in **Figure 4**, sulfasalazine shows a dose-dependent inhibition of cystine uptake and causes a near complete depletion of cellular GSH within 24 h. As a consequence, cells are compromised in their redox status and show growth arrest. Indeed, over prolonged incubation periods, cells undergo caspase-mediated apoptosis. When given to tumor-bearing animals by intraperitoneal injection, sulfasalazine was able to reduce tumor growth by 60–80% (**Figure 4**). To what extent these effects were due to cystine and or GSH depletion – versus a reduction of glutamate release and hence, reduced excitotoxicity – remains to be shown. However, these findings suggest that sulfasalazine may be a useful clinical drug to suppress system x_c^- function in patients with gliomas, a drug that may provide benefits with regards to direct tumor containment and may be of equal utility in inhibiting the generation of peritumoral

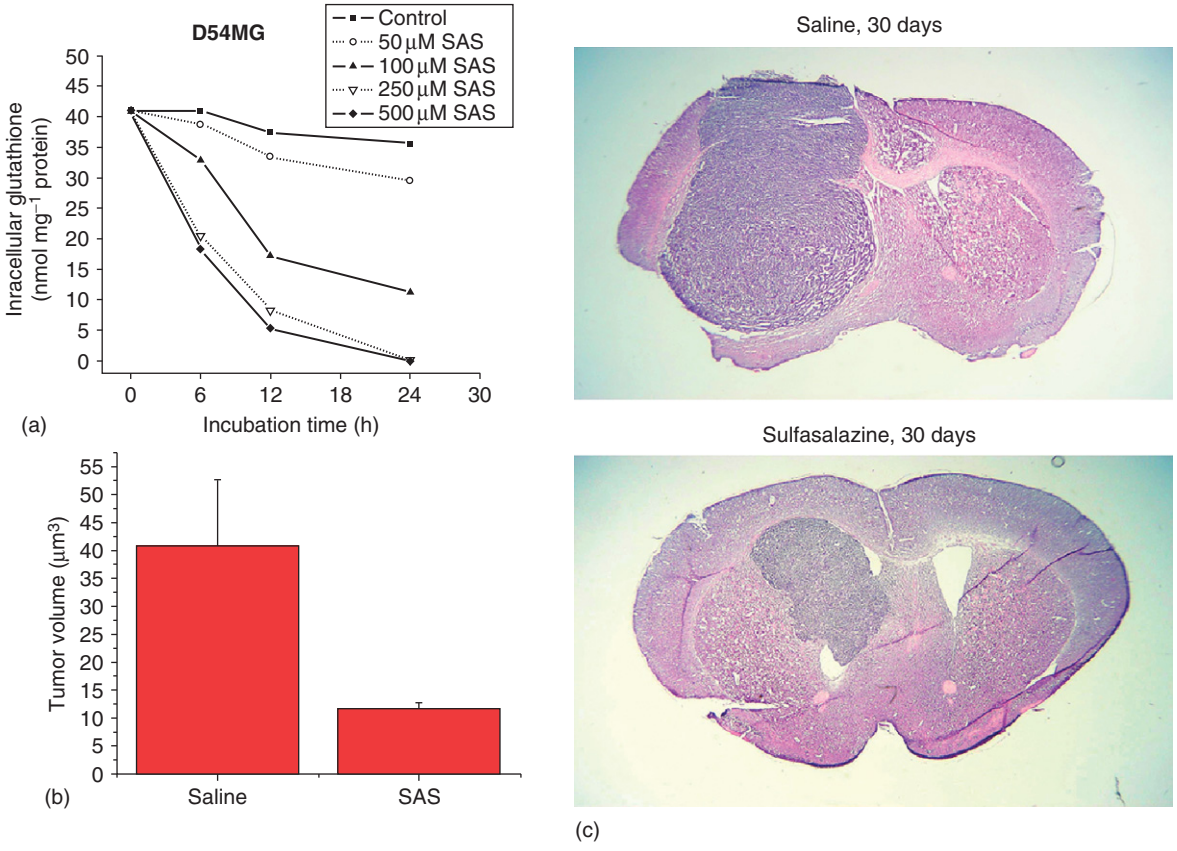

Figure 4 Inhibition of system x_c^- causes glutathione (GSH) depletion and reduces tumor size in vivo. (a) Sulfasalazine, which inhibits system x_c^-, causes a dose- and time-dependent reduction in GSH levels. (b) Intraperitoneal injection, twice daily, of 8 mg kg^{-1} sulfasalazine causes a 75% reduction in tumor volume in tumor-bearing animals. (c) A representative comparison of control saline-injected with sulfasalazine-treated animals at 30 days of treatment is shown in these brain cross sections. Reproduced from Chung WJ, Lyons SA, Nelson GM, *et al*. (2005) Inhibition of cystine uptake disrupts the growth of primary brain tumors. *Journal of Neuroscience* 25: 7101–7110.

seizures. Importantly, sulfasalazine can be safely given to children and may control seizures associated with low-grade gliomas that do not require surgical resection. Its clinical use as adjuvant treatment also deserves further consideration. The suppression of GSH observed in cell culture and animal studies suggests that gliomas would become more susceptible to radiation damage. Hence, sulfasalazine could be given in conjunction with exogenous beam radiation, which is the 'standard of care' treatment for patients with gliomas.

Glutamate and Migration or Dispersal of Glioma Cells

As we conducted animal studies with sulfasalazine, and as we examined the release and action of glutamate on glioma cells further, we made the unexpected observation that glutamate serves an important secondary role in the biology of gliomas – namely, aiding the invasive migration and dispersal of glioma cells. Similar to granule cells, glioma cells show oscillatory changes in intracellular Ca^{2+} as they migrate. In neurons, these oscillations are primarily triggered by glutamate activation of NMDA receptors. Glioma cells do not express NMDA receptors, but instead express Ca^{2+}-permeable AMPA receptors – i.e., receptors that lack the Glu-R2 subunit. Their activation appears to mediate intracellular Ca^{2+} fluctuations that are necessary for glioma-cell migration. This dependence of cell migration on glutamate and Ca^{2+} signaling is reminiscent of migrating cerebellar granule cells. However, the source of glutamate in this context turned out to be system x_c^-, releasing glutamate either onto the same or neighboring cells, hence acting as an autocrine or paracrine signal. Inhibition of either the Ca^{2+}-permeable AMPA receptor or system x_c^- caused the inhibition of cell migration and disrupted dispersal of tumors. In animal studies, tumors remained primarily as solitary growth centers rather than multiple dispersed tumors.

Summary and Challenges for the Future

Although the earlier-described data suggest a mechanism for seizure initiation, further animal studies are needed to determine that glutamate release from tumors are indeed causal of seizures. Therefore, tumor-bearing mice should be examined by imaging tumor volumes along with seizure monitoring (using EEG or related methodologies). It would be important to determine whether tumor size or location correlates with the severity of seizures. Furthermore, the therapeutic benefit of sulfasalazine should be investigated in these animal models. These experiments are in progress.

Taken together, these data suggest that glioma cells have co-opted the neurotransmitter glutamate as a means to kill peritumoral tissue to vacate room for their growth, as well as using the transmitter as a signal to aid the dispersal of tumor cells into normal brain. The collateral damage inflicted by the released glutamate is the over-excitation of neurons in the vicinity of the tumor, and this excitation may present as peritumoral seizures in many patients. The extent to which this glutamate release causes seizures depends on many factors. Tumor location appears to be a very important variable, as seizures are much more frequent in supratentorial tumors than infratentorial and also more prominent in temporal and parietal cortical locations than in occipital areas. Since glutamate is intrinsically linked to GSH production and hence redox status of the cell, it may not be surprising that those cancers with higher aerobic metabolically activity, and hence greatest GSH needs, would release the most glutamate. This factor indeed explains the increased likelihood for lower grade tumors, which have the highest metabolic activity, to present with seizures. The availability of a well-described FDA-approved drug may readily allow 'off-label' use to treat peritumoral seizures, and more extensive clinical evaluation of sulfasalazine as adjuvant treatment in all gliomas appears warranted.

Introduction

The neuron, and networks of neurons, has received the bulk of attention in research on the basic mechanisms of epilepsy. That focus seems reasonable given that epilepsy is a disorder in the electrical discharge of neurons, and the symptomatic manifestations associated with epilepsy – seizures – are driven by the activity of neurons. However, it has been observed that neuroglia, in particular astrocytes, populate a variety of seizure-related pathological foci in the brain. The best evidence for the role of astrocytes in epileptic foci comes from studies on hippocampal seizure foci in temporal lobe epilepsy (TLE). Hippocampi showing hippocampal sclerosis, characterized by patterned neuron loss and an accumulation of astrocytes, were reported over 100 years ago. Many investigators have argued that the sclerotic hippocampus is the cause of seizures in patients with mesial TLE with hippocampal sclerosis. Given the relative paucity of neurons in such seizure foci, however, it has been speculated that the glia at these foci may play an important role in seizure generation and maintenance. Of the various types of glia in the brain, the astrocytes appear to be the predominant cell type at hippocampal seizure foci, along with a population of microglia. Investigations of the properties of astrocytes in particular, and microglia to a lesser degree, have become active areas of recent research in epilepsy.

Background

Unique Properties of Astrocytes

The contribution that astrocytes may make to seizure production and epilepsy arises from some unique properties of astrocytes. Astrocytes express similar sets of ion channels and receptors as do neurons, but with varying relative strength of expression. In particular, their membrane potassium (K^+) channel density exceeds that of Na^+ channels, with a preferential expression of the inwardly rectifying $K_{ir}4.1$ channel. The $K_{ir}4.1$ channels are found predominantly on astrocytic end feet surrounding capillaries and synapses, where they are colocalized with the water channel Aquaporin 4. These two types of channels together help maintain K^+ and water homeostasis, thus reducing the possibility of excessive neuronal excitation in the normal brain. Two astrocyte-specific glutamate transporters – EAAT1 (GLAST) and EAAT2 (GLT-1) – play a significant role in the removal of glutamate released into the extracellular space by active neurons, and these transporters also help control neuronal excitability. Finally, astrocytes can also release neuroactive substances, including neurotransmitters; such release is dependent on Ca^{2+} release from intracellular stores, which in turn is mediated through the activation of a variety of receptors on astrocytes.

Astrocytes also make a unique contribution to brain metabolism, mediated by a set of enzymes not found in neurons. In particular, astrocytes possess the enzyme pyruvate carboxylase, which can de novo carboxylate pyruvate to oxaloacetate, used to replenish carbon skeletons lost from the tricarboxylic acid (TCA) cycle. Astrocytes also uniquely possess glutamine synthetase, which catalyzes the conversion of glutamate (released by neurons and taken up by astrocytes) into glutamine, which is returned back to neurons in a process described as the glutamate–glutamine cycle. Under conditions of high extracellular glutamate, the TCA cycle product α-ketoglutarate may leave the TCA cycle as malate, to be converted in the cytosol to

Investigations of the properties of astrocytes in particular, and microglia to a lesser degree, have become active areas of recent research in epilepsy.

Background

Unique Properties of Astrocytes

The contribution that astrocytes may make to seizure production and epilepsy arises from some unique properties of astrocytes. Astrocytes express similar sets of ion channels and receptors as do neurons, but with varying relative strength of expression. In particular, their membrane potassium (K^+) channel density exceeds that of Na^+ channels, with a preferential expression of the inwardly rectifying $K_{ir}4.1$ channel. The $K_{ir}4.1$ channels are found predominantly on astrocytic end feet surrounding capillaries and synapses, where they are colocalized with the water channel Aquaporin 4. These two types of channels together help maintain K^+ and water homeostasis, thus reducing the possibility of excessive neuronal excitation in the normal brain. Two astrocyte-specific glutamate transporters – EAAT1 (GLAST) and EAAT2 (GLT-1) – play a significant role in the removal of glutamate released into the extracellular space by active neurons, and these transporters also help control neuronal excitability. Finally, astrocytes can also release neuroactive substances, including neurotransmitters; such release is dependent on Ca^{2+} release from intracellular stores, which in turn is mediated through the activation of a variety of receptors on astrocytes.

Astrocytes also make a unique contribution to brain metabolism, mediated by a set of enzymes not found in neurons. In particular, astrocytes possess the enzyme pyruvate carboxylase, which can de novo carboxylate pyruvate to oxaloacetate, used to replenish carbon skeletons lost from the tricarboxylic acid (TCA) cycle. Astrocytes also uniquely possess glutamine synthetase, which catalyzes the conversion of glutamate (released by neurons and taken up by astrocytes) into glutamine, which is returned back to neurons in a process described as the glutamate–glutamine cycle. Under conditions of high extracellular glutamate, the TCA cycle product α-ketoglutarate may leave the TCA cycle as malate, to be converted in the cytosol to

pyruvate, catalyzed by the cytosolic malic enzyme (which is restricted to astrocytes). Glia, and in particular astrocytes, have a high capacity to produce lactate in the presence of normal oxygen levels. The presence of the lactate dehydrogenase 5 (LDH5) isoform in astrocytes favors conversion of pyruvate to lactate, which is released and used by neurons as an energy source. Changes in any of these unique properties of astrocytes may contribute to the development of epilepsy through a variety of mechanisms.

Methods

Our laboratory has used a variety of methods to study astrocyte properties at hippocampal seizure foci. A primary method has been the use of immunohistochemistry to localize and compare the expression of a variety of astrocytic proteins – such as metabolic enzymes, neurotransmitter receptors, and membrane transporters – in human hippocampi surgically removed for the control of medically intractable TLE. This approach has been supplemented by enzyme activity assays and in vitro slice electrophysiology (some of which has been done in laboratories other than our own but is relevant to this review). Most recently, we have adopted DNA microarray technology to study gene expression patterns in hippocampal seizure foci.

Results

Properties of Astrocytes in a Hippocampal Seizure Focus

Resting astrocytes in the brain are spatially distributed in such a manner that the terminal ends of their processes do not invade into the space occupied by adjacent astrocytes. This phemonenon is sometimes described as 'tiling.' This rather even distribution pattern of astrocytes changes in a seizure focus (i.e., the sclerotic hippocampus), where the astrocytes become 'reactive'; they show aberrant extension and intermingling of their processes, with an increase in expression of a microfilament protein glial fibrillary acidic protein (GFAP). Along with this 'reactive gliosis,' several other properties of the astrocytes also change.

Membrane ion channels

Several lines of investigation have demonstrated alterations in astrocyte membrane ion channels. Most patch clamp studies on astrocytes from a sclerotic seizure focus show an increase in Na^+ channels on their membranes and a more depolarized resting membrane potential (although in one study, no change was found). Astrocytes also have reduced K_{ir} channel function. Immunostaining for the L-type Ca^{2+} channels demonstrates an upregulation in sclerotic hippocampi, suggesting enhanced Ca^{2+} uptake.

Neurotransmitter receptors

Glutamate receptor expression on astrocytes is also altered. Immunoelectronmicroscopic examination of sclerotic hippocampi has revealed the expression of mGluR2/3, mGluR4, and mGluR8 in reactive astrocytes. In like manner, mGluR3, mGluR5, and mGluR8 are reported to be upregulated in the hippocampus in experimental animal models of TLE. Activation of these receptors leads to an increase in intracellular Ca^{2+} and Ca^{2+} wave propagation, leading to astrocytic glutamate release. An increase in calcium transients and calcium wave propagation can be demonstrated in primary astrocyte cultures from human seizure foci. An elevated flip-to-flop mRNA ratio of GluR1 (AMPA receptor) in reactive astrocytes from hippocampal seizure foci has also been reported, suggesting an increased responsiveness of astrocytes to glutamate. Indeed, it has been shown that astrocytes from hippocampal seizure foci can be depolarized to generate action potentials.

Transporter molecules

A downregulation of astrocytic glutamate transporters EAAT1 and EAAT2 has been hypothesized to explain the well-documented observation of increased levels of extracellular glutamate in hippocampal seizure foci. Consistent with this hypothesis, some authors have reported a downregulation of these glutamate transporters in sclerotic hippocampi; however, others have been unable to confirm such an observation. A careful review of these discrepant data leads to the conclusion that astrocytic glutamate transporter differences in sclerotic versus nonsclerotic hippocampi are an inadequate explanation for high extracellular glutamate levels observed by in vivo dialysis in seizure foci.

γ-Amino butyric acid (GABA) is an inhibitory neurotransmitter that contributes to the balance between inhibition and excitation in the normal brain. In vivo microdialysis studies in human hippocampal seizure foci have demonstrated reduced levels of extracellular GABA in the epileptogenic seizure focus during the ictal state. The expression of the GABA transporter GAT3 on astrocytes in the epileptogenic hippocampus appears to be increased, which may contribute to excess removal of GABA and thus explain the earlier observation.

Aquaporin 4 is a water transporter molecule that is found on astrocytes. Under normal conditions, the distribution of AQP4 molecules on astrocytes shows a polarity, with a high density of the transporter on the astrocytic perivascular end feet. However, in astrocytes at the sclerotic hippocampal seizure focus, the density of AQP4 is reduced along the perivascular membrane domain, with no change in density on the astrocytic membrane facing the neuropil.

Astrocyte-specific enzymes

The expression of the enzyme glutamine synthetase is significantly downregulated in astrocytes in hippocampal

seizure foci. Such a reduction in this enzyme is postulated to diminish the efficient removal of extracellular glutamate, and thus its accumulation – perhaps resulting in overstimulation of neurons and subsequent seizures. To date, there are no published studies on the astrocyte-specific enzymes pyruvate carboxylase, cytosolic malic enzyme, or LDH5 in hippocampal seizure foci.

Astrocytes and inflammatory responses

Astrocytes are known to contribute to the inflammatory response of the central nervous system. In vivo and in vitro studies have established that astrocytes can produce a range of immunologically relevant molecules, including class II major histocompatibility complex antigens, many cytokines and chemokines, interleukins (IL-1, IL-6, and IL-10), interferons (INF-α and β), tumor necrosis factor (TNF) α, and transforming growth factor (TGF). A strong association of a polymorphism in the *IL-1*β gene has been found in patients with hippocampal sclerosis (as compared to patients without sclerosis and to nonepileptic controls), and intrahippocampal injection of IL-1β in rats is reported to worsen seizures. IL-1β has been shown to regulate the phenotype of astrocytes. A biallelic polymorphism in the promoter region of the *IL-1*β gene favors high production of IL-1β in patients with hippocampal sclerosis. IL-1β can act on astrocytic IL receptors and induce, via the transcription factor NFkB, the expression of a variety of molecules such as chemokines (CCL2, CCL3, CCL4), the ezrin–radixin–meosin complex of proteins, cyclooxygenase-2, and others. Immunohistochemical analysis of sclerotic hippocampi from TLE patients has revealed increased expression of the NFkB-p65 subunit in astrocytes. Differential gene expression analysis of hippocampi from TLE patients shows that several genes regulated through the NFkB pathway are upregulated in the sclerotic hippocampi. Some of these – such as S100B, ezrin, radixin, and meosin; the chemokines CCL2, CCL3, CCL4, and CX3CL1, and the chemokine receptor CXCR4 – may be associated with astrocytes or endothelial cells at the astrocyte–endothelium interface, but this possibility needs verification.

Association with blood–brain barrier

Astrocytes in normal brain have a close association with the microvasculature. Astrocytic end feet wrap around the blood–brain barrier, formed by the tight coupling of endothelial cells, and play a role in the movement of water and other molecules between the blood and the brain parenchyma. The proliferation of the microvasculature in the sclerotic hippocampal seizure focus was reported over 100 years ago. More recently, it has been suggested that the blood–brain barrier may be altered – among other possibilities, it may become leaky – during seizures. Astrocytes in the sclerotic hippocampi show several changes in the expression of molecules on their end feet associated with the microvasculature. In addition to changes in AQP4 distribution (see earlier sections), plectin 1, erythropoietin receptor (EPO-r), and the multiple drug resistance protein P-glycoprotein (PgP) expression are increased.

Contribution of Astrocyte with Altered Properties to Seizure-Inducing Mechanisms

Astrocytes at epileptic foci, because of the altered properties they possess, may contribute to seizure-inducing mechanisms in a number of ways. In all of the physiological mechanisms in which astrocytes are involved, their impact on seizure generation is assumed to occur through influencing the excitability of surviving neurons – at the epileptic brain focus, or more probably on neurons in the penumbra of the epileptic focus (since sclerotic hippocampal foci have a paucity of neurons).

The prominent reduction in the astrocytic enzyme glutamine synthetase has been postulated to lead to inadequate clearance of glutamate from the extracellular space because of reduced catabolism of glutamate to glutamine in astrocytes, resulting in an accumulation of extracellular glutamate. While it has been argued by some that the reduction in astrocytic glutamine synthetase is secondary to inadequate uptake of glutamate by the astrocyte (because of reduced astrocytic glutamate transporters), this possibility appears unlikely in as much as reduction in astrocyte glutamate transporters is equivocal and perhaps minimal at best. Further, experimental blocking of glutamine synthetase function in the hippocampus (e.g., by competitive inhibition of glutamine synthetase with methionine sulfoximine (MSO)) also results in seizures and increased extracellular glutamate. Concomitant with reduced glutamate catabolism, there may also be glutamate release from astrocytes, contributing to the enhanced extracellular glutamate pool. For example, enhanced metabotropic glutamate receptors on astrocytes may be activated to induce intracellular Ca^{2+} release and glutamate release by astrocytes. While enhanced levels of intracellular Ca^{2+} release in astrocytes at human sclerotic seizure foci have been documented, there is no experimental evidence yet that this effect is due to metabotropic receptor stimulation or results in glutamate release. Additionally, while the unique metabolic pathways in astrocytes could result in their synthesizing additional glutamate for release, such a functional mechanism in reactive astrocytes has yet to be demonstrated.

Another mechanism by which astrocyte abnormalities at a seizure focus may influence seizure activity is via altered K^+ clearance. The downregulation of inwardly rectifying K^+ channels on astrocytes may be a cause of this impairment, and could be compounded by defective water homeostasis. The buffering of K^+ by means of inwardly rectifying K^+ channels on astrocytes depends

on a parallel flux of water through the plasma membrane of these cells. The loss of AQP4 from the perivascular membrane will impair such water movement, and lead to increased extracellular concentrations of K^+, which can depolarize neurons in adjacent regions (such as the subiculum in the case of hippocampal foci).

The immunological responsiveness of astrocytes at seizure foci may provide clues as to how a variety of initial precipitating factors trigger TLE and its associated pathology. Early childhood febrile seizures, which predispose adults to TLE, are associated with increased IL-1β levels in CNS and blood plasma. IL-1β can act on interleukin receptors on astrocytes, and via the transcription factor NFκB induce a variety of molecules, including the chemokines, cytokines, and ERM proteins that are upregulated in the sclerotic hippocampus. Infections of the brain – such as meningitis, human herpes virus 6 (HHV6), and herpes simplex virus (HSV1) – that are shown to be associated with TLE may also be the cause of the inflammatory responses of glia. The effect of these infectious agents on astrocytes may be via astrocytic toll-like receptors (TLR) or may be via activation of inflammatory factors like interleukins, both of which can trigger signal transduction pathways leading to the activation of the transcription factor NFκB; through activation of NFκB, other molecular pathways may be induced that cause intracellular Ca^{2+} release and subsequent glutamate release, as well as chemokine and cytokine mechanism that can modulate the seizure focus microvasculature. The presence of such mechanisms requires experimental confirmation.

The modification of the membrane properties of astrocytes – increased sodium channel densities, a more depolarized membrane potential, and the potential to generate action potentials if sufficiently depolarized – confers on them neuron-like properties. This phenomenon and its potential contribution to seizure generation have received little attention to date. Recently, investigators have reported that there is a population of glial cells in the normal rat brain that express the proteoglycan NG2 (also called CSPG2), and that these astrocytes can generate action potentials when depolarized. This observation takes on increased significance, as in the sclerotic hippocampus, where astrocytes with a predisposition to generate action potentials are found, there is a significant increase in expression of CSPG2 (as demonstrated in recent microarray and immunohistochemical studies). Could astrocytes in a seizure focus serve as a source of electrical excitation in the brain?

Microglia in the Hippocampal Seizure Focus

Relatively little is known about the role of microglia in brain seizure foci. The few available studies clearly point to their role in inflammatory responses. Increased expression of complement system proteins C1q, C3c, C3d, and the C5–C9 proteins of the membrane attack protein complex, is observed in cells of the microglial/macrophage lineage – especially in sclerotic hippocampi in regions of neuronal loss (such as the hilar area and CA fields). Direct infusion of the proteins of the membrane attack pathway into the hippocampus in rats induces behavioral and electrographic seizures, suggesting their potential role in modulating epileptogenicity. Additionally microglia in sclerotic hippocampal seizure foci show increased expression of HLA-DR (a Class II major histocompatibility antigen), IL-1b, IL-1 receptor Type 1, the low-affinity p75 neurotrophin receptor, and the chemokine receptor CXCR4. This known activation pattern of microglia is, in all likelihood, only but a snapshot of the role that microglia may play in seizure foci. How and why this activation occurs, and its potential for seizure induction, remain unclear.

Challenges for the Future

The study of the properties of astrocytes at a seizure focus, such as the sclerotic hippocampus in patients with TLE, has thrust glia into the forefront as significant contributors to the pathophysiology of focal epilepsies. The intriguing altered properties of astrocytes at a seizure focus suggest their participation in one or more of several mechanisms, leading to a number of questions that will undoubtedly guide future research. For example: (1) Does their function result in the production of pathologically high levels of glutamate, resulting in the excitation of neurons surrounding the focus to generate seizures? (2) Do they function as the agents mediating an inflammatory response to various initial seizure precipitation factors (fevers, infectious agents, etc.), which in turn directly or indirectly lead to seizure generation? If so, what are these mechanisms? (3) Do astrocytes constitute an electrically excitable substrate, in and of themselves, that can generate seizures?

Introduction

Epilepsy comprises a group of brain disorders characterized by the periodic and unpredictable occurrence of seizures. Even with optimal current antiepileptic drug (AED) therapy, ~30% of patients have poor seizure control and become medically refractory. Because many AEDs act as general CNS depressants and must be taken chronically for seizure suppression, they often have marked inhibitory effects on cognition.

Thus, more specific AEDs that target cellular and molecular abnormalities responsible for epilepsy but not globally affect cerebral function need to be developed. In this regard, recent developments in understanding glial (especially astrocytic) changes in epilepsy can potentially provide novel therapeutic targets. For simplicity, in this article we refer to different types of cells with astroglial properties as 'astrocytes.'

Background and Results

Glial Morphological Changes in Temporal Lobe Epilepsy

Alterations in astrocytic properties have been best described in the specific case of human temporal lobe epilepsy. The most common pathology found in patients with medically-intractable temporal lobe epilepsy is hippocampal sclerosis, more generally termed mesial temporal sclerosis. Mesial temporal sclerosis is characterized by neuronal cell loss in specific hippocampal areas, gliosis, microvascular proliferation, and synaptic reorganization. One striking hallmark of sclerotic hippocampus is that while there is a specific pattern of neuronal loss, there is also 'reactive gliosis' with hypertrophic glial cells exhibiting prominent Glial Fibrillary Acidic Protein (GFAP) staining and long, thick processes. Most of the changes in astrocytic channels and transporters described later have been discovered in sclerotic hippocampi from temporal lobe epilepsy patients. However, the cellular and molecular processes leading to astrocytic changes during epileptogenesis are not yet understood.

Glial Glutamate Receptors and Transporters in Temporal Lobe Epilepsy

Dysfunction of glutamate transport and synthesis

Glutamate transporters are expressed by several CNS cell types, but astrocytes are primarily responsible for glutamate uptake. The astroglial transporter GLT-1 is responsible for the clearance of bulk extracellular glutamate in the CNS, and increased extracellular levels of glutamate have been found in epileptogenic foci. GLT-1 knockout in mice caused spontaneous seizures and hippocampal pathology resembling alterations in temporal lobe epilepsy patients with mesial temporal sclerosis. Several human studies have supported the hypothesis that reduced or dysfunctional glial glutamate transporters in the hippocampus may trigger spontaneous seizures in patients with mesial temporal sclerosis (**Table 1**), yet the underlying mechanisms are unclear.

Because many AEDs act as general CNS depressants and must be taken chronically for seizure suppression, they often have marked inhibitory effects on cognition.

Thus, more specific AEDs that target cellular and molecular abnormalities responsible for epilepsy but not globally affect cerebral function need to be developed. In this regard, recent developments in understanding glial (especially astrocytic) changes in epilepsy can potentially provide novel therapeutic targets. For simplicity, in this article we refer to different types of cells with astroglial properties as 'astrocytes.'

Background and Results

Glial Morphological Changes in Temporal Lobe Epilepsy

Alterations in astrocytic properties have been best described in the specific case of human temporal lobe epilepsy. The most common pathology found in patients with medically-intractable temporal lobe epilepsy is hippocampal sclerosis, more generally termed mesial temporal sclerosis. Mesial temporal sclerosis is characterized by neuronal cell loss in specific hippocampal areas, gliosis, microvascular proliferation, and synaptic reorganization. One striking hallmark of sclerotic hippocampus is that while there is a specific pattern of neuronal loss, there is also 'reactive gliosis' with hypertrophic glial cells exhibiting prominent Glial Fibrillary Acidic Protein (GFAP) staining and long, thick processes. Most of the changes in astrocytic channels and transporters described later have been discovered in sclerotic hippocampi from temporal lobe epilepsy patients. However, the cellular and molecular processes leading to astrocytic changes during epileptogenesis are not yet understood.

Glial Glutamate Receptors and Transporters in Temporal Lobe Epilepsy

Dysfunction of glutamate transport and synthesis

Glutamate transporters are expressed by several CNS cell types, but astrocytes are primarily responsible for glutamate uptake. The astroglial transporter GLT-1 is responsible for the clearance of bulk extracellular glutamate in the CNS, and increased extracellular levels of glutamate have been found in epileptogenic foci. GLT-1 knockout in mice caused spontaneous seizures and hippocampal pathology resembling alterations in temporal lobe epilepsy patients with mesial temporal sclerosis. Several human studies have supported the hypothesis that reduced or dysfunctional glial glutamate transporters in the hippocampus may trigger spontaneous seizures in patients with mesial temporal sclerosis (**Table 1**), yet the underlying mechanisms are unclear.

Table 1 Involvement of astroglial membrane channels, transporters, and receptors in specific epilepsy syndromes

Epilepsy syndrome	*Astroglial molecule*	*Effect*	*Species*	*Methods*
Temporal lobe epilepsy	GLT-1 GLAST	No change No change	Human	IHC, WB, ISH
Temporal lobe epilepsy	GLT-1 GLAST	↓ No change	Human	IHC
Temporal lobe epilepsy	GLT-1 GLAST	↓ ↓	Human	IHC, ISH
Temporal lobe epilepsy	GLT-1 (Glutamine synthetase)	No change (↓)	Human	IHC, WB, enzyme activity
Temporal lobe epilepsy	GluR1 ('flip' variant)	↑	Human	PC, pharmacology (CTZ, PEPA), single-cell rtPCR, RA
Temporal lobe epilepsy	mGluR2/3 mGluR5 mGluR8	↑ ↑ ↑	Human	IHC
Temporal lobe epilepsy	Kir channel	↓	Human	PC
Temporal lobe epilepsy	Kir channel	↓ ↓	Human Rat (pilocarpine)	ISM, Ba^{2+}
Temporal lobe epilepsy	Kir channel	↓	Human	PC, Ba^{2+}, single-cell rtPCR
Temporal lobe epilepsy	AQP4	↑ overall ↓ perivascular	Human	IHC, rtPCR, gene chip, EM
Focal cortical dysplasia	mGluR2/3 mGluR5	↑ ↑	Human	IHC
Tuberous sclerosis	GLAST GLT-1	↓ ↓	*Tsc1*^{GFAP}CKO mouse	WB, PC
Tuberous sclerosis	Kir channel	↓	*Tsc1*^{GFAP}CKO mouse	PC, WB, Ba^{2+}, mRNA analysis
Tumor-associated epilepsy	GluR2	↓ Q/R editing	Human glioma	rtPCR, sequencing
Tumor-associated epilepsy	GLT-1 GLAST	↓ Mislocalized	Human glioma	IHC
Tumor-associated epilepsy	Kir channel	↓ Mislocalized	Human glioma	PC WB, IHC
Posttraumatic epilepsy	Kir and Kv channels	↓	Rat (fluid-percussion injury)	PC, ISM
Posttraumatic epilepsy	GLT-1 GLAST	↓ No change	Rat (ferrous chloride)	WB

CTZ, cyclothiazide; EM, electron microscopy; IHC, immunohistochemistry; ISH, in situ hybridization; ISM, ion-sensitive microelectrodes; PC, patch clamp; PEPA, 4-[2-(phenylsulfonylamino)ethylthio]-2,6-difluoro-phenoxyacetamide; RA, restriction analysis; rtPCR, reverse transcriptase polymerase chain reaction; WB, Western blot. Modified from Binder DK and Steinhäuser C (2006) Functional changes in astroglial cells in epilepsy. *Glia* 54: 358–368.

Alternatively, alterations in glutamate metabolism may be important. de Lanerolle's group has found reduced glutamine synthetase, an enzyme in astrocytes that converts glutamate into glutamine, in sclerotic rather than in non-sclerotic hippocampus of temporal lobe epilepsy patients (Table 1). Downregulation of glutamine synthetase would slow down glutamate–glutamine cycling and accumulation of the transmitter in astrocytes and in the extracellular space. This condition would provide a metabolic mechanism for astrocyte-dependent hyperexcitability.

Alterations of ionotropic glutamate receptors

A few studies have addressed the potential involvement of ionotropic glutamate receptors in seizure generation. Astrocytes abundantly express receptors of the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) subtype composed of the subunits GluR1 to GluR4. Combined functional and single-cell transcript analyses revealed that enhanced expression of GluR1 flip variants accounts for the prolonged receptor responses observed in hippocampal astrocytes of epilepsy patients with mesial temporal sclerosis (Table 1). Prolonged opening of receptor will promote influx of Ca^{2+} and Na^{+} ions. Steinhäuser's group has shown that enhanced intracellular Na^{+} blocks inwardly rectifying astroglial K^{+} (Kir) channels, further strengthening depolarization and reducing the K^{+} buffering capacity of astrocytes, and thus contributing to hyperexcitability.

Metabotropic glutamate receptors and astroglial Ca^{2+} signalling in epilepsy

mGluR3 and mGluR5 are the predominant metabotropic glutamate receptor subtypes expressed by glial cells. Activation of these receptors affects cAMP accumulation and leads to an increase in intracellular Ca^{2+}. Group II

mGluRs (mGluR 2, 3) have been shown to be coupled to cAMP levels in cultured astrocytes. mGluR-triggered rise in Ca^{2+} may cause oscillations and initiate Ca^{2+} wave propagation within the astrocyte network, activate Ca^{2+}-dependent ion channels, and induce glutamate release from astrocytes. In experimental epilepsy, reactive astrocytes of the hippocampus persistently upregulate mGluR3, mGluR5, and mGluR8 protein. Electron microscopic and immunohistochemical inspection of hippocampal tissue from temporal lobe epilepsy patients revealed expression of mGluR2/3, mGluR4, mGluR5, and mGluR8 in reactive astrocytes, suggesting an involvement of these receptors in gliosis. Upregulation of astroglial mGluR2/3 and mGluR5 was also observed in epileptic specimens from patients with focal cortical dysplasia (**Table 1**). However, the functional role of glial mGluR upregulation in epilepsy is not yet clear.

Astrocytic Glutamate Release in Epilepsy

Astrocytes are capable of releasing glutamate through a Ca^{2+}-dependent process, which could be involved in seizure generation. In chemically-induced, acute epilepsy models, it was recently reported that astrocytes contribute to the generation of synchronized epileptiform activity. In these studies, epileptiform discharges were provoked through the application of 4-aminopyridine, $GABA_A$ receptor antagonists, or bath solutions containing low concentrations of divalent cations. It appeared that astrocytic increase in $[Ca^{2+}]_i$ is sufficient to stimulate release of glutamate from glial cells, which was critical for the generation of paroxysmal depolarization shifts (PDSs), a hallmark of epileptiform activity. In addition, in vivo imaging showed that some antiepileptic drugs suppressed astrocytic Ca^{2+}-signalling. An important caveat to these studies is that human epilepsy is associated with significant morphological alterations that are absent in acute models that have been studied.

Astrocyte Potassium and Water Channels

Since both extracellular K^+ concentration and osmolarity have been shown to markedly modulate neural excitability, it is plausible that changes in astrocytic K^+ or water channels could contribute to hyperexcitability in epilepsy. Indeed, recent studies have found changes in astroglial Kir channels and AQP4 water channels in temporal lobe epilepsy specimens.

K^+ channels

During neuronal hyperactivity, extracellular $[K^+]$ may increase from ~3 mM to a ceiling of 10–12 mM; and K^+ released by active neurons is thought to be primarily taken up by glial cells. Any impairment of glial K^+ uptake would be expected to be proconvulsant. In the hippocampus, millimolar and even submillimolar increases in extracellular K^+ concentration enhance epileptiform activity. High-K^+ also reliably induces epileptiform activity in hippocampal slices from human patients with intractable temporal lobe epilepsy and hippocampal sclerosis.

A primary mechanism for K^+ reuptake is thought to be via inwardly rectifying glial K^+ channels (Kir channels). Glial Kir channels may contribute to K^+ reuptake and spatial K^+ buffering, which has been most clearly demonstrated in the retina. Although multiple subfamilies of Kir channels exist (Kir1–Kir7) differing in tissue distribution and functional properties, the expression of Kir4.1 in brain astrocytes has been investigated most thoroughly. Pharmacological or genetic inactivation of Kir4.1 leads to impairment of extracellular K^+ regulation. However, members of the strongly rectifying Kir2 family may also contribute to astroglial K^+ buffering.

Downregulation of astroglial Kir channels has been found in the injured or diseased CNS. Kir currents are reduced following injury-induced reactive gliosis *in vitro*, entorhinal cortex lesion, freeze lesion-induced cortical dysplasia, and traumatic and ischemic brain injury. In addition, several studies have indicated downregulation of Kir currents in specimens from patients with temporal lobe epilepsy. Using ion-sensitive microelectrodes, U. Heinemann's group compared glial Ba^{2+}-sensitive K^+ uptake in the CA1 region of hippocampal slices obtained from patients with or without mesial temporal sclerosis. Ba^{2+}, a blocker of Kir channels, augmented stimulus-evoked K^+ elevation in non-sclerotic but not in sclerotic specimens, suggesting an impairment in K^+ buffering in sclerotic tissue. Direct evidence for downregulation of Kir currents in the sclerotic CA1 region of hippocampus came from a comparative patch-clamp study in which a reduction in astroglial Kir currents was observed in sclerotic hippocampi compared with that in non-sclerotic hippocampi (**Table 1**). These data indicate that dysfunction of astroglial Kir channels could underlie impaired K^+ buffering and contribute to hyperexcitability in epileptic tissue. When and how this dysfunction develops during epileptogenesis is not yet clear.

Water channels

Alterations in astroglial water regulation could also highly affect excitability. Brain tissue excitability is extremely sensitive to osmolarity and the size of the extracellular space (ECS). Decreasing ECS volume produces hyperexcitability and enhanced epileptiform activity; conversely, increasing ECS volume with hyperosmolar medium attenuates epileptiform activity. These experimental data parallel extensive clinical experience indicating that hypo-osmolar states such as hyponatremia lower seizure

threshold while hyperosmolar states elevate seizure threshold.

The aquaporins (AQPs) are a family of membrane proteins that function as 'water channels' in many cell types and tissues in which fluid transport is crucial. Aquaporin-4 (AQP4) is expressed ubiquitously by glial cells, especially at specialized membrane domains including astroglial endfeet in contact with blood vessels and astrocyte membranes that ensheath glutamatergic synapses. Activity-induced radial water fluxes in neocortex have been suggested to occur as a result of water movement via aquaporin channels in response to physiological activity. Mice deficient in AQP4 have shown marked decrease in accumulation of brain water (cerebral edema) following water intoxication and focal cerebral ischemia and impaired clearance of brain water in models of vasogenic edema, suggesting a functional role for AQP4 in brain water transport. Similarly, mice deficient in dystrophin or α-syntrophin, in which there is mislocalization of the AQP4 protein, also show attenuated cerebral edema.

Alteration in the expression and subcellular localization of AQP4 has been described in sclerotic hippocampi obtained from patients with mesial temporal sclerosis. One study using immunohistochemistry, rt-PCR, and gene chip analysis reported an overall increase in AQP4 expression in sclerotic hippocampi. However, using quantitative immunogold electron microscopy, the same group found that there was mislocalization of AQP4 in the human epileptic hippocampus, with reduction in perivascular membrane expression (**Table 1**). The authors hypothesized that the loss of perivascular AQP4 perturbs water flux, impairs K^+ buffering, and results in an increased propensity for seizures.

Several lines of evidence support the hypothesis that AQP4 and Kir4.1 may act in concert in K^+ and H_2O regulation. First, reuptake of K^+ into glial cells could be AQP4-dependent, as water influx coupled to K^+ influx is thought to underlie activity-induced glial cell swelling. Second, studies in the retina have demonstrated subcellular co-localization of AQP4 and Kir4.1 via both electron microscopic and co-immunoprecipitation analyses. Third, Kir4.1$^{-/-}$ mice, like AQP4$^{-/-}$ mice, have impaired retinal and cochlear physiology presumably due to altered K^+ metabolism. Fourth, AQP4$^{-/-}$ mice have remarkably slowed K^+ reuptake in models of seizure and spreading depression in vivo associated with a near-threefold increase in seizure duration. Fifth, afferent stimulation of hippocampal slices from α-syntrophin-deficient mice demonstrates a deficit in extracellular K^+ clearance. These data are consistent with the idea that AQP4 and Kir4.1 participate in clearance of K^+ following neural activity. However, further studies are required to clarify the expression and functional interaction of AQP4 and Kir4.1 in the brain and their changes during epileptogenesis.

Astrocyte Dysfunction Involved in other Epilepsy Syndromes

Tuberous sclerosis

Tuberous sclerosis (TS) is a multisystem genetic disorder resulting from autosomal dominant mutations of either *TSC1* or *TSC2* genes. The *TSC1* gene encodes the protein hamartin and *TSC2* encodes tuberin, which are thought to be regulators of cell signalling and growth. Epilepsy occurs in 80–90% of cases of TS, frequently involves multiple seizure types and is often medically refractory. Cortical tubers represent the pathologic substrate of TS, and microscopically consist of a specific type of dysplastic lesion with astrocytosis and abnormal giant cells. Although this suggests that astrocytes are involved in the pathologic lesion, in itself this is not the evidence for a causative role of astrocytes in TS epileptogenesis. However, recent evidence using astrocyte-specific *TSC1* conditional knockout mice has provided insight into a potential role of astrocytes in the etiology of TS. These mice, which have conditional inactivation of the *TSC1* gene in GFAP-expressing cells (*Tsc1*^{GFAP}CKO mice), develop severe spontaneous seizures by 2 months of age and die prematurely. Intriguingly, the time point of onset of spontaneous seizures in these mice is concordant with increased astroglial proliferation. Furthermore, two functions of astrocytes – glutamate and K^+ reuptake – are impaired in these mice. These mice display reduced expression of the astrocyte glutamate transporters GLT1 and GLAST. In addition, recent evidence indicates that astrocytes from *Tsc1*^{GFAP}CKO mice exhibit reduced Kir channel activity, and hippocampal slices from these mice demonstrated increased sensitivity to K^+-induced epileptiform activity (**Table 1**). Together, these studies demonstrate that in this model, changes in glial properties may be a direct cause of epileptogenesis.

Tumor-associated epilepsy

Tumor-associated epilepsy is an important clinical problem, seen in approximately one-third of cases. Surgical removal of tumors usually results in seizure control, but many tumors cannot safely be resected, and tumor-associated seizures are often resistant to anticonvulsant therapy. Classic epilepsy-associated brain tumors include astrocytoma, oligodendroglioma, ganglioglioma, dysembryoplastic neuroepithelial tumor, and pleomorphic xanthoastrocytoma. Microdialysis studies of gliomas have revealed reduced glutamate in the tumor compared to peri-tumoral tissue. A 'glutamate hypothesis' of tumor-associated epilepsy has been advanced which suggests that tumors excite surrounding tissue by glutamate overstimulation. Two lines of evidence are relevant to this hypothesis. First, the glutamate receptor subunit GluR2 has been found to be underedited at the Q/R site in gliomas, which would

increase AMPA receptor Ca^{2+} permeability and potentially result in increased glutamate release by glioma cells (Table 1). Second, glioma cells release larger than normal amounts of glutamate *in vitro*. The release of glutamate from glioma cells is accompanied by a marked deficit in Na^+-dependent glutamate uptake, reduced expression of astrocytic glutamate transporters, and upregulation of cystine-glutamate exchange (Table 1). Hence, glioma cell glutamate release at the margins of the tumor may initiate seizures in peritumoral neurons. A distinct potential mechanism underlying tumor-associated epilepsy is altered K^+ homeostasis. In support of this hypothesis, both reduced Kir currents and mislocalization of Kir4.1 channels have been found in malignant astrocytes (Table 1).

Posttraumatic epilepsy

Posttraumatic epilepsy refers to a recurrent seizure disorder whose cause is believed to be traumatic brain injury. It is a common and important form of epilepsy, and develops in a variable proportion of traumatic brain injury survivors depending on the severity of the injury and the time after injury. Anticonvulsant prophylaxis is ineffective at preventing the occurrence of late seizures. Weight-drop and fluid-percussion injury animal models of posttraumatic epilepsy have demonstrated characteristic structural and functional changes in the hippocampus, such as death of dentate hilar neurons and mossy fiber sprouting. Recently, studies have also implicated altered astrocyte function in posttraumatic epilepsy models. Recordings from glial cells in hippocampal slices 2 days after fluid-percussion injury demonstrated reduction in transient outward and inward K^+ currents (Table 1), and antidromic stimulation of CA3 led to abnormal extracellular K^+ accumulation in posttraumatic slices compared to controls. This was accompanied by the appearance of electrical afterdischarges in CA3. Thus, this study suggests impaired K^+ homeostasis in posttraumatic hippocampal glia. Another study demonstrated reduction in expression of the astrocyte glutamate transporter GLT1 in a posttraumatic epilepsy model induced by intracortical ferrous chloride injection (Table 1), suggesting impaired glutamate transport. Further studies of the role of glial cells in posttraumatic epilepsy appear warranted now that reliable posttraumatic epilepsy animal models have been developed.

Perspectives and Future Directions

Astrocytes undergo cellular and molecular changes in epilepsy, including alteration in glutamate transporters and receptors as well as Kir channels and water channels. So far, most of these changes have been demonstrated in sclerotic hippocampi from patients with temporal lobe epilepsy or animal models resembling this particular human condition. However, the various functions of astrocytes in modulation of synaptic transmission and glutamate, K^+ and H_2O regulation suggest that astrocyte dysfunction could also be part of the pathophysiology of other forms of epilepsy.

One important recent development is the recognition of structural and functional heterogeneity of cells with astroglial properties. It is clear that a subset of hippocampal astroglial cells ('classical' astrocytes or GluT cells) expresses glutamate transporters and not ionotropic glutamate receptors and another (NG2 glia or GluR cells) expresses ionotropic glutamate receptors but not glutamate transporters. However, the lineage relationship of NG2 glia/GluR cells and the relative roles of *bona fide* astrocytes versus NG2 glia/GluR cells in epilepsy still remain unclear. In addition, the functional roles of ionotropic glutamate receptors, Kir and AQP4 channels in these subsets of glial cells in the hippocampus are not yet understood. Hippocampal NG2 glia/GluR cells lack gap junctional coupling but receive direct synaptic input from GABAergic and glutamatergic neurons. Gap junctions may also regulate excitability, although available data are inconsistent regarding the impact of altered connexin expression on epileptogenesis. The availability of mice with genetically uncoupled astrocytes will allow examination of this question, by separating the effects produced by alterations of neuronal versus glial gap junctions. It will be important in future studies to examine the cellular and molecular properties of subsets of hippocampal glial cells in human epileptic tissue and unravel the course of their functional alterations during epileptogenesis in appropriate animal models.

Another recent focus in astrocyte biology that may become important for epilepsy research is the 'gliovascular junction.' Microvascular proliferation in the sclerotic hippocampus was noted as early as 1899, but the role of the vasculature and the blood-brain barrier in epilepsy is not yet clear. The intimate relationship between astroglial endfeet ensheathing blood vessels, the targeted expression of AQP4 and Kir4.1 on astroglial endfeet, and the role of astrocytes in blood-brain barrier permeability and control of microcirculation have only recently been appreciated. Local pathological alterations in the gliovascular junction could perturb blood flow, K^+ and H_2O regulation and constitute an important mechanism in the generation of hyperexcitability. Indeed, a recent study suggests that transient opening of the blood-brain barrier is actually sufficient for focal epileptogenesis. The cellular and molecular roles of the gliovascular junction in metabolic homeostasis and changes during epileptogenesis are only beginning to be explored.

In conclusion, the exact changes taking place in astroglial functioning during epilepsy are still poorly understood. The term 'reactive gliosis' is too descriptive and should be replaced by careful morphological, biochemical, and electrophysiological studies of identified glial cell subtypes in human tissue and animal models. In addition to changes in preexisting glial cell populations, newly-generated glial cells with distinct properties may migrate into the hippocampus and contribute to enhanced seizure susceptibility. The available data likely represent only the 'tip of the iceberg' in terms of the functional role of astroglial cells in epilepsy. In view of the many physiologic functions of astrocytes that have been elucidated within the past decade, it can be expected that the next few years of research will yield evidence of similar important roles for glial cells in pathophysiology. Further study of astrocyte alterations in epilepsy should lead to the identification of novel molecular targets that might open new avenues for the development of alternative antiepileptic therapies.

Tumor-Induced Epilepsy

Introduction

Tumors were known to cause seizures as early as the eighteenth century (and likely earlier still), as evidenced by the standard text on epilepsy at that time – Samuel Auguste Tissot's 'Traité de l'épilepsie' of 1770. How tumors bring about seizures, however, has been a matter of continuing speculation, certainly well into the 1970s and indeed even today. Several theories about underlying mechanisms have been put forward, including (a) increased intracranial pressure per se, (b) deafferentiation, (c) loss of gap junctional coupling (particularly in highly malignant cells, which would as a consequence reduce spatial buffering of extracellular potassium, (d) increased glial cell excitability and glial acquisition of neuronal properties (including the ability to fire action potentials), and (e) glia-mediated shifts in synaptic properties of neurons.

Background

The earlier-mentioned theories provide several viable hypotheses. However, they can all be challenged owing to several reasons, and do not afford as yet a comprehensive explanation for the appearance of epileptic discharges with brain tumors. Although all classes of brain tumors (including metastases, neurinomas, and meningeomas) undoubtedly lead to an increase in brain pressure, the link between pressure and neuronal excitability is at present based only on clinical observation. The hypothesis has the advantage of 'explaining' tumors that do not grow within the CNS itself (such as meningeomas) but still appear to produce seizures, but the support is only correlative. Further research is needed to determine whether, e.g., mechanosensitive channels of the TRP-family could indeed be involved in pressure-induced hyperexcitability. Further, there is no direct correlation between the extent of edema/tumor expansion and the likelihood of seizure appearance.

The deafferentiation hypothesis was raised in the late 1950s, and was based mainly on the observation of increased electrographic activity in surgically isolated brain areas in vivo. Recent studies have supported the view that that deafferentation is associated with increased excitability, as reflected in enhanced recurrent connectivity in isolated neocortical areas (as demonstrated by mapping the number of sites at which optical-uncaging of glutamate is able to evoke EPSCs, and by measuring the corresponding EPSC amplitudes), and in impaired chloride extrusion in the neurons in these isolated cortical slabs (shown by measuring chloride equilibrium potential in perforated-patch recordings and assessing its recovery after chloride loading induced by muscimol-activation of GABA-receptors). However, the extent of deafferentiation induced by tumors has not been investigated yet, so the hypothesis is currently viewed as the one applying to brain injury rather than to brain tumors.

The loss of gap junctional coupling does occur in malignant gliomas, as demonstrated in migration/fluorescence studies in vitro of clonal glioma cell lines (correlating migration rate to coupling ratios, using dye diffusion). And loss of astrocytic gap junctional coupling can indeed support increased network excitability, as shown by recent connexin knockout studies. However, loss of gap junctional coupling does not result in spontaneous seizures, and more importantly does not explain why low-grade astrocytomas (presumably still expressing higher numbers of gap junctions) are much more likely to be associated with seizure activity than high-grade gliomas (or why non-glial tumors, such as meningiomas, produce seizures). Electrophysiological recordings from glial cells in slices taken from oligodendroglioma/gliobalstoma patients, as well as from glial in primary glial cultures obtained from these tissues, reveal glia with neuronal properties – i.e., these cells exhibit inward sodium and outward potassium currents sufficient to generate action potentials when the cells are depolarized to threshold. It is thus intriguing to speculate that the glia cells themselves partake in, or even initiate seizure activity. However, a follow-up study combining MEG/EEG techniques for source localization and electrophysiological investigations of sodium currents in glial cells revealed that seizure initiation in gliomas usually occurs in the tumor border zone – not in the tumor mass with highest glial cell density. More importantly, there was no correlation between sodium current expression in glia and focus localization. Hence, glial cells do not seem to be directly involved in seizure generation.

There is a growing body of evidence, however, showing that glial cells shape and determine a host of neuronal functions by providing transmitters (or their precursors) and substrates (such as lactate), by influencing the pH and

ionic micromilieu (for example, by spatial buffering of K^+), by uptake and release of neurotransmitters, etc. To review of these physiological actions is beyond the scope of this article. However, it is certainly conceivable that, at least in glial tumors, there are alterations of these glial functions that contribute to epileptogenesis. For example, it has been shown that in peritumoral areas of gliomas, there are shifts in NMDA and GABA-receptor densities; however, these changes are neither very specific nor consistent, since both up- and downregulations can be observed, not only in tumors but also in various other brain lesions. The same holds true for actual transmitter levels, as determined with in vivo microdialysis in patients. Paradoxically, most of such studies show a trend toward downregulation of glutamate levels within tumors (or in the peritumoral surround), and an upregulation of GABA content – both changes being difficult to reconcile with increased excitabiltiy. There is, however, conflicting evidence, for moderately increased glutamate levels in animal models with glioma implants. Bioluminescence and spectroscopic analyses of experimentally-induced tumor tissue in cats reveal alkalinization in the tumor border zone. Although such a pH shift is often associated with increased excitability, to date there is no evidence that it causes seizures. Taken together, the data summarized earlier do not satisfactorily explain epileptogenesis occurring with gliomas (the neoplasms on which attention has been most intensively focused) or with brain tumors in general; further experiments are necessary to unravel the underlying mechanisms.

Methods

For the investigation of tumor-induced epileptogenesis, several approaches have been taken. These approaches can be roughly grouped into three categories: (1) studies on patients or tissue/cells of human origin (usually glioma, ganglioglioma, astrocytoma, glioblastoma); (2) studies on animal glioma models; and (3) studies in surrogate models, not involving tumors but focusing on perhaps related conditions (e.g., traumatic lesions). The studies on human tissue involve the largest number of approaches, including clinical correlations of symptoms (seizures) to tumor mass (e.g., to assess the role of intracranial pressure in epileptogenesis), immunohistochemical analyses of receptor density or gap junction expression (e.g., to address indirectly such issues as synaptic or spatial buffering dysregulation), and measurements of transmitter levels; the latter studies may employ either in vivo analysis using microdialysis, or in vitro measurements (e.g., in tissue slices from tumor resections), using a 'functional' (and in the case of microdialysis, dynamic) approach to assessment of synaptic release. Further, several in vitro studies have used human brain tissue infiltrated with tumor cells (glioma, astrocytoma, glioblastoma, oligodendroglioma), employing either whole slices, slice-derived glial tissue cultures, or membrane/cell fractions (i.e., synaptosomes). Most of these studies have concentrated on the electrophysiological properties, primarily of glial cells and in a few instances of neurons (see below). Lastly, human glioma-derived cells lines have been investigated to test transmitter release/uptake in vitro, and have shown that glutamate uptake (in these cell lines) is decreased.

Experimental models of glioma, at least in the context of epilepsy-related research, have been used much more rarely. These models involve, in essence, transplantation of different glioma cell lines in rat (e.g., C6, RG2, or G5-glioma cell lines) or cat (glioma clone F98) brain (usually neocortex or striatum). In some studies, irradiation has been used to improve glioma cell growth rate.

Recent Results

A series of recent papers have addressed the hypothesis of increased transmitter levels in tumor tissue (initially put forward in the 1980s) by determining the correlation between glutamate release and malignancy/invasiveness of glioma tissue on the one hand, and glutamate release and the initiation of epileptic activity on the other (**Figure 1(a)**). Using subclones of the C6-glioma cell line, differentiated for their expression of excitatory amino acid carrier 1 (EAAC1), it became evident that the clones devoid of EEAC1 actively released glutamate and produced larger tumors when implanted in rat striatum, suggesting invasiveness to be linked to the ability to release glutamate (**Figure 1(b)**). Intriguingly, this invasiveness could be significantly reduced by treatment with NMDA-antagonists, suggesting that glutamate-receptor activation, presumably on neurons, made brain tissue permissive for tumor growth – possibly by inducing apoptosis/excitotoxic cell death in surrounding healthy nervous tissue, thus surrendering space to the neoplasm. In a follow-up study on acute models of epileptiform activity in vitro, investigators showed that astrocytes can indeed function as an extrasynaptic source of glutamate sufficiently large to trigger epileptiform discharges. Taken together, these findings suggest that glutamate released from gliomas could indeed act both as an excitotoxic and epileptogenic agent. Animal data on increased glutamate levels within and (more importantly) surrounding experimental gliomas in rats (RG2 cell line) appear to support this notion. However, clinical observations have challenged this interpretation, since microdialysis studies in glioma patients rather show a decrease in glutamate levels.

Very few studies actually focus on the consequences of tumor invasion for excitability of surrounding neuronal tissue, for example by assessing direct electrophysiological correlates such as repetitive or burst firing. In analysis of spontaneous activity and synaptically-induced firing of neurons in brain slices from patients with tumors (glioma,

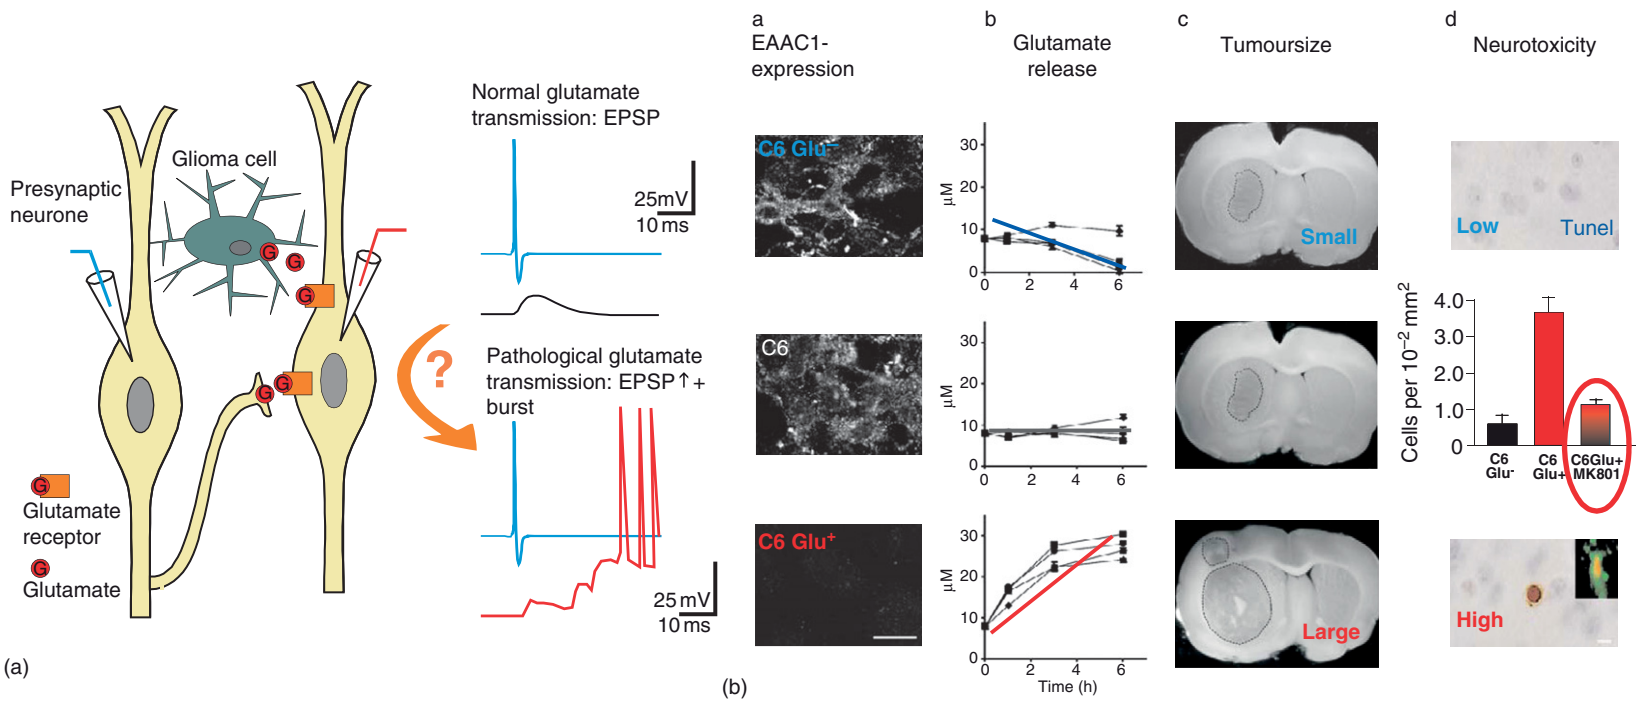

Figure 1 Processes leading to neuronal hyperexcitability in glioma models. A: Cartoon of glutamate release hypothesis: Normal synaptic transmission occurs at synaptic contacts between pre- and postsynaptic neuron. In case of excitatory contacts, the most common transmitter is glutamate (G) acting on glutamate receptors. In gliomas, astrocytes also release glutamate as a consequence of reduced expression of excitatory amino acid carrier 1 (EAAC1). This release may lead excitotoxic neuronal death and synaptic activation. As a – hitherto unconfirmed-consequence, glioma-mediated astrocytic glutamate release might also lead to prolonged/increased postsynaptic receptor-mediated potentials, converting normal EPSPs to pathologically increased responses and bursting. B: Rat glioma cell lines (C6) can be subcloned to yield cell lines with high (C6 Glu^-), normal (C6) and low (C6 Glu^+) EAAC1 expression (EEAC1 immunoreactivity of cell cultures in a), resulting in cell cultures showing decreasing, constant or increasing glutamate levels, respectively, corresponding to slow uptake, balanced uptake/release, and net release (plots of glutamate concentration over time in cell suspension in b). Implants of the corresponding cells into striate body result in gliomas significantly differing in size (histological sections of coronal slices of tumor-implanted rat brains in c) and, importantly, associated with low or high levels of neuronal degeneration (as evidenced by TUNEL staining) in Glu^- and Glu^+ groups, respectively (TUNEL-histochemistry in d). This neuronal degeneration could be significantly reduced (to levels of the Glu-group) if NMDA-receptor blocker MK-801 was administered to the animas (bar chart in d showing TUNEL positive neurons per mm^2). Adapted from Takano *et al*. (2001), *Nature Medicine* 7(9): 1010–1015, copyright 2001, with permission from Macmillan Publishers Ltd.

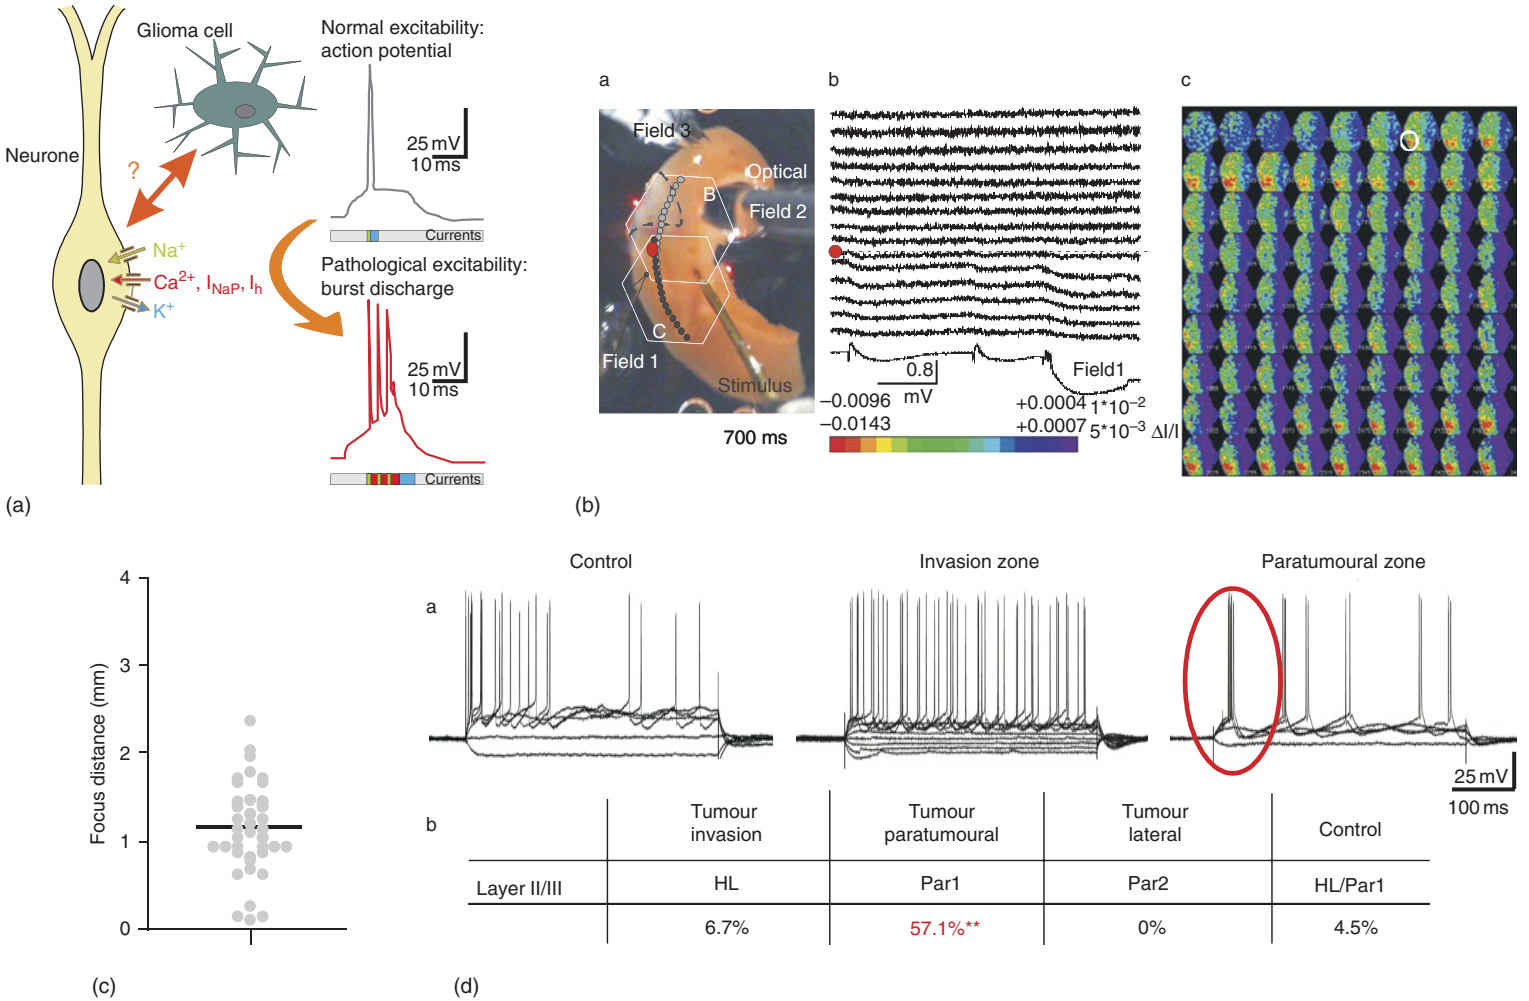

Figure 2 Processes leading to neuronal hyperexcitability in glioma models. A: Cartoon of hyperexcitabiltiy hypothesis: Glioma cells induce (by hitherto unknown interaction with neurons; arrow and question mark) an altered expression of transmembraneous ion channels. This converts action potentials into burst-discharge behaviour, i.e., normal excitability is shifted to pathological one, as a consequence, neurons fire repetitively. The contribution of different ion cannels to the membrane potential changes is indicated as colour-coded bars symbolising the periods during which the respective currents are active. Putative currents responsible for the initiation and plateau phase of bursts (red) are calcium, persistent sodium or hyperpolarization-activated unspecific cation currents (Ca^{2+}, I_{NaP}, I_h). Fast sodium (Na^+) and repolarising potassium currents (K^+) are coded in green and blue, respectively. B: Identification of foci of epileptiform activity in glioma model. a. Photograph of cortical brain slice with invasive glioma induced 2 weeks earlier by C6-glioma-cell injection. The tumor border is marked by the dotted line. Hexagrams indicate optical recording fields (opt; B, C); field 1 and field 2 denote recording positions of conventional microelectrodes for field potential recording. (b) Traces of photodiode signals (deflection downwards = depolarization; recording position B of Ba) and conventional field potential recording (field 1) of initiation of ictal discharge induced by perfusion of 0-Mg^{2+} solution. The red dot marks the trace with the initial signal, indicating the focus. C: False-color coding of a series of 81 consecutive optical recordings taken at intervals

astocytoma, oligodendroglioma), investigators showed that some neurons in the superficial cortical layers – 0.5–2 cm away from the lesion rim – exhibit burst firing. Although the specificity of this finding is difficult to gauge (there was no appropriate control tissue), this discharge pattern is atypical of supragranular-layer neurons (e.g., as seen in temporal lobe epilepsy specimens). This observation suggests that tumors may actually change intrinsic neuronal properties – especially considering these changes were seen comparatively far away from the tumor border, and might be much more pronounced in cells closer to the lesion. A recent investigation explored this phenomenon in more detail (**Figure 2**). In rat glioma-implantation experiments, spontaneous epileptiform activity induced by epileptogenic conditions ($0Mg^{2+}$) were observed to arise in the border zone of the lesion, 1–2 mm from its rim (**Figure 2(b,c)**) – a finding reminiscent of EMG/EEG data in patients who show epileptic foci in close proximity to, but not within, the glioma. It is in this border zone where disproportionately many bursting neurons were observed in supragranular layers of cortex. This increased density of burst-generating cells might be viewed as pivotal for the generation of the epileptic activity seen in ECoG recordings from these animals (**Figure 2(a,d)**). In summary, the observations of increased glial glutamate release and changes of intrinsic excitability of peritumoral neurons are likely to represent important facets of tumor-related (glioma-induced) epileptogenesis.

Future Goals

Future investigations of tumor-induced epileptogenesis should pursue the specific leads described earlier, and more generally look for common factors associated with epilepsy-inducing tumors in the clinical setting. Such common factors may constitute likely candidate mechanisms of epileptogenesis, and can be exploited (e.g., in the development appropriate animal models) for mechanistic studies. Among specific questions to be investigated, the issue of loss of gap junctional coupling in gliomas still needs to be addressed in studies that actually establish a correlation to K^+ spatial buffering defects or alterations in resting K^+ levels. Further, the pH changes seen in vitro must be systematically confirmed in vivo, and linked to excitability changes of neurons (and glia). In view of the neuron-like properties of glial cells from a variety of tumors, it will also be interesting to clarify (in vitro or in vivo) whether there is any pathological communication between these cells and surrounding neurons, be it via gap junctions or (as suggested by some recent findings) via transmitters released from glioma cells. That is, studies should examine whether activation of glia indeed leads to neuronal or EEG spiking. In this context, further systematic combined microdialysis/electrophysiological experiments are needed to reconcile the opposing findings on glutamate levels in human brain and animal models, and to correlate these changes with network excitability changes. Both tumor type and the degree of disease progression may be important factors here. Regarding the observation of bursting neurons in the surround of implanted gliomas, experiments on human tissue (looking at cells closer to the tumor border than previously investigated) are necessary to confirm this finding in the clinical setting. Additionally, the processes underlying these changes need to be unravelled. Possible candidate mechanisms include alterations of transmembranous currents associated with bursting behaviour (e.g., I_m, I_h, persistent I_{Na}, and low-threshold calcium).

More generally, one of the main criticisms one can raise against the experimental findings to date is that not only gliomas (and especially the lower-grade malignant type rather than very invasive ones), but above all also other tumors such as meningeomas or metastases, will readily (and perhaps even more efficiently than gliomas or glioblastomas) induce seizures. Hence, new animal models have to be established in which to investigate these tumor types. One single denominator common to all brain neoplasms is an increase in brain pressure. Therefore, a brain-pressure model in which the investigator can mimic slow increases of intracranial pressure may be useful for investigating network and neuronal excitability changes.

Tumor Treatment-Induced Excitabiltiy Changes

Not only brain tumors, but also their treatment, may affect neuronal excitability. This important point is evident as one reads case reports on the epileptogenic (and also antiepileptic) potential of cytostatic drugs. Radiotherapy, at least transiently, appears to support epilepsy management in tumor patients. And although tumour surgery is, in most cases, beneficial for patients with respect to seizure

of 5 ms each. Red denotes depolarization, blue normopolarization. White circle identifies the focus in the recording; the position corresponds to the red dot in optical recording position B (of Ba). C: Scatter plot of all epileptic foci identified by optical methods as a function of their distance from the tumor rim. The bar denotes the median value at around 1.2 mm. Da: Discharge patterns of neurons in control preparations, in the immediate invasion zone of glioma-invaded tissue, and from the paratumoral zone, i.e., 1–2 mm from the tumor rim. Only in the zone in which the foci are located, more than half of the neurons show burst firing. Db: Table giving the percentages of neurons displaying burst firing in upper cortical layers II and III in the immediate tumor invasion zone (hindlimb area; HL), in the paratumoral zone corresponding to parietal area 1 (Par1), lateral to the tumor (parietal area 2, Par2) and in control tissue without tumor in HL and Par1 regions. activity, a pro-epileptic outcome has occasionally been observed. The mechanisms underlying these mostly clinical observations are only now beginning to emerge.

Recent Developments

Chemotherapy. Only few drugs used in the treatment of brain tumors, be they primary or metastatic, have been investigated for their effects on neuronal/network excitability. Vincristine, a toxin inhibiting microtubule arrangement, has been hypothesised to disturb intramembranous receptor anchoring. Indeed, IP3-induced upregulation of GABAergic currents can be blocked by vincristine, suggesting a pro-epileptic mechanism. A follow-up investigation on vincristine's effects on postsynaptic density composition, however, failed to establish a link to GABA-receptor clustering. Methotrexate, a folate antagonist, was hypothesised to interfere with transmitter uptake mechanisms, and in vitro studies in brain slices have confirmed this notion. The details of its interaction with transporters remains to be elucidated. Cyclosporine A (CsA) a drug used experimentally in gliomas (and more commonly in leukemia treatment) as a protein phosphatase 2B (calcineurin) inhibitor, may have a number of epilepsy-relevant effects on intracellular signalling cascades, including: a possible inhibition of potassium currents (demonstrated in annelids), a disruption of K_v 2.1 clustering, a block of cholinergically-induced downregulation of voltage-gated calcium current (and as a result, rendering cells more vulnerable to excitotoxicity), and a block of KCC2-activation in neurons (likely resulting in depolarizing GABA-actions). The cytostatic agent Temozolomide was recently reported to have anti-epileptic potential in the clinical setting (treatment of glioblastoma), but experimental data which might explain this effect are lacking.

Radiotherapy. Ionizing radiation has also been reported to dampen excitability. Recent (and not so recent) publications suggest this effect is dose- and time-dependent. Low dose radiation appears to be associated with an increase in excitability; similarly, high dose treatment appears to be associated with an early increase in excitability due to increases in membrane resistance, but is then followed by decreases in resistance. Further, radiation appears to downregulate presynaptic release machinery (SNAP25), and to interfere with presynaptic depolarization – resulting in a reduction of transmitter release. A note of caution is appropriate here: Most of the studies conducted to date in this field have been made in the context of defense/warfare issues, and not with the aim to clarify actions of therapeutic radiation. Future studies should be tailored to radiation schemes used in the clinical setting.

Surgery. Neurosurgery, in essence, produces 'controlled trauma' in the brain. Rare clinical reports on seizures initiated in tissue remaining at the rim of the resection zone suggest that tissue defects/deafferentiation may be a common mechanism for both traumatic epilepsy and these rare instances of surgery-induced hyperexcitability. Recent studies have revived the initial experiments of the 1950s on so-called undercutting lesions, whereby the grey matter of the cortex is undercut to sever it from ascending afferents. These studies show that both chloride-extrusion mechanisms after chloride loading (prolonged inhibitory GABAergic activation) are slowed in neurons from tissue treated in this manner, and that the density and amplitude of recurrent excitatory innervation is higher. Both changes would result in increased excitability, as GABA-ergic potentials are more likely to become depolarizing, and overall glutamatergic input is increased. Clinical studies are needed to reveal to what extent such processes actually occur as a result of surgery, and what impact they may have on seizure activity in patients.

Future Challenges

The questions in the field of treatment-induced changes of neuronal excitability in the context of brain tumor therapy are far from resolved. Regarding chemotherapeutic agents, basic research into their actions on the neuronal level must be extended. Radiation studies should be focused on experimental designs relevant to clinical treatment, and should also include in vivo animal experiments to clarify whether seizure susceptibility is reliably altered by radiation protocols. Lastly, clinical studies are needed to assess the extent of surgery-induced excitability changes associated with surgical tumor resections.

Introduction

Among the most complex neurological disorders, the epilepsies have been traditionally associated with hyperexcitability resulting from an impaired balance between excitation and inhibition in neuronal circuits. Temporal lobe epilepsy (TLE) is the most common adult form of treatment-resistant epilepsy. Patients suffering from TLE present seizures involving the temporal cortex and limbic structures such as the hippocampus and the entorhinal cortex. In the hippocampus, TLE is associated with a complex functional and structural reorganization involving principal cells and different subtypes of inhibitory interneurons. The mechanisms of TLE have been extensively studied in experimental animal models such as the kainic acid (KA) model, which reproduces well the main features of human TLE. Using this model, we searched for the factors that might contribute to imbalance between excitation and inhibition in the CA1 hippocampus. We found that, apart from axonal sprouting and synaptic reorganization in CA1 pyramidal cells, cell type-specific loss and synaptic remodeling occur in CA1 inhibitory circuits, thus contributing to local network hyperexcitability. Specifically, cellular loss affects a subpopulation of parvalbumin- and somatostatin-positive GABAergic interneurons in stratum oriens/alveus (O/A). This cell type-specific vulnerability is not due to the differential sensitivity of different subtypes of inhibitory interneurons to the excitotoxic action of KA because interneurons within stratum oriens/alveus (vulnerable population) and lacunosum moleculare (LM; resistant population) demonstrate similar membrane depolarizations and associated somatic Ca^{2+} elevations in response to acute KA application. However, interneuron type-specific vulnerability may result from the activation of other glutamate receptor mechanisms – e.g., the group I metabotropic glutamate receptors (mGluRs), which are differentially expressed in distinct subpopulations of hippocampal interneurons. Alternatively, this vulnerability may reflect the cell type-specific synaptic remodeling induced at interneuron excitatory synapses by epileptiform activity, which may lead to the interneurons' overexcitation and death. Indeed, specific cell loss is significantly reduced by treatment with a

Introduction

Among the most complex neurological disorders, the epilepsies have been traditionally associated with hyperexcitability resulting from an impaired balance between excitation and inhibition in neuronal circuits. Temporal lobe epilepsy (TLE) is the most common adult form of treatment-resistant epilepsy. Patients suffering from TLE present seizures involving the temporal cortex and limbic structures such as the hippocampus and the entorhinal cortex. In the hippocampus, TLE is associated with a complex functional and structural reorganization involving principal cells and different subtypes of inhibitory interneurons. The mechanisms of TLE have been extensively studied in experimental animal models such as the kainic acid (KA) model, which reproduces well the main features of human TLE. Using this model, we searched for the factors that might contribute to imbalance between excitation and inhibition in the CA1 hippocampus. We found that, apart from axonal sprouting and synaptic reorganization in CA1 pyramidal cells, cell type-specific loss and synaptic remodeling occur in CA1 inhibitory circuits, thus contributing to local network hyperexcitability. Specifically, cellular loss affects a subpopulation of parvalbumin- and somatostatin-positive GABAergic interneurons in stratum oriens/alveus (O/A). This cell type-specific vulnerability is not due to the differential sensitivity of different subtypes of inhibitory interneurons to the excitotoxic action of KA because interneurons within stratum oriens/alveus (vulnerable population) and lacunosum moleculare (LM; resistant population) demonstrate similar membrane depolarizations and associated somatic Ca^{2+} elevations in response to acute KA application. However, interneuron type-specific vulnerability may result from the activation of other glutamate receptor mechanisms – e.g., the group I metabotropic glutamate receptors (mGluRs), which are differentially expressed in distinct subpopulations of hippocampal interneurons. Alternatively, this vulnerability may reflect the cell type-specific synaptic remodeling induced at interneuron excitatory synapses by epileptiform activity, which may lead to the interneurons' overexcitation and death. Indeed, specific cell loss is significantly reduced by treatment with a

group I mGluR antagonist. Moreover, we found that both subtypes of the group I mGluRs (mGluR1a and mGluR5) contribute to epileptiform discharges in O/A interneurons but not in LM cells. Additionally, we observed specific alterations in the l-methyl-D-aspartate receptor-mediated currents at excitatory synapses onto O/A interneurons of KA-treated animals. The mechanisms of this cell type-specific synaptic remodeling are unknown, but may involve mGluR1a/5, which play an important role in synaptic plasticity. Thus, we attempted to characterize the cellular and molecular mechanisms of mGluR1a/5 signaling in O/A interneurons. We found that mGluR1a and mGluR5 are localized to distinct dendritic microdomains, linked to specific intracellular Ca^{2+}-signaling cascades producing Ca^{2+} rises with distinct temporal properties, and play specific functional roles in O/A interneurons. In the following paragraphs, we will discuss the view that mGluR1a/5 subtype-specific mechanisms are involved in the induction of synaptic plasticity and contribute to epileptiform activity, suggesting that their activation during seizures may induce long-lasting modifications at excitatory synapses onto O/A interneurons. The findings in support of this hypothesis may be particularly important, since they identify cell type-specific targets that are activated in epilepsy, and provide a basis for the development of target-selective therapy.

Background

mGluR1/5 Signaling and Epileptiform Activity

Group I metabotropic glutamate receptors (mGluR1 and 5) represent a family of $G_{q/11}$-protein coupled receptors. In the hippocampus, mGluR1a demonstrates cell type-specific distribution, while mGluR5 is present in the majority of neurons. Subcellularly, mGluR1/5 is located near excitatory synapses, at peri- and extrasynaptic sites. Accordingly, high-intensity presynaptic activity, leading to the glutamate 'spillover,' is required to activate these receptors. mGluR1/5 activation is classically linked to the phospholipase C (PLC)/inositol 1,3,5-triphosphate (IP_3)/Ca^{2+} release pathway. However, mGluR1/5 may also be organized with members of Homer scaffolding proteins into multiprotein complexes, suggesting additional coupling to different transduction pathways. Indeed, there is now considerable evidence demonstrating G-protein-independent signaling via group I mGluRs. For instance, in CA3 pyramidal neurons, mGluR1/5 is linked to the activation of Src-family nonreceptor tyrosine kinase. Furthermore, mGluR1/5 has been demonstrated to activate the extracellular signal-regulated kinase (ERK1/2)/mitogen-activated protein kinase (MAPK) cascade in a number of preparations. While mGluR1 has been shown to physically interact with a member of the canonical subfamily of transient receptor potential (TRP) channels (TRPC1), mGluR5 is linked to the NMDA receptors by a chain of anchoring proteins, including PSD-95, Shank, and Homer. Furthermore, mGluR1/5-L-type Ca^{2+}-channel interaction has been reported and represents a potential mechanism for the regulation of the Ca^{2+}-channel function by synaptic activity. Thus, group I mGluRs may be involved in multiple cellular functions, from neuronal excitability and different forms of synaptic plasticity to neuronal differentiation and cell-death mechanisms.

Importantly, these receptors are involved in both induction and maintenance of epileptiform activity. Indeed, in hippocampal CA3 pyramidal cells, transient activation of mGluR5 alone is capable of inducing epileptiform discharges that last for hours, and involve protein synthesis-dependent mechanisms. Furthermore, concurrent mGluR1/5 participation in epileptiform discharges significantly increases the duration of epileptic events, leading to the initiation of ictal discharges and facilitating seizure propagation. Interestingly, while mGluR5 has been shown to play a principal role in the induction phase of epileptiform activity, mGluR1 has been implicated as a key player in the maintenance of ictal-like discharges. These receptor-specific roles may be explained by particular signaling microdomains formed by each receptor, as well as by unique receptor-interacting partners. Indeed, generation of prolonged epileptiform discharges in CA3 pyramidal neurons involves specific TRPC channels. Given that these channels may physically interact with mGluR1, their activation may represent the mGluR1-specific mechanism of seizure prolongation. These data point to important roles for both mGluR subtypes in the initiation and spread of epileptiform activity. Furthermore, cell type-specific functions of mGluR1/5 in the hippocampus, and in particular in different types of inhibitory interneurons, may determine the behavior of a particular cell type during epileptiform activity. While such cell type-specific mechanisms may be critically important for our understanding of cellular basis of network reorganization, very little is currently known about mGluR1/5 cell-specific roles throughout epileptogenesis.

Methods

To study receptor-specific signaling mechanisms, as well as the roles of distinct receptor subtypes in interneuron function in normal and pathological conditions, we combine whole-cell patch-clamp electrophysiology, cellular imaging, and immunohistochemistry in rat hippocampal slices from normal and epileptic animals. We use a KA model of TLE in rats, as well as a model of acute epileptiform activity induced in hippocampal slices by application of the $GABA_A$ receptor antagonist bicuculline and the K^+-channel blocker 4-aminopiridine. Patch-clamp recordings in voltage- and current-clamp

mode are performed from distinct interneuron types, visually identified using the infrared and differential interference contrast microscopy. To study specific Ca^{2+}-signaling mechanisms activated by different receptor subtypes, we use two-photon Ca^{2+} imaging in combination with whole-cell patch-clamp recordings in acute hippocampal slices. We also perform morphological and neurochemical post hoc identification of recorded interneurons, using intracellular labeling with biocytin or fluorescent dyes and immunohistochemistry for specific Ca^{2+}-binding proteins and neuropeptides.

Recent Results

mGluR1/5 Signaling Mechanisms in O/A Interneurons

Group I mGluRs (specifically mGluR1a) are abundantly expressed in O/A interneurons. We first determined the mechanisms of these receptors' activation under physiological conditions. Using a combination of two-photon Ca^{2+} imaging and whole-cell recordings, we found that mGluR1a/5 can be activated by intense repetitive synaptic stimulation, consistent with their perisynaptic location. The receptors' activation in interneuron dendrites was associated with a relatively slow Ca^{2+} transient (CaT; time-to-peak, ~1 s; decay time, ~10 s) and an inward current sensitive to both the mGluR1a antagonist LY367385 and the mGluR5 antagonist MPEP. In addition, theta-burst synaptic stimulation coupled with postsynaptic depolarization also provided efficient activation of mGluR1a/5, pointing to a regulation of receptor function by membrane depolarization. Together, these data indicate that both mGluR subtypes contribute to excitatory transmission under conditions of high excitation.

We next attempted to examine specific signaling mechanisms linked to mGluR1a versus mGluR5. Using two-photon Ca^{2+} imaging and micropressure applications of the group I mGluR agonist (*S*)-3,5-DHPG to interneuron dendrites, we were able to discriminate between Ca^{2+} signaling microdomains produced by local activation of mGluR1a or mGluR5, and subsequently focus on receptor subtype-specific signaling mechanisms. The results of these experiments showed that mGluR1a activation produces a relatively fast-rising Ca^{2+} signal (time-to-peak, 1–2 s) resulting from Ca^{2+} entry via TRP channels, with a minor contribution of intracellular Ca^{2+} release. Using Western blot analysis and immunocytochemistry, we also found mGluR1a-dependent activation of ERK via Src tyrosine kinase in O/A interneurons. Moreover, mGluR1a-TRP Ca^{2+} signal in interneuron dendrites was dependent on Src and ERK activation, pointing to an important role of Src/ERK cascade in the regulation of the TRP-channel function and mGluR1a Ca^{2+} signaling. Although it is unclear which particular type of TRP channels may be coupled with mGluR1a in O/A interneurons, several recent findings in our laboratory point to a role of TRPC1/5. First, mGluR1a/5 CaTs are associated with outwardly rectifying membrane currents, similar to those produced by the activation of heteromeric TRPC1/5 channels in heterologous expression systems. Second, TRPC1 and TRPC5 show overlapping distribution in the hippocampus and are detected in O/A interneurons. In addition, mGluR1a-TRPC1 interaction has been reported in cerebellar Purkinje neurons; this interaction resulted in the generation of inward current similar to that induced by mGluR1a activation in O/A interneurons. Finally, our data on the TRP channel regulation by ERK point to a specific ERK–TRP interaction. Indeed, TRPC1 has a few potential ERK phosphorylation sites on its intracellular N-terminal. Interestingly, recent data indicate that both ERK and TRP channels may be involved in the generation of prolonged epileptiform discharges in CA3 pyramidal cells. Thus, ERK–TRP-channel interaction may represent a novel cell type-specific mechanism for the generation of epileptiform activity.

In contrast to mGluR1a Ca^{2+} signaling, mGluR5 activation in O/A interneuron dendrites produced slowly rising, plateau-like CaTs (time-to-peak, ~6 s) or Ca^{2+} oscillations (peak power at 0.37 Hz), which resulted solely from intracellular Ca^{2+} release via ryanodine-sensitive stores. These Ca^{2+} signals occurred independently of Src but were negatively modulated by ERK. Thus, while mGluR1a is linked to Src, ERK, and TRP channels (as well as intracellular Ca^{2+} stores), mGluR5 is coupled exclusively to internal stores. Together, these data show that mGluR1a/5 in O/A interneuron dendrites form distinct Ca^{2+}-signaling microdomains with specific properties that may serve specific signaling functions (**Figure 1**).

mGluR1/5 Contribution to Synaptic Plasticity

What can be the functional roles of these receptor subtype-specific dendritic Ca^{2+} microdomains in O/A interneurons? First, postsynaptic Ca^{2+} elevations control the induction of different forms of synaptic plasticity in central neurons. Excitatory synapses of O/A interneurons demonstrate a Hebbian form of long-term potentiation (LTP) induced by pairing synaptic theta-burst stimulation with postsynaptic depolarization. The induction of this form of LTP is critically controlled by mGluR1a and postsynaptic Ca^{2+} elevation. Indeed, LTP is blocked by the mGluR1a antagonist LY367385 or intracellular BAPTA, and is impaired in mGluR1a knockout mice. Moreover, specific mGluR1a Ca^{2+} signaling via TRP channels, regulated by Src/ERK cascade and store-dependent mechanism, appears to be directly involved in LTP induction: blocking TRP channels alone, or blocking Src/ERK together with intracellular Ca^{2+} stores, prevents LTP induction at interneuron excitatory synapses. In contrast, mGluR5 does not

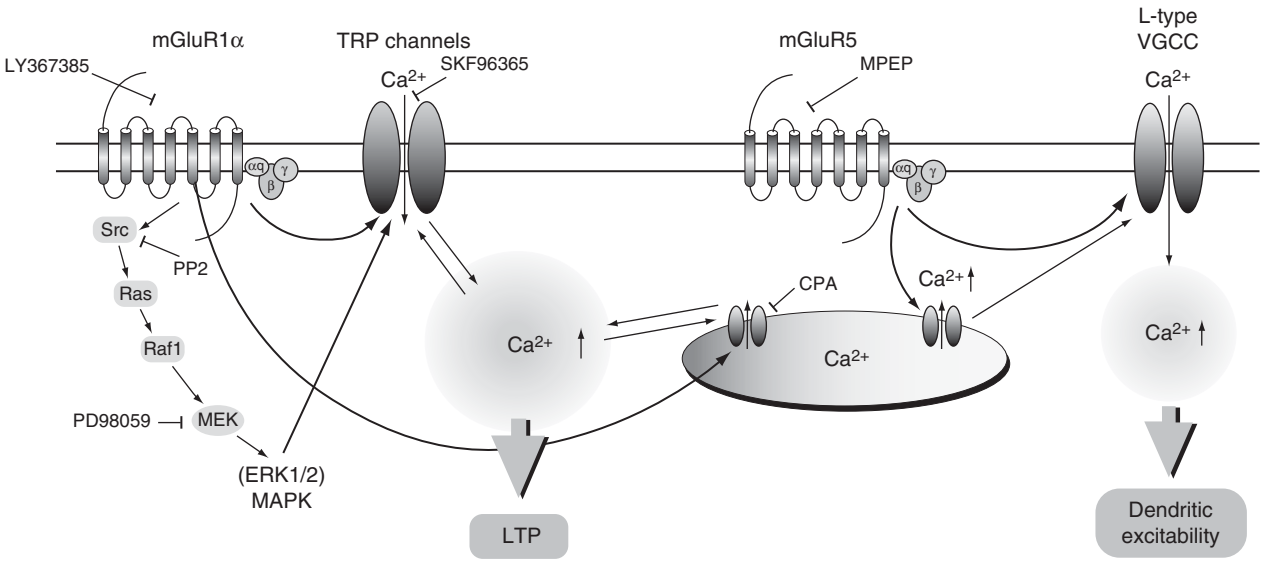

Figure 1 Schematic representation of mGluR1a- versus mGluR5-mediated Ca^{2+}-signaling pathways and their physiological roles in O/A inhibitory interneurons. mGluR1a activation initiates two parallel Ca^{2+}-signaling pathways: Src/ERK-dependent Ca^{2+} entry via TRP channels and intracellular Ca^{2+} release from internal stores. Ca^{2+} signal arising from the interaction between these two pathways control the induction of LTP at interneuron excitatory synapses. mGluR5 activation produces intracellular Ca^{2+} release but may be directly linked to the L-type VSCC. mGluR5-induced long-term potentiation of Ca^{2+} signal via L-type VSCCs represents an important mechanism for the modulation of dendritic excitability, which may play a role in the regulation of synaptic plasticity and other cellular functions. Reproduced from Topolnik L, *et al*. (2006) mGluR1/5 subunit-specific Ca2+ signalling and long-term potentiation in rat hippocampal oriens/alveus interneurons. *Journal of Physiology (London)* 575: 115–131, with permission from Wiley-Blackwell.

contribute to the induction of this form of synaptic plasticity in O/A interneurons. In principal cells, mGluR5 activation is involved in the potentiation of NMDA receptor function via G-protein- and PKC-dependent pathway. Given the essential role of NMDA receptors for a wide range of CNS functions (from neuronal development to synaptic plasticity), their regulation represents an important adapting mechanism to activity-dependent changes. However, it remains to be determined whether an mGluR5–NMDA receptor interaction operates in inhibitory neurons.

Second, local Ca^{2+} signaling may play an important role in the modulation of ion-channel function and dendritic excitability. Accordingly, by tuning the function of specific ion channels, it can provide an alternative mechanism for the regulation of synaptic plasticity. Indeed, our recent data point to the mGluR5-induced regulation of the L-type Ca^{2+}-channel function. It should be noted that multiple Ca^{2+} sources contribute to Ca^{2+} signaling in dendrites of O/A interneurons, including different types of voltage-sensitive Ca^{2+} channels (VSCCs). For instance, R/T-, L-, and P/Q-types of VSCCs contribute to CaTs evoked by bursts of action potentials (APs). Interestingly, local activation of mGluR5 produces long-lasting potentiation of APs-CaTs. This potentiation is not affected by the P/Q- or R/T-types of VSCC blockers, but prevented by the intracellular store inhibitor ryanodine or L-type VSCC blocker nifedipine. Moreover, APs-CaT potentiation is associated with an increased contribution of L-type VSCCs. What can be the functional significance of this mGluR5-induced L-type VSCC potentiation in O/A interneurons? Our data show that L-type VSCCs are activated during pairing protocols, which induce a Hebbian LTP at interneuron excitatory synapses. Furthermore, blocking these channels prevents LTP induction. This observation suggests that L-type VSCCs contribute to a build-up of Ca^{2+} signal necessary for LTP induction. Accordingly, modulation of these channels may represent a mechanism for modulation of synaptic plasticity. From this point of view, mGluR5-induced potentiation of L-type VSCCs may act as a priming stimulus, decreasing the Ca^{2+} threshold necessary for LTP induction. Indeed, our data show that in O/A interneuron dendrites, mGluR1a/5 activation is associated with distinct Ca^{2+}-signaling microdomains that play specific physiological roles. While mGluR1a is primarily involved in the induction of synaptic plasticity, mGluR5 acts as a regulator of specific ion-channel function and, by this means, regulates synaptic plasticity.

mGluR1a/5 Involvement in Seizure Activity In Vitro

How do these mechanisms function under pathological conditions – e.g., during epileptiform activity? Do mGluR1a/5 subtype-specific Ca^{2+} signals demonstrate similar properties and involve the same mechanisms as under normal conditions? Are there still plastic changes induced by the mGluR1a/5 activation? And what can be their role throughout epileptogenesis? To begin

answering these questions, we first determined whether mGluR1a/5 are activated during acute epileptiform activity, and examined how mGluR1a/5 may participate in epileptiform discharges. In disinhibited slices (in the presence of bicuculline and 4-aminopiridine), a brief train of electrical stimulation induced prominent long-lasting epileptiform discharges in O/A interneurons. Interestingly, this type of activity was cell type-specific, since the same stimulation paradigm applied to LM cells elicited epileptiform activity of significantly lower magnitude and duration. Given that O/A and LM interneurons differ in their mGluR1/5 content, it was particularly interesting to examine the different mGluR contribution to cell type-specific epileptiform activity. Our data showed that both mGluR1a and mGluR5 contributed to epileptiform activity in O/A interneurons but not in LM cells. Moreover, while mGluR5 played a principal role in the generation of current underlying epileptiform discharge, mGluR1a contributed specifically to a slow, long-lasting component of the discharge. These data are in agreement with previous findings in CA3 principal neurons, where mGluR5 was shown to be critically involved in the induction of epileptiform activity, while mGluR1a contributed to its prolongation and generation of ictal-like discharges. The mechanisms underlying the different roles of mGluR5 versus mGluR1a in the generation of epileptiform activity in O/A interneurons are presently unclear, but suggest receptor subtype-specific consequences of activation of mGluR1a/5 during seizures. Moreover, our data show that interneuron-type specific distribution of mGluR1a/5 may underlie the differential involvement of different types of inhibitory interneurons in epileptiform activity. Furthermore, the receptor-subtype specific roles of distinct mGluRs suggest that differential activity-dependent plastic changes might occur in particular cell types during epileptiform activity. Such activity-dependent changes may underlie the functional modification at interneuron excitatory synapses or the induction of cellular death mechanisms in specific populations of hippocampal inhibitory neurons.

Epileptiform Activity and Synaptic Remodeling in O/A Interneurons

Following epileptiform discharges, hippocampal circuitry undergoes extensive synaptic reorganization. Given that long-lasting changes in the molecular composition of synapses are typically associated with the incorporation of newly synthesized proteins, seizure-induced synaptic reorganization may be associated with activity-dependent gene expression and new protein synthesis. Indeed, at least several classes of transcription factors, including c-*jun* and c-*fos*, are induced by pathological (seizure) activity. It should be noted that the same factors play an important role in hippocampal synaptic plasticity, suggesting that the same pathways may control activity-dependent plastic changes in normal and epileptic hippocampus. Both mGluR1a and mGluR5 induce specific plastic modifications in O/A interneurons in normal hippocampus. Both receptor subtypes are also activated during epileptiform activity and may trigger Ca^{2+}-sensitive gene transcription. Thus, mGluR1a/5-specific Ca^{2+} mechanisms may be involved in synaptic remodeling in O/A interneurons. Indeed, in parallel with interneuron loss, we have recently uncovered changes at excitatory synapses of KA-resistant O/A interneurons. Single-fiber excitatory postsynaptic currents in O/A interneurons showed slower kinetics in KA-treated animals. Interestingly, only NMDA receptor-mediated current appeared to be changed, suggesting a specific alteration in NMDAR composition at excitatory synapses of O/A interneurons as a mechanism contributing to hippocampal remodeling. The cellular or molecular mechanisms of this plasticity are currently unknown but may involve activation of mGluR1a/5, since mGluR5 has been demonstrated to play an important role in the regulation of NMDAR function. However, its role in synaptic reorganization in O/A interneurons in normal and pathological conditions remains unknown, and elucidating this role will be an interesting direction for future studies.

Future Directions

Our findings demonstrate that, in interneurons, distinct group I mGluRs are linked to specific Ca^{2+}-signaling pathways, control different types of synaptic plasticity, and contribute to epileptiform activity in a cell type- and synapse-specific manner. Given this important role of mGluR1a/5 in epileptiform activity and regulation of interneuron excitation, it would be interesting in future studies to focus on the signaling mechanisms activated by mGluR1a/5 in different interneurons during epileptic activity, and the consequences of differential activation for synaptic function. Specifically, the role of Src/ERK cascade, TRP and L-type calcium channels, and protein synthesis should be explored in this context, as well as the involvement of mGluR1a/5 in modification of NMDAR expression and function. Uncovering the roles of mGluR1a/5 in epileptiform activity and seizure-induced synaptic remodeling would improve our understanding of the mechanisms underlying the functional reorganization of inhibitory circuits in epilepsy.

Introduction

Glutamate receptors are the most abundant type of excitatory neurotransmitter receptors in the mammalian forebrain. Glutamate receptors are responsible for the excitatory drive in neuronal networks, and are uniquely involved in activating downstream signaling cascades required for synaptic plasticity, learning, and memory. Overactivation of glutamate receptors occurs during a seizure, and in vivo microdialysis studies reveal increased extracellular glutamate during status epilepticus. Glutamate receptor antagonists are potently anticonvulsant in in vitro and in vivo models of epilepsy and seizures. Importantly, during early development, excitatory synaptic density is highest compared to any other part of the lifespan, while functional inhibitory neurotransmission is still relatively underdeveloped compared to later in life.

Background

Clinically, seizure incidence is highest in the neonatal period and during infancy. Neonatal seizures are commonly refractory to conventional AEDs, suggesting that their mechanisms are uniquely different from seizure mechanisms in the adult. In addition, seizures in early postnatal development result in an increased risk of later life epilepsy, as well as cognitive impairment, including autism. Animal studies mimic this low threshold for seizures in infants; in rodents, this heightened seizure-susceptibility is observed between 1 and 2 weeks of age. Compared to the adult, the immature animal shows a lower threshold for seizures induced by a variety of insults, including chemoconvulsants, increased temperature, trauma, and hypoxia or hypoxia/ischemia. Introduction

Glutamate receptors are the most abundant type of excitatory neurotransmitter receptors in the mammalian forebrain. Glutamate receptors are responsible for the excitatory drive in neuronal networks, and are uniquely involved in activating downstream signaling cascades required for synaptic plasticity, learning, and memory. Overactivation of glutamate receptors occurs during a seizure, and in vivo microdialysis studies reveal increased extracellular glutamate during status epilepticus. Glutamate receptor antagonists are potently anticonvulsant in in vitro and in vivo models of epilepsy and seizures. Importantly, during early development, excitatory synaptic density is highest compared to any other part of the lifespan, while functional inhibitory neurotransmission is still relatively underdeveloped compared to later in life.

Background

Clinically, seizure incidence is highest in the neonatal period and during infancy. Neonatal seizures are commonly refractory to conventional AEDs, suggesting that their mechanisms are uniquely different from seizure mechanisms in the adult. In addition, seizures in early postnatal development result in an increased risk of later life epilepsy, as well as cognitive impairment, including autism. Animal studies mimic this low threshold for seizures in infants; in rodents, this heightened seizure-susceptibility is observed between 1 and 2 weeks of age. Compared to the adult, the immature animal shows a lower threshold for seizures induced by a variety of insults, including chemoconvulsants, increased temperature, trauma, and hypoxia or hypoxia/ischemia. The developmental regulation of a number of factors that

control neuronal excitability likely contributes to the increased seizure susceptibility of the immature brain. The balance between excitation and inhibition is tipped to create more excitable neuronal networks, as excitability is necessary for synaptogenesis and synaptic plasticity, both of which are heightened during this critical period of early development.

The enhanced excitability of the immature brain is multifactorial, but two major features that likely contribute to this condition are: (1) GABAergic inhibition is relatively underdeveloped compared to the adult brain and (2) glutamate receptors, the major class of excitatory neurotransmitter in the brain, are robustly expressed in the immature brain (see Silverstein and Jensen in Further Reading section). There are several subtypes of excitatory glutamate receptors found on neurons in forebrain structures (neocortical, hippocampal, and limbic structures) known to be activated in epilepsy models. Glutamate receptors can be divided into two categories, ionotropic and metabotropic. Considerable information is available regarding the potential involvement of ionotropic receptors in epilepsy; the contribution of metabotropic receptors is less well understood. For the purposes of this review, we focus on ionotropic glutamate receptors.

The ionotropic glutamate receptors include the *N*-methyl-D-aspartate receptor (NMDAR), the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPAR), and the kainate receptor. NMDARs and AMPARs are primarily located postsynaptically on principal cells and interneurons, while kainate receptors have been observed to be both pre- and postsynaptic, depending on the cell type. In the adult brain, NMDARs are permeable not only to Na^+ and K^+ but also to Ca^{2+}, while AMPA and kainate receptors – on principal neurons – are permeable only to Na^+ and K^+ (interneurons possess Ca^{2+} permeable AMPARs). NMDARs require membrane depolarization, with consequent releases Mg^{2+} channel blockade, to become activated. The subsequent Ca^{2+} influx through NMDAR channels has been linked to the activation of many Ca^{2+}-dependent signaling cascades, involved in posttranslational protein modification, the induction of protein synthesis, and the induction of gene transcription, that have been implicated in normal activity-dependent synaptic plasticity. All iontropic receptors are heteromeric and composed of different subunits. The function of ionotropic receptors is dictated by their subunit composition. Importantly, glutamate receptor subunit expression is developmentally regulated. The obligate subunit of NMDARs is the NR1 subunit, and receptors are made up of combinations of the NR1 subunit with NR2 or NR3 subunits. Rodent studies reveal that NR2A is expressed at higher levels in the adult brain, whereas NR2B is present in the first 2 postnatal weeks. Human studies reveal a similar pattern of early NR2B expression in the infant brain. When NR2B is expressed, current decay times are prolonged, increasing excitability. In addition, the sensitivity of the NMDAR to Mg^{2+} blockade is decreased when NR2D and NR3A are expressed, and these are expressed predominantly in early postnatal development in rats and humans.

Similar to the NMDAR, the AMPAR is also developmentally regulated in a manner that increases postsynaptic excitability and signaling in early development coincident with the critical period (**Figure 1**). AMPARs can contain GluR1, GluR2, GluR3, and GluR4 subunits. In the adult brain, many receptors appear to be GluR1 and GluR2/3 containing. GluR1 isoforms are differentially expressed over development. The 'flip' isoform of GluR1 is associated with less glutamate desensitization than when the 'flop' isoform is expressed. During early development, the expression of the 'flip' isoform is high, increasing synaptic excitability. In addition, in early development (i.e., the first 2 weeks in the rodent and the first 1–2 years in the human), principal neurons show a relative lack of GluR2 in forebrain structures such as hippocampus and cortex. The presence of GluR2 renders the AMPARs impermeable to Ca^{2+}; hence, the absence of this subunit in the immature neurons renders them more Ca^{2+}-permeable. In addition, the GluR2 mRNA undergoes an editing step in the adult brain, substituting a Q for R in its sequence. When the mRNA is edited, a functional GluR2 protein is translated; however, when the editing step is omitted, the unedited form of GluR2 is nonfunctional, and equivalent to the GluR2-deficient condition.

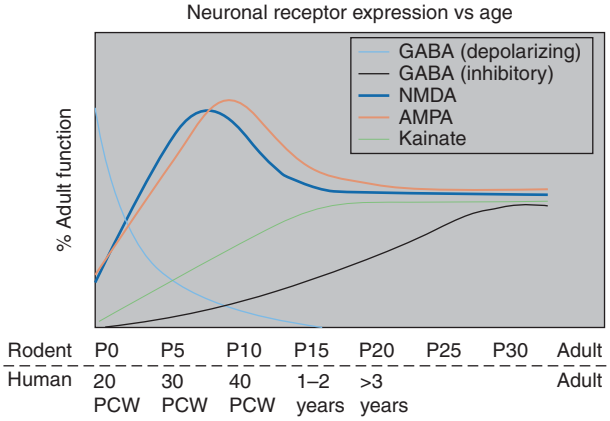

Figure 1 Schematic depiction of maturational changes in glutamate and GABA receptor expression and function in the developing brain. Developmental pattern for rat (top X axis) and human (bottom x axis) are shown. GABA receptors are depolarizing early in the first postnatal week in the rat and up to and including the neonatal period in the human, while functional inhibition is gradually reached over development (6). Prior to full maturation of GABA-mediated inhibition, the NMDA and AMPA subtypes of glutamate receptors peak between the first and second postnatal weeks in the rat and in the neonatal period in the human. Kainate receptor binding is initially low and gradually rises to adult levels by the fourth postnatal week (12). Reproduced from Silverstein FS and Jensen FE (2007) Neonatal seizures. *Annals of Neurology* 62: 112–120, with permission Wiley-Blackwell.

To date, no GluR2 editing is known to take place during development, although editing can take place in response to injury and seizures (see the following sections).

Kainate receptors are comprised of GluR5, GluR6 and/or KA1 and KA2 subunits. Like GluR2, the GluR5 and GluR6 subunits can undergo an editing step and the unedited subunit protein results in increased Ca^{2+} permeability. Regarding their maturational profile, kainate receptors on principal neurons have been observed to gradually increase in expression with development. However, kainate receptors on GABAergic interneurons are expressed at high levels early in development, when the GluR5-containing kainate receptors are localized at terminals where they can directly inhibit GABA release. Hence, kainate appears to have important modulatory actions on GABAergic transmission in the immature brain.

A number of rodent protein and gene analyses, as well as electrophysiological studies, have revealed a baseline enhanced expression of excitatory glutamate receptors subtypes that promote excitability of the immature brain compared to the adult. Given the enhanced excitability of the immature brain, there are a number of approaches that have been taken to investigate the effects of glutamate receptor expression on seizures during development, to explore both mechanisms leading to long term epilepsy and to elucidate neurocognitive impairment associated with early seizures.

Methods

In our laboratory, we have used a model of neonatal seizures (in the Long Evans rat) that is based on the natural epileptogenic potential of hypoxia (rather than a chemoconvulsant). Hypoxic or hypoxic/ischemic encephalopathy is the most common cause of neonatal seizures clinically, and these seizures can be refractory to conventional AED medication and lead to long-term epilepsy and neurocognitive deficits. Hence, we use hypoxia as our epileptogenic stimulus, and have based the timing of its delivery (i.e., the animal's age) on the developmental profile of glutamate receptor expression in Long Evans rats (**Figure 1**). Global hypoxia induces EEG and behavioral seizure activity optimally at postnatal days 10–12 (P10–12) in our animals. This period of development is characterized by heightened expression of calcium-permeable GluR-2-deficient AMPARs, as well as expression of NR2B and NR3A containing NMDARs. We have also evaluated these developmental profiles in Sprague–Dawley rats, which appear to be developmentally advanced compared to the Long Evans strain. The gestational period in the Sprague–Dawley rat is 23 days, whereas the Long Evans is only 21 days; hence, for postconceptional age, a P10–12 Long Evans rat is equivalent to a P7–8 Sprague–Dawley rat. Indeed, we have shown that with respect to the developmental regulation of AMPAR subunit expression, these relative ages appear to be analogous. In addition, preliminary unpublished studies from our laboratory have shown that the C57/BL6 mouse is more similar to the Sprague–Dawley rat than the Long Evans rat in terms of the cortical and hippocampal neuronal and glial AMPAR expression.

We expose the rats to graded hypoxia, starting with room air and decreasing the oxygen content to 4% over a 15-min period. Too rapid a decline in O_2 results in an isoelectric EEG, severe bradycardia, and apnea, whereas a more gradual decrease appears permissive of only mild bradycardia, sustained respiration, and prominent EEG and behavioral seizures (**Figure 2**). Others and we have also shown that animals that experience these early hypoxic seizures go on to develop long-term increases in susceptibility to seizure-induced neuronal injury and exhibit learning impairment. In addition, recent unpublished studies have shown that these animals have a high incidence of EEG and behavioral spontaneous seizures at P50–80 (**Figure 2**). Hence, this model is well suited to the study of factors responsible for acute seizure susceptibility as well as mechanisms of epileptogenesis and the long-term neurobehavioral deficits. In addition, we have employed this model to conduct therapeutic trials aimed at both acute seizure suppression and antiepileptogenic intervention.

We study this model at several levels. First, whole animal behavioral and EEG studies show that there is a seizure phenotype acutely and chronically. Depth electrodes show activation of cortical and hippocampal areas acutely. We can also evaluate behavioral and learning deficits: these animals show deficits in water maze as well as open field and handling tests, suggesting limbic and hippocampal dysfunction. Hence, we have both acute and long-term outcomes for therapeutic trials. Second, we can evaluate acute and long-term modification of gene and protein expression. A major advantage of this model is that, like other models of early life seizures, there is no acute neuronal injury. Thus, observed changes in gene and protein expression are less likely related to cell death cascades (which are often confounding features of some adult chemoconvulsant models where there is prominent acute cell death). In addition to sacrificing animals at intervals following seizures to track gene and protein alteration, we have performed both extracellular and whole cell patch clamp studies on hippocampal and cortical slices, removed ex vivo at intervals ranging from immediately after the hypoxia-induced seizure (at P10) to weeks after the acute seizures. These slice studies allow us to characterize changes in glutamate and GABA receptor function in specific neuronal populations, and to correlate these changes with altered protein or gene expression.

In order to determine the clinical relevance of our findings related to developmental glutamate receptor

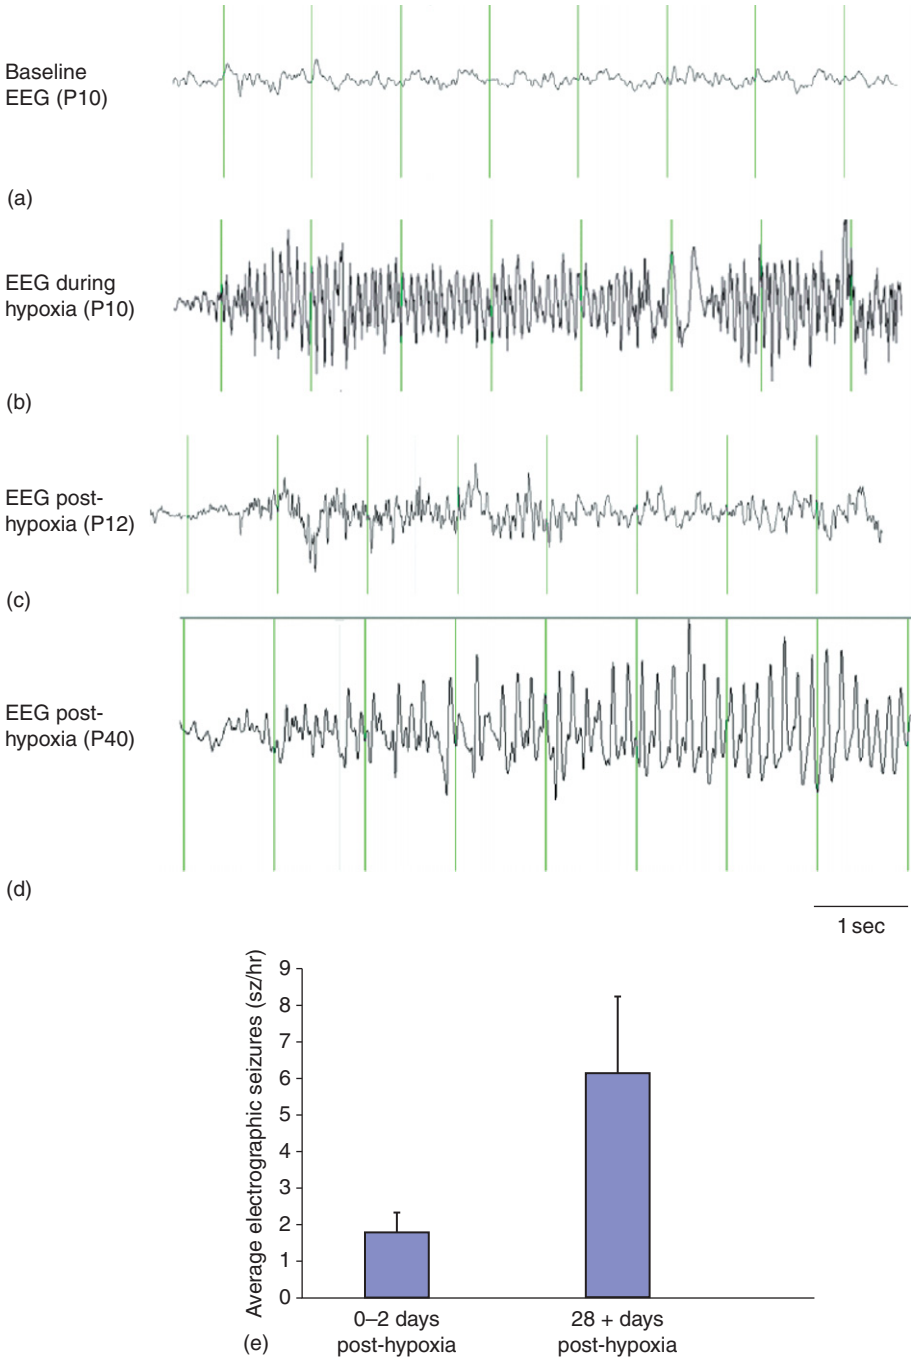

Figure 2 Electrographic seizures recorded from rat pups during and post hypoxia. Electrographic recordings obtained using subdermal wire electrodes in rat pups show abnormal epileptiform activity during graded global hypoxia (b) 2 days following hypoxia induction (c) and at 4 weeks following hypoxia induction (d). Baseline EEG activity in a P10 long Evans rat pup is shown (a). The average seizure frequency recorded using video-EEG recording apparatus is shown in (e).

regulation and alterations due to early life seizures, we have evaluated postmortem samples of normal human brain, at ages ranging from midgestation to adulthood. Double labeling with glutamate receptor subunit-specific antibodies in combination with neuronal and glial markers has allowed us to make comparisons, across ages, between rodent and human cortical samples.

Recent Results

Early studies using this hypoxia model suggested a critical role for AMPARs, in that systemic pretreatment with the AMPAR antagonist NBQX was effective in blocking the acute seizure activity (at P10) as well as the long-term outcome. The NMDAR antagonists MK-801 and the

GABA agonists phenobarbital and lorazepam had minimal effects. Given that clinically there are no biomarkers to identify hypoxic infants at risk for seizures, we next evaluated *post*seizure treatment. We used both NBQX and the clinically available drug, topiramate – which has AMPAR antagonist action; both agents exhibited protective effects against the long-term outcomes when administered over 48 h post seizure. These results suggested that seizure-induced changes in neuronal excitability could be prevented following the initial seizures, and that AMPAR activation appeared to be necessary and sufficient for these changes.

Given that AMPARs appeared to play a role, and that their antagonists showed efficacy in the rodent model treatment trials, we next evaluated whether glutamate receptors were developmentally regulated in the human brain in a manner similar to that observed in the rat. Indeed we showed that cell-specific AMPARs expression was developmentally regulated, with cortical and hippocampal neuronal glutamate subunit expression studies showing the presence of GluR2-deficient AMPARs during the neonatal period and throughout the first year of life. In addition, our unpublished studies reveal that these neurons also express NR2B and NR3A containing NMDARs, which are expressed at much lower levels later in infancy and childhood. Parallel studies of developmental expression in human tissue help validate the experimental observations in the animal model.

Recently, we have been examining how early-life seizures alter hippocampal and cortical networks. Using hippocampal and cortical slices removed at intervals following P10 hypoxia-induced seizures, we have shown (with both extracellular recordings and whole cell patch clamp recordings) that there is a rapid and sustained increase in network excitability. AMPAR currents are rapidly increased in amplitude and frequency, and they become more inwardly rectifying in CA1 pyramidal cells from hippocampal slices removed within hours following seizures. In addition, there is no increase in paired pulse facilitation, suggesting that the change is largely due to a postsynaptic modification. In the setting of an increased/decreased receptor mediated current, paired pulse stimulation can help determine the presynaptic vs. postsynaptic source for the change in synaptic strength; any change in the amplitude of the second of two paired pulses is generally thought to indicate a change in presynaptic transmitter release, while the absence of an altered paired pulse response is more consistent with a postsynaptic modification. Indeed, we recently showed that sites on the AMPAR GluR1 (ser 831 and ser 845) and GluR2 (ser 880) are phosphorylated rapidly following seizures (**Figure 3**). These posttranslational subunit modifications have been observed by a number of laboratories studying models of long-term potentiation, where AMPAR-mediated synaptic efficacy is enhanced. GluR1 phosphorylation at Ser 831 and Ser 845 results in trafficking of the GluR1 subunit to the synaptic membrane, with a functional increase the amplitude and open time of AMPARs. Phosphorylation of GluR2 at Ser 880 results in subunit removal from the membrane. GluR2-deficient synapses are characteristically inwardly rectifying and Ca^{2+}-permeable compared to GluR2-containing synapses. Indeed, we have shown that within hours to days after hypoxic seizures, AMPARs are more inwardly rectifying. In addition, using the cobalt uptake assay as a surrogate for calcium permeability, we have shown significant increases in cobalt staining of pyramidal neurons in CA1 following seizures at P10.

In addition to these changes at the AMPAR, we have recently investigated seizure-induced alterations in NMDARs. NMDARs are NR2B-containing in hippocampal CA1 neurons at P10, and show a characteristic ifenprodil sensitivity. However, whole cell patch clamp recordings in slices removed at 24 h following seizures at P10 show a decrease in ifenprodil sensitivity. In addition, NR2B expression is reduced on western blot analysis of hippocampal homogenates at 24 h post seizure. Analysis of other NMDAR subunit changes, and studies to determine whether or not these rapid changes are posttranslational, are ongoing.

Other studies using this model include an investigation of the mechanism of protection by posttreatment with AMPAR antagonists. We hypothesized, based on our earlier observations, that the rapid alterations in glutamate receptor trafficking might represent early steps in the epileptogenic cascade in this model. To test this hypothesis, we treated rats immediately following hypoxic seizures with AMPAR antagonists, and then either sacrificed the rats for hippocampal slice electrophysiology or for immunoprecipitation and western blot analysis for phosphorylated AMPAR subunits. We found that if AMPAR antagonist posttreatment was initiated immediately following the initial hypoxia-induced seizures, the expected alterations in AMPAR function and subunit phosphorylation were blocked, as was the increased seizure susceptibility. We tested NBQX and topiramate, as well as the new AED candidate drug talampanel, which is an uncompetitive AMPAR antagonist (GYKI 53773). NBQX 30 mg kg^{-1}, topiramate 20 g kg^{-1}, or talampanel 7.5 mg kg^{-1}), when administered immediately following seizures at P10, prevented the seizure-induced alterations in AMPAR function when slices were prepared at 2–3 h after hypoxia in vivo. In addition, hippocampal homogenates from rats sacrificed at 24 h after two doses (immediate and at 12 h post seizure) showed that treatment blocked the posttranslational changes in subunit phosphorylation. These studies demonstrate how this model can be used to examine putative steps in the epileptogenic cascade and determine points for therapeutic intervention.

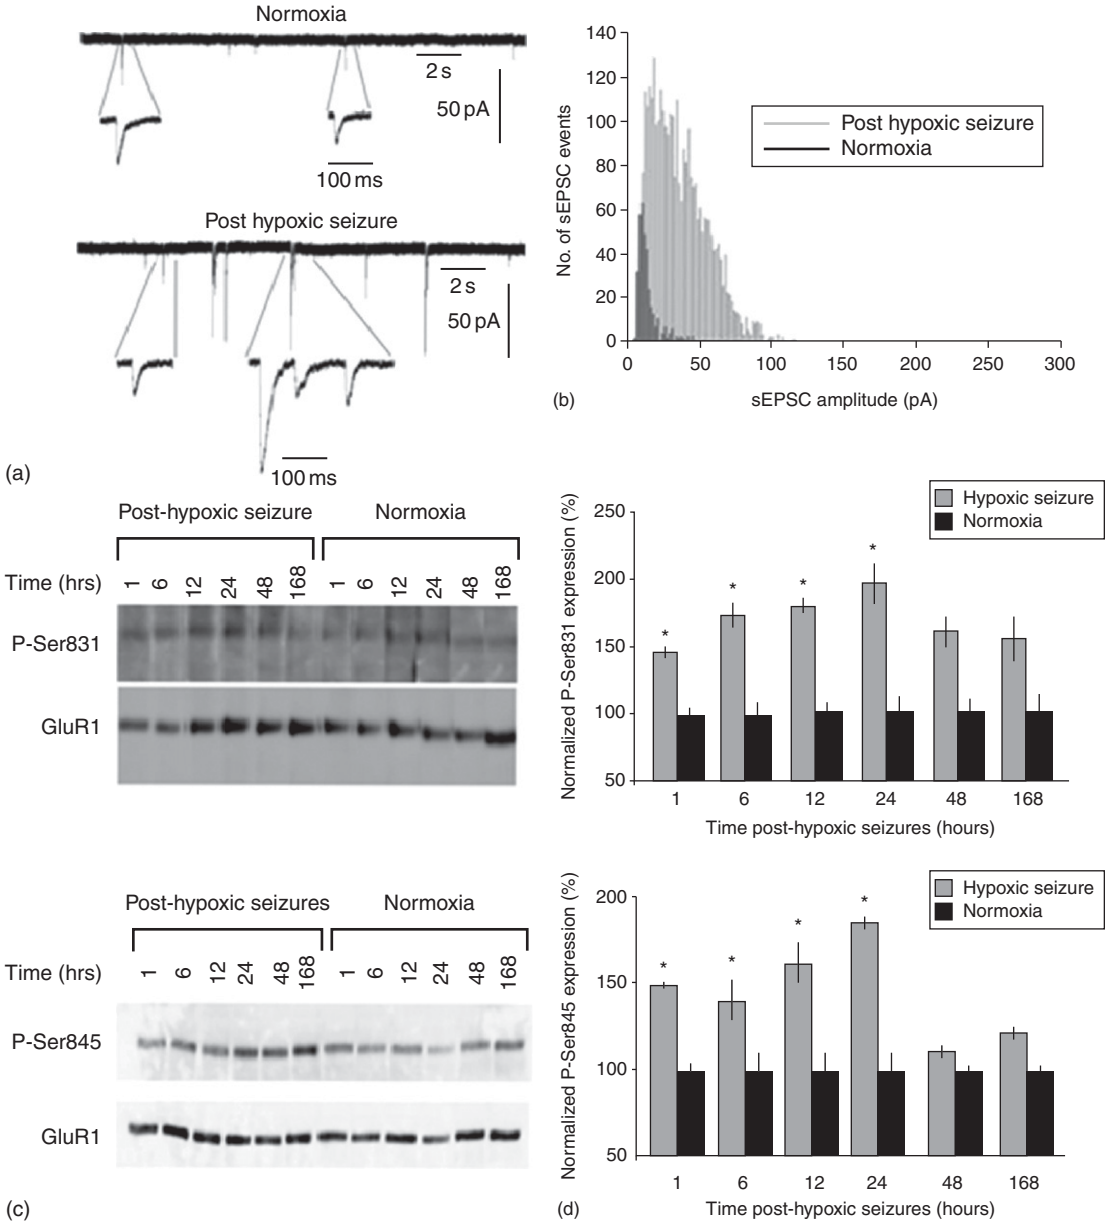

Figure 3 Enhanced AMPAR-mediated sEPSCs in CA1 pyramidal neurons and rapid increase in phosphorylation of GluR1 S831/S845 immediately following hypoxic seizures. (a) Representative recordings of AMPAR-mediated sEPSCs in CA1 neurons from normoxic control hippocampal slices (top) versus slices removed at 1 h after hypoxic seizures in vivo at postnatal day 10 (bottom). Individual sEPSCs are shown in detail at expanded time scale below the continuous traces (whole cell patch-clamp recordings at room temperature). (b) Amplitude histograms (normoxia sEPSC event $n = 368$, post-hypoxic seizure event $n = 3161$) were increased with larger amplitudes in CA1 pyramidal neurons in slices removed after hypoxic seizures (-24.4 ± 2.5 pA; $n = 12$) compared to control slices (-15.4 ± 1.0 pA, $n = 12$, $p < 0.05$). (c) Immunoblots showing significant, increase in phosphorylation of GluR1 S831, and (d) GluR1 S845 at 1, 6, 12, and 24 h post-hypoxia. Densitometric analysis and relative quantitation of phosphorylation of GluR1 subunit revealed the maximal increase at 24 h post-hypoxia for both GluR1 S831, (183%, $n = 3$, $p < 0.05$) and GluR1 S845 (190%; $n = 3$, $p < 0.05$) compared to normoxic controls. (2008) Early alterations of AMPA receptors mediate synaptic potentiation induced by neonatal seizures. *Journal of Neuroscience* 28: 7979–7990, with permission from Journal of Neuroscience.

Future Directions

We have employed a model that has been useful in identifying the roles of glutamate receptors in contributing to baseline seizure susceptibility in the developing brain, and for determining the consequences of glutamate receptor activation in early steps in epileptogenesis. The model has clinical relevance in that it uses a physiological convulsant stimulus, hypoxia, to generate ictal activity. Future studies will continue to probe the timeline of changes in glutamate receptors and their downstream signaling cascades that occur during brain development.

Beyond the early posttranslational changes, there are likely modifications in gene expression and in protein synthesis, and alterations in microarchitecture. Many status epilepticus models show that at any age, seizures appear to trigger the expression of more immature forms of glutamate receptors, even in mature tissue. Thus, insights into therapeutic interventions gained from investigations during early development, when these forms are robustly expressed, may have application to other epilepsy syndromes. In this context, we have begun to examine cortical dysplasias and tuberous sclerosis-associated lesions. Many laboratories have shown that neurons and glia in these 'islands' of cortical maldevelopment appear to have similar glutamate receptor expression patterns compared to those seen in early development.

Importantly, the contribution of the immature forms of glutamate receptors to the enhanced excitability of the immature brain does not occur in isolation. Inhibition is likewise developmentally regulated, with the full complement of functional GABAergic inhibitory synapses developing later than the peak expression for glutamatergic synapses. In addition, GABA receptors that are present contain a higher fraction of the α4 subunit, which encodes relative benzodiazepine insensitivity. Also, concurrent with the immature expression of glutamate receptors, the GABARs are depolarizing by virtue of the higher intracellular Cl^- concentration, as determined by the age-dependent relative expression of membrane Cl^- cotransporters (the importer NKCC1 and the exporter KCC2). During early postnatal development in the rat, KCC2 is expressed at low levels, and Cl^- remains high intracellularly; thus, upon activation of the GABAR, Cl^- flows out of the cell rather than in, resulting in a depolarization of immature neurons. We have recently shown that NKCC1 is upregulated in the second postnatal week in the rat and in the first year of life in the human, while KCC2 is expressed at minimal to low levels. Consequently, NKCC1 blockers (such as bumetanide) appear to improve the efficacy of GABAR agonists in suppressing seizures in the immature brain, including those in the hypoxia model. It is likely that there are a number of major factors contributing to seizures in the immature brain in addition to the unique patterns of expression of excitatory and inhibitory neurotransmitters. Future directions will include the study of interaction between the developmental regulation of glutamate receptors and other systems regulating circuit excitability.

Finally, we are in the process of developing this hypoxia-seizure model in mice. Given our observations suggesting critical roles for particular glutamate receptors and downstream signaling pathways, studies on transgenic mice – with up- or down-regulation of key factors – represent important 'proof-of-principle' experiments. We are presently evaluating the contribution of posttranslational modification of the GluR1 AMPAR subunit, using Ser 831/Ser 845 double phosphomutant mice in which these sites cannot be phosphorylated. These animals show decreased LTP and learning, and our hypothesis is that if the GluR1 site phosphorylation is truly necessary and sufficient to activate later events in epileptogenesis (following P10 hypoxia-induced seizures), these animals should show fewer seizures and less long-term epileptogenesis than wild-type mice. Similarly, we can evaluate the role of other glutamate receptor subunits. For example, using the NR3A knockout mouse, we will determine if the transient increase in NR3A seen in the seizure-susceptible second postnatal week in the rodent (and in the human neonatal brain) is essential for the process of epileptogenesis in the developing brain. Other mice, such as TSC2 mutant mice, where glutamate receptors are abnormally expressed on dysplastic neurons, might be useful in determining how seizure activity in early life affects glutamate receptor expression on dysplastic neurons. Our studies of human cortical biopsy tissue from TSC patients show that the dysplastic neurons and glia in tubers express immature forms of glutamate receptors NMDAR and AMPAR subunits, reminiscent of those expressed on immature neurons, radial glia and astrocytes in fetal and infant forebrain. The TSC2 mutant mouse is a good example of how these mouse models might prove useful in determining the role of specific glutamate receptors in generating epilepsy in rodent developmental models.

The developmental expression of glutamate receptors is likely to play an important role in a variety of early life seizure models. Many investigators have observed the relative hyperexcitability of the immature brain, as well as a relative underdevelopment of GABAergic inhibition. Given that much is being learned about age-specific targets for epilepsy suppression, investigators are now addressing specific mechanisms whereby seizures in early life disrupt network function beyond simply inducing epilepsy. Detailed understanding about the unique signaling cascades mediated by these immature glutamate receptors will be an important advance that could yield novel therapeutic strategies for the prevention of epilepsy and neurocognitive comobidities that arise in patients with early life seizures.

Introduction

In the search for animal models of seizures, treatment with convulsant compounds provides models of differing utility. Both acute and chronic models of seizures have a place in epilepsy research. Where the aim is primarily pharmacological, acutely generated seizures provide a convenient method for the assessment of anticonvulsant activity. In contrast, where the aim is to investigate basic mechanisms that may underlie seizures, the model should mimic epilepsy as much as possible – showing, for example, persistent, progressive seizures and appropriate histological changes. Since the 1970s, kainic acid has been known to produce acute seizure activity that was readily explained by dramatic neuronal depolarization caused by potent activation of glutamate receptors.

Administration of kainate in vivo, either intracerebroventricular (i.c.v.) or intraperitoneal (i.p.), results in seizures and hyperexcitability long after the kainate itself would have dissipated from the affected areas. The seizure induction in the kainate model is also accompanied by hippocampal neuronal loss and glial proliferation as observed in temporal lobe epilepsy. Thus, by displaying appropriate pathology, the model went beyond mere pharmacological mimicry of seizures. These observations served to promote i.c.v. kainate treatment as a model for temporal lobe epileptiform activity.

This early use of kainate tacitly recognized that there would be long-lasting consequences, although at that time there was no clear idea how these could occur. Major progress in defining some ideas and new hypotheses that could be tested resulted from advances in the understanding of glutamate receptor subtypes and the roles played by different subunits. We now realize, for example, that early use of kainate may not have discriminated between AMPA and kainate subtypes of glutamate receptors. Furthermore, the demonstration of metabotropic actions of glutamate receptors has now provided a plausible mechanism for seizure activity, which outlasts the presence of transmitter.

Background

Introduction

In the search for animal models of seizures, treatment with convulsant compounds provides models of differing utility. Both acute and chronic models of seizures have a place in epilepsy research. Where the aim is primarily pharmacological, acutely generated seizures provide a convenient method for the assessment of anticonvulsant activity. In contrast, where the aim is to investigate basic mechanisms that may underlie seizures, the model should mimic epilepsy as much as possible – showing, for example, persistent, progressive seizures and appropriate histological changes. Since the 1970s, kainic acid has been known to produce acute seizure activity that was readily explained by dramatic neuronal depolarization caused by potent activation of glutamate receptors.

Administration of kainate in vivo, either intracerebroventricular (i.c.v.) or intraperitoneal (i.p.), results in seizures and hyperexcitability long after the kainate itself would have dissipated from the affected areas. The seizure induction in the kainate model is also accompanied by hippocampal neuronal loss and glial proliferation as observed in temporal lobe epilepsy. Thus, by displaying appropriate pathology, the model went beyond mere pharmacological mimicry of seizures. These observations served to promote i.c.v. kainate treatment as a model for temporal lobe epileptiform activity.

This early use of kainate tacitly recognized that there would be long-lasting consequences, although at that time there was no clear idea how these could occur. Major progress in defining some ideas and new hypotheses that could be tested resulted from advances in the understanding of glutamate receptor subtypes and the roles played by different subunits. We now realize, for example, that early use of kainate may not have discriminated between AMPA and kainate subtypes of glutamate receptors. Furthermore, the demonstration of metabotropic actions of glutamate receptors has now provided a plausible mechanism for seizure activity, which outlasts the presence of transmitter.

Background

Through the 1990s, the cloning and characterization of glutamate receptor subunits led to a now conventional

view of glutamate receptors. We now think of three types of tetrameric ionotropic receptors (AMPA receptors, NMDA receptors, and kainate receptors) as well as a 7-transmembrane domain, G protein-coupled metabotropic glutamate receptor. In tandem with these developments, the use of pharmacological tools that distinguished between the receptor categories helped investigators to build a picture of where and how these receptors contribute to neurotransmission.

The tetrameric kainate receptor (KAR) can comprise five different subunits (GluR5, GluR6, GluR7, KA1, and KA2). This diversity of subunit composition obviously allows for functional differences, which may also be correlated with the regional or cellular expression of the KAR. This point is illustrated by the research on postsynaptic and presynaptic actions of KARs.

KAR genes are common throughout the brain, but good evidence for their contribution to synaptic transmission was elusive until the advent of ligands that distinguished between the various glutamate receptors. The glutamatergic epsc was first shown to contain a kainate receptor component in pyramidal cells of the hippocampal CA3 region; synaptic activation of KARs has now been described for several synapses throughout the brain and spinal cord. In most cells, the KAR synaptic current has a peak amplitude that is small compared with that of the rest of the epsc, and has a slower time course.

In addition to their anticipated function in generating the epsc, KARs have also been shown to depress the release of both inhibitory and excitatory transmitters. Depression of glutamate release is thought to be caused by presynaptic KARs that decrease stimulus-evoked calcium influx. Depression of GABA release is caused by a presynaptic GluR5-containing KAR that is linked to G proteins and that requires PKC. It was this action on inhibitory synapses that first showed that kainate receptors on interneurons had a metabotropic function, usefully described by Lerma as 'noncanonical' signaling. The evolution in our understanding of KAR signaling is charted in a number of reviews, which are included in the Further Reading section.

Following the elucidation of ionotropic glutamate receptor subtypes and their respective functions in synaptic physiology, there were a few outstanding paradoxes where KARs failed to contribute to synaptic responses. For example, in CA1 pyramidal cells KARs cause robust inward currents, which are lacking in GluR6-deficient mice, yet these active receptors make no contribution to excitatory synaptic responses. This demonstration of a KAR whose main ionotropic action was unused, and the potential for its mediating metabotropic effects, provided the stimulus for our work on the role of KARs and intrinsic excitability.

One of the most prominent postsynaptic targets of metabotropic transmitter action in the hippocampus is the slow afterhyperpolarization (sAHP) of CA1 and CA3 pyramidal cells. This calcium-dependent potassium current is activated according to the number and frequency of action potentials within a burst, and provides a negative feedback on excitability. In this review, we use the acronym sAHP to refer either to the voltage recording or to the underlying current. The large variety of transmitters (and their second messengers) that inhibit the sAHP includes noradrenaline via cAMP/protein kinase A and muscarinic actions of acetylcholine via Ca^{2+}-calmodulin-dependent protein kinase II. Protein kinase C activation also represents a potent pathway for sAHP inhibition; although initially PKC was presumed to be the second messenger for acetylcholine, this notion had been discredited and the transmitter/receptor for this PKC action is unclear.

We tested whether high-affinity KAR sites might provide a postsynaptic metabotropic function in CA1 pyramidal cells. The likely target of the metabotropic action was postulated to be the slow AHP. This current is susceptible to modulation by a wide range of transmitters that increase excitability (as described earlier) and had been known, years before, to be attenuated in kainate epilepsy models. Here, we describe some key experiments that tested the hypothesis and provided a basis for understanding the transduction mechanism.

Methods

The work described in this article was performed on the slice preparation of a rat hippocampus maintained in vitro. Single cell electrophysiological recordings were used as the functional readout for investigations into kainate receptor actions in hippocampal CA1 pyramidal cells. Well-defined synaptic pathways within the slice are preserved and can be stimulated to release endogenous glutamate. The hippocampal slice is additionally accessible to pharmacological interventions at either the extracellular or the intracellular level. In the latter case, compounds can be introduced into the cell via whole cell recording pipettes, and assessed for their actions in modulating second messenger pathways.

Recent Results

An important first step was to distinguish between metabotropic and ionotropic actions of kainate. **Figure 1(a)** shows that application of 200 nM kainate inhibited the slow AHP by 30–40%. This inhibition had an IC_{50} of ~15 nM and a plateau of 100 nM; these values are comparable to the reported binding affinities of the KAR. However, at these concentrations kainate does not generate inward currents in CA1 pyramidal cells; that is, no detectable ionotropic response is generated.

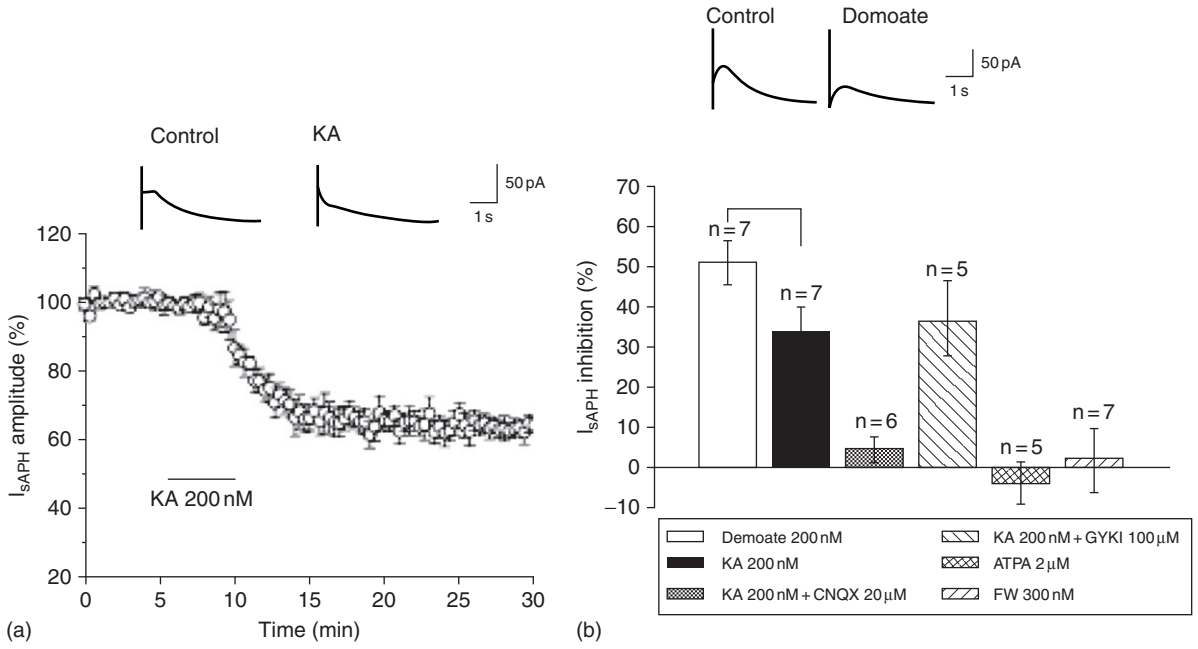

Figure 1 Inhibition of the sAHP current is mediated by kainate receptors. (a) Time course of sAHP inhibition ($n = 7$). Traces show the sAHP current before and after application of 200-nM kainate. (b) Traces show the effect of 200-nM domoate on the sAHP current. The histogram shows average percentage inhibition of sAHP current (mean ± SEM). Domoate and kainate both inhibit the sAHP current; this is blocked by the mixed GluR5/GluR6 antagonist CNQX. The action is not blocked by a GluR5 antagonist (GYKI52466). The GluR5-preferring agonist ATPA and the AMPA receptor agonist fluorowillardine (FW) had no inhibitory effect on the sAHP current.

Following this initial finding, we carried out a series of experiments to test whether exogenous kainate was acting directly on CA1 cells, and then to define the receptor type that might be involved. Significantly, the KAR ligand, domoate – which is more potent as a KAR agonist than kainate itself – caused greater inhibition of the sAHP. This result lent credence to the idea that a KAR was involved in this effect. **Figure 1(b)** shows the activity of different AMPA and KAR ligands on the inhibition of the sAHP. The inhibitory action of kainate on the sAHP was neither blocked by GluR5-preferrring antagonists (GYKI) nor mimicked by GluR5-preferring agonists (ATPA). This pharmacology distinguishes the KAR composition on the CA1 pyramidal cell from that found on interneurons, where GluR5 is a component subunit. A potent AMPA receptor agonist was without effect of the sAHP, even though the nonselective AMPA-kainate receptor antagonist CNQX was an effective blocker of kainate action. These data were supported by later work in other laboratories, which showed that metabotropic regulation of the sAHP by kainate was absent in GluR6-deficient mice and persisted in GluR5 deficiency. In summary, both pharmacological and genetic manipulations suggest that kainate receptors containing GluR6 subunits are essential for modulation of the sAHP by KARs.

It is clear then that kainate application can alter the membrane properties of hippocampal pyramidal cells. A more valuable interpretation can be placed on this information if we know that these KARs can be engaged by synaptically released glutamate. Glutamate is released by the vast majority of the excitatory afferents onto CA1 pyramidal cells. To test if this endogenous transmitter could generate metabotropic activity of KARs, synaptic stimulation was performed in the presence of a cocktail of blockers, which excluded the following from possible contributions to an effect: AMPA receptors, NMDA receptors, $GABA_A$ and $GABA_B$ receptors, metabotropic glutamate receptors, and muscarinic, opioid, and cannabinoid receptors.

Under these conditions, the synaptic current in response to afferent fiber stimulation is abolished and no further ionotropic response is observed even after a short tetanus (**Figure 2(a)**). The sAHP was then subjected to a control recording period of 10 min, after which the glutamate released by the short stimulus train was sufficient to cause inhibition of the sAHP, as illustrated by the pooled data from eight cells in **Figure 2(b)**. This action was blocked by CNQX and so was likely to result from synaptically released glutamate acting on KARs left operational by the blocking cocktail. Following the synaptic release of glutamate, the time course of inhibition of the sAHP was similar to that observed with bath-applied kainate. Since we can safely assume that synaptically released glutamate is taken up quite rapidly in comparison with washout of bath-applied kainate, we postulated that the prolonged time course of the inhibition may reflect the transduction mechanism.

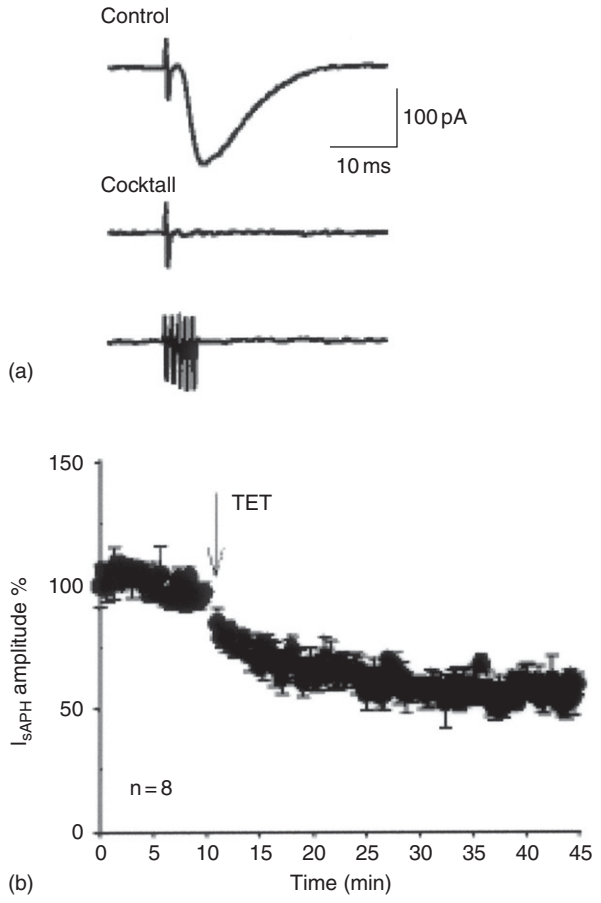

Figure 2 Synaptically released glutamate inhibits the sAHP current. (a) An epsc evoked by stimulation of the Schaffer/commissural afferents to CA1 is blocked by an antagonist mixture (see text for details). No further synaptic response was evoked by a short train of five stimuli. (b) Time course of inhibition of the sAHP current ($n = 8$) following the train of five stimuli to evoke glutamate release. Reproduced from Melyan *et al*. (2004) *Journal of Neuroscience* 24: 4530–4534, with permission from the Society for Neuroscience.

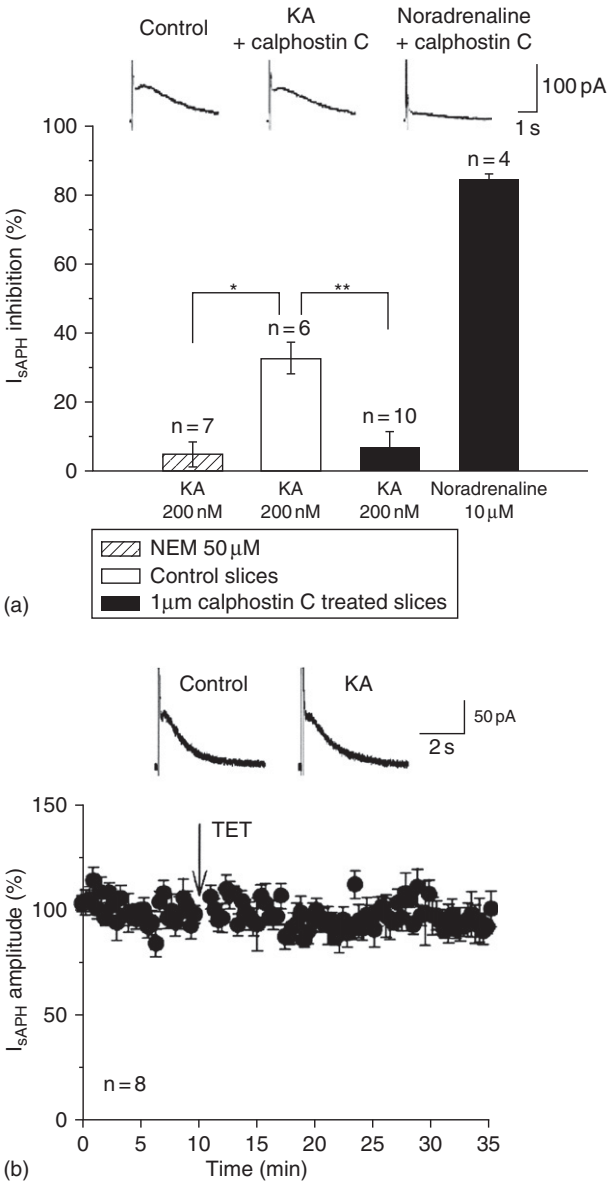

Figure 3 Metabotropic action of kainate receptors on the sAHP current. (a) Sample traces showing that calphostin treatment prevents the action of kainate (KA) while sparing noradrenaline inhibition of sAHP current. The first three bars in the histogram show that inhibition of sAHP current by 200-nM kainate is blocked by the G protein inhibitor NEM or the PKC inhibitor calphostin C. The final bar shows that inhibition by noradrenaline is intact after block of PKC. (b) Time course of sAHP current after tetanic stimulation to release glutamate in calphostin C-treated hippocampal slices. PKC is required for the action of both kainate and synaptically released glutamate. Reproduced from Melyan *et al*. (2004) *Journal of Neuroscience* 24: 4530–4534, with permission from the Society for Neuroscience.

It is axiomatic that a metabotropic receptor action requires a G protein, which acts to couple the receptor with downstream elements of the transduction mechanism. There is no working hypothesis to account for this G protein coupling for a classical ionotropic receptor, and to date it remains somewhat a puzzle – although pharmacological approaches unequivocally point to involvement of G proteins. First, we showed that inhibition of the sAHP by kainate was prevented by NEM (**Figure 3(a)**), which is a known blocker of pertussis toxin-sensitive G proteins. Since NEM is not a very specific inhibitor; we performed follow-up experiments using intracellular exposure to pertussis toxin itself or the $G\alpha_{i/o}$ blocker, NF023. These compounds preferentially depressed kainate action, but β-adrenergic inhibition of the sAHP was unaffected (a control). Thus, three pharmacologically distinct blockers point to the involvement of $G\alpha_{i/o}$ in the metabotropic action of KARs.

Protein kinase C has long been known to inhibit the sAHP. When first observed, this effect was assumed to be linked with muscarinic receptor action. As this and other receptors were invalidated as triggers, PKC-dependent inhibition of the sAHP started to look like an orphan

mechanism. However, in 1998 Rodriguez-Moreno and Lerma reported a role for PKC and presynaptic KARs. This report prompted us to perform similar tests, which demonstrated that inhibition of PKC (using calphostin C) blocked the action of kainate to inhibit sAHP (**Figure 3(a)**). In contrast, the inhibitory action of noradrenaline (a cAMP-dependent mechanism) applied later in the same experiment remained unaffected. Corresponding to these observations, calphostin C also abolished the action of synaptically released glutamate on the sAHP (**Figure 3(b)**).

One general limitation of antagonist experiments is that they may simply demonstrate a constitutive requirement rather than revealing a step in a critical pathway. To provide a fuller picture of the role of PKC, we tested specifically whether PKC activation alone could inhibit the sAHP. Both indolactam V and OAG activate PKC directly, and both caused inhibition of the sAHP (**Figure 4(a)** and **4(b)**), which corroborated earlier data using phorbol esters.

We also noted interesting quantitative differences in their action. The action of OAG was partial and reversible (**Figure 4(b)**); these properties are possibly because OAG is a synthetic analog of the natural ligand (DAG) and is subject to metabolic breakdown. In contrast, indolactamV is a powerful but unnatural activator; accordingly, inhibition ($IC_{50} \sim 110$ nM) was complete at 1 μM. The inactive analog of indolactam was without effect.

Up to this point, these data demonstrated that both kainate and synaptically released glutamate could act on -GluR6-containing KARs in CA1 pyramidal cells to trigger a PKC-mediated inhibition of sAHP. In the study of PKC action, we had been using noradrenergic inhibition of the sAHP as a comparator, to contrast with the transduction mechanism involved in the action of kainate and act as a control. To complete the logic of assessing the presumed independence of the two transduction pathways, we performed the reverse experiment – that is, blocking the protein kinase involved in noradrenergic action (PKA) while examining kainate action. The result overturned our expectations and we were instead surprised to discover that PKA was required for kainate inhibition of the sAHP. Two distinct PKA inhibitors (Rp-cAMPs and H89) prevented the action of kainate; the adenylyl cyclase inhibitor DDA showed that there was also a corresponding requirement for cAMP production. In an attempt to impose an order on these observations, we performed experiments to determine the position of PKA and PKC in the signaling pathway. The action of PKC on the sAHP was unaffected by inhibition of PKA, which led to the proposal that PKC is downstream of PKA.

Despite these new observations about the KAR transduction mechanism, it was still difficult to account for the slow recovery from kainate action. Did this slow recovery represent a unique property of KARs or an unexplored property of the transduction pathway? In CA1 cells, both PKC and β-adrenergic receptors, acting

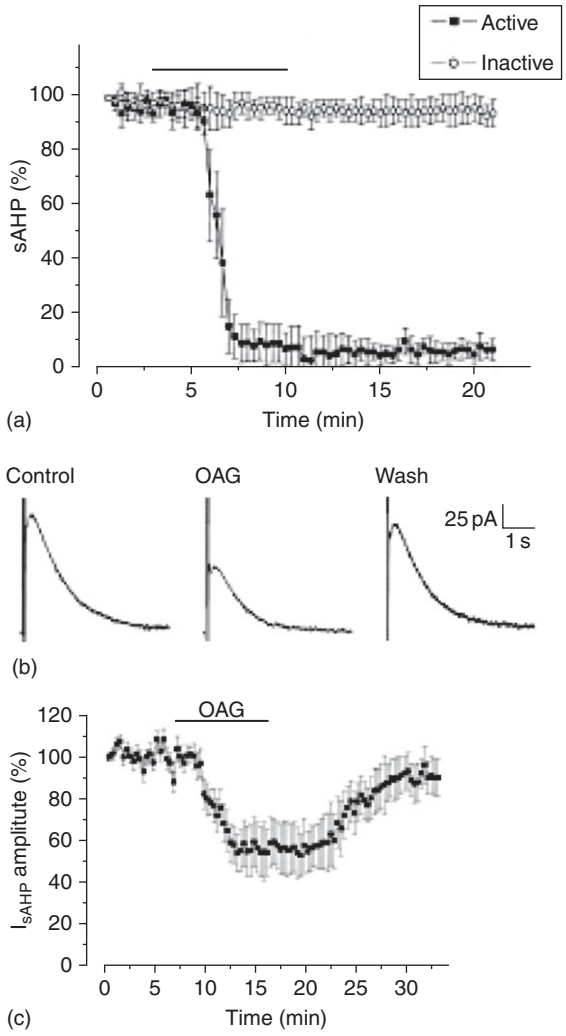

Figure 4 PKC activity is sufficient to inhibit the sAHP current. (a) Time course of the sAHP current in response to extracellular application of active or inactive forms of the PKC activator indolactam V (1 μM, $n = 8$). (b) Extracellular application of the PKC activator diacylglycerol analog OAG (50 μM, $n = 5$) causes reversible inhibition of the sAHP current.

via PKA, are able to engage the MAP kinase cascade. This effector mechanism had not been tested on the sAHP, but had the potential to account for long-lasting actions of transmitters since MAP kinases are known to be involved in late stage long-term potentiation. This action is not, however, inevitable because activation of MAP kinases by β-adrenergic receptors is a product of time and transmitter concentration.

Normally, brief exposure to isoprenaline causes profound inhibition of the sAHP, which recovers fully. Given that β-adrenergic receptor coupling to MAP kinase depends on the duration of receptor activation, we tested extended isoprenaline exposure. The result was a prolonged inhibition of the kind seen with KARs. As a consequence we were encouraged to test the involvement of MAP kinase in kainate inhibition of sAHP.

MAP kinase activity was tested initially with an in vitro assay for phosphorylated MAP kinase. This testing revealed that tonic MAP kinase activity exists in the hippocampus under the conditions of our experiments, and that this MAPK kinase activity is enhanced by 15-min exposure to 200-nM kainate; recovery back to a stable control level occurs within 30 min. The effect of kainate is abolished by the overall loss of phosphorylated MAP kinase in the presence of the MEK inhibitor U0126 (**Figure 5(a)**).

The ability of bath-applied kainate to inhibit the sAHP was blocked either by U0126 or by a structurally distinct inhibitor, PD098059. These data illustrate that the MAP kinase cascade contributes to the metabotropic response of GluR6-containing KARs in the hippocampus. To assess further the physiological readout of the MAP kinase activity observed in the in vitro assay, we measured (in two separate groups of experiments) the sAHP during up- or downregulation of MAP kinase. **Figure 5(b)** illustrates that the slow AHP increases during extracellular application of the MEK inhibitor U0126; conversely, when activated MAP kinase is included within the recording pipette to provide access to the cytoplasm, the slow AHP is suppressed (**Figure 5(c)**). These results provide a demonstration of a bidirectional mechanism in which MAP kinase activity is 'read out' as changes in electrical membrane properties and neuronal excitability.

Future Goals

There is an important missing link in the presumptive metabotropic aspect of KAR function: namely, that there is no obvious molecular mechanism to explain how the glutamate receptor subunits that comprise KARs might allow for G protein interaction. A proper accounting for the observations with G protein inhibitors will be an important test of the metabotropic hypothesis of KAR function.

The finding of a requirement for the MAP kinase cascade represents the most recent part of our work and so raises the most unanswered questions. Obviously, we need to know what happens next – does MAP kinase activation by KARs lead to regulation of gene expression, as proposed in synaptic plasticity? A more general, but important, question is to determine if MAP kinase represents a common hub through which many transmitters act to inhibit the slow AHP. This unifying notion would help to explain why many receptors seem able to target this particular current.

Studies of β-noradrenergic receptors suggest that duration of receptor occupancy can be an important determinant of downstream events – in particular, activation of second messengers that do not become involved when there are more transient changes in transmitter. This characteristic may be an adaptive feature in the case of long-term potentiation. In other circumstances, prolonged exposure to transmitter may be maladaptive. For example, what are the long-term consequences when glutamate receptors are exposed to prolonged glutamate release during seizure activity? The metabotropic action of KARs

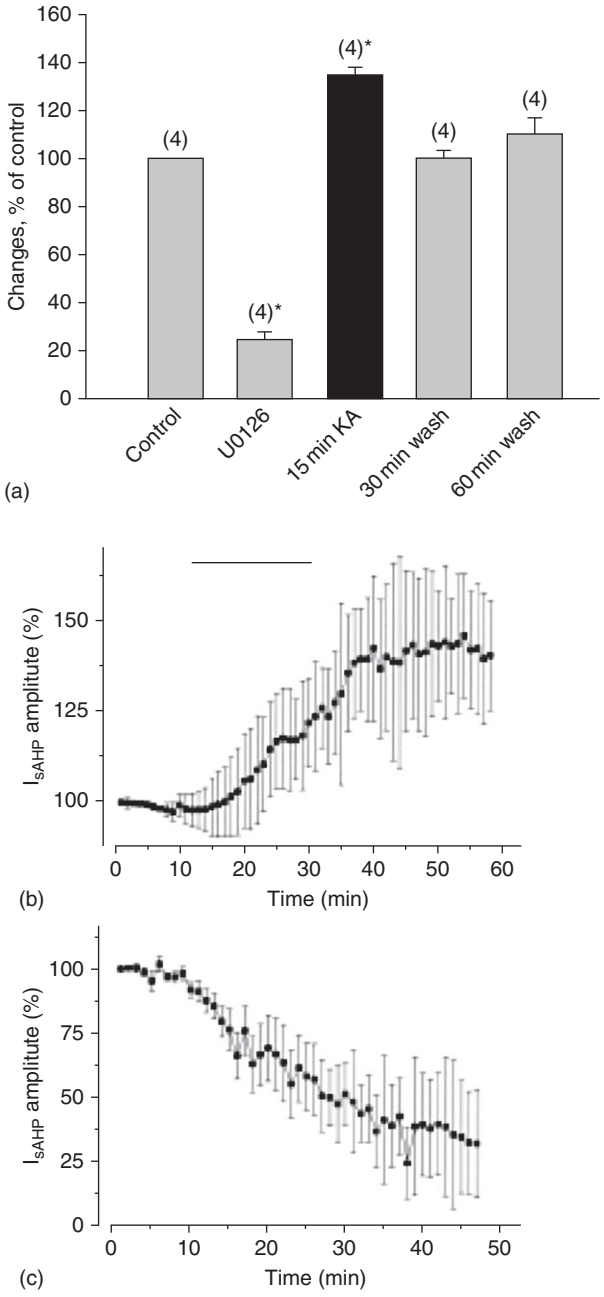

Figure 5 The MAP kinase signaling pathway is involved in suppression of the sAHP current by kainate. (a) Fluorescence intensity measurements of a phosphorylated MAP kinase assay. Kainate enhances the phosphorylated MAP kinase signal; this effect was not observed in the presence of U0126, which greatly reduces levels of phosphorylated MAP kinase. Bars represent mean ± SEM from four experiments (b) Time course of the effect of application of U0126 (bar, 10 μM) on amplitude of the sAHP current ($n = 4$). (c) Effect of intracellular dialysis with activated MAPK on the amplitude of the sAHP current.

would predict a persistent loss of the slow AHP – a phenomenon that has been described after i.c.v. kainate. Even in normal tissue, this loss would enhance excitability because the cell would be more responsive to all excitatory input. Additionally, since the slow AHP functions partly to curtail bursting, loss of this negative feedback could lead to an increased frequency and duration of the paroxysmal depolarization shifts seen in epileptiform activity. Thus, activation of KARs during seizure activity could have long-term consequences for neuronal electrical properties by sensitizing and exacerbating the responses to epileptogenic stimuli.

Persistent Changes in Network Excitability Induced by Group I Metabotropic Glutamate Receptor Activation : Impact on Seizure Expression and Implications for Epileptogenesis

L R Merlin, SUNY Downstate Medical Center, Brooklyn, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptogenesis is the process in which normal brain develops a persistent propensity for the spontaneous production of seizure discharges. In adults, this process can take place following cortical strokes, head trauma, or an episode of status epilepticus; a latent period of months to years is typical before the chronic recurrent seizures are expressed. The changes that initiate this transformation are numerous: in many cases, there is neuronal cell death and rewiring of neural circuits via aberrant axonal sprouting. Gliosis and hemosiderin deposits may also be present and contribute to the process. Temporal lobe, especially hippocampus, seems particularly vulnerable to the epileptogenic process, and hippocampal sclerosis or other evidence of gross structural damage is a common finding in those who develop epilepsy following head trauma. However, there are patients who sustain relatively minor head trauma, with no obvious lesion on imaging studies, who go on to develop posttraumatic epilepsy. The cascade of events that finally culminates in epilepsy remains unclear. One common initiating factor is unequivocal: in all patients, there is massive glutamate release accompanying the inciting event. The primary focus of the studies undertaken in our laboratory is to understand the potentially-epileptogenic long-term sequelae of excessive glutamatergic activation, in hopes of finding ways to interfere with the epileptogenic process.

Background

Glutamate, the major excitatory neurotransmitter of the brain, acts on two classes of receptors: ionotropic (NMDA

would predict a persistent loss of the slow AHP – a phenomenon that has been described after i.c.v. kainate. Even in normal tissue, this loss would enhance excitability because the cell would be more responsive to all excitatory input. Additionally, since the slow AHP functions partly to curtail bursting, loss of this negative feedback could lead to an increased frequency and duration of the paroxysmal depolarization shifts seen in epileptiform activity. Thus, activation of KARs during seizure activity could have long-term consequences for neuronal electrical properties by sensitizing and exacerbating the responses to epileptogenic stimuli.

Persistent Changes in Network Excitability Induced by Group I Metabotropic Glutamate Receptor Activation : Impact on Seizure Expression and Implications for Epileptogenesis

Introduction

Epileptogenesis is the process in which normal brain develops a persistent propensity for the spontaneous production of seizure discharges. In adults, this process can take place following cortical strokes, head trauma, or an episode of status epilepticus; a latent period of months to years is typical before the chronic recurrent seizures are expressed. The changes that initiate this transformation are numerous: in many cases, there is neuronal cell death and rewiring of neural circuits via aberrant axonal sprouting. Gliosis and hemosiderin deposits may also be present and contribute to the process. Temporal lobe, especially hippocampus, seems particularly vulnerable to the epileptogenic process, and hippocampal sclerosis or other evidence of gross structural damage is a common finding in those who develop epilepsy following head trauma. However, there are patients who sustain relatively minor head trauma, with no obvious lesion on imaging studies, who go on to develop posttraumatic epilepsy. The cascade of events that finally culminates in epilepsy remains unclear. One common initiating factor is unequivocal: in all patients, there is massive glutamate release accompanying the inciting event. The primary focus of the studies undertaken in our laboratory is to understand the potentially-epileptogenic long-term sequelae of excessive glutamatergic activation, in hopes of finding ways to interfere with the epileptogenic process.

Background

Glutamate, the major excitatory neurotransmitter of the brain, acts on two classes of receptors: ionotropic (NMDA

and AMPA/kainate) and metabotropic. The metabotropic receptors are G-protein-coupled and activate various second messenger systems, resulting in both short-term and long-term changes in cellular excitability. Eight subtypes of metabotropic glutamate receptors (mGluRs) have been identified and classified into three subgroups. Group I mGluRs are primarily postsynaptically localized and have mostly excitatory effects, while group II and group III mGluRs are predominantly presynaptic and suppress transmitter release. A controversial ninth mGluR subtype appears to be linked to phospholipase D (PLD) activation and does not belong to any of the three subgroups; this receptor can be activated by cysteine sulfinic acid. Work in my laboratory has focused on the group I and PLD-coupled mGluRs and their roles in the expression of synchronized activity in the hippocampal network.

The Group I mGluRs

The group I mGluRs (comprised of mGluR1 and mGluR5) are located in numerous regions throughout the brain, and are especially prominent in the CA3 region of the hippocampus, where they are expressed in pyramidal cells, interneurons, and glia. These receptors tend to be perisynaptically localized, suggesting that they are recruited primarily during enhanced synaptic activity, with the increased glutamate release resulting in spillover into perisynaptic zones. Such enhanced activity might occur during normal physiological functions such as learning and memory, as well as pathological events such as strokes, seizures, and head trauma. The group I mGluR subgroup consists of the only phosphoinositide-linked glutamate receptors identified to date. They are coupled to the activation of phospholipase C (specifically, PLCβ1), which catalyzes the production of diacylglycerol (resulting in protein kinase C (PKC) activation) and inositol triphosphate (resulting in intracellular calcium mobilization). The cascade of events initiated by either of these pathways could potentially contribute to the induction and/or maintenance of long-lasting excitatory effects mediated by group I mGluRs.

Effects of Group I mGluR Activation on Cellular Excitability

Activation of group I mGluRs elicits depolarization of hippocampal neurons through several mechanisms, including suppression of a variety of intrinsic potassium conductances, activation of a nonspecific cationic conductance, activation of the sodium-calcium exchange current, and induction of a novel voltage-gated inward current. Most of these effects are seen within milliseconds of receptor activation and are not necessarily persistent. Hence, these cellular effects would be expected to contribute to the early excitatory synaptic and network effects of group I mGluR activation.

Long-Lasting Effects of Group I mGluR Activation on Synaptic Efficacy and Network Excitability

At the synaptic level, the group I mGluRs have been shown to participate in hippocampal long-term potentiation (LTP) and long-term depression (LTD), and therefore activation of these receptors is likely to be important for cognition. Increased glutamate release has also been a reported effect of group I mGluR activation. Although increased glutamate release could be secondary to depolarization-induced increases in cell firing, it may also result from direct activation of presynaptic or glial mGluRs. Either way, increases in glutamate release could increase activation of perisynaptic mGluRs, thereby further increasing the mGluR response. At both the synaptic and network levels, one would expect this domino effect to assist in producing the types of plasticity necessary for learning and memory consolidation; however, in excess, one might expect such hyperexcitation at synapses and neuronal networks to have damaging effects. Consistent with this assumption, in vivo studies reveal that group I mGluR activation not only elicits seizures but can also result in excitotoxic neuronal injury.

It should then be not surprising that baseline expression of group I mGluRs has been correlated with differences in seizure susceptibility in rodents. Additional studies in knockout mice suggest that seizures expressed in patients with Fragile X syndrome may be the result of hyperexcitation of group I mGluRs. Indeed, group I mGluR antagonists have been demonstrated to have anticonvulsant efficacy in several models.

Our studies and findings (among the first to explore this area of interest) have been consistent with those of others: group I mGluR activation does indeed enhance the expression of seizure discharges in the hippocampal slice preparation, and group I mGluR antagonists can suppress the expression of these discharges. What struck us, however, as the most significant effect of group I mGluR activation in our in vitro experiments was that the resultant seizure discharges do not disappear upon removal of the agonist, indicating that a long-lasting modification of network excitability is induced by group I mGluR agonist exposure. This effect is different from those seen in other in vitro models in which pharmacologic manipulations are employed to elicit acute seizure discharges. Given these observations, we have hypothesized that these receptors may be involved in the initiation of epileptogenesis. Our laboratory has consequently embarked on studies to elucidate the underlying pathways involved in greater detail.

Methods

The Guinea Pig Hippocampal Slice

Our laboratory uses the guinea pig acute hippocampal slice preparation. Guinea pigs are used because, unlike mice and rats, their brains mature at a much earlier time point after birth; in fact, they are born at a later stage of development than humans, whereas mice and rats are born relatively premature. Hence, our studies are believed to be relevant to the adult human condition.

We have used 400 μm acutely-prepared transverse hippocampal slices for our experiments. The acute hippocampal slice preparation offers many advantages over other experimental systems. Unlike in vivo studies, one can precisely control the environment of the slice (temperature, pH, oxygenation, delivery of metabolites). Furthermore, carefully titrated pharmacological manipulations are easily carried out and prolonged intracellular recordings can be obtained. In addition, in contrast to the dissociated cell preparation, much of the normal circuitry of the hippocampus is retained in the slice preparation by virtue of the lamellar organization of this particular brain region, allowing for the expression of network-generated activity.

Electrophysiological and Pharmacological Approaches

Electrophysiological approaches used in our lab include intracellular recordings from pyramidal cells and concurrent extracellular field recordings to document synchronized activity; dual intracellular recordings may be performed as well. The interface chamber is used to maintain the acutely-prepared slice in a stable environment, maintaining the health of the slice for the duration of the experiment (typically 3–6 h of recording). In such a system, activity recorded may be evoked with a stimulating electrode placed in a pathway afferent to the recorded cell; alternatively, spontaneous activity may be observed at rest and in response to pharmacological manipulations. Pharmacologically-evoked activity may be elicited by bath perfusion of the agent or by brief focal application. Recordings are amplified and digitized, then stored for later analysis.

The Picrotoxin Model of Interictal Activity

Numerous studies have explored mechanisms of synchronization in the hippocampal slice, and these studies have revealed a critical role for AMPA and NMDA receptors in the generation of the paroxysmal depolarization shift, the intracellular correlate of the interictal spike. Picrotoxin is a commonly used agent for the generation of interictal-like activity in the hippocampal slice: via the block of $GABA_A$ receptor-mediated inhibition, spontaneous recurrent synchronized bursts are generated. Each of these bursts is typically less than half a second in duration (see, for example, control bursts in **Figure 1**) and is mediated entirely by AMPA/kainate and NMDA activation (the ionotropic glutamate receptors). Additional blockade of $GABA_B$ receptors has little effect on the length of these bursts (**Figure 1(a)** left), indicating that complete block of all GABAergic inhibition in the acute guinea pig hippocampal slice is insufficient to elicit ictal-length discharges. We therefore begin all our experiments with picrotoxin, which serves as a useful gauge of network integrity and allows us to begin our manipulations with uniformly healthy slices (so that interslice variability is minimized). This baseline treatment also allows us to eliminate the GABA receptor or interneuron as a site of action of our mGluR agonist.

Recent Results

Epileptogenic Propensity Resulting from Selective Group I mGluR Activation

In hippocampal slices, we have observed that exposure to selective group I mGluR agonists such as (*S*)-3,5-dihydroxyphenylglycine (DHPG) or (*S*)-3-hydroxyphenylglycine (3HPG) results in the expression of long synchronized oscillatory discharges (each burst 1–8 s in duration; **Figure 1**). We consider these oscillatory discharges to be ictaform because: (1) they are synchronized, (2) they exceed 1 s in duration, suggesting that a clinical correlate (i.e., seizure) would occur if such a burst was experienced in vivo, and (3) the oscillations comprising the discharges gradually change in frequency and amplitude, which is typical of a seizure discharge. Hence, this finding suggests that group I mGluR activation can be a trigger for the interictal-to-ictal transition. These data are supported by results of in vivo experiments from other laboratories, which reveal that group I mGluR activation elicits seizures, and that seizures in numerous models can be suppressed with group I mGluR antagonists.

Unlike other in vitro models of pharmacologically-induced epileptiform activity, the ictaform discharges elicited by transient exposure to group I mGluR agonist persist following washout of the agonist (**Figure 2**). Additional experiments have supported the contention that this observation represents true evidence of network plasticity induced by the activation of the group I mGluRs. Should such plasticity be induced in vivo, it would likely predispose the subject to experience recurrent unprovoked seizures. We therefore refer to this finding as 'in vitro epileptogenesis.' True epileptogenesis, of course, would take longer to occur and would persist indefinitely; our system only allows us to follow the phenomenon for several hours. Nevertheless, we believe that this finding has relevance to the earliest inciting events that trigger the epileptogenic process, and left unchecked would likely result in full-blown epileptogenesis.

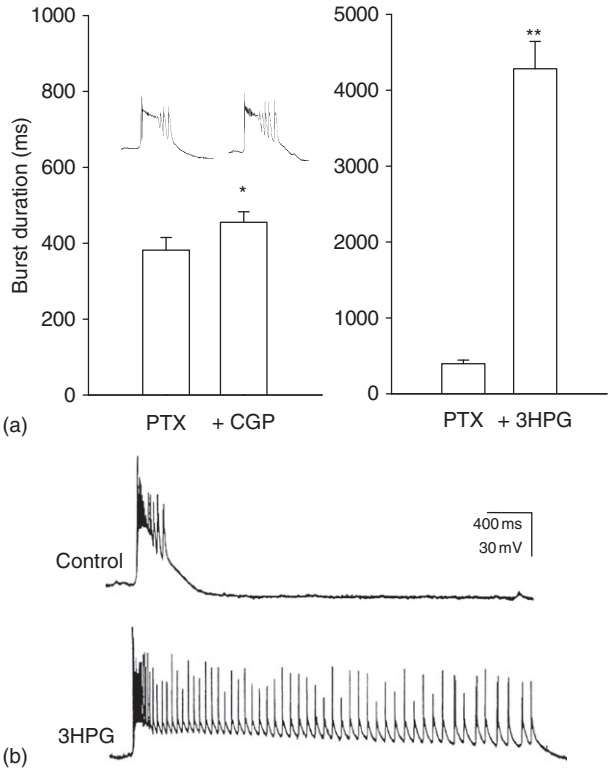

Figure 1 *Selective activation of group I mGluRs elicits interictal-to-ictal transition*. (a), *Left:* Summary data of effect of $GABA_B$ antagonist on length of picrotoxin-induced interictal bursts, revealing minimal lengthening, with bursts remaining below 540 ms in duration in all cases. Inset above graph displays bursts from one representative experiment before and after $GABA_B$ antagonist (adapted with permission from Huszár P and Merlin LR (2004) Contribution of $GABA_B$ receptor-mediated inhibition to the expression and termination of group I mGluR-induced ictaform bursts. *Epilepsy Research* 61: 161–165). (a), *Right:* Summary data of effect of selective group I mGluR agonist on PTX bursts (note difference in Y axis scale of the two bar graphs), with induced bursts ranging from 1–7 s in duration (adapted with permission from Merlin LR and Wong RKS (1997) Role of group I metabotropic glutamate receptors in the patterning of epileptiform activities in vitro. *Journal of Neurophysiology* 78: 539–544). *, $P < 0.05$; **, $P < 0.01$. (b): Representative recordings from a CA3 pyramidal cell in a guinea pig hippocampal slice. Initial interictal burst ('control') is a synchronized discharge expressed in the presence of picrotoxin, the $GABA_A$ receptor antagonist. After introduction of 3HPG, a selective group I mGluR agonist, synchronized bursts gradually lengthened, reaching ictal length (over 1 s duration) within 20–40 min (reproduced with permission from Merlin LR and Wong RKS (1997) Role of group I metabotropic glutamate receptors in the patterning of epileptiform activities in vitro. *Journal of Neurophysiology* 78: 539–544). PTX: picrotoxin, a $GABA_A$ antagonist; CGP: CGP35348, a $GABA_B$ antagonist; 3HPG: selective group I mGluR agonist.

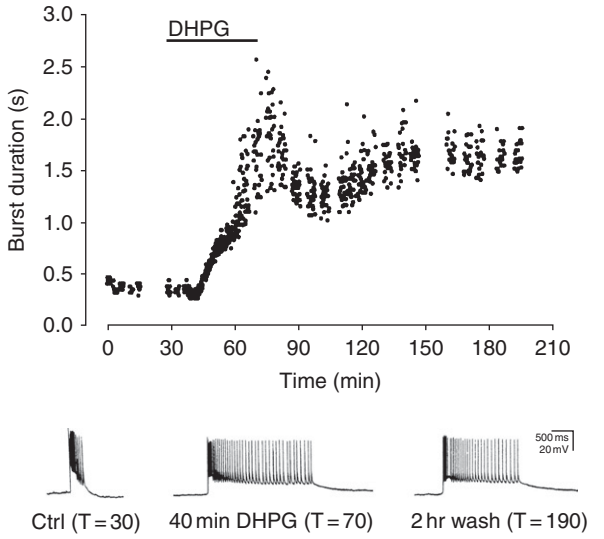

Figure 2 *Selective activation of group I mGluRs elicits persistent epileptiform activity*. Example of time course of change in burst length following 40 min exposure to DHPG, a selective group I mGluR agonist. Note that after removal of the agonist, ictal-length bursts continue to be expressed, suggesting initiation of epileptogenesis. Traces below graph are bursts recorded at times indicated on graph (reproduced with permission from Merlin LR (1999) Group I mGluR-mediated silent induction of long-lasting epileptiform discharges. *Journal of Neurophysiology* 82: 1078–1081).

Induction of In Vitro Epileptogenesis via Group I mGluR Activation: Key Features

The evaluation of the mechanisms for the network plasticity that underlie epileptogenesis is similar to the evaluation of synaptic plasticity mechanisms underlying LTP. One needs to tease apart the factors that are critical for induction (i.e., the initial trigger for the plasticity) vs. the factors that underlie the maintenance (i.e., the sustained expression of the enhanced activity). We have embarked on these studies; a summary of our findings to date is provided in **Table 1**. The agents that can suppress the expression of the seizures in the maintenance phase may be effective anticonvulsants for mGluR-induced seizures, but only the agents the can block induction are likely to have antiepileptogenic potential in patients whose epilepsy is induced by hyperstimulation of group I mGluRs.

Of the experimental findings on **Table 1**, the following are noteworthy: (1) the lack of involvement of NMDA receptor activation in the induction process, which is in marked contrast to many types of LTP; (2) the requirement of active protein synthesis for induction but not maintenance (the rapidity of the response suggesting no need for transcription, only translation); and (3) the ability of group I mGluR activation alone (in the absence of other glutamate receptor activation), and especially mGluR5 activation, to induce the persistent prolonged bursts. These findings suggest that AEDs that block AMPA or NMDA receptor-mediated excitation, while potentially effective at suppressing the expression of seizure discharges, will not suffice to prevent progression of the subclinical

Table 1 Induction vs. sustained expression of group I mGluR-induced epileptogenesis

Experimental protocol	*Effect on induction (i.e., blocks epileptogenesis?)*	*Effect on expression (i.e., suppresses seizures?)*
AMPA receptor blocker	Does not impede induction	–
NMDA receptor blocker	Does not impede induction	Does not suppress seizure expression or length of seizure discharges
Combined AMPA and NMDA receptor blockers	Does not impede induction	Blocks expression of both interictal and ictal-length synchronized discharges
mGluR1 antagonist	Does not impede induction	*Markedly reduces length of seizure discharges*
mGluR5 antagonist	*Blocks induction*	*Moderately reduces length of seizure discharges*
Protein synthesis inhibitors	*Blocks induction*	Does not suppress seizure expression or burst length
Activation of PLD-coupled mGluRs with CSA	*Blocks induction*	Does not suppress seizure expression or burst length
PKC inhibitor chelerythrine	Does not impede induction	Does not suppress seizure expression or burst length
$GABA_B$ receptor blocker	–	*Increases length of seizure discharges*

epileptogenic process potentially driven by group I mGluR activation.

Once this enhanced network excitability has been induced, the normal state cannot be restored; all we can do is reversibly suppress the expression of the seizure discharges. Hence the key to 'curing' the epilepsy is in prevention of epileptogenesis. To date, only two types of agents with potential clinical usefulness have been found effective in preventing mGluR-induced epileptogenesis in our model: an mGluR5-selective antagonist and cysteine sulfinic acid, an agonist of the putative (elusive) PLD-coupled mGluR. Although protein synthesis inhibitor is also effective, it is hard to envision a method by which to deliver such an agent without invoking excessive toxicities.

Maintenance of Group I mGluR-induced Epileptogenesis: What Underlies the Sustained Expression of Ictal Discharges?

One might expect NMDA receptor activation to be a participant in the expression of group I mGluR-induced prolonged bursts in light of the facts that (1) NMDA activation can indeed elicit burst prolongation in other systems, and (2) group I mGluR activation can enhance NMDA receptor-mediated responses. Surprisingly, blocking NMDA receptors had no impact on the length of the seizure discharges induced by group I mGluR activation. The only effective agent for reversibly shortening the persistent bursts is group I mGluR antagonist, suggesting that the transient activation of group I mGluRs persistently enhances the ability of these same receptors to participate in the ongoing expression of ictal discharges. This action could be the result of direct enhancement of receptor excitability or responsiveness to glutamate, increased number of receptors or insertion of receptors in the membrane, or their translocation to the synapse, increased anchoring protein (Homer), and/or reduced desensitization or constitutive receptor activation, to name a few possibilities. Once induced, neither protein synthesis inhibitors nor cysteine sulfinic acid can suppress the ongoing seizures, even though either agent is highly effective at blocking the epileptogenic process when present during attempted induction.

Further studies were performed to unravel the separate roles of mGluR1 vs. mGluR5 (the two members of group I) in the induction and expression of the group I mGluR-induced prolonged bursts. Although both receptor subtypes participate in the ongoing expression of persistent prolonged bursts, we revealed that mGluR1 antagonist is substantially more effective at suppressing the ongoing expression of the bursts, virtually restoring the bursts to interictal length; in contrast, while the mGluR5 antagonist could significantly shorten the bursts, they remained significantly longer than the initial picrotoxin-induced activity (**Figure 3**). These observations are in stark contrast to the mechanism of induction of the epileptogenesis, where mGluR1 antagonist alone was ineffective for the prevention of epileptogenesis mGluR5 antagonist could completely prevent the induction process.

Downstream Second Messengers: Interplay of PKC Isoforms in Induction vs. Suppression of In Vitro Epileptogenesis

The mGluR-mediated induction of long-lasting effects in the neuronal network is likely to involve the activation of various second messengers. Identification of the pathways involved could aid in the development of novel antiepileptogenic agents that target these pathways specifically. The PKC family is oftentimes involved in mGluR-mediated effects such as synaptic plasticity. Yet group I mGluR activation still elicits persistent ictaform discharges in the presence of chelerythrine, a relatively broad-spectrum

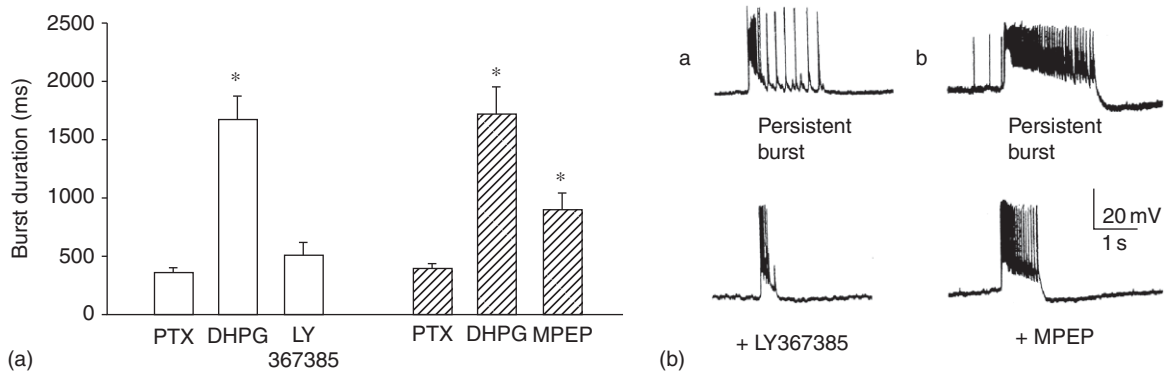

Figure 3 *Selective mGluR1 and mGluR5 antagonists significantly shorten ongoing DHPG-induced ictaform bursts*. (a): Summary data revealing effect of the group I mGluR agonist in inducing persistent burst prolongation, then comparing efficacy of mGluR1 antagonist (LY367385) vs. mGluR5 antagonist (MPEP) at suppression of the ongoing ictaform activity. The mGluR1 antagonist reversibly restores bursts to interictal length, while the mGluR5 antagonist, although having a significant suppressive effect of its own, is less effective and unable to prevent fully the expression of ictal-length bursts. (b): Recordings from CA3 pyramidal cells, revealing the persistent prolonged bursts before and after application of the mGluR1 (a on left) or mGluR5 (b on right) antagonist. Upper traces were recorded at 1 h washout of group I mGluR agonist, just before introduction of subtype-selective antagonist. Lower traces were after 20–30 min exposure to the antagonist. (reproduced with permission from Merlin LR (2002) Differential roles for mGluR1 and mGluR5 in the persistent prolongation of epileptiform bursts. *Journal of Neurophysiology* 87: 621–625).

PKC inhibitor, suggesting a lack of involvement of most PKC isoforms. In contrast, PKC activation via the PLD-linked mGluR seems to have an inhibitory effect on mGluR-induced epileptogenesis: cysteine sulfinic acid's suppressive effect on the induction process can be blocked with chelerythrine, revealing PKC dependence of the effect. Although these data suggest that PKC activation may be antiepileptogenic, preliminary data with phorbol esters contradict this hypothesis, as they alone, via activation of PKC, elicit prolonged ictaform discharges. These conflicting effects may turn out to be PKC isoform-specific, or depend on the microcellular compartment in which the PKC is activated.

Future Goals and Challenges

So where do we go from here? These findings provide core evidence that the group I mGluRs may be useful targets for anticonvulsant drugs as well as antiepileptogenic agents, but they may prove to be effective only in the subset of patients in which this pathway is involved. Therefore, one important problem to be addressed is identification of the patient population in which these data are relevant. There may be patients with genetic mutations that result in overexpression or hyperexcitability of the group I mGluR system, or its downstream partners such as Homer and assorted second messengers; one would expect such mutations to result in mGluR-driven seizures which would be responsive to group I mGluR antagonists or other relevant agents discussed herein. At present, we lump most epileptic patients on the basis of clinical seizure presentation and history, but we know little about the underlying physiological abnormalities in a given patient. Some patients may have hyperactive NMDA receptors; others may be in muscarinic overdrive; still others may have abnormalities of voltage-gated channels making the cells more excitable. In the foreseeable future we will undoubtedly develop the means to identify patients on the basis of physiological and/or genetic abnormality, and will then be able to select which AED is appropriate for which patient – on the basis of the patient's underlying mechanism instead of the hit-or-miss technique now in use by clinicians.

It is noteworthy that 30–40% of patients with epilepsy have not achieved control of their seizures, despite the large number of pharmaceutical agents in our armamentarium to date. Perhaps this situation suggests the models of epilepsy currently used for drug testing and development are not representative of all patients. Advances in genetic testing may allow us to determine whether these refractory patients share a common physiological mechanism underlying their seizures, one which is not currently targeted by the FDA-approved agents on the market. Among this group may be patients whose seizures are mediated by activation of the group I mGluRs. Our in vitro model of mGluR-induced epileptogenesis may serve as a novel system in which new categories of drugs can be evaluated.

Validating this model may involve in vivo studies. Examination of the role of the group I mGluRs in post-traumatic seizures and poststroke seizure would be of interest; the use of knockout mice in these studies may serve to clarify the importance of these receptors as well.

Of course, as our studies to date have been performed in guinea pigs, switching to mice is no small task, and knockout guinea pigs are not yet available.

Screening patients for mGluR or Homer mutations may not only be relevant to patients presenting with epilepsy (to allow for mechanism based drug selection) but may also serve to assist in the potential treatment of trauma patients with antiepileptogenic therapy. Studies need to be done to determine what makes individuals with seemingly equivalent brain injuries have different outcomes (e.g., with respect to posttraumatic or poststroke epilepsy). Perhaps patients have different inherent susceptibilities for the development of epilepsy, in some cases based on differences in their group I mGluR or PLD-coupled mGluR systems. We may someday be able to offer prophylactic antiepileptogenic therapies to patients on the basis of their individual susceptibilities.

Finally, group I mGluR activation itself need not automatically result in epilepsy. We have shown that activation of these receptors with nonselective, broad spectrum mGluR agonist will elicit similar-length seizure discharges, but will not induce a persistent epileptic state – these discharges promptly disappear upon washout of the broad-spectrum agonist. Therefore, further studies are needed to clarify the factors that determine whether ictogenic activity becomes epileptogenic, and clarify the mGluR-induced intracellular cascade involved in initiating epileptogenesis. It is remarkable that, unlike the persistent bursts induced by selective agonist, the nonpersistent long bursts elicited by nonselective mGluR agonist are completely unaffected by either PLD activation or $GABA_B$ antagonist. These data suggest that the generation mechanisms for mGluR-dependent persistent vs. nonpersistent seizure discharges may be significantly different. The mechanisms responsible for determining whether mGluR-induced epileptiform activity becomes persistent or remains nonpersistent have yet to be discovered, but the data suggest that it is inadequate for us to simply identify the group I mGluR subgroup as a target for antiepileptogenic treatments; we must pursue a deeper understanding of what determines whether or not the induced ictaform activity results in a persistent epileptic state. Identification of the PKC isoforms involved (via molecular/biochemical studies) in ictogenesis vs. epileptogenesis, and identification of the critical proteins underlying the induction process in this protein synthesis-dependent pathway, may help shed light on these matters. Such insight would provide hope that we may some day be able to offer help to patients at risk for developing epilepsy and prevent the epileptogenic process from proceeding, thereby preventing the development of epilepsy in that subset of patients in whom this pathway is the culprit.

Role of Kainate Receptors in Glutamatergic Synaptic Transmission: Implications for Acute and Chronic Seizure Generation

J Epsztein, V Crépel, and A Represa, INMED, INSERM U29, Université de la Méditerranée, Marseille, France

Introduction

Temporal lobe epilepsies (TLEs) are frequently observed in adults (30–40% of all forms of epilepsies) and are often refractory to pharmacological medication. Though many morpho-functional changes have been linked to this syndrome, the physiopathological mechanisms responsible for the epileptic condition require further elucidation. A large part of our present understanding of the physiopathology of TLE comes from studies using acute and chronic animal models. The first and most investigated model of TLE relies on systemic or intracerebral injections of a neurotoxin and neuroexcitant: kainic acid (KA). KA is an agonist of a subtype of ionotropic glutamatergic receptors (KA receptors (KARs)) the activation of which induces prolonged depolarization of hippocampal neurons, leading to epileptiform discharges in the hippocampus and associated limbic structures, as well as secondarily generalized limbic seizures (to which we shall refer as *acute seizures*). In addition to these ictogenic properties, KA injections are also epileptogenic. Injected animals that survive the initiating status epilepticus show, after a seizure-free latent period of several weeks, recurrent spontaneous seizures of hippocampal origin and became *chronically epileptic*. A considerable effort has been made to understand the epileptogenic effect of kainate injections. A current widely accepted hypothesis is that the epileptogenic basis is established as a consequence of multiple factors, involving neuronal cell death and reactive axonal rewiring, following kainate-induced status epilepticus. This reorganization further leads to quantitative and qualitative alterations in both the synaptic and intrinsic properties of surviving neurons, which result in an increased excitability.

More recently, the availability of new pharmacological tools together with progress in molecular biology allowed fast progress in the understanding of the physiological properties of kainate receptors. Notably, a role was recently proposed for kainate receptors in fast glutamatergic neurotransmission in the hippocampus, together with AMPA and NMDA receptors. This article will summarize the basic properties of kainate receptors and kainate receptors mediated synaptic transmission and to which extend they shed new lights on the ictogenic and epileptogenic actions of KA injections.

Background

Structure and Diversity of Kainate Receptors

The first autoradiographic studies using radioactive kainate [^{3}H]-KA revealed the presence of high-affinity KA binding sites in the brain. These observations suggested the existence of specific KARs that could be major players in the generation of acute epileptic seizures. In the early 1990s, KAR subunits were cloned and identified as members of the ionotropic glutamatergic receptor family (together with AMPA and NMDA receptors). As is the case for AMPA receptors, KARs are tetramers formed from four subunits. The cloned KAR subunits are termed GluR5, GluR6, GluR7, KA1, and KA2. GluR5–7 subunits have a low affinity for KA and can form functional homomeric receptors when expressed in heterologous systems; KA1 and KA2 have a higher affinity for KA and must be associated with GluR5–7 subunits to form functional receptors. Post-translational modifications, such as mRNA editing or alternative splicing, further increase the diversity of KARs subunits. Alternative splicing is seen mainly on the C-terminal domain of GluR5–7 subunits, and the results of this alternative splicing can modify KAR subunit trafficking to the plasma membrane and their interactions with intracellular partners. GluR5 and GluR6 mRNA can also be edited at a Q/R site in the second pore-forming membrane domain. Unedited subunits have a neutral glutamine at this site, while edited subunits have a positively-charged arginine. The fully edited subunits have a ring of positive charges in the pore of the channel that result in a lower Ca^{2+} permeability.

Physiological Role of Kainate Receptors in Glutamatergic Synaptic Transmission

For a long time, the lack of specific antagonists for KA (versus AMPA) receptors has precluded the study of their specific physiological role. Indeed, most molecules used to block AMPA (versus NMDA) receptors (such as CNQX) also blocked KARs. Recently, the development of a series of 2,3-benzodiazepines (such as GYKI 53655 and GYKI 52466), which are noncompetitive AMPAR-selective antagonists, has allowed the study of native KARs. The use of genetically engineered mice which lack specific KAR subunits further accelerated these

studies. While the role of AMPARs in glutamatergic synaptic transmission is well established, the role of KARs has emerged more recently, mainly from studies of the mossy fiber synapse between dentate granule cells and CA3 pyramidal cells of the hippocampus. It was reported that in CA3 neurons, excitatory postsynaptic currents (EPSCs) could be evoked by mossy fiber synapses in the presence of the selective AMPAR antagonist GYKI 53655 – with strong-and/or high-frequency electrical stimulation of mossy fibers, but not after a single shock. It was concluded that these EPSCs were mediated by KARs because they were insensitive to NMDA receptors antagonists and were further blocked by a mixed AMPARs/KAR-santagonist, CNQX. Interestingly, EPSCs mediated by KARs ($EPSC_{KA}$), differed from $EPSC_{AMPA}$ not only in their pharmacology but also in electrophysiological characteristics – i.e., their smaller amplitude and slower kinetics. In subsequent studies, KARs were shown to be involved in synaptic transmission onto inhibitory interneurons of the hippocampus, and in many other structures of the brain such as cerebellar Golgi cells, Purkinje cells, interneurons and principal cells of the neocortex, and neurons in the amygdala.

From these studies emerged the notion that KARs could participate in glutamatergic synaptic transmission, but only when large amounts of glutamate were released during repetitive activation of afferent fibers. This limitation was thought to be due to an extra-and/or peri-synaptic location of KARs. Recently, we reexamined the conditions under which postsynaptic KARs could be activated, and observed that they are involved in 'miniature' synaptic transmission (i.e., release of the small amount of glutamate contained in individual synaptic vesicles or quanta). Indeed, in CA3 pyramidal cells and CA1 interneurons, miniature excitatory postsynaptic currents (mEPSCs) solely mediated by kainate receptors ($mEPSC_{KA}$) can be recorded in the presence of specific AMPAR antagonists; these $mEPSC_{KA}$ are blocked by further addition of the mixed AMPAR/KAR antagonist CNQX or by SYM 2081, a compound that selectively desensitizes KARs. This result strongly argues that KARs can be activated by small amounts of glutamate, and against the view that these receptors are located at extrasynaptic sites. Our view has recently been confirmed by electron microscopy experiments showing the presence of GluR6 and KA2 subunits within the postsynaptic density of mossy fiber synapses. Our study also confirmed the slow time course and smaller amplitude of $mEPSC_{KA}$s when compared to $mEPSC_{AMPA}$s. Finaly, we showed that KARs carry as much as half the total glutamatergic current in hippocampal neurons and KARs are thus key players in physiological glutamatergic synaptic transmission. Interestingly, we also observed the presence of miniature EPSCs mediated by the coactivation of both AMPA and kainate receptors ($mEPSC_{AMPA/KA}$) that are likely colocalized at the same postsynaptic site.

Another specific feature of KAR-mediated synaptic transmission (when compared to AMPAR-mediated synaptic transmission) is its cellular and synaptic specificity. Early autoradiographic studies suggested that kainate receptors were specifically enriched in the stratum lucidum of the CA3 area, the zone of mossy fibers termination onto CA3 pyramidal cells in the hippocampus. Indeed, high affinity [^{3}H]-KA binding sites were abundant within this area, and lesions of the mossy fiber pathway or of CA3 pyramidal cells resulted in a dramatic reduction of the mean density of [^{3}KA] binding sites. More recently, physiological experiments using selective AMPA receptors showed that $EPSC_{KA}$ couldn't be evoked in CA1 pyramidal cells of the hippocampus by stimulation of the Schaffer collaterals. Consistent with this result, no $mEPSC_{KA}$ or $mEPSC_{AMPA/KA}$ can be recorded in CA1 pyramidal cells – or in dentate granule cells of the hippocampus. In addition to this CA3 cellular specificity, KAR-mediated synaptic transmission is also pathway specific. Indeed, in CA3 pyramidal cells, postsynaptic KARs can be selectively activated by stimulation of the mossy fiber pathway but not stimulation of other glutamatergic afferents (such as the associative/commissural fibers). Furthermore, removal of the mossy fiber pathway in organotypic slice cultures suppresses the KAR-mediated component of miniature glutamatergic transmission.

Altogether, these studies demonstrate that AMPARs and KARs can be activated by the same amount of released glutamate, and that KARs are key players in glutamatergic synaptic transmission in the hippocampus (and probably in other brain structures). KAR-mediated synaptic transmission is intriguingly different from AMPAR-mediated transmission, in time course, amplitude and cellular and synaptic specificity.

Degenerative Changes and Mossy Fiber Sprouting in the Kainate Models of TLE

The most common anatomo-pathological alteration observed in TLE patients is the sclerosis of the Ammon's horn, characterized by the degeneration and loss of pyramidal cells and interneurons, and leading to the shrinkage of the hippocampal complex together with reactive sprouting of the mossy fibers. In rats treated with KA, seizures induce the death of CA3 pyramidal cells (**Figure 1**) and eventually CA1 (the latter most likely due to anoxic mechanisms). Hilar mossy cells, the cells of origin of the excitatory (glutamatergic) associational-commissural input to dentate granule cells, also degenerate as a consequence of seizures (**Figure 1**). In addition, many interneurons within the hilus also degenerate, thus decreasing the number of GABAergic terminals impinging upon the dentate granule cells (**Figure 1**). These degenerative changes occur within the first three days following the KA-induced SE insult, and are associated with typical reactive glial reaction

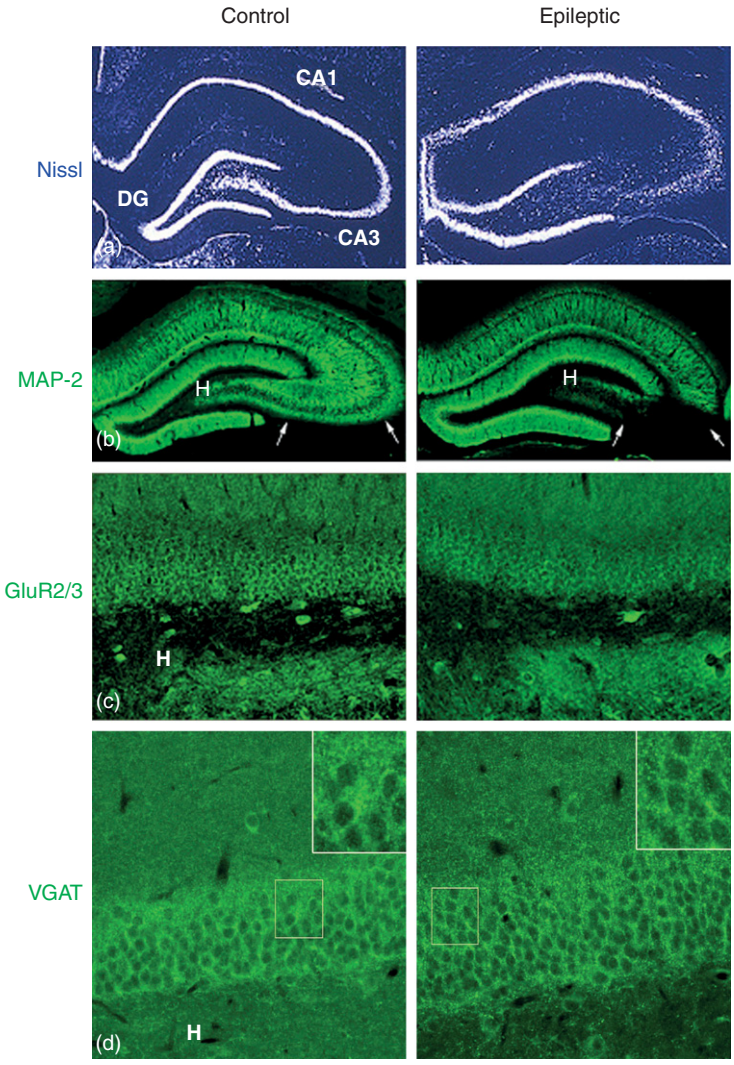

Figure 1 Degenerative changes in experimental TLE. Hippocampal sections from control (left) and chronic epileptic rats (right) sacrificed 30 days after injection of vehicle (a, c, e, g), kainate (b, c), or pilocarpine (f, h). (a) Nissl staining depicting a significant loss of CA3 neurons in chronic epileptic rats. (b) Microtubule associated protein MAP-2 immunostainings illustrate a lack of CA3 pyramidal neurons in chronic epileptic rats. (c) Immunostaining of glutamate receptors GluR2/3 decorates granule cells and hilar mossy cells. The number of the later was reduced in chronic epileptic rats. (d) Vesicular GABA transporter VGAT immunostaining reveals a partial loss of GABAergic terminals in the dentate gyrus of chronic epileptic rats. characterized by the proliferation and hypertrophy of astrocytes and microglia-macrophage activation. As a consequence of this cell loss, remaining dentate gyrus granule cells lack: i) the glutamatergic input of mossy cells, which innervate the proximal third of granule cell dendrites, and ii) the GABAergic input from hilar interneurons. At time of cell degeneration (within the first few days after SE), animals do not display motor nor EEG seizures, but only low frequency interictal-like epileptiform activities. These results suggest that degenerative lesions per se are not sufficient for the emergence of spontaneous seizures.

Brain degeneration is frequently associated with the emergence of a reactive sprouting which is likely aimed at compensating for the absent synaptic inputs. In most case, this plasticity involves the formation of abnormal connections. This reorganization has been particularly well analyzed in the dentate gyrus of kainate-treated rats, in which collateral sprouting of mossy fibers takes place within the hilus; the newly formed mossy fiber axon collaterals cross through the granule cell layer and branch throughout the inner third of the molecular layer, thus replacing the glutamatergic terminals of degenerated mossy cells (**Figures 2** and **3**). Electron microscopy analysis clearly demonstrated that these terminals establish synaptic contacts with granule cell dendrites, and that these newly formed synaptic contacts display the typical features of conventional mossy fiber synapses (i.e., similar to the contacts between mossy fiber terminals and their normal

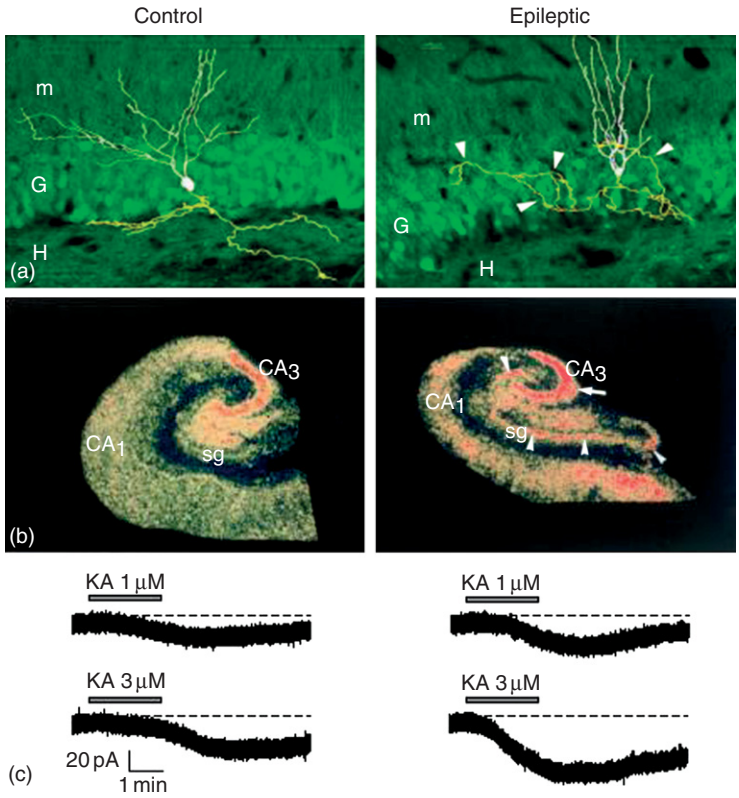

Figure 2 Sprouting of mossy fibers is linked to an increase of kainate binding sites. Arrowheads depict axon collaterals passing through the granule cell layer and distributing within the inner molecular layer. (b) Representative autoradiographs depicting the distribution of kainate binding sites in the hippocampus from a child with generalized epilepsy (right) as compared to a nonepileptic one (left). Note that the binding for kainate was increased in the dentate gyrus (the subgranular layer: sg; arrow heads) but also in other hippocampal fields (e.g., the CA3 stratum oriens: arrow). (c) Kainate receptor-mediated current induced by bath application of kainate in a control granule cell (left) and a granule cell from epileptic rat (right).

target, the CA3 pyramidal cell dendrite), including boutons of giant size, containing a high density of synaptic vesicles, developing numerous asymmetric synaptic contacts with giant spines. As a consequence of this sprouting, a direct recurrent excitatory, granule cell-to-granule cell network emerges (see below).

The sprouting of mossy fibers is an event that starts after a relatively long delay after the initial insult, and requires considerable time to be completed – this period coinciding approximately with the time course of the latent period (~30 days). In the kainate model of epilepsy, the first signs of sprouting were observed 12 days after the KA injection, and 15 more days were required before maximal sprouting was observed. After this time, no major changes were observed, as the newly established contacts appeared stable (were still observed in animals sacrificed up to one year later). The recurrent mossy fiber network is functional, as shown first in the pioneering study by Tauck and Nadler; these investigators showed that the activation of a few granule cells, by antidromic activation of the mossy fiber pathway, resulted in interictal-like recurrent network activity that could not be evoked by similar stimulations in the dentate gyrus from control rats. This activity, initially described in the CA3 area, is generated by recurrent excitatory networks within a context of decreased inhibition. Focal stimulations, using glutamate uncaging, reveal the functionality of the recurrent mossy fiber network. In such experiments, the selective stimulation of a small group of granule cells induced an increase in the frequency of excitatory synaptic events recorded in distant granule cells in KA-treated epileptic animals but not in controls. More recently, Scharfmann and colleagues, using paired intracellular recordings, produced direct experimental confirmation for the presence of monosynaptic excitatory connections between dentate granule cells in epileptic rats. The functionality of the recurrent excitatory network is also reflected in the increased frequency of excitatory postsynaptic events recorded in dentate granule cells from epileptic rats (compared with control rats), which is correlated with the level of mossy fiber sprouting. Recurrent mossy fibers share several physiological properties with control mossy fibers, such as a strong

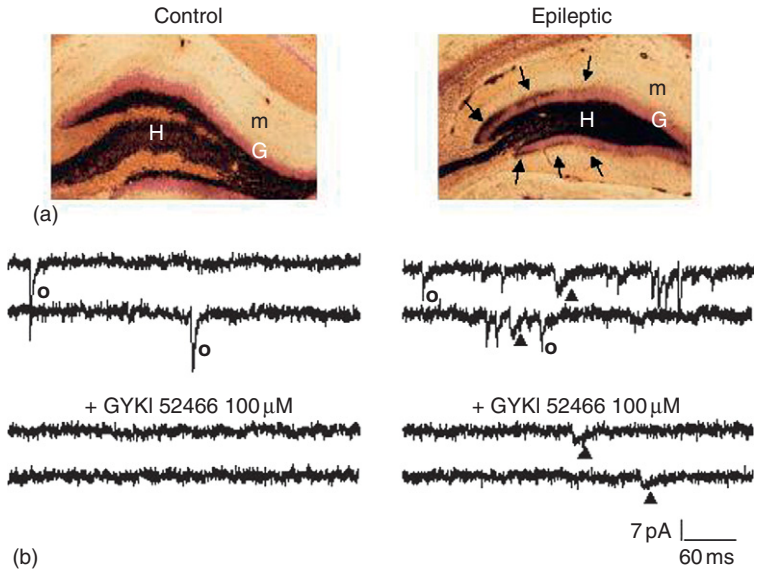

Figure 3 Ganule cells from epileptic rats generate aberrant slow kainate receptor-mediated synaptic events. (a) Timm staining of hippocampal mossy fibers of control (left) and chronic epileptic (rigth) rats. Arrows depict the inner molecular layer invaded by mossy fiber terminals. (b) Spontaneous EPSC recordings ($V_h = -70$ mV) from a control granule cell (left) and a granule cell from a chronic epileptic rat (right). Note that in control tissue all synaptic events are fast (open circle) and mediated by AMPARs because they are fully abolished by 100 μM GYKI 52466. In contrast, in the epileptic tissue, the EPSCs additionally includes slow kainate receptor-mediated events (close triangle) that are resistant to 100 μM GYKI 52466.

facilitation of synaptic transmission with a small increase in stimulation frequency ('frequency facilitation'), sensitivity to the mGluR2/3 agonist DCGIV, and the ability to release dynorphin.

Mossy fiber sprouting has also been observed in the hippocampus of human patients with TLE and hippocampal sclerosis, as seen in histochemical, immunochemical and autoradiographic analysis. Recent in vitro work, using surgically resected hippocampal slices from TLE patients, has shown that mossy fiber sprouting is correlated with the severity of induced seizures. Mossy fiber sprouting has also been observed in other forms of epilepsy. In a case of a child who died after severe epileptic seizures (Figure 2), the hippocampus exhibited no signs of significant cell death, but histochemical analysis demonstrated an increased density of mossy fiber terminals not only in the dentate gyrus but in the CA3 region as well.

Taken together, the clinical data strongly suggest that the hippocampus of TLE patients is generally characterized by the formation of this recurrent excitatory loop, which together with a decreased inhibition would increase the excitability of surviving neurons and facilitate the synchronization of the network-allowing the emergence of seizures.

Methods

Our group investigated the properties of dentate granule cells and networks, from chronically epileptic Wistar rats, using patch-clamp and extracellular recordings in hippocampal acute slices. The identification of recorded neurons is made possible by introducing biocytin into the recording pipette, and then reconstructing the recorded cell post-hoc using camera lucida or Neurolucida systems. To obtain chronically epileptic rats, an initiating period of status epilepticus is induced by intraperitoneal injection of kainate or pilocarpine. Morphological analysis of neuronal cell types and axonal terminals are carried out using histochemical (Nissl and Timm) and immunohistochemical techniques.

Results

Role of Kainate Receptors Activation in Acute Seizure Generation

Well before the cloning of kainate receptors, several arguments pointed to the activation of specific kainate receptors as one of the main determinants of the epileptogenic actions of kainic acid injections. The first argument for this hypothesis is the high density of high-affinity kainate binding sites in seizure prone regions like the hippocampus or the amygdala. A second argument is that measured concentrations of kainic acid in these regions after systemic injections (50–250 nM) were well below concentrations needed to activate other types of glutamatergic receptors like AMPA receptors. These low concentrations of KA, however, could induce powerful ictal-like activities when directly injected in the hippocampus in vivo or

in vitro. Furthermore, limbic motor seizures associated with kainic acid injection were not observed before the full development of the mossy fiber pathway (which mainly develops postnatal) and high affinity kainate binding sites in the hippocampus. Indeed, studies performed in our Institute have shown that the developmental profile of kainate-induced seizures in the intact isolated hippocampus in vitro was correlated to the development of postsynaptic kainate receptor-mediated current evoked in CA3 pyramidal cells. Accordingly, when the normal development of dentate granule cells and mossy fibers is impaired, KA binding sites are lost in the hippocampus and kainic acid applications fail to generate any seizure in the hippocampus in vitro. More recently, the link between kainate receptor activation and kainic acid-induced acute seizures in the hippocampus has been reevaluated using knockout mice for specific KAR subunits. In GluR6−/− mice, bath applications of kainate at submicromolar concentration (that specifically activates KARs over AMPARs) do not generate any current in CA3 pyramidal cells. Postsynaptic responses mediated by kainate receptors after stimulation of the mossy fiber pathway are also disabled, and no seizures are observed after systemic kainic acid injections using conventional concentrations. Seizures can be observed when high doses of kainate are used ($30\,mg\,kg^{-1}$), although it is not clear whether these seizures are the classical secondarily generalized seizures usually observed after kainate injections or are a tonic–clonic seizure type (usually observed after $GABA_A$ receptor antagonist injections). The lack of the GluR6 subunit also prevented the generation of epileptiform bursts after KA application onto hippocampal slices. These experiments suggest that postsynaptic KARs that include the GluR6 subunit in CA3 pyramidal cells are important for the induction of acute seizures after systemic KA injections. CA3 pyramidal cells form a network of strongly interconnected neurons, through recurrent excitatory connections, and have a low threshold for generating epileptiform burst activity under conditions of increased excitability (i.e., increase excitation or reduced inhibition). Such epileptiform activities would then propagate to the CA1 area, and from there to other associated limbic structures.

In addition to being expressed in principal cells of the hippocampus, KARs are also expressed in hippocampal interneurons. These receptors include the GluR5 subunit and can thus be selectively activated by specific agonists such as ATPA. Activation of these receptors leads to a prolonged depolarization of interneurons and results in a marked increase of the tonic inhibition of CA1 pyramidal cells. Thus, in the CA1 area, KA acting on GluR5-containing receptors would have an overall inhibitory effect; GluR5 agonists decrease the spontaneous discharge of CA1 pyramidal cells and reduce the propagation of seizures triggered by bicuculline in an in vitro preparation of interconnected neonatal hippocampi. GluR 5 is also expressed by interneurons in the CA3 area of the hippocampus. Studies have shown that the threshold for seizure generation in this area is decreased (in hippocampal slices) from GluR5−/− knock out mice. In contrast to this inhibitory effect mediated by Glur5-containing KARs, ATPA systemic injections induce clonic seizures in mice. This somewhat confusing effect might be due to activation of neurons of the basolateral amygdale, in which GluR5 containing receptors are involved in glutamatergic synaptic transmission.

KARs are also expressed on presynaptic mossy fiber axons and terminals from dentate granule cells. On presynaptic mossy fiber terminals, KARs have a dual effect on synaptic transmission: at low concentration (20–50 nM), kainate increases glutamatergic release onto CA3 pyramidal cells, whereas at higher concentrations KA (200–500 nM) decreases release. Thus, the low concentration of KA that reaches the hippocampus after systemic injections could bind to presynaptic KARs and enhance then the release of glutamate onto CA3 pyramidal cells, increasing the excitability of the CA3 hippocampal network. Kainate receptors are also expressed presynaptically by inhibitory GABAergic terminals of the hippocampus, were they have been shown to decrease the release of GABA. In accordance with this, specific antagonism of presynaptic GluR5-containing receptors prevents epileptiform activities induced by the muscarinic agonist pilocarpine. However, since KARs also directly depolarize interneurons through GluR5 containing receptors, the global effect of KA injections on inhibitory synaptic transmission in the hippocampus is not easy to predict.

Role of Kainate Receptors in Chronic Seizure Generation

We have seen that the activation of KARs by exogenously applied KA induces epileptic seizures. Do KARs (activated by endogenous glutamate) play a role in seizure generation in chronically epileptic rats? Recent experiments from our group support this hypothesis.

Early autoradiographic studies showed that mossy fiber sprouting is accompanied by a gradual increase of ^{3}H-KA binding sites, in the inner molecular layer of the dentate gyrus that reaches a maximum 30 days after the initial KA injection (**Figure 2**). These changes appear to be due to the expression of functional postsynaptic KARs, since we observed an increase in the amplitude of KAR-mediated currents induced by bath application of kainate (unpublished observations, **Figure 2**). The presence of aberrant postsynaptic KARs was further confirmed by the observation that stimulations in the inner one-third of the molecular layer of the dentate

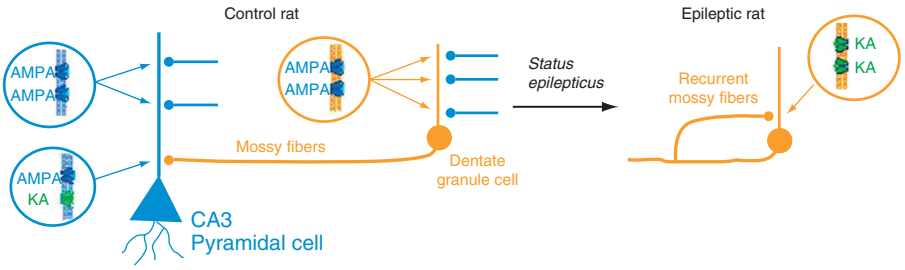

Figure 4 Schematic representation to illustrate that recurrent mossy fibers establish aberrant kainate receptor-operated synapses on granule cells from epileptic rats.

gyrus (the termination zone for recurrent mossy fibers) induces a slow KAR-mediated synaptic response in granule cells from chronic epileptic rats – but not from age-matched control rats were only fast $EPSC_{AMPA}$ could be evoked (Figure 3). The presence of slow $EPSC_{KA}$ was correlated with the appearance of recurrent mossy fibers since $EPSC_{KA}$ were not observed 4–5 days after the inaugurating status epilepticus (before mossy fiber sprouting). Furthermore, $EPSC_{KA}$ presented a pharmacological and physiological profile specific to mossy fiber synapses such as a strong facilitation of synaptic transmission with a small increase in stimulation frequency ('frequency facilitation') and sensitivity to the mGluR2/3 agonist DCGIV. Finally, $EPSC_{KA}$ could be evoked in granule cells from epileptic rats by focal stimulation of distant granule cells through the recurrent mossy fiber network whereas in control rats in the absence of the recurrent mossy fiber network similar stimulation failed to evoke any EPSPs in distantly recorded dentate granule cells. Together, these data demonstrate that mossy fibers sprouting induce the expression of functional postsynaptic kainate receptors in abnormal target cells (Figure 4). Finally, we observed that KARs are involved in the synchronized network-driven activities supported by recurrent mossy fibers in the dentate gyrus from epileptic rats. These data suggest that aberrant postsynaptic KARs located at mossy fiber synapses onto dentate granule cells could participate, together with the abundant recurrent axonal innervation, in the pathological synchronization of the dentate gyrus neurons.

Future Directions and Implications

The observations described in this article may have interesting implications for the treatment of human TLE, since changes in [^{3}H]-KA binding sites have been observed in the dentate gyrus of children with epilepsy (as compared with age-matched controls) (Figure 2). Furthermore, a specific increase in KAR subunit expression has been observed in granule cells from patients with TLE. Kainate receptors display a specific and selective distribution within the brain, particularly in temporal areas. Our recent observations support the notion that in chronic epilepsy, some cells (e.g., the dentate granule cells) abnormally express this glutamate receptor subtype at synaptic sites and that this abnormal distribution contributes to increased hippocampal excitability. Therefore, this receptor subtype constitutes an interesting pharmacological target, especially since its inhibition would not markedly perturb glutamatergic transmission at most synapses, but would reduce excitability of specific cell types and circuits involved in epileptogenesis.

Another important implication of synaptic KAR expression by dentate granule cells, is the resulting major changes in the kinetics of EPSPs received by these cells. EPSP kinetics can profoundly modify several fundamental neuronal functions, such as temporal integration of incoming synaptic inputs as well as temporal firing precision. Indeed, computational studies have shown that fast $EPSP_{AMPA}$s must be very synchronous, or generated at high frequencies, to induce spiking, whereas slow $EPSP_{KA}$s can generate a sustained depolarization (even at low frequencies) through their temporal summation. Changes in EPSP kinetics will also modify the interaction between synaptic and intrinsic properties in dentate granule cells and can modify the computational properties of these cells. Thus, beside effects on seizure generation, these modifications of KARs could contribute to cognitive dysfunctions that are frequently observed in patients with TLE. Future work should address these questions, using state of the art techniques to record and manipulate single cells and networks in intact in vivo preparations.

Introduction

The dentate gyrus is thought to be a key structure for information transfer into the hippocampus proper. In chronic human and experimental epilepsy, manifold changes occur within the dentate gyrus. These range from changes in the abundance of identified neuron populations (i.e., neurogenesis of dentate granule neurons and loss of certain types of interneurons), axonal reorganization of excitatory and inhibitory neurons, and profound changes in the expression and function of neurotransmitter receptors and ion channels. This article begins with an introduction into the basic functional anatomy of the hippocampus. The following sections will provide a synopsis of the changes observed in chronic epilepsy, and present a number of current hypotheses on how these changes may conspire to produce hyperexcitability.

Background – Functional Anatomy of the Dentate Gyrus

The dentate gyrus receives its major input from the entorhinal cortex (perforant pathway) via glutamatergic synapses. The perforant path axons terminate on the dendritic tree of granule neurons within the molecular layer. The dentate granule cells (DGCs) project via the distinctive, nonmyelinated mossy fibers to the hilar and CA3 regions. Mossy fibers form en-passant synapses onto the proximal dendrites of the pyramidal neurons of the CA3 region. In the CA3 region, an intriguing feature of mossy fiber boutons is that they also contact numerous interneurons with filopodial-like processes. In fact, mossy fibers in the normal CA3 region contact many more inhibitory interneurons than CA3 pyramidal cell dendrites. Thus, the output of dentate granule neurons carries a powerful inhibitory component.

In addition to innervating CA3 neurons, mossy fibers collateralize in the hilar region and innervate various target-cell types. These cells may be glutamatergic (i.e., mossy cells) or one of numerous classes of interneurons utilizing the inhibitory neurotransmitter γ-aminobutyric acid (GABA). GABAergic neurons in the hilus and in other areas of the dentate gyrus provide a remarkably strong inhibition in this region. They can be subclassified into numerous categories on the basis of their soma location and dendritic arborization patterns, their axonal termination patterns, as well as their characteristic spiking patterns following depolarization. In addition, neurochemical criteria have been used to refine the definition of interneuron subclasses. In this context, a major criterion with perhaps the highest degree of functional relevance is onto which principal neuron compartments interneurons form synapses (i.e., the somatic or axonal compartment, the dendritic compartment or both). A more detailed description of different interneuron classes is beyond the scope of this article (see Further Reading). Nevertheless, it is important to note that the presence of different types of interneurons allows GABA release onto DGC soma and dendrites with precise spatiotemporal control, mediating powerful feed-forward and feed-back inhibition.

Methods

A large number of techniques have been used to address the function and dysfunction of granule neurons. First, electrophysiological techniques have been used to record the membrane potential of granule neurons. Such techniques include sharp microelectrode recordings in which neurons are impaled with a thin glass microelectrode, or patch-clamp recordings. Such recordings allow us to determine the resting electrophysiological properties of granule cells (such as the membrane potential and passive electrical properties), the properties of individual action potentials, and their repetitive discharge behavior. In addition, these techniques also allow the investigator to record the response of granule cells to the activation of excitatory and inhibitory synapses (excitatory and inhibitory postsynaptic potentials). These techniques have been used to glean information on the intrinsic and synaptic properties of granule neurons under control conditions, and in chronic epilepsy.

Besides being eminently useful, microelectrode recording techniques permit recording from one, two, or at most three neurons simultaneously from a slice preparation. Alternative techniques have therefore involved the sampling of activity, at high-temporal resolution, in larger neuronal populations. One of these techniques is imaging with voltage-sensitive dyes (which have molecules that integrate into cell membranes upon perfusion into a slice). Upon excitation with light of appropriate wavelength, these fluorophores emit a fluorescent signal that is dependent on the membrane voltage. It has been shown that this emission can be calibrated to neuronal membrane voltage. These dyes complement microelectrode recording techniques, and open the exciting possibility to monitor the activity of neuronal ensembles at high speeds.

In addition to functional techniques, classical morphological techniques have been used to address altered morphology of granule neurons and interneurons in the dentate gyrus. These approaches include analyzing the morphology of these cells by filling them with tracers such as biocytin, and then reconstructing their dendritic and axonal arbors. In addition, the axonal projections of granule neurons can be readily labeled with the Timm staining procedure, which takes advantage of the high concentration of zinc in mossy fibers. Immunohistochemical techniques are widely used to assess the expression of marker proteins that allow classification of different cell types in the dentate gyrus. Finally, immunolabeling and molecular tools such as quantitative real-time RT-PCR, expression profiling, and immunoblotting have been used to address the specific molecular changes in ion channels, receptors, and other proteins in different cell types in the dentate gyrus.

Recent Results

Increased Neurogenesis of Dentate Granule Neurons

In discussing changes occurring in the epileptic hippocampus, we first focus on changes in the abundance of different neuron populations and their functional connectivity. One of the most striking changes in the epileptic dentate gyrus is the increased generation of dentate granule neurons. The subgranular zone of the dentate gyrus is one of the niches in the adult brain, which contain neuronal precursors that continue to produce new neurons throughout life. Neurogenesis in this region is strongly increased in animal models of mesial temporal lobe epilepsy (TLE). In human epilepsy, experimental protocols aimed at labeling newly generated neurons in vivo cannot be used. Nevertheless, dentate granule neurons in patients with TLE show increased expression of markers for cell division, as well as markers labeling neural progenitors and immature neurons. The increased generation of granule cells raises several interesting questions: (1) how do newly generated neurons integrate within preexisting neuronal networks, (2) do granule neurons generated following seizures integrate differently from those produced by 'normal' neurogenesis, and (3) is the effect of augmented neurogenesis anti- or proepileptogenic?

Systematic analyses using labeling of newly generated neurons with BrDU or viral transfection have revealed

that the majority of newly generated granule cells migrate within the granule-cell layer. In addition, in chronic human and experimental epilepsy, some newly generated neuronal precursors migrate aberrantly to the hilus and molecular layer after prolonged seizures and differentiate into ectopic DGCs. These findings raise the question whether aberrant migration of newly generated granule cells might contribute to granule-cell dispersion, a characteristic broadening of the granule-cell layer seen in some forms of experimental epilepsy, and in human TLE with Ammon's horn sclerosis. This question is still under debate. An alternative hypothesis contends that dispersion may be caused by aberrant localization of mature granule cells.

Regardless of the precise localization of newly generated granule cells, the question remains as to what their functional role in the epileptic hippocampus is. Recordings from putative newly generated ectopic granule cells in rodents have revealed that they share intrinsic properties with normally located granule cells. However, they seem to be easily recruited into seizure activity occurring in the CA3 region. This may be a specific feature of ectopic granule cells. A recent study has compared granule cells within the granule-cell layer generated following seizures to granule cells generated following behavioral stimuli. In this study, viral labeling techniques were used to unequivocally identify newly generated granule neurons. Intriguingly, aberrantly and 'normally' generated granule cells displayed similar intrinsic membrane properties. However, new neurons born following seizures differed with respect to synaptic drive and short-term plasticity of both excitatory and inhibitory afferents. The net effect of these differences in functional afferent connectivity would be consistent with the newly generated granule-cell population being less excitable on a network level. The role of newly generated granule neurons in seizure discharges on a network level, however, is not yet clear, and will also depend on the properties of efferent synapses formed by these neurons within the hippocampus.

Changes in the Functional Connectivity of Dentate Granule Neurons

What is the output of dentate granule neurons in chronic epilepsy? The mossy fiber axons of DGCs undergo characteristic changes both in experimental and human TLE. Sprouting of mossy fiber axons in the epileptic hippocampus results in the formation of aberrant, excitatory synapses of mossy fiber boutons onto the proximal dendrites of dentate granule neurons (Timm staining of the mossy fibers in control and epileptic hippocampus depicted in **Figure 1(a)** and **1(b)**, respectively). Mossy fiber sprouting is a characteristic feature of many experimental models of epilepsy, in particular, models that utilize prolonged status epilepticus for the induction of chronic epilepsy. It is also commonly observed in human TLE with Ammon's horn sclerosis.

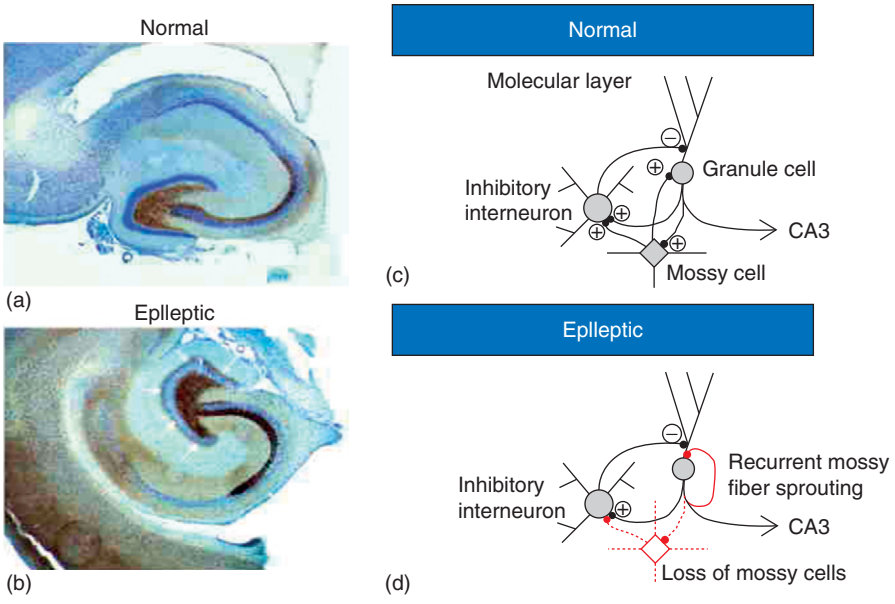

Figure 1 Mossy fiber sprouting and altered synaptic connectivity in the epileptic dentate gyrus. (a, b): Timm-stained sections of control hippocampus (a) and hippocampus from a chronically epileptic rat (pilocarpine model of epilepsy, b). The brown staining product labels mossy fibers (arrows in b). Note the de novo projection of mossy fibers within the inner molecular layer of the dentate gyrus. (c, d): Schematic diagram of altered connectivity in the dentate gyrus in chronic epilepsy. Changes in epilepsy (i.e., loss of mossy cells and recurrent sprouting of mossy fibers) are depicted in red. (+) and (−) indicate excitatory (glutamatergic) and inhibitory (GABAergic) synapses.

What is the functional consequence of mossy fiber sprouting? This question has fascinated neuroscientists for several decades. Morphological studies have shown that virtually all the synapses formed by mossy fibers in the granule-cell and inner molecular layers are with other granule cells, and electrophysiological recordings from pairs of granule cells have proven the existence of monosynaptic connections between granule neurons in epileptic hippocampus. These results suggest an interesting difference of aberrant and normal mossy fiber terminals: Whereas normal mossy fiber terminals in the CA3 region form many more inhibitory synapses than excitatory synapses, it seems as if recurrent mossy fiber synapses provide a monosynaptic, exclusively excitatory feedback pathway that is not normally present (see **Figure 1(c)** vs. **1(d)**). It is important to realize that the normal dentate gyrus is not devoid of excitatory feedback pathways. Here, excitatory feedback is derived via mossy fibers that activate mossy cells, which in turn project back to dentate granule neurons (**Figure1(c)**). Since mossy cells are lost in human and experimental epilepsy, this disynaptic excitatory feedback circuit is replaced by a more local, monosynaptic one in epileptic tissue (**Figure 1(d)**). Apart from creating a monosynaptic recurrent excitatory loop, mossy fibers release zinc when activated. Because granule cells in chronic human and experimental epilepsy express GABA receptors with increased zinc sensitivity, this has been hypothesized to cause a decrease of GABAergic inhibition during seizure activity, but direct evidence for this is lacking.

The cellular mechanisms underlying aberrant sprouting of mossy fibers have been partially identified. The loss of CA3 target neurons may cause mossy fibers to seek alternate postsynaptic targets. Another attractive hypothesis is that axons emanating from newly generated granule cells may grow abnormally into the inner molecular layer. While this may be the case, newly generated neurons are almost certainly not the only source of recurrent mossy fiber sprouting, because disrupting granule-cell neurogenesis by irradiation does not interfere with the development of mossy fiber sprouting in experimental epilepsy. It is likely that following induction of sprouting, the trajectories of outgrowing axons are determined by multiple components of the extracellular matrix, signaling molecules or synaptic adhesion molecules that mediate axon repulsion or attraction. Significant changes in many such molecules have been observed both in human and experimental epilepsy.

Loss of Interneuron Populations in the Epileptic Dentate Gyrus

In the face of increased generation of granule cells, what is the fate of interneuron populations in chronic epilepsy? This question is of great importance because interneurons have crucial roles in mediating feed-forward and feedback inhibition in the dentate gyrus. They have also been shown to be important in the generation of synchronous population activity. Numerous studies have used markers of interneurons to examine which subtypes are affected in chronic human and experimental epilepsy. In some animal models, loss of interneurons and inhibition takes place in the hippocampus. However, in the human hippocampus the majority of inhibitory interneurons appear to be preserved, even though loss of some subtypes (such as parvalbumin-containing interneurons) has been reported. Electrophysiological recordings from epileptic human hippocampus support the presence of strong inhibition, despite the loss of some subtypes of GABAergic neurons. This question has been further investigated by a quantification of the number of perisomatic inhibitory (symmetric) synapses made by parvalbumin-containing presynaptic terminals onto granule cells. In human epileptic specimens with Ammon's horn sclerosis, there was no reduction in the number of inhibitory synaptic contacts onto the granule-cell bodies or proximal dendrites. In fact, there was an increase in the coverage of axon initial segments by parvalbumin-containing inhibitory terminals. Thus, it seems as if a loss of parvalbumin-immunopositive interneurons may reflect a transient down-regulation of parvalbumin expression rather than a loss of interneurons. Alternatively, the reduced number of parvalbumin-immunopositive interneurons may sprout, resulting in the maintenance of inhibitory synapse numbers. There is some evidence for such reorganization of axonal systems of surviving interneurons. The precise anatomical localization and the quantitative contribution of different types of interneurons are much less clear than for principal neurons. This is primarily due to the presence of many distinct classes of interneurons, which makes it necessary to label and track individual axons of functionally and neurochemically identified cells.

Changes in the Elementary Properties of Synapses and Receptors

A large body of evidence exists supporting altered excitatory and inhibitory neurotransmission in the dentate gyrus. It should be stressed that the majority of these studies is based on recordings from granule neurons, without a determination whether these were newly generated neurons or not. Thus, the changes observed could be due to the fact that part of the neurons included in these datasets were newly born granule cells, or to altered properties of synapses onto preexisting granule cells. Assuming a homogeneous population on adult granule neurons, recordings of synaptic input will in most cases reflect a mixture of preexisting and newly formed synapses. Newly formed synapses appear to have properties that distinguish them from preexisting synapses, and

it will be important to extend our understanding of the elementary properties of these synapses.

Regardless of the mechanisms, excitatory glutamatergic synaptic transmission onto granule neurons has been shown to be altered both in chronic experimental and human epilepsy (see **Table 1**). A large body of evidence has accumulated supporting altered properties of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Epilepsy-associated changes in NMDA receptor function include a prolongation of channel opening, an increase in agonist sensitivity, or a decrease in Mg^{2+} sensitivity. These changes have been proposed to contribute to hyperexcitability in the kindling model of TLE and in human epilepsy. They are unlikely to be caused by persistent changes in the expression of NMDA receptor subunits or splice variants. Instead, there is good evidence that there is an altered regulation of the NMDA receptor complex, most likely via a less-efficient dephosphorylation by the Ca^{2+}-dependent phosphatase 2B. In contrast to NMDA receptors, the subunits underlying α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor complexes show transcriptional changes in experimental epilepsy. The precise functional consequences of these changes on a network level are so far unclear. Glutamatergic synaptic transmission is powerfully modulated by metabotropic glutamate receptors and other presynaptic autoreceptors. Metabotropic glutamate receptors also undergo changes in human and experimental epilepsy. So far, at least eight mGluR subunits are known, which can be grouped according to sequence similarities and mode of action. Class I mGluRs (mGluR1 and mGluR5) are located predominantly postsynaptically, and cause a release of Ca^{2+} from intracellular stores. Class II (mGluR2 and 3) and III mGluRs (mGluR4, mGluR6-8) are predominantly located presynaptically and modulate neurotransmitter release. Presynaptic receptors were shown to be down-regulated in the lateral perforant path in chronic experimental epilepsy and epilepsy patients with Ammon's horn sclerosis, resulting in less mGluR-dependent depression of glutamate release. In contrast, postsynaptic types of mGluRs were shown to be up-regulated in chronic human and experimental epilepsy and may promote epileptogenesis. Changes in $GABA_B$ receptors include an up-regulation of postsynaptic $GABA_B$ responses in addition to a down-regulation of presynaptic $GABA_B$ receptors, resulting in enhanced inhibition in experimental TLE. Given the large changes in glutamatergic neurotransmission in the dentate gyrus, as well as profound changes in Ca^{2+} dynamics and handling in dentate granule neurons, it is not surprising that the potential of the perforant path-dentate gyrus synapses to exhibit synaptic plasticity is severely impaired in human epilepsy with Ammon's horn sclerosis, as well as in some models of experimental epilepsy.

The GABA system also displays a number of changes in chronic epilepsy (see **Table 1**). GABA binding to ionotropic $GABA_A$ receptors causes opening of the receptor ionophore, which is permeable to Cl^- and – to a lesser extent – to HCO_3. In the presence of a normal adult transmembrane Cl^- gradient, this channel opening results in the expression of an inhibitory postsynaptic current that hyperpolarizes the postsynaptic neuron. In the

Table 1 Summary of changes in voltage-gated ion channels and neurotransmitter receptors in dentate granule neurons in chronic epilepsy

	Changes in animal model	*Molecular mechanisms*
Voltage-gated ion channels		
A-type K^+ current (I_A)	–	–
Delayed rectifier K^+ current (I_K)	–	–
H-currents (I_h)	Up-regulation of I_h	Transcriptional up-regulation of HCN subunits, other mechanisms
Ca^{2+} currents	Altered Ca^{2+}-dependent inactivation of Ca^{2+} channels	Loss of calbindin-D_{28k}
Neurotransmitter receptors		
NMDA	Up-regulation of NMDA receptor function	Altered modulation by phosphatase 2B, resulting in prolonged NMDA receptor opening
AMPA	No large functional changes detected	Transcriptional changes
Metabotropic glutamate	Down-regulation of presynaptic Group III metabotropic glutamate receptors in the perforant path	Down-regulation of mGluR8 function
$GABA_A$	Increase of Zn^{2+} sensitivity, altered magnitude of tonic $GABA_A$ receptor-mediated currents	Change in subunit composition, change in synaptic vs. extrasynaptic localization of subunits
$GABA_B$	Up-regulation of postsynaptic $GABA_B$-mediated responses, down-regulation of presynaptic $GABA_B$-mediated actions	Altered expression of pre- and postsynaptic $GABA_B$ receptors, other mechanisms

NMDA, *N*-methyl-D-aspartate; AMPA, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid; GABA, γ-aminobutyric acid.

dentate gyrus, profound transcriptional changes in $GABA_A$ receptor subunit expression take place. These changes result in altered function and pharmacology of the $GABA_A$ receptor complex, including an increased sensitivity to blockade by the divalent cation Zn^{2+}. This finding is important because recurrent mossy fibers contain large amounts of vesicular Zn^{2+}, and might release it during seizures. This release could potentially lead to a dynamic block of $GABA_A$ receptors and a collapse of inhibition. This attractive hypothesis has not been so far directly proven. Further changes in GABAergic synapses include a change in the precise localization of GABA receptors composed of specific subunit combinations at perisynaptic vs. postsynaptic locations. Such changes have been proposed to impair fast (phasic) synaptic inhibition at individual GABAergic synapses. A second type of inhibition, mediated by extrasynaptic GABA receptors persistently exposed to low ambient GABA levels (tonic inhibition), may also be increased as a consequence of such changes in subsynaptic localization of receptors.

Changes in Intrinsic Properties of Dentate Granule Neurons via Altered Expression of Voltage-Gated Ion Channels

In contrast to the manifold changes in synaptic properties, the intrinsic firing behavior of granule neurons seems to be more stable, especially when compared with other hippocampal subregions. Unlike the majority of CA1 neurons, which convert from regular-firing to a burst-firing mode in experimental epilepsy, DGCs retain a regular-firing mode. Even though there are no changes in firing mode of dentate granule neurons in different models of epilepsy, there may be epilepsy-related changes in some aspects of neuronal discharge. For instance, a reduction in spike after hyperpolarizations of medium duration were observed in a subgroup of granule cells from patients with Ammon's horn sclerosis. This loss of medium spike after hyperpolarization was quite likely related to the loss of spike frequency accommodation that is characteristic both of rodent granule cells as well as of granule cells recorded from epilepsy patients without Ammon's horn sclerosis. In addition, action potential thresholds were increased, and an enlarged fast after hyperpolarization was observed. Which changes in voltage- or calcium-dependent conductances may underlie these phenomena have not been determined. However, changes in many voltage-gated conductances have been reported both on the expression and functional level (see **Table 1**). For instance, voltage-gated sodium channels display changes in voltage-dependence; however, slow inactivation processes, the time-dependent properties of activation and inactivation, and recovery from inactivation are unaffected in the pilocarpine model of epilepsy. Voltage-gated transient (A-type) and persistent (delayed rectifier) potassium currents displayed no changes in the pilocarpine model of epilepsy. Changes in other types of currents both on the expression and functional level in granule cells have been reported. It should be noted that in many cases, differing results have been obtained with different models, and a correlation between expression and functional data is not always obvious.

An analysis of firing behavior with somatic recording electrodes, however, does not capture all aspects of intrinsic excitability, for instance, changes in distal dendrites. Changes in dendritic excitability may profoundly affect integration of dendritic excitatory input to an action potential output. Regrettably, recording from thin granule-cell dendrites is technically difficult, and so direct data on dendritic processing in granule neurons is scarce. However, there are several hints that dendritic processing may be affected in chronic epilepsy. For instance, there is a powerful up-regulation of HCN subunits within the dentate gyrus both in experimental epilepsy, and subgroups of epilepsy patients with Ammon's horn sclerosis. HCN subunits give rise to the H-current, a mixed cationic current activated by hyperpolarization, which is normally concentrated in the dendritic compartment and strongly influences dendritic integration in other types of principal neurons.

Collective Properties of the Dentate Gyrus in Seizure Discharge

How can these manifold sets of data be developed into a hypothesis regarding the function of the dentate gyrus in chronic epilepsy? This important issue has recently been directly addressed experimentally. Simultaneous voltage-sensitive dye imaging and patch-clamp recordings in hippocampal slices have allowed investigators to record the activity of different neuronal ensembles in the hippocampus at high-temporal resolution. These experiments have led to a significant advance in our understanding the role of the epileptic dentate gyrus in the context of the hippocampal network. So far, such experiments have addressed how inputs to the dentate gyrus from cortical areas are processed, and have confirmed that the normal dentate gyrus exerts a powerful control on information transfer from the cortex into the hippocampus proper. This idea has led to the dentate gyrus being termed the dentate 'gate.' Surprisingly, this control was virtually unchanged in chronically epileptic animals, contrary to previous hypotheses that the function of the dentate gyrus might be impaired. Thus, it seems as if the undoubtedly present changes that might contribute to a loss of dentate gating function (i.e., the earlier-mentioned changes in NMDA or GABA receptors) are offset, or homeostatically compensated, by other cellular changes that maintain the function of the dentate gate. It is interesting to note that these experiments have led to an alternate hypothesis regarding the ignition of seizure activity within the

hippocampus proper: It is likely that a direct cortical input to the CA1 region, the temporoammonic pathway, is weak in normal animals. In epileptic animals, the efficacy of this pathway in recruiting CA1 neurons is massively increased. It is likely that the dysregulation of this pathway provides an alternate route to permit activation of the CA1 and CA3 neuron by temporal afferents that bypasses the dentate gyrus.

Outlook

The dentate gyrus is one of the better-investigated structures in the brain. Nevertheless, there is much left to be learned about this structure. A continuation of the detailed dissection of the cellular properties of individual neuron types, as well as analysis of their synaptic connectivity will hopefully provide a more complete view of the functional matrix of the dentate gyrus. In addition, there are a number of novel issues and techniques that should be taken into account for future investigations.

First, the function of dentate granule neurons and most interneurons has been investigated virtually exclusively using somatic voltage- and current-clamp recording. In contrast, the properties of granule-cell dendrites are virtually unknown. Studies on CA1 and cortical neurons have shown that dendrites are structures with fascinating active properties, which strongly influence how different types of synaptic input converging on dendrites are integrated. These processes are not understood in DGCs.

Second, many studies to date have employed slice recording techniques to examine the functional alterations of granule cells and interneurons. These high-resolution approaches are indispensable to precisely analyze the properties and synaptic connectivity of different neuron types. However, it would be highly desirable to learn more about the in vivo behavior of identified neuron types during the initiation, maintenance, and termination of different types of seizure activity. These types of in vivo recording are increasingly being carried out to understand the relation of interneuron and principal cell firing during characteristic cortical activity patterns associated with cognitive processes. These techniques could be readily applied to epilepsy.

Finally, a general question to be answered in the future is what signalling pathways are evoked that convert granule cells from their normal physiological state to an 'epileptic' granule cell, a process termed *epileptogenesis*. Our knowledge of the transcriptional and translational control mechanisms that govern the coordinated production of proteins in neurons is rapidly expanding, and some intriguing novel studies have identified key pathways involved in epileptogenesis. Apart from the neurobiological importance of such mechanisms, they may open new avenues in the treatment and prevention of chronic epilepsy.

Phenotypic Plasticity of the Granule Cells and its Relation to Epilepsy

Introduction

Epileptic activity is generated when the balance of excitation and inhibition is impaired and when excitatory activity, normally conveyed by cells releasing glutamate, surpasses inhibition, which is exerted by interneurons releasing the inhibitory amino acid, γ aminobutyric acid (GABA). Sets of inhibitory interneurons not only control excitability but also fine-tune network activity, thus enabling generation of rhythms important for cognitive functions. However, the often-assumed view that glutamate excites and GABA inhibits is rather simplistic, and only true in part. Indeed, besides its well-known excitatory actions, glutamate can have inhibitory actions by depressing neurotransmitter release through the activation of presynaptic receptors, both with ionotropic or metabotropic activity. Alternatively, the inhibitory transmitter GABA can exert excitatory actions by directly depolarizing postsynaptic cells under certain circumstances, or by causing disinhibition – e.g., when one inhibitory interneuron inhibits another inhibitory cell. Irrespective of the direction of the actions exerted by these amino acids, it has been traditionally considered that some cells release glutamate and other cells release GABA, but not that a given cell can release both amino acids. Yet, in view of the presence of GABA in the glutamatergic mossy fibers (MFs, the axons of dentate gyrus granule cells), could it be that these cells release both neurotransmitters? If so, what impact would the simultaneous release of glutamate and GABA have on the excitability of the postsynaptic cell and, finally, on the overall excitability of the network under study? As evidence accumulates supporting the hypothesis that granule cells (GCs) corelease these amino acids, new possibilities of neural computation arise. Moreover, because a tight maintenance of the excitation–inhibition balance is needed to avoid the emergence of epileptic activity, such a mechanism would provide an effective means to rapidly auto-regulate the system.

Background

Granule-Cell Connectivity and Plasticity

The dentate gyrus (DG) is the main target of cortical input to the hippocampus. The principal cells of the DG, the GCs, project through the MF pathway to area CA3, where they release glutamate to excite pyramidal cells and local inhibitory interneurons. The latter, in turn, inhibit pyramidal cells to sustain feed-forward inhibition (**Figure 1**). Besides releasing glutamate, the GCs also contain and release dynorphin, enkephalin, Zn^{2+}, brain-derived neurotrophic factor (BDNF), and other peptides such as somatostatin, neuropeptide Y, neurokinin B, and cholecystokinin. Finally and surprisingly, the GCs also contain and release the inhibitory amino acid GABA. Most of the peptides that the GCs contain, as well as GABA and its synthesizing enzyme GAD_{67}, are regulated by activity – which is especially apparent after epileptic activity.

The activity-dependent plasticity of the GCs and their MFs, including the changes associated with epileptiform activity, is being actively explored with different experimental approaches. Particularly, in several models of experimental epilepsy, permanent and transient changes have been described at the molecular, functional, and anatomical level. In all experimental models of epilepsy, as well as in human epileptic patients, a series of plastic changes have been identified in the GCs. Among these plastic changes are alterations of the effects, metabolism, and content of Zn^{2+}; expression of neurotrophins and their receptors; sprouting of the MFs and formation of atypical GCs with basal dendrites; changes in the content and release of opioid peptides; induction of immediate early genes; regulation and transcription of opioid peptide genes and transcription factors; changes in the homeostasis of Ca^{2+} and ionic fluxes; and expression of GAD and GABA. Some of these changes appear to be adaptive and may serve to limit the risk of seizure generation, while others facilitate this process. Furthermore, some of these plastic phenomena seem not to be exclusively related to epilepsy but can occur after synaptic strengthening by long-term potentiation (LTP) induction.

In the DG-to-CA3 projection, each GC contacts ~15 pyramidal cells with 'giant boutons' and ~40–50 CA3 interneurons through philopodia and en passant terminals. Thus, it is clear that a major target of the MFs is onto inhibitory interneurons, thus involving the activation of feed-forward inhibitory circuits. The GCs also synapse proximally onto DG basket cells (providing local recurrent inhibition in the DG) and pyramidal-like neurons in the hilus; each GC makes 140–150 contacts of these latter types. Another important anatomical aspect of the MF pathway is that it

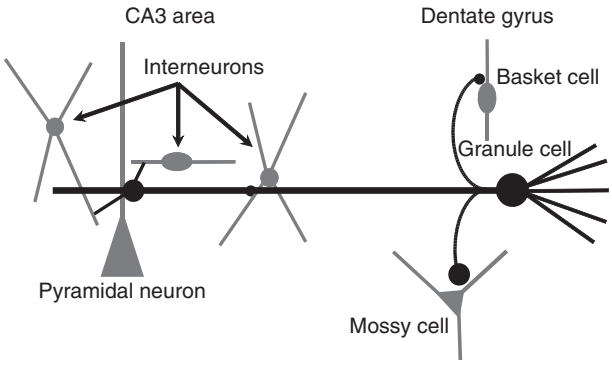

Figure 1 Diagram representing the multiple types of contacts made by granule cells. Within the dentate/hilar region collaterals of the mossy fibers innervate both mossy cells and inhibitory basket cells. In area CA3, the mossy fibers contact pyramidal neurons via large expansions and a large number of interneurons through either filopodial extensions from the large boutons or smaller en passant expansions along mossy-fiber axons. Reproduced from Jaffe DB and Gutiérrez R (2007) Mossy fiber synaptic transmission: Communication from the dentate gyrus to area CA3. In: Scharfman HE (ed.) *The Dentate Gyrus: A Comprehensive Guide to Structure, Function, and Clinical Implications*, Amsterdam: Elsevier.

is restricted to a narrow band running within the stratum lucidum, where the large terminals make contacts onto the most proximal portions of pyramidal neuron apical dendrites. In addition, there is a less extensive infrapyramidal MF projection onto the proximal basal dendrites of pyramidal neurons in the CA3b,c subregions.

Dual Glutamatergic–GABAergic Phenotype of Dentate Granule Cells

GABA was initially found to be present in the glutamate-containing terminals of the MFs of monkey and human hippocampi. However, since its synthesizing enzyme (glutamic acid decarboxylase, GAD) was not known to be expressed in GCs, it was thought that the amino acid was either transported from the extracellular space or originated from an alternative route of synthesis. The discovery of GABA in MFs led to the hypothesis that at least a component of the inhibitory synaptic potentials evoked in pyramidal cells by stimulation of the DG was of MF origin, and that the GABA released by the MFs could modulate the normal glutamatergic responses. Later work conclusively demonstrated the presence of GAD_{67} and GABA in human, monkey, and rat GCs, and that their expression was transiently up-regulated after seizures provoked by chemical convulsants, by the kindling method, and in a genetic epilepsy model.

Moreover, it was established that GAD_{67} could be transiently up-regulated in the GCs (**Figure 2(a)–2(c)**) and their MFs in an activity-dependent manner, even in the absence of epileptiform activity. Therefore, if the GCs had the necessary enzyme for the synthesis of GABA, and GABA itself was present, it seemed reasonable that GABA was probably used for fast neurotransmission. Soon after these demonstrations, the coexistence of glutamate and GABA in single MF boutons, and of their respective receptors in apposition to the presynaptic terminal, were confirmed. Finally, the mRNA of the vesicular GABA transporter (VGAT) was shown to be expressed in GCs in an activity-dependent manner (**Figure 2(d)**), although the transporter protein has not been detected in the MF, with the available antibodies. It was recently established that for the expression of the markers of the GABAergic phenotype in the GCs, calcium influx produced by glutamate, neurotrophin receptor activation, and protein synthesis were required.

Altogether, this evidence compellingly established that the adult GCs express a dual glutamatergic–GABAergic phenotype, whereby the latter is expressed in an activity-dependent manner. However, the expression of the GABAergic phenotype in GCs is constitutive during development. This observation has been one of the arguments that underlie the proposal that epileptogenesis recapitulates ontogenesis. Indeed, during the first three weeks of life, the GCs contain not only glutamate and its vesicular transporter, but also GABA, GAD_{67} and VGAT mRNA. These GABAergic markers abruptly disappear upon completion of early development and, as previously noted, can be reinduced in an activity-dependent manner.

As a result of these studies, investigators assumed that GABA synthesis in the MFs was a means to counteract the enhanced excitability caused by epileptic activity. But does the coexpression of a GABAergic phenotype in these glutamatergic cells turn them into inhibitory cells?

Methods

Electrophysiological Recordings

Adult Wistar rats (250 g) of control and epileptic groups (see later) were decapitated under deep ether anaesthesia, and combined entorhinal cortex–hippocampus slices (400 μm) were obtained and maintained in vitro at (35 ± 0.5)°C. They were constantly perfused with oxygenated artificial cerebrospinal fluid (ACSF) containing the following (in mM): NaCl, 124; KCl, 3; NaH_2PO_4, 1.25; $MgSO_4$, 2; $CaCl_2$, 2; $NaHCO_3$, 26; glucose, 10; pH 7.35. The drugs used were diluted in the ACSF – namely, the NMDA receptor antagonist (DL)-2-amino-5-phosphonovaleric acid (APV, 30 μM, Tocris); the non-NMDA receptor antagonist 6-nitro-7-sulphamoylbenzo(f)quinolaxine-2,3-dione (NBQX, 10 μM, Tocris, Tocris-Cookson, St. Louis, MO, USA); the $GABA_A$-receptor antagonist bicuculline methiodide (20 μM, Sigma, Sigma Aldrich, St. Louis, MO, USA); the group II metabotropic GluR agonist (2S,2′R,3′R)-2-(2′,3′-dicarboxycyclopropyl) glycine (DCG-IV, 1 and 10 μM, Tocris); the group III

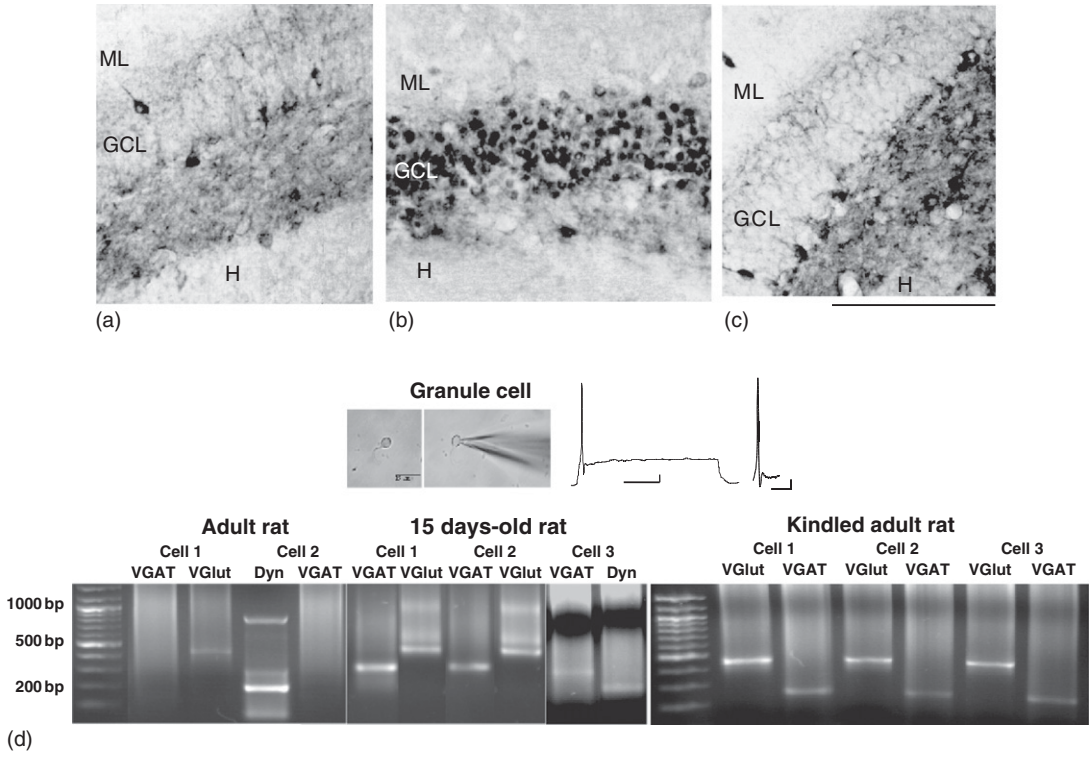

Figure 2 The granule cells express the markers of the GABAergic phenotype in an activity-dependent manner. (a) Immunohistochemical detection of GAD67 is normal in interneurons, but not in granule cells of the adult rat. (b) After seizures, the granule cells transiently up-regulate their expression of the enzyme. (c) A month after the last seizure, GAD67 is again undetected. The calibration bar represents 50 μm. (d) With single granule-cell PCR, we determined the expression of the glutamate (VGlut) and vesicular GABA transporters (VGATs), and dynorphin (Dyn) as a specific marker for granule cells. Granule cells of 15-day-old rats express Dyn, VGlut, and VGAT mRNAs. Adult healthy rats only express VGlut and Dyn mRNAs. After seizures, the expression of VGAT mRNA is up-regulated. (a—c) Modified from Ramírez and Gutiérrez (2001) Activity-dependent expression of GAD_{67} in the granule cells of the rat hippocampus. *Brain Research* 917: 139–146. (d), Modified from Gómez-Lira G, Lamas M, Romo-Parra H, and Gutiérrez R (2005) Programmed and induced phenotype of the hippocampal granule cells. *Journal of. Neuroscience* 25: 6939–6946, with permission from Society for Neuroscience.

metabotropic GluR agonist L(+)-2-amino-4-phosphonobutyric acid (L-AP4, 10 μM); the $GABA_B$ receptor agonist baclophen (3 μM, Sigma); and the protein inhibitor, cycloheximide (60 μM; Sigma).

Intracellular activity of pyramidal cells and interneurons in CA3 was recorded with glass microelectrodes (50–80 mΩ) filled with potassium acetate (2 M) and an AxoClamp 2B amplifier. (Molecular Devices, Foster City, CA) For evoking synaptic potentials, single-pulse electrical stimulation of the granule-cell layer of the DG was delivered at an intensity that evoked an excitatory postsynaptic potential (EPSP) with 60–70% of the amplitude required to make the cell fire action potentials. For extracellular recordings, we used glass microelectrodes (10–15 mΩ) filled with NaCl (155 mM). Field spontaneous activity was exported from pClamp8 and analyzed with ad-hoc programs written in MATLAB 7.0 (R14, MathWorks, Inc. Natick, MA). Samples of spontaneous field activity of either 10 or 16 s were acquired every 20 s throughout the experiments (usually lasting >2 h); they were digitized at 400 Hz and notch filtered at 60 Hz. Windowed Fourier analysis was applied using a Hanning window with 50% overlap. Through a graphical user interface, we were able to simultaneously visualize spectrograms and to calculate specific peak values and mean values for specific user-defined frequency windows.

Kindled and Acutely Induced Seizures

The rats were anaesthetized with ketamine (60 mg/kg i.p.) and implanted with bipolar stainless steel electrodes (80 KΩ) into the left basolateral amygdala (AP 2.5; L 5; H 8.5). Starting 7–10 days after the operation, the animals were stimulated daily with a 1-s train of square pulses (0.1-ms pulse duration, 60 Hz, 500 μA) until five generalized convulsive seizures (stage V) were evoked. Acute seizures were induced with a single i.p. administration of pentylenetetrazol (PTZ, 70 mg/kg, Sigma).

Kindling In Vitro

A bipolar (tip separation, 25 μm), glass-insulated platinum wire (50 μm) electrode was placed over the perforant path

or the granule-cell layer of the DG for stimulation. The stimulation protocol consisted of three trains of 0.1-ms pulses at 100 Hz; the train duration was 1 s and the intertrain interval was 1 min. These trains were delivered every 15 min, without varying the stimulus intensity. Between the kindling stimulation trials, synaptic responses were evoked with single pulses at 0.1 Hz delivered to the granular cell layer of the DG. The response to these single pulses was acquired and analyzed off-line with the program pClamp6 (Axon Instruments). For the experiments in which protein synthesis was inhibited, the slices were incubated in cycloheximide (60 μM) 15 min before initiation of the kindling stimulation protocol and for as long as it lasted (3 h). Intracellular recordings began at least 30 min after the removal of cycloheximide from the bathing medium, and could last several hours. The kindling stimulus intensity used for these experiments was previously determined, and set at a value needed to obtain 50% of the maximum amplitude of the DG population response to test pulses.

Immunohistological Studies

For the detection of GAD_{67} immunoreactivity, the slices of kindled epileptic rats, of PTZ-treated rats, or slices stimulated in vitro were processed simultaneously with control slices. They were fixed in phosphate buffer, 0.1 M, at pH 7.4 with paraformaldehyde at 4% for 48 h and transferred to a buffer with sucrose (30%) for 24 h. The slices were then frozen and cut at 30 μm in a microtome and collected in PBS (0.9% NaCl). The slices were incubated free-floating in PBS with 0.3% H_2O_2 to block endogenous peroxidase activity. After rinsing for three periods of 10 min in PBS, they were incubated in 10% horse serum (Gibco), 1% gelatin (Sigma) and 0.2% Tween-20 (Sigma), to avoid unspecific GAD staining. Slices were then incubated in the presence of GAD_{67} antibody (Chemicon) at 1:1000 (controls) or 1:1500 (stimulated) in PBS and horse serum (5%; 4°C) during 36 h with agitation. After four 10-min washing periods, they were incubated in the presence of an anti-rabbit biotinylated IgG (1:800; Amersham Pharmacia Biotech). The slices were then rinsed 4 times and processed with the ABC kit (Vectastain, Vector Laboratories) for 1 h at room temperature. After four 10-min washing periods, the slices were developed with diaminobenzidine (Sigma; 10 mg per 25 ml PBS (10 mM)) for 10 min and contrasted with nickel sulphate (30%).

Single-cell RT-PCR

The GCs were dissociated and used for whole-cell electrophysiological recordings. After recording, the cytosolic content of the cells was extracted by applying gentle negative pressure with the recording pipette; contents were placed in a PCR tube containing 8 μl of buffer 5× (one-step RT-PCR kit, Quiagen, Valencia, CA), 1.6 μl of dNTPs (final concentration 10 mM; One-Step RT-PCR kit Quiagen), 50 pmol of each oligonucleotide (to amplify the selected RNAs; see below), 40 units of RNAse inhibitor (Invitrogen, Carlsbad, CA), and 3 μl of the mixture of 'Omniscript' reverse transcriptase, 'Sensiscript' reverse transcriptase, and 'HotStarTAq' DNA polymerase (one-step RT-PCR kit, Quiagen), yielding a final volume of 40 μl. The RT-PCR reaction was then carried out in a thermocycler (PCR express, Hybaid, Ashford, UK) as follows: 30 min at 50°C; 15 min at 95°C; 30 s at 94°C, 30 s at 52°C, 1 min at 72°C (40 PCR cycles), and, finally, 10 min at 72°C. A second PCR reaction was then conducted with nested oligonucleotides. The product of the first amplifying protocol (3–5 μl) was used as a template for the second PCR protocol, in a final volume of 25 μl. The PCR solution contains PCR buffer 10× (Ammersham Biosciences, Piscataway, NJ), 10 μM of dNTPs (Invitrogen), 1-unit Taq DNA polymerase (Ammersham), and 50 pmol of each oligonucleotide. The reaction was carried out as follows: 2 min at 94°C, 30 s at 94°C, 30 s at 55–58°C, and 1 min at 72°C (35 PCR cycles). The specific oligonucleotides for each gene were custom-designed (Invitrogen) based on the indicated references. The oligonucleotides were for VGAT (sense, antisense, nested (antisense)); dynorophin (sense, antisense, nested (sense)); VGlut-1 (sense, antisense, nested). The products were visualized by electrophoresis in agarose gels (1.5%) with ethidium bromide. The expected weight of each final PCR product is VGAT, 250 bp; VGlut-1, 450 bp; and dynorphin, 200 bp. For controls, we conducted multiple sham experiments in which the surrounding bath solution was collected and processed in parallel. We did not detect the expression of mRNA in cells where we omitted the reverse transcriptase from the RT reaction.

Recent Results

Activation of the Mossy Fibers Provokes $GABA_A$ Receptor-Mediated Monosynaptic Responses in their Target Cells of CA3

The electrophysiological evidence of the presence of GABAergic transmission from the MFs to CA3 is in total agreement with the aforementioned immunohistochemical and molecular biological data. When the GABAergic markers are expressed (e.g., during development or after the induction of hyperexcitability), stimulation of the MFs – in the presence of glutamate receptors blockers – produces $GABA_A$ receptor-mediated monosynaptic responses both in pyramidal cells and interneurons of the CA3 area. It has been proposed that the MFs are, in fact, primarily GABAergic during the first days of life; subsequently, as development proceeds, more and more fibers are recruited to the dual use of GABA and glutamate, constituting a dual-phenotype pathway.

Finally, by the beginning of the fourth week of life, the GABAergic phenotype shuts off.

It has been known for many years that the activation of the MFs monosynaptically excites pyramidal cells and local inhibitory interneurons, and that the interneurons in turn inhibit pyramidal cells. Thus, activation of the DG provokes monosynaptic excitation and disynaptic inhibition on CA3 neurons that, with intracellular recordings, are evidenced as sequences of excitatory and inhibitory postsynaptic potentials. The perfusion of the NMDA-type glutamate receptor antagonist 5APV and the AMPA-kainate-type receptor antagonist NBQX blocks all synaptic responses, demonstrating that the inhibitory transmission in the MF-to-CA3 projection is disynaptically mediated (**Figure 3(a)**). However, under the same experimental conditions, the stimulation of the MFs in developing rodents leads to monosynaptic GABAergic responses in CA3 pyramidal cells and interneurons. Further, these GABAergic responses have the same pharmacological and plastic properties as those reported for glutamatergic MF transmission – i.e., they exhibit strong frequency-dependent facilitation, and they are presynaptically inhibited by the activation of metabotropic glutamate receptors (mGluR).

As already mentioned, in the healthy adult rat, in which the GABAergic markers are not expressed in MFs, MF GABAergic transmission cannot be observed. Interestingly, in rats subjected to kindling, stimulation of the MF in the presence of glutamate receptor blockers provokes a monosynaptic bicuculline-sensitive inhibitory postsynaptic potential (IPSP) (**Figure 3(b)**). This monsynaptic IPSP has the same latency as the control EPSP and is strongly inhibited by the activation of mGluR. Moreover, this response is transient; it is observed 24–48 h after the last-kindled seizure but not if the experiment is carried out a month after the last seizure (**Figure 3(c)**). If seizures are again produced, these monosynaptic GABAergic responses reappear. Experiments also showed that the kindled epileptic state was not necessary for this monosynaptic IPSP to be expressed, as a

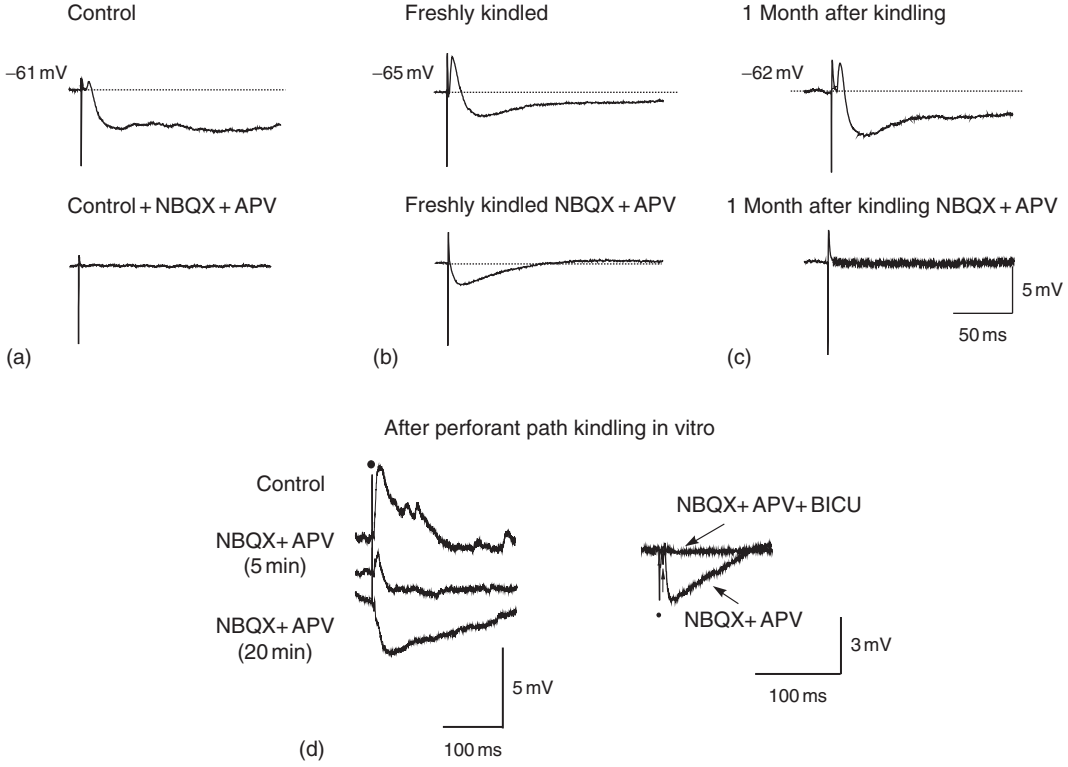

Figure 3 Synaptic responses of CA3 pyramidal cells to DG stimulation in preparations from healthy rats (a) and 24 h (b) and a month after the last generalized kindled seizure (c). In cells from freshly kindled rats, DG stimulation under NBQX + APV perfusion elicited IPSPs, which were blocked by bicuculline (lower trace). A month after the last seizure, DG stimulation in the same conditions no longer evokes GABAR-mediated responses. Note the correspondence of these responses with the expression of GAD_{67} depicted in **Figure 1** (d) Repeated application of an LTP-like protocol (in vitro kindling) to a hippocampal slice from a healthy rat produces the emergence of GABAR-mediated monosynaptic transmission from the mossy fibers. Traces are averages of six responses. (a—c), Modified from Gutiérrez and Heinemann (2001) Kindling induces transient fast inhibition in the dentate gyrus-CA3 projection. *European Journal of Neuroscience* 13: 1371–1379, with permission from Blackwell Publishing. (d), Modified from Gutiérrez (2002) Activity-dependent expression of simultaneous glutamatergic and GABAergic neurotransmission from the mossy fibers in vitro. *Journal of Neurophysiology* 87: 2562–2570, with permission from American Physiological Society.

single seizure could provoke its emergence. Furthermore, the repeated application of an LTP-inducing protocol in the perforant path or in the MF themselves – which does not produce epileptiform activity – provokes the emergence of MF GABAergic monosynaptic transmission (**Figure 3(d)**). These experiments demonstrated that a certain level of sustained excitation, and not the presence of epileptic activity, is required for the GCs to express the GABAergic phenotype and GABAergic transmission. These experiments also showed that this process requires protein synthesis. Activation of the postsynaptic cell is not required for the induction of MF monosynaptic GABAergic transmission; i.e., the novel incorporation of $GABA_A$-R in the postsynaptic site does not account for the appearance of GABAergic responses on MF stimulation.

As previously noted, the putative release of glutamate and GABA from the MF takes place onto both their targets in CA3 (the pyramidal cells and the interneurons) and also onto hilar interneurons. In fact, for each contacted pyramidal cell, the MFs contact 50 interneurons. This difference can have profound functional significance given that feed-forward inhibition is a powerful mechanism that controls CA3 excitability. And as discussed here, at least in some respects the release of glutamate and GABA onto interneurons seems to be different from the release onto pyramidal cells.

Intracellular recordings from interneurons in CA3 of healthy adult rats revealed that MF-evoked EPSP/IPSP sequences can be totally blocked in the presence of glutamatergic antagonists (**Figure 4(a)** and **(4b)**), thus demonstrating that inhibitory transmission onto interneurons, as onto pyramidal cells, is disynaptically mediated. However, as previously described in pyramidal cells, MF activation in the presence of glutamatergic antagonists provokes monosynaptic IPSPs with the same latency as the control EPSP after seizures or LTP-like stimulation (**Figure 4(c)** and **4(d)**). However, although MF monosynaptic GABAergic transmission is expressed onto interneurons under these conditions, the effect of the MF glutamatergic transmission surpasses the inhibitory one. In animals subjected to seizures or tetanic stimulation, activation of the MF pathway provokes a high amplitude and long-lasting EPSP that totally obscures the underlying IPSP in interneurons. In contrast, pyramidal cells in these preparations display an enhanced IPSP that partially shunts the EPSP. Thus, the interneurons are more readily excited than pyramidal cells. The pyramidal cells thus receive a strong inhibitory input from the interneurons within CA3, in addition to the monosynaptic MF GABAergic signal. Activation of MF at high frequencies provokes the more pronounced IPSPs in pyramidal cells to be potentiated, and their summation leads to pyramidal-cell hyperpolarization. In interneurons, high frequency stimulation leads to summation of EPSPs and readily provokes interneuron spiking (**Figure 4(g)** and **4(h)**). These experiments show that although both pyramidal cells and interneurons receive the same dual MF input, the released glutamate-GABA ratio onto the target cells can be different. This differential response of pyramidal cells and interneurons of CA3 prevents disinhibition of CA3 and, as discussed later, can modify the interneuronal network-mediated oscillatory activity.

There is another mechanism that controls the release of neurotransmitters at the MF synapse. Glutamate and GABA released from the MFs can exert presynaptic inhibition of nearby MFs, the terminals of which contain mGlu, and $GABA_A$ and $GABA_B$ receptors. Activation of different presynaptic mGluRs differentially inhibits glutamate or GABA release, and it is also likely that the density of presynaptic mGluRs and $GABA_A$ and $GABA_B$ receptors differ in large MF terminals, in en passant boutons, and in filopodial extensions (**Figure 4(e)** and **4(f)**; see also **Figure 6**).

Functional Implications with Regard to Epilepsy

It has been proposed that the DG serves as a filter that limits the transfer of information from the entorhinal cortex to the pyramidal layer of the hippocampus. However, in kindled animals, this filtering mechanism seems to be altered. Clearly, in the hippocampus of epileptic rats, one of the compensatory changes is the expression and release of GABA from the DG. Therefore, in the adult rat, the transient expression of a GABAergic phenotype in the otherwise glutamatergic GCs seems to be a response to counteract enhanced excitation. Stimulation of the DG, or direct activation of MFs, produces IPSPs in pyramidal cells and interneurons; when recorded extracellularly, $GABA_A$ receptor-mediated field responses can also be detected, indicating that a considerable number of boutons of a well-defined GABAergic pathway simultaneously release GABA onto a large number of receptors. This observation shows that the MF pathway constitutes a 'GABAergic-also' pathway after seizures, and that GABA release has a strong impact on the CA3 area as a whole. This enhanced GABAergic transmission from the DG-to-CA3 could be involved in the anterograde amnesia that appears for some time after seizures, particularly after status epilepticus, which can hamper storage of information in the hippocampal network. Indeed, changes in the phenotype of MFs may have an impact on the capability of the network to generate rhythmic activities such as theta and gamma oscillations. In fact, the MF GABAergic input to CA3 has been shown to modulate its spontaneous oscillatory activity after seizures. Inhibiting release of MF GABA by the activation of mGluRs provokes the enhancement of β/γ activity in CA3 by a presynaptic mechanism (**Figure 5**).

These experimental results suggest that, after seizures, the MF projection exerts a tonic inhibitory control on

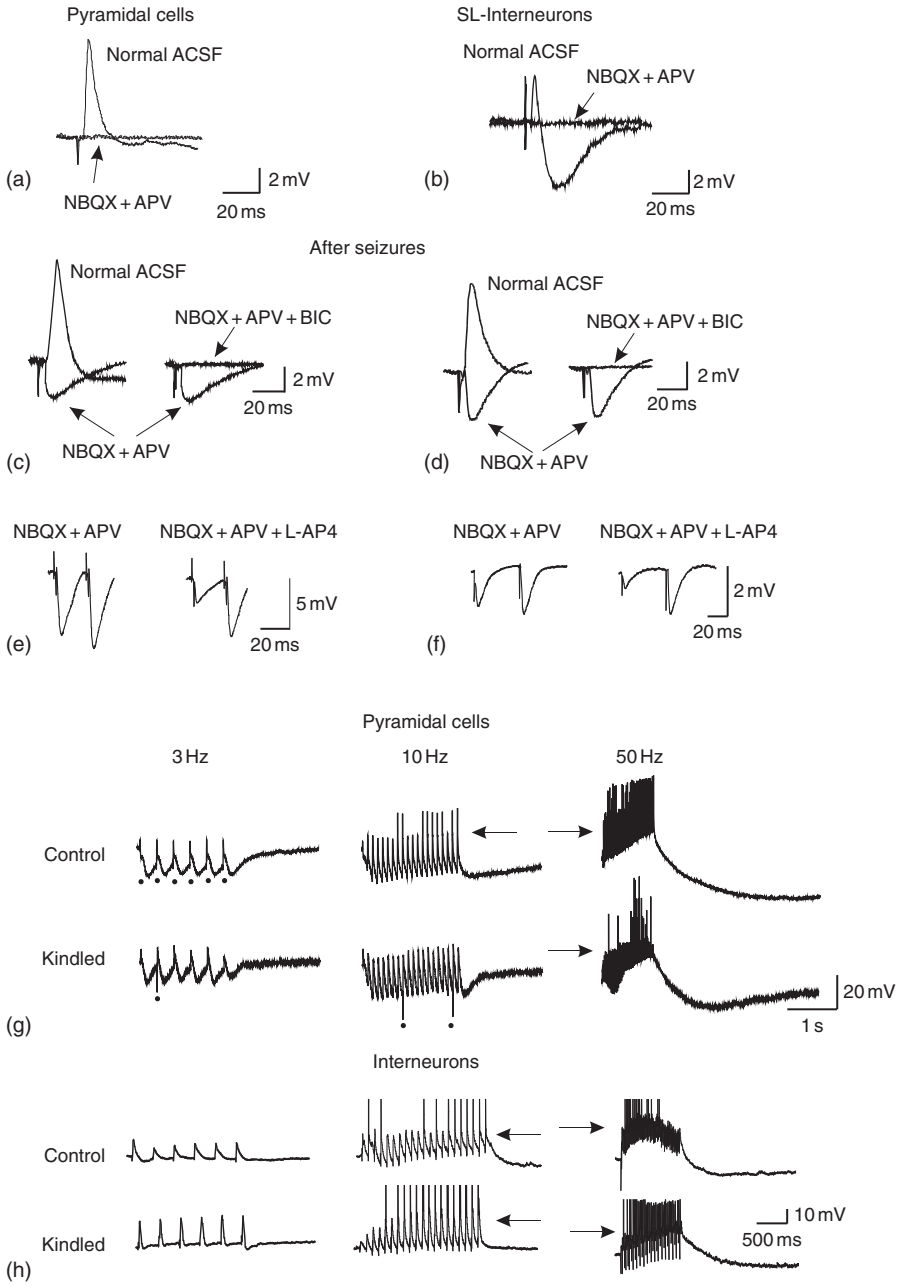

Figure 4 Mossy fibers simultaneously release glutamate and GABA onto all its target cells in CA3 area. In electrophysiologically and anatomically identified pyramidal cells (a) and Stratum lucidum interneurons (b) from control preparations, MF stimulation produced EPSP/IPSP sequences that were blocked by iGluR antagonists. In preparations from rats that were subjected to seizures, the same stimulation produced a monosynaptic $GABA_A$-R-mediated IPSP in the presence of NBQX and APV. This IPSP was blocked by the addition of bicuculline (c, d). A paired-pulse stimulation paradigm that produced potentiation of the second response was used to reveal the presynaptic inhibition of the $GABA_A$-R-mediated responses by activation of mGluR-III with L-AP4. The first response to the pair of pulses was depressed by L-AP4, while the $IPSP_2$:$IPSP_1$ ratio was enhanced, both in pyramidal cells (e) and in interneurons (f). Synaptic responses of CA3 pyramidal cells (g) and interneurons (h) to mossy-fiber activation at 3, 10, and 50 Hz in preparations from a control and from a kindled rat. Pyramidal cells from kindled rat presented less action potentials per train than those from control rats, whereas interneurons from kindled rats reached threshold for action potentials more easily than those from control rats. The arrow shows the point above which the responses were action potentials. The dots indicate stimulus artifacts. All traces are averages of three successive trials. (a–f), Adapted from Treviño M, Vivar C, and Gutiérrez R (2007) β/γ oscillatory activity in the CA3 hippocampal area is depressed by aberrant GABAergic transmission from the dentate gyrus after seizures. *Journal of Neuroscience* 27: 251–259, with permission from Society for Neuroscience. (g, h), Modified from Gutiérrez and Heinemann (2001) Kindling induces transient fast inhibition in the dentate gyrus-CA3 projection. *European Journal of Neuroscience* 13: 1371–1379, with permission from Blackwell Publishing and from Vivar C (2006) Plasticity of mossy fiber transmission onto the interneurons of the CA3 area of the hippocampus, doctoral dissertation, CINVESTAV.

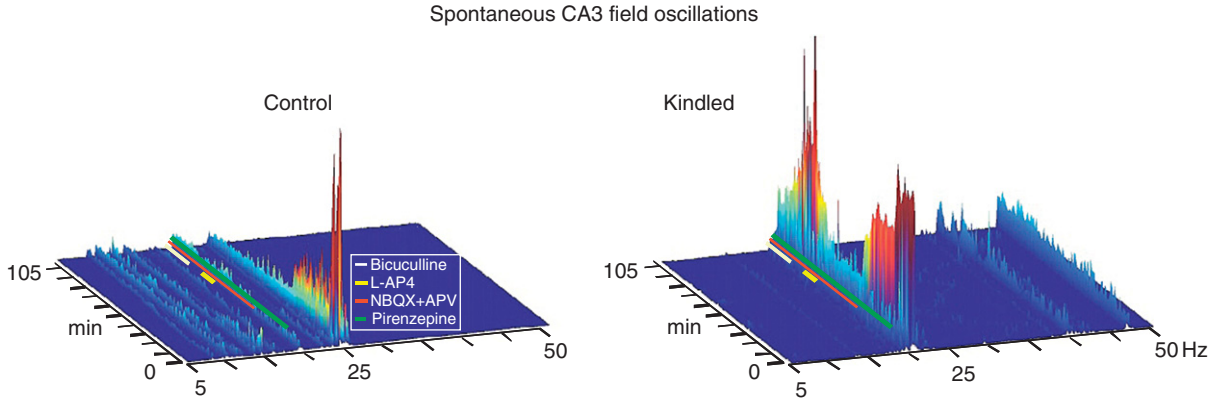

Figure 5 Mossy-fiber GABAergic input affects spontaneous field oscillations in the CA3 area after seizures. 3D layout of the spectrograms (from 5 to 50 Hz, traces of 4 s, *x* axis) were obtained throughout the experiment (FFT of traces of 10 s of duration, acquired every 20 s, *z* axis), in different pharmacological conditions. Spectral power is indicated in a color scale (*y* axis) where warm colors depict high power and cold colors depict low power. Colored lines over the mesh indicate the addition of pirenzepine (blue), NBQX + APV (red), L-AP4 (yellow), and bicuculline (white) to the normal ACSF. Note that the mGluR-III agonist, L-AP4, which presynaptically inhibits GABA release from the mossy fibers potentiates β/γ activity. In contrast, L-AP4 is ineffective in control preparations, where GABA release from the mossy fibers is not present. This is indicative of a tonic inhibition of the mossy fibers on the oscillations originated by the GABA interneuronal network in CA3. Adapted from Treviño M, Vivar C, and Gutiérrez R (2007) β/γ oscillatory activity in the CA3 hippocampal area is depressed by aberrant GABAergic transmission from the dentate gyrus after seizures. *Journal of Neuroscience* 27: 251–259, with permission from Society for Neuroscience.

CA3. A possible effect of the release of GABA from the MF would be to enhance GABA concentration in the extracellular space, which is likely to enhance tonic GABA currents. It has been shown that tonic GABA currents represent the most powerful inhibitory mechanism controlling the excitability of hippocampal cells. Oscillatory activity in area CA3 is intrinsically generated by the interneuronal GABA network, and MF input exerts its inhibitory control precisely on this network (**Figure 6**). Consequently, not only interneurons within CA3, but also the principal cells of the DG may be engaged in setting the tone for oscillations – to be expressed or suppressed – in the hippocampus (**Figure 6**).

In human temporal lobe epilepsy and respective animal models, MFs rearrange such that they also innervate neighboring glutamatergic projection cells (GCs) in addition to their 'normal' physiological innervation of mossy cells and basket cells in the hilus. These connections provide for a strong coupling between different lamellae in the hippocampus and thus may contribute to seizure spread. Yet to be explored is whether recurrent MFs, which develop after epilepsy and that innervate other GCs, also release GABA. Interestingly, aberrant, recurrent, sprouted MFs have been thought to underlie enhanced excitability of the DG. However, if these aberrant MFs were also to release GABA, it is unclear what the impact of this recurrent dual transmission would be on the activity and excitability of the DG. Corelease of GABA and glutamate after acute seizures would presumably prevent (or reduce the likelihood of) the activation of neighboring GCs and may also prevent activation of hilar mossy cells. Reduced activation in these cells may help to explain reduced seizure susceptibility, which is frequently observed after temporal lobe seizures.

Future Goals

The data reviewed compellingly show that the GCs can transiently express a dual glutamatergic–GABAergic phenotype during development, and also in adult animals following high levels of activity, particularly seizures. The morphological evidence that GABA can be exocytosed at MF synapses to act on postsynaptic $GABA_A$ receptors is as strong as that indicating that glutamate is released. However, the available body of electrophysiological evidence, although compelling, is indirect. Simultaneous recordings of synaptically connected granule and pyramidal cells are needed to unequivocally prove this hypothesis. Although this task is technically difficult (single GCs only contact few pyramidal cells), accomplishing it would help to clarify whether glutamate and GABA are released from single or different MF terminals and/or from single or different release sites. Another intriguing issue of GCs plasticity is the nature of the vesicular transporter for GABA in the MFs. Such a transporter has not been found in MF terminals, despite the presence of its mRNA and the modulation of vesicular transporter mRNA by activity, as determined by single-cell RT-PCR. This result suggests that in some GABAergic cells, as in the GCs, a yet unidentified GABA transporter exists and is expressed in an activity-dependent manner.

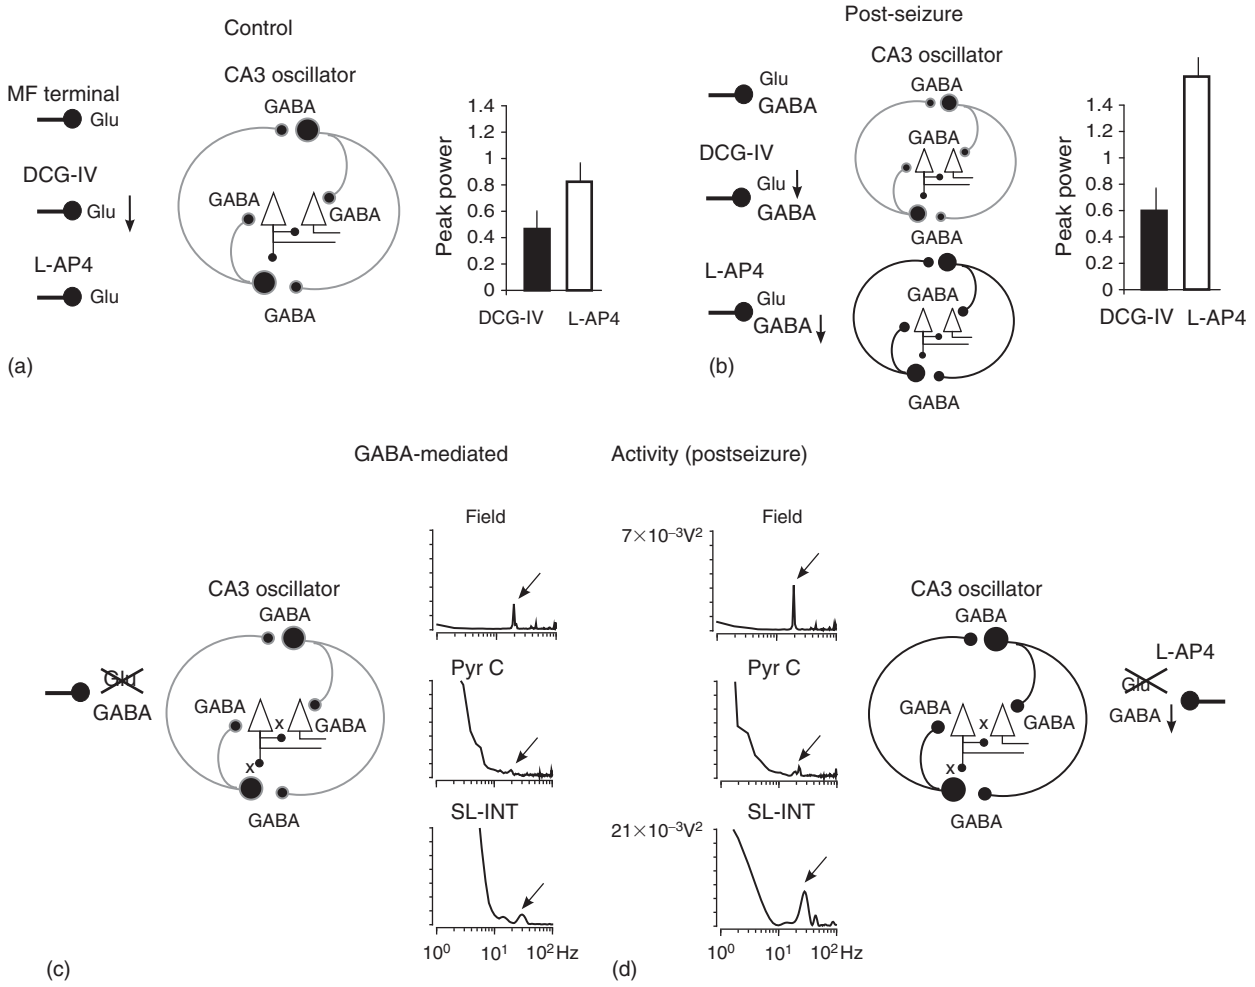

Figure 6 β/γ activity in the CA3 region is inhibited by mGluR-sensitive, GABA-mediated aberrant transmission from the mossy fibers. (a) CA3 is an endogenous oscillator, which receives a glutamatergic input from the MF. Activaiton of group II mGlu presynaptic receptors inhibits glutamate release from the MF and strongly depresses oscillatory activity, while activation of group III mGlu presynaptic reptors with L-AP4, which inhibite GABA release from the MF, produces a noticeable enhancement of the β/γ power. This uncovers the tonic inhibitory control of the MF on the oscillatory activity. This control is exerted on GABA-mediated oscillations because it is observed in the presence of iGluR blockers. (c) Indeed, in the absence of glutamatergic input, GABA-mediated oscillatory β/γ activity (arrows) can be observed in field recordings and in subthreshold spontaneous membrane oscillations of stratum lucidum interneurons of area CA3 after seizures. (d) Activation of group III mGluR relieves the inhibition of GABA-mediated β/γ oscillations (arrows) in the CA3 field, which is primarily reflected in the subthreshold spontaneous membrane oscillations of stratum lucidum interneurons. Reproduced from Gutiérrez R, *et al*. (2003) Plasticity of the GABAergic phenotype of the 'glutamatergic' granule cells of the rat dentate gyrus. *Journal of Neuroscience* 23: 5594–5598, with permission of the Society for Neuroscience.

Finally, we are still to answer the important questions about what molecular 'switch' is responsible for turning off the GABAergic phenotype in GCs as development proceeds, and conversely, what turns on GABAergic expression after epileptic activity? A number of candidate molecules (mostly transcription factors) regulating the expression of GABAergic markers have been described, and it is likely that one or some of them are involved in the regulation of this phenotypic plasticity in the GCs. This intriguing field of investigation will certainly give us important insights, not only into the generation and maintenance of epileptic activity, but also into a powerful neuronal communication tool.

Introduction

The hippocampus is required for declarative memory, the type of memory accessible to conscious recollection. For an individual to distinguish similar memories, he must encode distinct representations of the temporal and spatial relationships comprising events. This component of memory formation, referred to as pattern separation, depends on the activity of dentate granule cells. These neurons comprise the first stage of information processing within the hippocampus. Excitatory input from all parts of the cerebral cortex is fed through the entorhinal cortex and then dispersed onto a large number of granule cells having a low (0.1–1 Hz) baseline firing rate. This arrangement enables individual granule cells to receive and relay only a small, distinct fraction of the total input. Granule cells are electrically compact. Their dendritic properties support the precise temporal integration of synaptic signals at frequencies up to the top of the gamma range. The granule-cell firing rate increases (to 10–40 Hz) during behavioral tasks that activate memory formation. Granule-cell axons, the mossy fibers, transfer these discrete information sets to the pyramidal cells of hippocampal area CA3. In the rat, each granule cell innervates an average of only 14 CA3 pyramidal cells and each pyramidal cell receives a single mossy-fiber synapse apiece from only 50 granule cells. In contrast to this sparse projection, each granule cell innervates 40–50 CA3 interneurons. The ability of granule cells to achieve pattern separation derives, in part, from strong mossy fiber-evoked feed-forward inhibition that prevents the spread of excitation from the few targeted CA3 pyramidal cells to the rest of the synaptically interconnected pyramidal-cell population. Pattern separation also depends on the relatively low probability of glutamate release from mossy-fiber boutons when they are activated at frequencies that correspond to baseline granule-cell firing. The net effect of granule-cell output, which favors inhibitory drive onto area CA3 during low-frequency activity, switches to net excitation at higher discharge frequencies, such as those at which granule cells fire during memory formation. Frequency-dependent facilitation is of greater magnitude and operates over a much broader dynamic range at mossy-fiber synapses on pyramidal cells than on interneurons. Moreover, some mossy-fiber synapses on CA3 interneurons

Introduction

The hippocampus is required for declarative memory, the type of memory accessible to conscious recollection. For an individual to distinguish similar memories, he must encode distinct representations of the temporal and spatial relationships comprising events. This component of memory formation, referred to as pattern separation, depends on the activity of dentate granule cells. These neurons comprise the first stage of information processing within the hippocampus. Excitatory input from all parts of the cerebral cortex is fed through the entorhinal cortex and then dispersed onto a large number of granule cells having a low (0.1–1 Hz) baseline firing rate. This arrangement enables individual granule cells to receive and relay only a small, distinct fraction of the total input. Granule cells are electrically compact. Their dendritic properties support the precise temporal integration of synaptic signals at frequencies up to the top of the gamma range. The granule-cell firing rate increases (to 10–40 Hz) during behavioral tasks that activate memory formation. Granule-cell axons, the mossy fibers, transfer these discrete information sets to the pyramidal cells of hippocampal area CA3. In the rat, each granule cell innervates an average of only 14 CA3 pyramidal cells and each pyramidal cell receives a single mossy-fiber synapse apiece from only 50 granule cells. In contrast to this sparse projection, each granule cell innervates 40–50 CA3 interneurons. The ability of granule cells to achieve pattern separation derives, in part, from strong mossy fiber-evoked feed-forward inhibition that prevents the spread of excitation from the few targeted CA3 pyramidal cells to the rest of the synaptically interconnected pyramidal-cell population. Pattern separation also depends on the relatively low probability of glutamate release from mossy-fiber boutons when they are activated at frequencies that correspond to baseline granule-cell firing. The net effect of granule-cell output, which favors inhibitory drive onto area CA3 during low-frequency activity, switches to net excitation at higher discharge frequencies, such as those at which granule cells fire during memory formation. Frequency-dependent facilitation is of greater magnitude and operates over a much broader dynamic range at mossy-fiber synapses on pyramidal cells than on interneurons. Moreover, some mossy-fiber synapses on CA3 interneurons

undergo frequency-dependent depression. Finally, intense synaptic bombardment of granule cells by the perforant path produces a sizable depolarization that can spread to mossy-fiber boutons and facilitate transmitter release. These cellular properties allow granule cells to serve as high-pass filters for the transfer of cortical information to the rest of the hippocampus.

The same cellular properties that subserve pattern separation also allow dentate granule cells to resist the propagation of seizures from the highly excitable entorhinal cortex to the equally excitable CA3 area. The low baseline firing rate of granule cells may be explained by strong synaptic and tonic γ-aminobutyric acid (GABA) inhibition, a high resting membrane potential, high K^+ conductance, low Ca^{2+} conductance, little or no h current (hyperpolarization-activated cation current – I_h), and a virtual lack of monosynaptic recurrent excitation. The near absence of mossy-fiber → granule-cell synapses allows each individual neuron to serve as a functional unit for encoding a distinct fraction of the total perforant path input and discourages synchronous discharge. In the normal brain, intense activation of granule cells by the perforant path is required for seizure propagation through the dentate gyrus, a phenomenon termed 'maximal dentate activation'. In epileptic brain, dentate granule cells are more easily recruited into epileptiform activity even though their excitability may appear unchanged in some tests. Changes in the intrinsic properties of granule cells, changes in granule-cell innervation, and the addition of hyperexcitable ectopic granule cells to dentate gyrus circuitry could explain these findings. To the extent that abnormal granule cell function contributes to seizure propagation, pharmacotherapy directed against these abnormalities may improve seizure control.

Background

The term 'granule cell' refers to a neuron with a small (8–12-μm diameter) round-to-oval cell body. Dentate granule cells in rodents usually have two spiny apical dendrites that branch extensively in the molecular layer. Rodent granule cells generally lack a basal dendrite, although ~2% have a recurrent basal dendrite, defined as a process opposite to the apical dendrite that is directed into the hilus and then eventually curves back into the molecular layer. However, ~25% of primate granule cells have a basal dendrite. The innervation of dentate granule cells is strongly laminar: Each excitatory and inhibitory afferent projection forms synapses on a distinct and usually nonoverlapping region of the plasma membrane. The major excitatory afferent projection, the perforant path, arises from the layer II stellate cells of the entorhinal cortex and forms synapses on the distal two-thirds of the apical dendrites. The perforant path conveys processed information from all regions of the cerebral cortex. The proximal third of the apical dendrites is innervated by the associational–commissural pathway, which originates from the mossy cells of the dentate hilus. This pathway provides polysynaptic feedback excitation from mainly more caudal regions of the ipsilateral dentate gyrus and from the contralateral dentate gyrus. Monosynaptic innervation from other granule cells replaces the associational–commissural projection in many persons with temporal lobe epilepsy and in animal models of this disorder (where many hilar mossy cells are lost). A rudimentary projection of this type has been demonstrated in the caudal dentate gyrus of normal rodents. Because granule-cell basal dendrites serve as targets for mossy fibers, monosynaptic recurrent excitation may be a more prominent feature of dentate granule cells in humans than in rodents. Granule cells receive synaptic inhibition from six distinct local GABA neuron populations. One interneuron population, the basket cells, has a unique role in generating the gamma frequency oscillations thought to be important for pattern separation. Dentate granule cells also receive sparse innervation from several subcortical regions of the brain, including the supramammillary nucleus of the hypothalamus, the medial septal–diagonal band complex, the nucleus locus coeruleus, and the dorsal raphe nucleus. There is currently no evidence for a back projection from CA3 pyramidal cells, except for the disynaptic pyramidal-cell → mossy-cell → granule-cell pathway. Pyramidal cells of the caudal CA3 area do send a projection to the molecular layer of the dentate gyrus, raising the possibility of monosynaptic feedback excitation. It has not been established, however, whether these fibers innervate granule cells or interneurons.

Dentate granule cells project to CA3 pyramidal cells and interneurons of area CA3 and the dentate gyrus. Short- and long-term plasticity at mossy-fiber synapses allow this pathway to impart mainly excitatory or mainly inhibitory drive to area CA3, depending on the frequency and synchrony of granule-cell discharge.

In addition to excitatory and inhibitory synaptic inputs, granule-cell excitability is regulated by membrane ionic currents, most importantly by tonic GABA current, the slow delayed rectifier K^+ current (I_K), the BK- and SK-type Ca^{2+}-dependent K^+ currents, and T-type Ca^{2+} current. Tonic GABA current is produced by ambient extracellular GABA and released GABA that escapes the synaptic cleft. It is thought to depress the baseline excitability of granule cells. The generation of an intrinsic granule-cell burst depends on the activation of slow inward currents by the action potential. Because of the high granule-cell resting membrane potential, action potentials activate low-threshold T-type Ca^{2+} current, which contributes prominently to the spike afterdepolarization characteristic of these cells. A sufficiently large afterdepolarization can

trigger additional action potentials comprising a cellular burst. The effect of T-type Ca^{2+} current is counteracted mainly by activation of BK-type or high conductance Ca^{2+}-dependent K^+ current. SK-type or low conductance Ca^{2+}-dependent K^+ current and I_K also suppress bursting behavior in these cells. BK-type current mainly limits the size of the spike afterdepolarization, whereas SK-type current is mainly responsible for spike frequency adaptation. The high resting membrane potential is maintained by K^+ conductance. Membrane potential is a linear function of extracellular K^+ concentration between 3 and 6 mM and increases at a slower rate above 6 mM. Modification of any of these channels may predispose to breakdown of the granule cell's filtering function and the emergence of seizures.

Methods

Our studies use rats that had developed status epilepticus after administration of the muscarinic receptor agonist pilocarpine. We normally allow status epilepticus to self-terminate without administration of an anticonvulsant. Animals that experience prolonged (6–8 h) status epilepticus exhibit very extensive and uniform hilar lesions followed by robust recurrent mossy-fiber growth, as observed in many persons with temporal lobe epilepsy. The pilocarpine model also replicates the accumulation of ectopic granule cells observed in those persons. Rats that experience pilocarpine-induced status epilepticus invariably develop unremitting spontaneous seizures after a delay of 1–3 weeks. In these respects, the pilocarpine model produces more consistent outcomes than the alternatives, such as the kainic acid or electrical stimulation models. Finally, pilocarpine-induced status epilepticus kills fewer CA3 pyramidal cells than does kainic acid or electrical stimulation, better replicating the lesion most commonly observed in surgically resected hippocampi and facilitating the placement of a stimulating electrode in the mossy-fiber bundle of hippocampal slices.

Most of our studies are performed during the chronic epileptic period 10 weeks or longer after status epilepticus. By this time, the granule-cell network appears to be fully mature. Some analyses are also performed 4–6 days after status epilepticus, before the new circuitry can be detected. Hippocampal slices are prepared for electrophysiological studies. Extracellular recording, whole cell and cell-attached patch clamp recording, and perforated patch recording are used, as appropriate, to define granule-cell properties, the physiology and pharmacology of mossy-fiber → granule-cell synapses, and the role of the novel circuitry in granule-cell epileptiform activity. In parallel studies, histological, ultrastructural, immunohistochemical, and immunocytochemical approaches are used to describe and quantitate the cytopathology of the lesion and the anatomical response to the lesion.

Results

Research in our laboratory and in others has described profound changes in the innervation and neurotransmitter mechanisms of dentate granule cells in animal models of epilepsy. In lesional models, excitatory innervation from other granule cells replaces the degenerated associational–commissural projection. In addition, epileptogenesis is associated with enhanced perforant path synaptic transmission. Paired-pulse facilitation of perforant path synaptic transmission is depressed, implying a greater probability of glutamate release. The NMDA receptor-mediated component of the perforant path EPSC is prolonged, suggesting a change in receptor kinetics and leading to crosstalk among perforant path synapses. In the kindling model of epilepsy, NMDA channels in granule cells have a greater mean open time, longer burst duration, longer cluster duration, and enhanced sensitivity to high-energy phosphates, whereas their sensitivity to Mg^{2+} decreases. Enhancement of NMDA receptor function has been shown to promote the synchronized discharge of granule cells.

Of the inhibitory projections to dentate granule cells, innervation from HIPP (soma located in the hilus, projection to the perforant path terminal zone) cells is most likely to be lost. HIPP cells coexpress somatostatin and neuropeptide Y with GABA. They account for ~40% of all hilar GABA interneurons and probably contribute 40–50% of the feedback (mossy fiber-evoked) inhibition to granule cells. HIPP cell axons form synapses mainly on the necks of granule-cell dendritic spines. Because perforant path synapses are found on the head of those spines, the HIPP cell innervation is believed to regulate the efficacy of perforant path innervation. Loss of this regulation is expected to augment cell firing in response to perforant path activation. Although some findings suggest axon sprouting by surviving GABA interneurons, electrophysiological studies have not demonstrated any significant recovery of inhibition attributable to this mechanism. Granule cells do recover, at least to some extent, from the loss of feedback inhibition and enhanced excitability that result from the loss of GABA interneurons. Suggested mechanisms for recovery include the repetitive activation of surviving interneurons by reverberating mossy-fiber activity, a somewhat increased number of mossy-fiber synapses on those interneurons, increased interneuron excitability, facilitated GABA release, and increased tonic GABA current. The net effect of these changes may be to restore baseline granule-cell excitability to near normal. However, granule-cell function must, in fact, be grossly abnormal because of the rewiring and

altered neurotransmitter mechanisms needed to achieve this state.

In contrast to synapses and neurotransmitter receptors, intrinsic properties of dentate granule cells appear little changed during epileptogenesis. The resting membrane potential, input resistance, and action potential threshold are unchanged. Similarly, we found no change in T-type Ca^{2+} current. The retention of spike frequency adaptation and lack of facilitated cellular bursting suggest little change in Ca^{2+}-dependent K^+ current. There is, however, some loss of the intracellular Ca^{2+}-binding protein calbindin-D_{28k}. Loss of this protein increases the Ca^{2+}-dependent inactivation of voltage-dependent Ca^{2+} currents, thus limiting Ca^{2+} influx. In addition, granule cells increase the expression of HCN1 h channel subunit during epileptogenesis. Expression of h current might be expected to enhance granule-cell excitability. It is unknown, however, whether functional h channels are actually expressed. Granule cells normally express HCN1, but attempts to evoke I_h have been unsuccessful. Evidently, either h channel subunits do not normally form functional assemblies in these cells or the assembled channels fail to insert into the plasma membrane.

Perhaps the most interesting change in dentate granule cells of epileptic brain is the appearance of functionally different granule-cell populations due to enhanced neurogenesis. Seizures are especially powerful stimuli for granule-cell neurogenesis. Most of the neurons generated after seizures migrate into the granule-cell body layer and differentiate normally. However, a sizable number migrate aberrantly into the dentate hilus. Granule cells that are born after seizures and migrate normally appear to be less excitable than control granule cells. In contrast, we find that hilar ectopic granule cells (HEGCs) retain some properties of immature granule cells despite their morphological differentiation. These properties maintain the high excitability characteristic of the immature state. Most HEGCs possess intrinsic burst capability related to a large T-type Ca^{2+} current (Figure 1). Other properties that enhance excitability include a relatively low mean resting membrane potential, high input resistance, reduced spike frequency adaptation, sparse synaptic inhibition, and abundant mossy-fiber innervation, even on the cell body. At near physiological temperature and in the presence of a modestly elevated extracellular K^+ concentration, HEGCs were reported to burst in synchrony with CA3 pyramidal cells. Although the significance of this observation is unclear, it suggests that HEGC bursting may be driven by extrinsic as well as intrinsic mechanisms.

Future Goals

Properties of dentate granule cells control cell firing in such a way that cortical information is transmitted effectively to CA3 pyramidal cells only when required for memory formation. At other times, granule cells are relatively quiescent. Epileptogenesis disrupts some of these control mechanisms. Both excitatory and inhibitory innervation, neurotransmitter receptor expression, and calcium currents change in ways that could either promote or inhibit seizures. Further effects on granule-cell innervation and cellular properties may yet be discovered. Clearly, dentate granule cells in epileptic brain function differently from those in nonepileptic brain. How do these differences impact pattern separation and ultimately cognitive function? To what extent do the requirements for

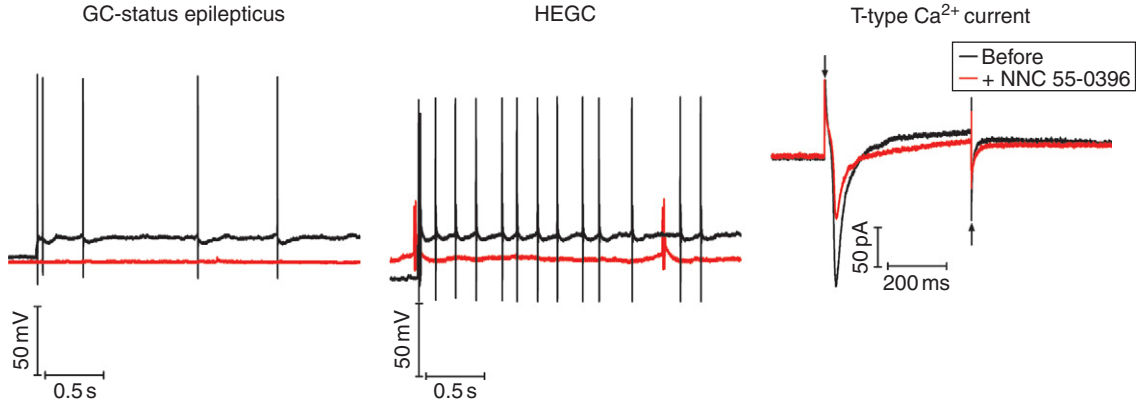

Figure 1 (Left) Normally located dentate granule cell is silent at resting V_m (red trace) and fires repetitive action potentials when depolarized to −48 mV (black trace) 10+ weeks after pilocarpine-induced status epilepticus. Marked spike frequency adaptation is evident. (Center) HEGC bursting at resting V_m (red trace) converts to repetitive action potential firing when the cell is depolarized to −48 mV (black trace). Spike frequency adaptation is reduced when compared with normally located granule cells. (Right) Large T-type Ca^{2+} current evoked in HEGC. Cells were voltage-clamped at −90 mV for 4 s before applying a 500 ms voltage step to −60 mV (between arrows). The superfusion medium contained blockers of high voltage-activated Ca^{2+} channels, voltage-dependent Na^+ channels, voltage-dependent K^+ channels, and ligand-gated ion channels. The selective blocker NNC 55-0396 (10 μM) reduced the peak current.

seizure propagation through the dentate gyrus change as a result of altered granule-cell function?

The addition of hyperexcitable HEGCs adds a new dimension to dentate gyrus physiology. HEGCs receive monosynaptic innervation from normally located granule cells and in most cases from the perforant path. Their mossy fibers project to normally located granule cells and probably to all the normal granule-cell targets. They therefore become thoroughly integrated into dentate gyrus circuitry. How does the introduction of spontaneously firing or bursting neurons into this circuitry alter pattern separation and seizure propagation? What factors beside T-type Ca^{2+} current contribute to their high rate of activity? Do they receive monosynaptic innervation from CA3 pyramidal cells and, if so, how does that alter circuit function? Why do they retain the hyperexcitable phenotype of immature granule cells when newly generated granule cells that migrate normally do not?

Introduction

17β-Estradiol (E_2) and progesterone (P_4) are members of a class of hormones known as steroid hormones, which are derived from cholesterol, and secreted primarily by the gonads. As illustrated in Figure 1, P_4 – the primary endogenous progestin – is metabolized by the 5α-reductase enzyme to 5α-dihydroprogesterone (DHP), which in turn is reduced by the 3α-hydroxysteroid dehydrogenase enzyme to 3α-hydroxy-5α-pregnan-20-one (3α,5α-THP). Notably, P_4 and its metabolites have disparate mechanisms of action for their functional effects.

E_2, a metabolite of testosterone, also can have different effects and mechanisms than its precursor. Both clinical reports and basic research suggest that estrogens and progestins can alter neuronal excitability. Yet, the nature of their effects depend upon a number of factors – not only the precise molecule/hormone being investigated, but also the absolute concentration of and proximate changes in that hormone, and its potential to activate a diverse number of targets.

The following sections will present and discuss data in support of a role of ovarian hormones in modulating seizures. First, we will discuss data demonstrating an association between endogenous variations in both E_2 and P_4 and how these variations correlate with changes in seizure susceptibility. Second, effects of E_2 alone on ictal activity will be presented. Third, the mediation of seizure activity by progestins will be discussed. And fourth, the putative mechanisms by which estrogen and progestins have their anticonvulsant effects will be presented. Throughout our discussion, we include evidence that the hippocampus is an important brain area involved in hormonal modulation of seizures.

Background

Endogenous Variations in Ovarian Hormones

Clinical reports of cyclic variations in seizures among women with epilepsy support a role of ovarian hormones in the mediation of seizures. Catamenial epilepsy refers to

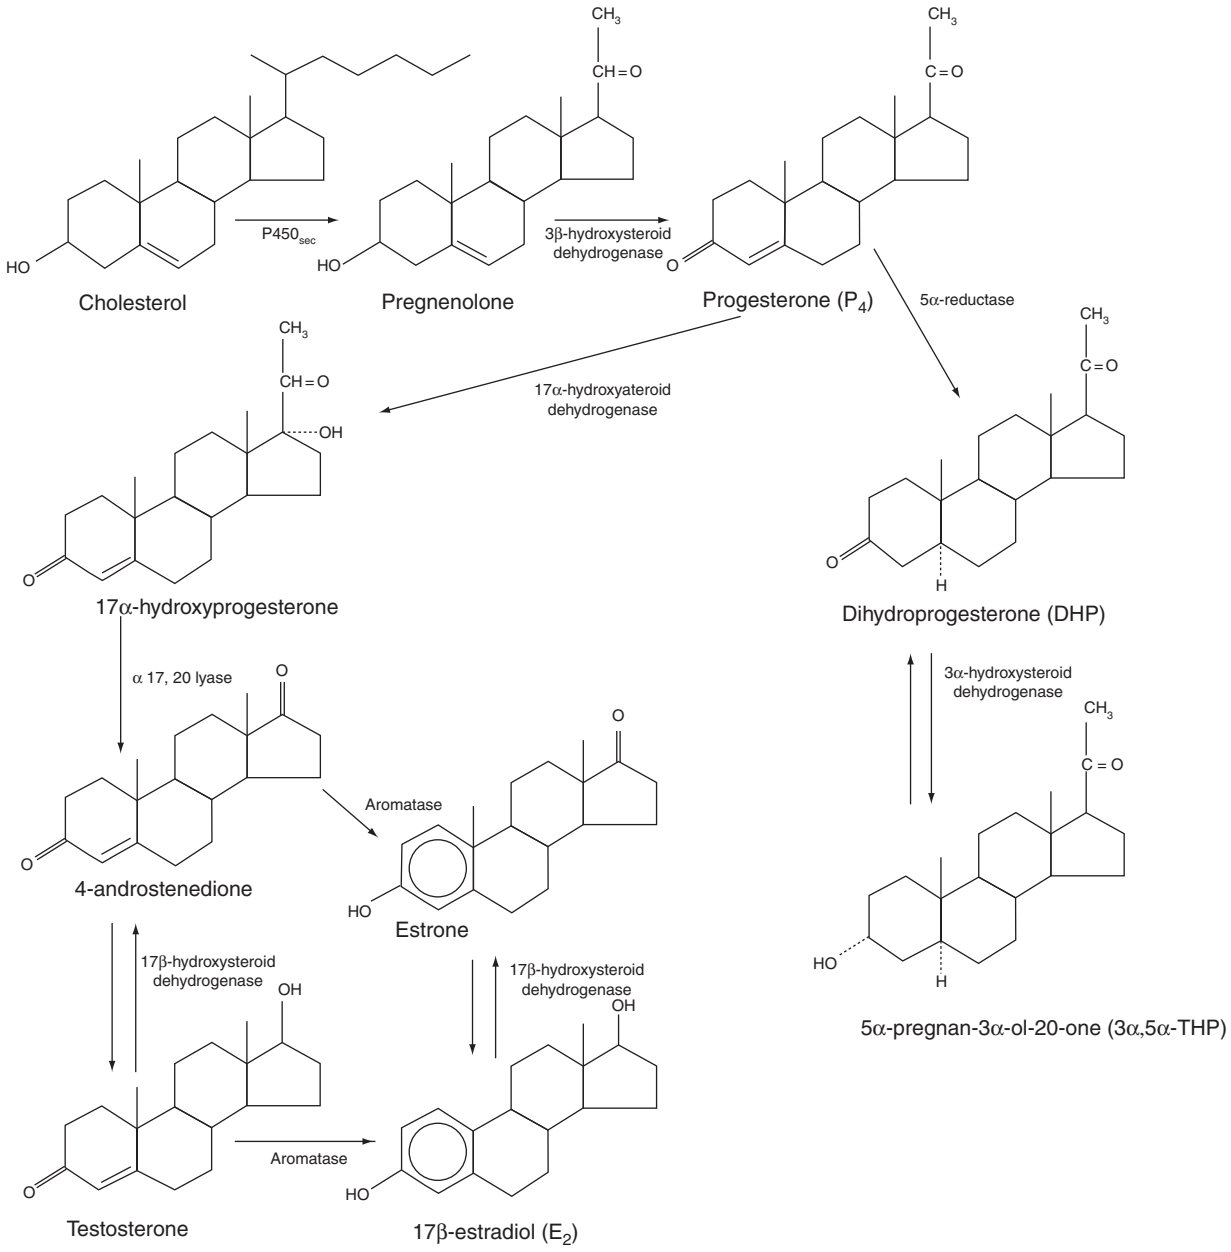

Figure 1 Diagram of formation of progestins, estrogen, and testosterone from cholesterol.

alterations in seizures associated with the menstrual cycle. Women with catamenial epilepsy typically have fewer seizures during the mid-luteal phase when P_4 levels are highest (**Figure 2**). Various patterns of catamenial epilepsy have been observed, including cases in which seizure frequency is increased during the perimenstrual phase (due to the withdrawal from P_4), during the preovulatory phase (due to increased E_2), or during an inadequate luteal phase cycle (due to lower than normal P_4 secretion during the second half of the cycle). Thus, there is heterogeneity in the manner in which catamenial epilepsy is expressed.

Prior research using animal models also supports the role of ovarian hormones in the modulation of seizures. Across the estrous cycle in rats, seizures are typically reduced during the afternoon of proestrous, when E_2 and P_4, are at their peak, rather than in diestrous when these same hormones are at their lowest (**Figure 3**, top).

In addition, findings from human and animal studies suggest there are typically opposing effects of E_2 (proconvulsant) and P_4 (anticonvulsant) on seizures. Hence, antiseizure effects during proestrous may be due to P_4's attenuation of E_2-mediated effects, via actions at various neurotransmitter systems, such as increases in

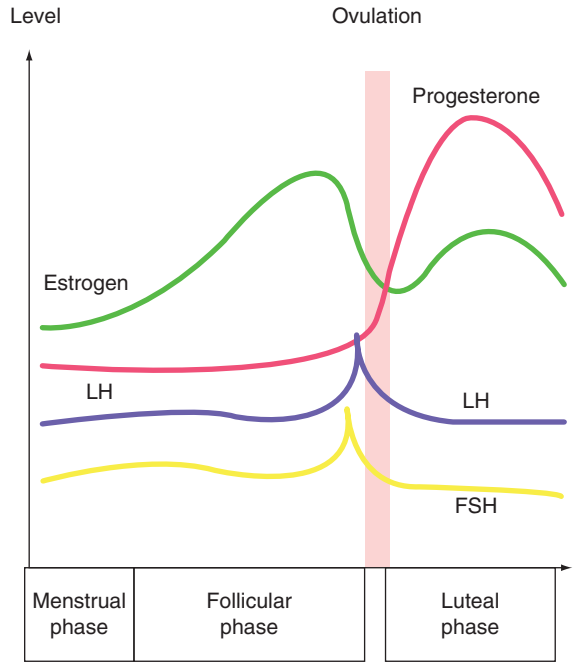

Figure 2 Schematic of estrogen, progesterone, luteinizing hormone (LH), and follicle stimulating hormone (FSH) across the menstrual cycle.

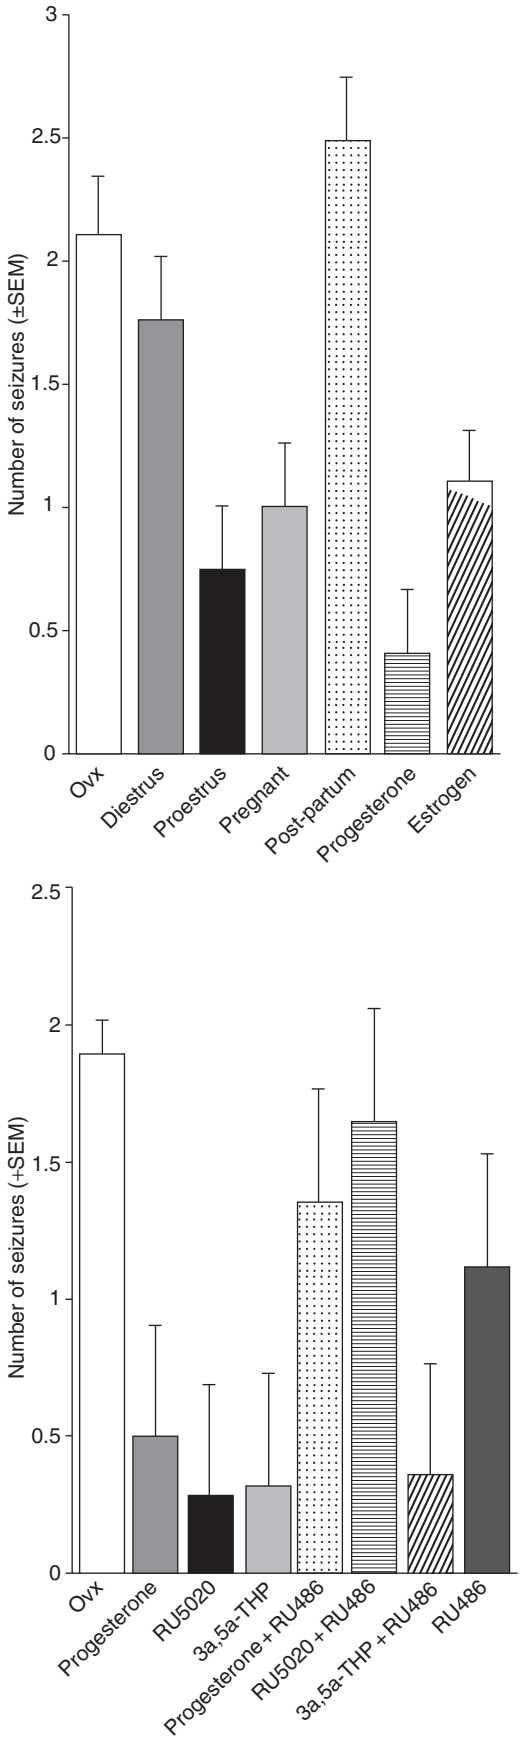
glutamatergic activity, that are implicated in epileptiform processes. Although these data clearly demonstrate an association between ovarian hormones and seizures, the relative influence of progestins versus estrogens requires further discussion.

Estrogen's Effects on Seizures

Emphasis has been placed on seizures increasing when there are natural, cyclic elevations in the E_2-to-P_4 ratio. Among women with epilepsy, menopause is often associated with an increase in seizures, which may be due in part to higher E_2 concentrations that are unopposed by P_4 (due to a decline in ovarian P_4 secretion). E_2-based oral contraceptives have also been shown to increase ictal activity among young women with epilepsy. Further, intravenous E_2 administration produced increases in seizures or epileptiform activity (or both) in women. These clinical findings suggest that E_2 has proconvulsant effects in women.

Findings from animal models also suggest that E_2 has proconvulsant effects. Systemic administration of E_2 lowers seizure thresholds in electroshock, kindling, pentylenetetrazol, kainic acid, and ethyl chloride seizure models. Further, central or intravenous E_2 administration to rabbits increases spontaneous electrical activity. However, in low, physiological concentrations, E_2 can have anticonvulsant effects (Figure 3, top). These experimental results, together with the above clinical observations, suggest that E_2 can increase neuronal excitability but that this effect is typically due to more robust changes in, or higher concentrations of, E_2.



Progestins' Effects on Seizures

In contrast to E_2, progestins typically have anticonvulsant effects. Women with epilepsy often experience a decrease in seizure incidence during pregnancy, when progestin levels are ~10 times higher than at any other point in the lifespan. Progestin concentrations fall precipitously immediately following parturition, and this change is often associated with an increase in seizures. P_4 administration can help reduce seizures of women with catamenial epilepsy. Intravenous administration of P_4 increases serum P_4 to levels similar to those seen during the luteal phase, and decreases interictal spikes. Oral administration of natural P_4 improves control of intractable complex partial seizures. Two explanations for P_4's beneficial therapeutic effects have been posited. First, steroid hormones and antiepileptic drugs are both metabolized by hepatic enzymes. P_4 therapy offers an increase in the substrate for these liver enzymes, thus reducing their efficiency in degrading antiepileptic drugs and thereby enhancing the therapeutic efficacy of those drugs. Second, direct depressant actions of P_4 metabolites may underlie P_4's anticonvulsant effects. In support of this latter possibility, oral synthetic progestins, which do not readily metabolize to depressant progestins, have not demonstrated antiseizure effects in clinical investigations. Thus, metabolism of P_4 appears to be important for some of its anticonvulsant effects.

Progestins also have antiseizure effects in animal models. Pregnant rats, with high endogenous levels of progestins, have fewer seizures than do rats that are 1–2 days postpartum, when progestin levels are lower than during pregnancy (Figure 3, top). Removal of the primary endogenous source of P_4, the ovaries, increases seizures; reinstatement of P_4 produces the opposite effects, reducing kainic acid-, pentylenetetrazol-(PTZ), and perforant pathway-induced seizures in ovariectomized (ovx) rats. Direct administration of P_4 to the brain also has been shown to have antiseizure effects. In cats, application of P_4 to the cortex inhibited electrical discharges in a penicillin focus. In rats, application of P_4 to the hippocampus reduces PTZ-induced seizures.

Methods

There are a number of animal models of seizure disorders and our lab has used several of these over the years. We have used perforant path stimulation as a model of partial seizures. More often, we have used the chemoconvulsants, such as kainic acid or PTZ, as models of generalized

seizure disorders. We have found the effects of steroid hormones on ictal activity to generalize well across these models. A number of years ago, the reliability and availability of kainic acid became problematic. Hence, we switched to PTZ. Because of inconsistencies reported by other laboratories when using PTZ, we take a number of steps to offset such effects. PTZ is made up immediately prior to testing and animals are weighed immediately prior to testing to ensure correct dosing of PTZ. Animals are administered PTZ via intraperitoneal injections and some myoclonic activity is typically observed within 1 min. We monitor animals for 10 min following PTZ administration, recording the latency to, and number of, myoclonic twitches, forelimb clonus, tonic–clonic seizures, and hindlimb extensions. The seizure progression produced with our PTZ regimen (70 mg kg^{-1} for rats, 85 mg kg^{-1} for mice) is consistent, and reliably observed and quantified, using a modification of the scale devised by Racine (mouth and facial movements, head nodding, forelimb clonus, rearing, and rearing and falling). We observe consistent effects of estrogens and progestins on each stage of seizure progression (myoclonus, tonic–clonic seizures, and survival). The data presented in the subsequent section are based on measurements of latency and incidence of tonic–clonic seizures.

Recent Data

Mechanisms of Ovarian Hormones for Modulation of Seizures

Given the consensus that E_2 and P_4 influence ictal activity in women, and in animal models, it is important to elucidate the mechanisms by which ovarian hormones exert these effects. E_2 and progestins can have multiple mechanisms of action for their functional effects. One framework in which to think about actions of E_2 and progestins is classical versus nonclassical mechanisms. Steroid hormones have actions at intracellular steroid receptors specific for their class of hormones. E_2 can act at estrogen receptors (ERs) and P_4 at progestin receptors (PRs). Actions at intracellular receptors regulate the transcription of target genes, and as such are relatively slow,

Figure 3 Top panel represents average number (±SEM) of seizures of ovariectomized (white bar), diestrous (gray bar), proestrous (black bar), pregnant (light gray bar), postpartum (dotted bar), progesterone-administered (horizontal stripe bar), and estrogen-administered (diagonal stripe bar) rats. Bottom panel represents average (±SEM) of seizures of ovariectomized rats administered vehicle (white bar), progesterone (gray bar), RU5020 (black bar), 3α,5α-THP (light gray bar), progesterone + RU486 (dotted bar), RU5020 + RU486 (horizontal stripe bar), 3α,5α-THP + RU5020 (diagonal stripe bar), and RU486 (dark gray bar).

typically requiring at least 15 min, but often much longer. Actions at intracellular steroid receptors were long thought to be the only mechanism by which steroid hormones could produce changes in behavior and physiology. However, more recent research has demonstrated that steroid hormones can have actions via other substrates. Both E_2 and progestins can have rapid actions that are independent of activation of intracellular receptors. In support of that view, E_2 activates a number of kinases, including protein kinase A and mitogen-activated protein kinase, and may also act via a membrane ER. Progestins also have effects via nonclassical mechanisms. Two of the most investigated substrates for progestins include $GABA_A$ and NMDA receptors. Data from our laboratory, presented later, suggests that progestins can mediate seizure processes via both classical and nonclassical mechanisms.

Classical Actions of E_2 for Antiseizure Effects

As discussed earlier, E_2 is generally considered to have proconvulsant effects. However, recent data suggest that E_2 can be anticonvulsant and that such effects may be due, at least in part, to actions at intracellular ERs. Notably, there are two ER isoforms that have been characterized. Actions at ERα, the originally identified ER, are typically associated with modulation of reproductive physiology and behavior. E_2's actions via the recently identified ERβ are associated more with nonreproductive behaviors and processes. In our laboratory, we have examined effects on seizures of low dosages (0.1 mg kg^{-1}, s.c.) of selective ER modulators (SERMs) to begin to elucidate the mechanisms by which E_2 may have antiseizure effects. Administration of the ERβ-selective SERMs, coumestrol or DPN, decreases seizures to levels similar to those seen with low-dose E_2 administration, while ERα-selective SERMs, 17α-E_2 and PPT, are no more effective than vehicle at reducing seizures (Table 1). However, as discussed earlier, E_2 has multiple modes of action. Hence, it is likely that E_2 has effects via other mechanisms, including actions at membrane receptors and/or activation of signal transduction pathways. Indeed, E_2's ability to alter brain-derived neurotrophic factor in the hippocampus has also been shown to play a role in E_2's modulation of seizure activity. These data suggest that one mechanism through which E_2 may have its antiseizure effects is via actions at ERβ.

Table 1 Number of full seizures of rats administered vehicle, E_2, ERβ-selective SERMs (coumestrol, DPN), or ERα-selective SERMs (17α-E_2, PPT)

	Number of seizures
Vehicle	6.0 ± 0.3
E_2	1.7 ± 0.5
Coumestrol	2.8 ± 0.8
DPN	1.8 ± 0.5
17α-E_2	5.1 ± 0.4
PPT	5.5 ± 0.4

Classical Actions of P_4 for Antiseizure Effects

To reveal the extent to which progestins have classical actions at PRs to mediate ictal activity, we examined effects of progestins with varying degrees of affinity for PRs on seizure activity. Ovariectomized rats were administered P_4, RU5020, 3α,5α-THP, or vehicle. P_4 and RU5020 have actions at intracellular PRs, while 3α,5α-THP does not. However, P_4 can be metabolized to 3α,5α-THP, while RU5020 cannot. Hence, comparing effects of these progestins allowed us to begin to parse out the role of each of these ligands and substrates for antiseizure effects. P_4, 3α,5α-THP, and RU5020 had similar effects in reducing tonic–clonic seizures (compared to vehicle) (Figure 3, bottom). We have also examined effects of blocking PRs (in conjunction with progestin administration) on seizures. Rats were administered P_4, 3α,5α-THP, RU5020, or vehicle concomitant with administration of the PR antagonist, RU38486. Coadministration of RU38486 with P_4 and RU5020 had modest effects to increase seizures relative to vehicle-administered controls; however, there was no effect of RU38486 administration together with 3α,5α-THP on ictal activity compared with 3α,5α-THP alone (Figure 3, bottom). We have also examined P_4's antiseizure effects in PR knockout mice (no functional PRs). P_4 administration to PR knockouts has moderate effects to reduce seizures compared with P_4 administration to wildtype mice with functional PRs (Figure 4, top).

These data suggest that P_4 can have antiseizure effects in part via its actions at PRs.

Nonclassical Actions of Progestins for Antiseizure Effects

A focus of our research has been to identify the functional role of steroids' actions via classical steroid receptors versus other substrates. Reproductive behavior of rodents requires both traditional actions at steroid receptors and nonclassical actions of steroids. The finding that steroid hormones have actions at substrates other than intracellular steroid receptors broadened the putative role that steroid hormones might play in physiology and behavior. Steroid hormones' effects and mechanisms were no longer relegated only to brain areas containing intracellular steroid receptors or hypothalamically mediated reproductive behaviors. Indeed, steroid hormones have salient neurotrophic effects, especially in the hippocampus, and clinical studies have shown that circulating levels of 3α,5α-THP contribute more to antiseizure effects than do P_4 concentrations.

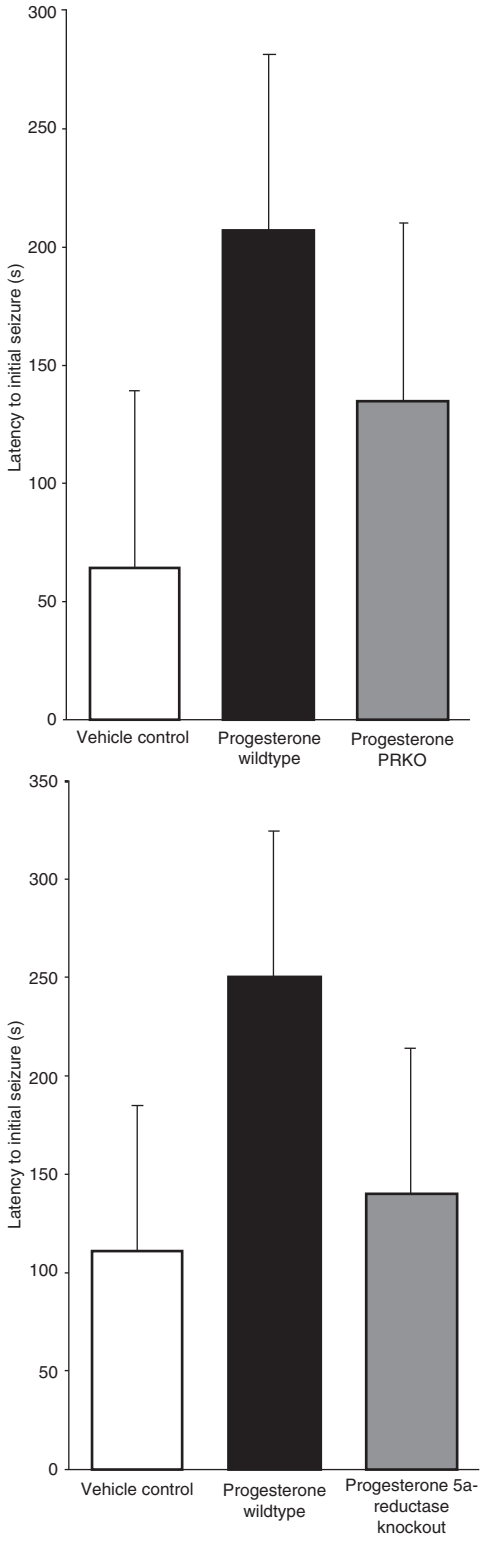


Figure 4 Top panel represents average number (±SEM) of seizures of vehicle control (white bar), progesterone-administered wildtype (black bar), and progesterone-administered PRKO (gray bar) mice. Bottom panel represents average number (±SEM) of seizures of vehicle control (white bar), progesterone-administered wildtype (black bar), and progesterone-administered 5α-reductase (gray bar) mice.

Our investigations of putative nonclassical mechanisms of progestins' antiseizure effects have focused primarily on the hippocampus. P_4 administration to 5α-reductase knockout mice that are genetically unable to metabolize P_4 to 3α,5α-THP is not more effective than to vehicle-administered rats at decreasing seizure activity (**Figure 4**, bottom). In rats, administration of systemic or intrahippocampal finasteride, which attenuates formation of 3α,5α-THP from P_4, blocks P_4's antiseizure effects (**Figure 5**).

Thus, actions of 3α,5α-THP in the hippocampus may underlie some of its antiseizure effects.

The notion that 3α,5α-THP may be a modulator of P_4's antiseizure effects is important given that P_4 and

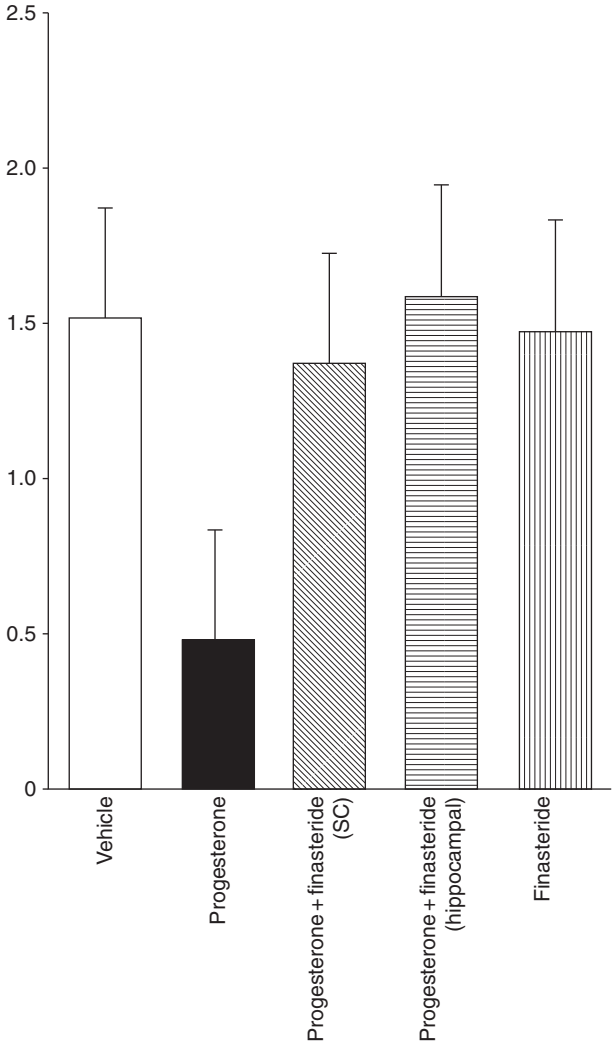

Figure 5 Average number (±SEM) of seizures of ovariectomized rats administered vehicle (white bar), progesterone (black bar), progesterone + systemic finasteride (diagonal striped bar), progesterone + intrahippocampal finasteride (horizontal striped bar), and vehicle + finasteride (vertical striped bar).

3α,5α-THP have different mechanisms of action. Notably, 3α,5α-THP is a very potent modulator of $GABA_A$ receptors and can alter the function of NMDA receptors but is devoid of activity at PRs. In contrast, P_4 binds well to PRs but is only weakly active at $GABA_A$ receptors and NMDA receptors. Hence, our investigations of progestins' nonclassical mechanisms for antiseizure effects have focused on $GABA_A$ and NMDA receptors. Administration of bicuculline, a $GABA_A$ receptor antagonist, to the hippocampus of hormone-primed rats attenuates P_4's antiseizure effects (**Figure 6**, top).

Rats administered MK801, a nonselective NMDA receptor antagonist, to the hippocampus had significantly more seizures than did vehicle-administered rats (**Figure 6**, bottom). These data suggest that progestins' antiseizure effects may involve both $GABA_A$ receptors and NMDA receptors. In conjunction with prior findings, it seems that antiseizure effects of progestins involve multiple classical and nonclassical substrates in the hippocampus.

Stress, 3α,5α-THP, and Seizures

Exposure to stressors can induce changes in hypothalamic–pituitary–adrenal (HPA) axis function, the primary mediator of neuroendocrine stress responses. Notably, 3α,5α-THP acts to dampen stress responses via its agonist-like actions at $GABA_A$ receptors. Given that stress may alter seizure susceptibility, in part due to altering secretion of 3α,5α-THP, we have examined effects of altered HPA function on seizure susceptibility. Adrenalectomized (ADX) or sham-ADX rats were administered P_4 or 3α,5α-THP and observed for seizure activity following PTZ administration. P_4 and 3α,5α-THP significantly reduced the number of seizures of sham, but not ADX rats, compared with vehicle administration (**Table 2**). These data suggest that some of progestins effects on seizures may involve the HPA axis as a target. Given that 3α,5α-THP is secreted in response to stress, and seizures can increase 3α,5α-THP, it is possible that 3α,5α-THP levels before and/or in response to seizures may influence their incidence or sequelae. Notably, P_4 therapy and ganaxolone, the B isomer of 3α,5α-THP, are currently under investigation in clinical trials for treatment of some seizure disorders.

Future Goals

The data presented and discussed here support a role of ovarian hormones in the modulation of seizure processes. Estrogens typically have proconvulsant effects, while progestins are generally anticonvulsant. However, it is important to note that E_2 and progestins do not act independent of one another. E_2 can increase the conversion of P_4 to 3α,5α-THP. When administered in low, physiological concentrations that are sufficient to enhance P_4's conversion, anticonvulsant effects of E_2 are observed. Hence, it is

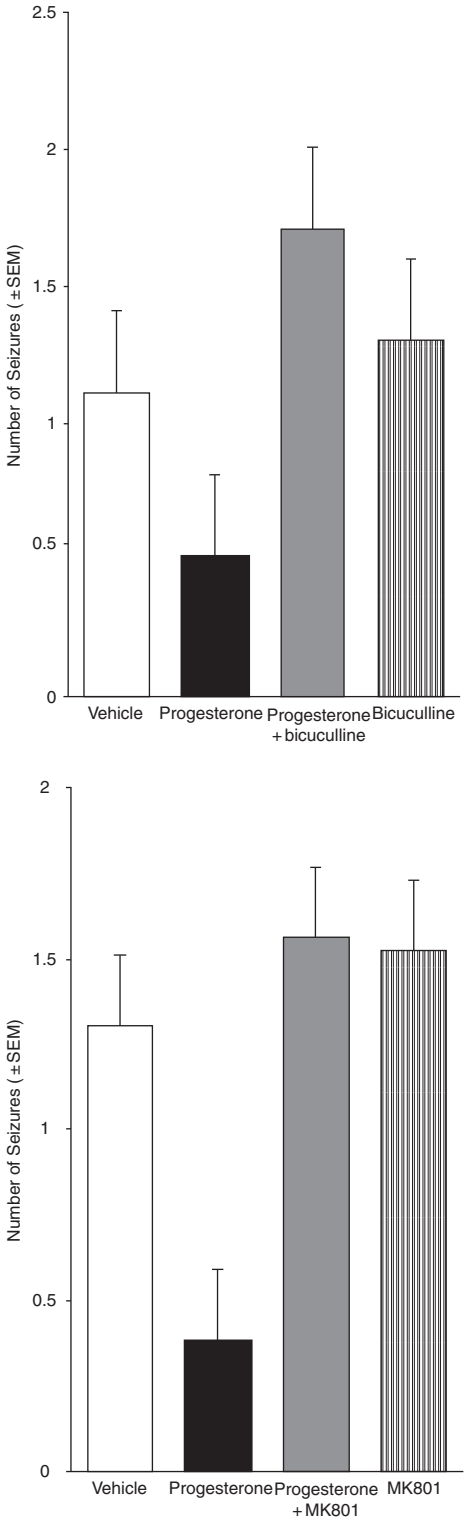

Figure 6 Top panel represents average number (±SEM) of seizures of ovariectomized rats administered vehicle (white bar), progesterone (black bar), progesterone + intrahippocampal bicuculline (gray bar), and vehicle + bicuculline (vertical striped bar). Bottom panel represents average number (±SEM) of seizures of ovariectomized rats administered vehicle (white bar), progesterone (black bar), progesterone + intrahippocampal MK801 (gray bar), and vehicle + MK801 (vertical striped bar).

Table 2 Number of tonic–clonic seizures of sham-ADX or ADX rats administered vehicle, P_4, or 3α,5α-THP

	Number of seizures	
	Sham-ADX	*ADX*
Vehicle	1.4 ± 0.4	2.0 ± 0.1
P_4	0.4 ± 0.1	1.6 ± 0.4
3α,5α-THP	0.3 ± 0.2	1.5 ± 0.4

important to fully understand how estrogens and progestins influence one another and their subsequent effects on seizure processes. It is also important to begin to elucidate the sources of 3α,5α-THP that modulate seizures, given that stress can induce 3α,5α-THP secretion. Further, androgens also vary in females and can alter ictal activity. In addition, antiepileptic drugs can alter steroid hormone metabolism and thereby the efficacy of oral contraceptives and hormone therapies. As such, understanding the role of steroid hormones and seizures, and the relationships between steroid hormones and therapeutic drugs (and their influence on seizures) are of great importance.

Introduction

Sex hormones influence neuronal excitability, depending on the hormone type or its metabolite. Hormone-induced changes in neuronal activity are believed to be an underlying mechanism for several disorders, such as migraine, depression, and epilepsy (e.g., catamenial epilepsy). The hormone-related disorders can occur in both sexes but are mostly studied and are best characterized in women owing to marked changes in women hormonal state throughout their lifespan. Hormonal fluctuations during the menstrual cycle mark the catamenial occurrence of seizures in some women. Another important factor in neuronal excitability among women is the loss of peripherally generated sex hormones at menopause. This profound hormonal decline is also associated with alterations in seizure patterns. Since the brain is a sexually dimorphic structure, the effects of sex hormones on neuronal

Hormonal Modulation of Neuronal Excitability

J Velíšková and L Velíšek, Albert Einstein College of Medicine, Bronx, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Sex hormones influence neuronal excitability, depending on the hormone type or its metabolite. Hormone-induced changes in neuronal activity are believed to be an underlying mechanism for several disorders, such as migraine, depression, and epilepsy (e.g., catamenial epilepsy). The hormone-related disorders can occur in both sexes but are mostly studied and are best characterized in women owing to marked changes in women hormonal state throughout their lifespan. Hormonal fluctuations during the menstrual cycle mark the catamenial occurrence of seizures in some women. Another important factor in neuronal excitability among women is the loss of peripherally generated sex hormones at menopause. This profound hormonal decline is also associated with alterations in seizure patterns. Since the brain is a sexually dimorphic structure, the effects of sex hormones on neuronal

excitability are sex-specific. Sex hormones exert their action on neurons either by changes in gene expression or by regulating membrane excitability through their own membrane receptors, as well as via direct action on neurotransmitter receptors and ion channels.

Background

Hormones influence neuronal activity either through excitatory or inhibitory mechanisms. Classical effects of sex hormones are mediated by activation of intracellular receptors, which are specific for individual hormones and can be found either in the cytoplasm or within the nucleus. Binding of a hormone to intracellular receptors mediates regulation of gene expression at the nuclear level. The subsequent effects have delayed onset but long duration, which extends beyond the period of the hormone presence in the tissue. In contrast, steroid hormones also produce rapid changes in neuronal excitability by activation of membrane-bound receptors as well as directly regulating neurotransmitter receptors or ion channels. Direct effects of steroid hormones on membranes last only when the hormone is bound to the receptor.

The importance of hormonal action in the brain is documented in reports showing the local *de novo* production of steroid hormones by neurons and glia in the central nervous system (CNS). These 'neurosteroids' are known for their nongenomic acute effects, especially at NMDA receptors and at synaptic and extrasynaptic $GABA_A$ receptors, and are responsible for 'fine tuning' of neuronal excitability. Also, neurosteroids play an important role in neuronal survival in developing as well as in aging brain.

The role of steroid hormones in neuronal excitability is very complex and depends on many factors, including the type of hormone, sex, age, regional distribution of hormone receptors, treatment duration, time interval for initiation of hormonal treatment following gonadal removal, or route of administration.

In our laboratory, we concentrate on the effects of the main female sex hormones, β-estradiol and progesterone, on neuronal activity. Although it is believed that progesterone decreases while estrogen increases neuronal excitability, this issue remains controversial. Bath application of β-estradiol as well as progesterone increases long-term potentiation (LTP) and enhances spreading depression induced by microinjection of KCl in neocortical slices. In the hippocampus, bath application of β-estradiol has no effect on pyramidal cell excitability in slices from female rats, but increases excitability of pyramidal neurons in slices from male rats. Interestingly, excitability of pyramidal neurons also shows sex-dependent sensitivity to bath administration of testosterone. While brain slices from males do not show any change in hippocampal excitability following testosterone, slices from female rats have estrous cycle stage-dependent responses; in slices obtained from females at diestrus, testosterone increases the excitability, but in slices from females at proestrus, testosterone decreases excitability.

Methods

Adult female Sprague Dawley rats from Taconic farms have been used. Rats were ovariectomized under Methofane anesthesia one week prior to hormone supplementation.

Region-specific Effects of β-Estradiol and Progesterone on Low $Mg^{2\pm}$-induced Epileptiform Activity

Ovariectomized female rats were injected with two subcutaneous injections of 17β-estradiol benzoate (EB) 24 hours apart. The dose of EB was 2 μg/0.1 ml/rat, which restores β-estradiol levels within physiological range. Combined entorhinal cortex-hippocampal slices were obtained 24 hours following the last EB (or oil control) injection. Another group of ovariectomized females received 500 μg/0.1 ml/rat of progesterone (P) 2 hours prior to slice preparation. Finally a group of ovariectomized females received a combination of both treatments (EB + P) and slices were prepared 2 hours after P administration. EB and progesterone were dissolved in peanut oil, which was injected (0.1 ml) in appropriate ovariectomized controls (instead of hormone treatment). To prepare slices, rats were sacrificed under CO_2 anesthesia, brain quickly removed from the skull and combined entorhinal cortex-hippocampal slices (400 μm thick) were cut on a vibratome in ice-cold artificial cerebrospinal fluid (ACSF). ACSF composition was (in mM): NaCl – 126; KCl – 5; NaH_2PO_4 – 1.25; $MgCl_2$ – 2; Ca Cl_2 – 2; $NaHCO_3$ – 26; glucose – 10; pH = 7.3; bubbled with 95% O_2/5% CO_2. Slices were then transferred to an interface chamber perfused with pre-warmed (34 °C) ACSF, and pre-incubated for 1 hour. Extracellular recording micropipettes (resistance 1–5 MΩ) were filled with 2 M NaCl. Recording electrodes were positioned either in layers IV-V of the medial entorhinal cortex or in the CA1 pyramidal layer of hippocampus. Following baseline recording, the slices were introduced to Mg^{2+}-free ACSF. Onset of epileptiform discharges was determined.

Effects of EB on Paired Pulse-induced Population Excitatory Postsynaptic Potentials in the Dentate Gyrus Granule Cells

Ovariectomized female rats were injected with either one or four injections of EB 24 hours apart. Controls received

oil instead of EB. The dose of EB was 2 μg/0.1 ml/rat. Combined entorhinal cortex-hippocampal slices were obtained 24 hours following the last EB/oil injection, as described previously. A stainless steel bipolar stimulating electrode was positioned in the mixed perforant path (over the outer and middle third of the molecular layer). Paired square pulses (50–400 μA, 150 μs duration) were delivered using a stimulator coupled to a stimulus isolation unit, at interstimulus intervals of 10–1000 ms. A glass recording micropipette (1–5 MΩ) was filled with 2 M NaCl and placed in the middle third of the external blade of the dentate gyrus granule cell layer (stratum granulosum) to record extracellular evoked responses (population spikes). Population spike amplitude was used as a measure of granule cell responses to perforant path paired-pulse stimulation (Figure 1). For each interstimulus interval, 6–10 responses were averaged to obtain stability of the responses. The interval between each paired stimulation was 30 s. Digitized data were computer analyzed using Axoscope software.

ANOVA and Student *t*-test were used for statistical analyses. Level of significance was always preset to $P < 0.05$.

Results

Region-specific Effects of β-Estradiol and Progesterone on Low $Mg^{2\pm}$-induced Epileptiform Activity (Table 1)

Removal of Mg^{2+} from the bathing medium induces epileptiform-like discharges (Figure 2) by activation of NMDA receptors, enhancement of transmitter release, and reduction of surface charge screening, all of which leads to an increase in neuronal excitability. In Most slices from female rats (as in slices from males), in the entorhinal cortex, low Mg^{2+} first induces seizure-like events characterized by long duration discharges with a negative DC shift. Additionally, in about 20% of slices from females, the discharges start as short bursting activity. Both types of initial discharges spontaneously develop into status epilepticus-like activity, characterized by 1–10 sec recurrent discharges and persisting as long as the slices are perfused with the low Mg^{2+} ACSF. In the entorhinal cortex, the onset of seizure-like events was delayed by progesterone treatment. However, EB or the combination of EB with progesterone had no effect on the seizure-like event onset. The progression of seizure-like discharges into the status-like pattern was not influenced by any hormonal treatment paradigm. In the CA1 hippocampal region, the epileptiform-like activity induced by low Mg^{2+} in slices from female rats starts as recurrent brief discharges (as in slices from male rats). In contrast to the entorhinal cortex, however, these short-duration discharges in the CA1 region simply increase frequency and amplitude over time, but maintain their initial appearance as 'interictal' activity. Progesterone accelerated the onset of seizure-like events in the CA1 region; EB or EB with

EB: β-estradiol benzoate.

progesterone treatment, however, had no effect on the onset of the epileptiform-like activity.

These data show that low dose EB does not influence neuronal excitability in the entorhinal cortex or in the CA1 hippocampal region. In contrast, progesterone has biphasic and region-specific effects on neuronal excitability in this model. Since progesterone was administered just 2 hours prior to slice preparation, its effects on neuronal activity are likely to be mediated by membrane nongenomic effects of progesterone metabolites. While some of progesterone metabolites enhance $GABA_A$ receptor mediated transmission, other metabolites may decrease the GABA-mediated Cl^- currents. Interestingly, in the CA1 region, bath application of some progesterone metabolites induces depolarizing $GABA_A$ receptor-mediated postsynaptic potentials. This effect may explain accelerated onset of the low Mg^{2+}-induced discharges in the CA1 region of progesterone-treated females.

Effects of EB on Paired Pulse-induced Population Excitatory Postsynaptic Potentials in the Dentate Gyrus Granule Cells (Table 2)

The paired pulse paradigm in vitro is a convenient way to test the physiological balance of excitatory/inhibitory functions. The paired pulse curve is calculated as a ration between the second response (R = population spike amplitude) and the first response (R2/R1) at increasing interstimulus intervals. The curve consists of 3 components referred to as: 1. early inhibition/depression (10–50 ms) characterized by prevailing $GABA_A$ receptor-mediated events; 2. intermediate facilitation (70–125 ms) when kainate/AMPA and later also NMDA receptor-mediated events prevail; and 3. late inhibition/depression (150–1000 ms) characterized by slow G-protein-mediated transmission mediated by e.g., $GABA_B$, neuropeptides, and metabotropic glutamate receptors.

A single EB injection did not change the paired pulse curve compared to oil controls. Chronic EB administration (for 4 days) enhanced the late paired pulse inhibition. These data suggest that the EB-mediated suppression of dentate granule cell excitability involves activation of gene expression, which requires longer EB treatment.

Future Goals

Effects of steroid hormones on neuronal excitability are complex and not well understood. The main controversy arises from the fact that the steroid hormone-induced effects are sensitive to many variables, and each laboratory chooses a slightly different paradigm for its experiments. Thus, it is hard to compare the data available in the literature.

In this article, I've emphasized the more controversial findings in order to stimulate discussion and appeal for more studies, which would help to increase our understanding of hormonal effects in the CNS. Such knowledge is very important, especially for developing treatment strategies for people with epilepsy. Also, epileptic patients (both men and women) often suffer with reproductive disorders not only as a result of seizures but also due to their antiepileptic treatments. The proconvulsant effect of estrogen is widely advertised, but some bench studies and also some clinical data do not support this view. Further, estrogens have been associated with neuroprotective effects, and several animal studies suggest that β-estradiol may be beneficial to prevent development of hippocampal sclerosis in rat models of temporal lobe seizures following status epilepticus.

Better knowledge of how sex hormones affect neuronal activity may help to prevent, or at least better manage seizures sensitive to hormonal changes, especially during puberty, the menstrual cycle, and menopause.

Introduction

Puberty, menarche, menses, and menopause are often critical times when reproductive hormones may have a profound impact on seizures. An example is the shift from absence epilepsy to generalized tonic–clonic seizures that has been noted during puberty in some children with childhood absence epilepsy. There is however no direct evidence to substantiate the suggestion that this switch is due to changes in reproductive hormones. Data from research in laboratory animals show that gonadal hormones can exert a profound influence on neuronal excitability, seizures, and epilepsy. Similarly, environmental stressors are known to facilitate various types of epilepsy; it seems likely, therefore, that adrenal stress hormones are involved in regulation of seizures.

These observations have led to a focus on corticosteroids and ovarian steroid hormones, estrogen and progesterone, to clarify how these steroid hormones influence seizures in patients under stress and in women with epilepsy. The prevailing view on gonadal hormones is that estrogen is proconvulsant, whereas progesterone is anticonvulsant. The cyclical changes of these ovarian hormones appear to play a key role in the genesis of catamenial seizures. However, estrogen and progesterone are not the only reproductive hormones to be considered in evaluating excitability, seizures, or epilepsy in the female.

Testosterone also modulates seizure susceptibility, and it has been recently hypothesized that its pro- or anticonvulsant action depends on the concentrations of its specific metabolites.

It seems unlikely that these steroid hormones would exert single and uniform actions given our current understanding of their complex pharmacological and physiological relationships. Their modulatory effects on brain excitability and seizures are likely to depend on the endocrine state of a subject, their relative concentration, metabolism, and many other factors. Some recent advances have helped clarify past confusion in the literature: acute pharmacological studies show that progesterone dose-dependently increases spike-wave discharges (SWDs), but during pregnancy – when progesterone concentration is high – SWDs are reduced. Although the outcomes of the first study suggest a positive relationship between concentrations of progesterone and the number of absence seizures, the pregnancy study shows a negative relationship between concentration of progesterone and absence seizures. Clinical and animal research, designed with the relevant endocrinological and neurobiological issues in mind, will help advance this field in the future.

Introduction

Puberty, menarche, menses, and menopause are often critical times when reproductive hormones may have a profound impact on seizures. An example is the shift from absence epilepsy to generalized tonic–clonic seizures that has been noted during puberty in some children with childhood absence epilepsy. There is however no direct evidence to substantiate the suggestion that this switch is due to changes in reproductive hormones. Data from research in laboratory animals show that gonadal hormones can exert a profound influence on neuronal excitability, seizures, and epilepsy. Similarly, environmental stressors are known to facilitate various types of epilepsy; it seems likely, therefore, that adrenal stress hormones are involved in regulation of seizures.

These observations have led to a focus on corticosteroids and ovarian steroid hormones, estrogen and progesterone, to clarify how these steroid hormones influence seizures in patients under stress and in women with epilepsy. The prevailing view on gonadal hormones is that estrogen is proconvulsant, whereas progesterone is anticonvulsant. The cyclical changes of these ovarian hormones appear to play a key role in the genesis of catamenial seizures. However, estrogen and progesterone are not the only reproductive hormones to be considered in evaluating excitability, seizures, or epilepsy in the female.

Testosterone also modulates seizure susceptibility, and it has been recently hypothesized that its pro- or anticonvulsant action depends on the concentrations of its specific metabolites.

It seems unlikely that these steroid hormones would exert single and uniform actions given our current understanding of their complex pharmacological and physiological relationships. Their modulatory effects on brain excitability and seizures are likely to depend on the endocrine state of a subject, their relative concentration, metabolism, and many other factors. Some recent advances have helped clarify past confusion in the literature: acute pharmacological studies show that progesterone dose-dependently increases spike-wave discharges (SWDs), but during pregnancy – when progesterone concentration is high – SWDs are reduced. Although the outcomes of the first study suggest a positive relationship between concentrations of progesterone and the number of absence seizures, the pregnancy study shows a negative relationship between concentration of progesterone and absence seizures. Clinical and animal research, designed with the relevant endocrinological and neurobiological issues in mind, will help advance this field in the future.

Background

Hormones and Their Action

Hormones are classically classified according to their chemical structure into peptide hormones (e.g., growth hormone, insulin, and antiduretic hormone), steroid

hormones (e.g., estrogen, progesterone, and testosterone), and tyrosine derivates (e.g., thyroxine and adrenaline). Peptide hormones are stored in vesicles and released by exocytosis in response to appropriate stimuli; steroid hormones are lipophilic, not stored in vesicles for secretion, and their rate of release is determined by their rate of synthesis; tyrosine derivates are synthesized by specific pathways in thyroid and adrenal medulla.

Circulating hormones of the gonads, adrenals, and thyroid gland have many effects on the brain. Some of these effects are permanent, while others are reversible. Many effects occur via the stimulation of gene expression through well-characterized intracellular receptors, whereas other effects take place rapidly at the surface of nerve cells via different type of neurotransmitter receptors. Many of these central effects are not confined to reproduction.

Twenty years ago, neurosteroids – steroids which are synthesized in the central and the peripheral nervous systems – were discovered. Neurosteroids are precursors (pregnenolone, dehydroepiandrosterone, and their sulfates) and metabolites (allopregnanolone, allotetrahydrodeoxycorticosterone) of steroid hormones, which influence the excitability of neurons predominantly by nongenomic mechanisms. They can be synthesized de novo in brain tissue mainly from cholesterol (e.g., pregnenolone or dehydroepiandrosterone) or are produced from hormones transported to the brain from peripheral sources (e.g., allotetrahydropregnanolone or allotetrahydrodeoxycorticosterone). Several of these steroids accumulate in the brain after local synthesis or after metabolism of adrenal or gonadal steroids. Progesterone is also a neurosteroid, and a progesterone receptor has been identified in peripheral and central glial cells. Pregnenolone appears to be among the most quantitatively important neurosteroids in the rat brain, and is a major precursor of the neurosteroid progesterone.

Neurosteroids may have the same action in the brain as steroid hormones; however, they exert their effects mainly through nongenomic mechanisms. Nongenomic steroid effects are principally characterized by their insensitivity to inhibitors of transcription and protein synthesis. The most obvious experimental evidence for the nongenomic effect is the rapid (i.e., within minutes) onset of action. These very rapid effects of steroids, mainly affecting intracellular signaling, are incompatible with the genomic mode of action. Instead, the rapid effects of steroid hormones are likely to be mediated through ion-gated neurotransmitter membrane receptors with pharmacological properties distinct from those of the intracellular steroid receptors. Neuroactive steroids may modulate – at low concentrations – the $GABA_A$ receptor, as allosteric coagonists or antagonists of GABA. Thus, their mechanism of action appears to be dependent on the specific structure of the $GABA_A$ receptor (with its subunits forming ligand-gated ion channels). At higher concentrations, they can also act as allosteric modulators of neurotransmitter receptors, such as NMDA, glycine, nicotinic, muscarinic, and sigma receptors.

Steroid hormones modulate seizure propensity in all types of epilepsy, including absence. Fluctuations in plasma and brain concentrations of steroid hormones and their neuroactive metabolites, over different stages of the reproductive cycle, play an important role in modulation of neuronal excitability. There is a unique relationship, however, between absence epilepsy and GABA. The pharmacological profile of absence epilepsy is opposite to the profiles typical of other types of seizures. Absences are associated with hyperfunction of GABAergic inhibitory system, while other seizure types are usually associated with a hypofunction of the GABAergic system. This counter-intuitive relationship between GABA and absence tends to complicate studies investigating the effects of neurosteroid hormones on absence; indeed, those that exhibit GABA-mimetic properties are proepileptic (i.e., they exacerbate absence seizures). Further, pharmacological studies have shown that whereas systemic administration of GABA-mimetic drugs enhances absence seizure activity, local administration of the same drugs may suppress SWDs. These observations make it difficult to predict the effect of steroids hormones such as progesterone (known to modulate the GABAergic system) on the occurrence of absence. It is necessary, therefore, to investigate local effects of these hormones directly.

Method

The majority of the studies reported here were carried out on WAG/Rij rats, a genetic model of absence epilepsy. GAERS (genetic absence epileptic rats from Strasbourg, originally described by Christian Marescaux and Marguerite Vergnes) and WAG/Rij rats (Wistar Albino Glaxo rats bred in Rijswijk) are most commonly used to study intrinsic, network, and behavioral features of absence epilepsy. All individuals of both strains show an age-dependent increase in the number of SWDs. The SWDs are accompanied by small but clear clinical signs typical of absence epilepsy. The SWDs show a circadian distribution, with a minimum at the onset of the sleep phase (of a 24 h sleep-wake cycle) when rats have a preponderance for deep slow wave sleep, and a maximum during the dark period. Both rat strains are well-validated models of absence epilepsy.

We have examined the relation between absence episodes and hormone levels in rats that are implanted with EEG electrodes in the cortex; effects of hormonal manipulations are assessed based on the frequency and duration of SWDs in freely moving animals over the course of many days. Blood samples are taken, to determine circulating hormonal levels, via the jugular vein (in chronic studies) or via incisions at the end of the rat's tail (in acute studies); up to 300 µl collected for these analyses (via RIA).

Recent Results

Progesterone and Related Neurosteroids

The most widely studied steroid hormone is progesterone. We addressed the question of whether (and how) progesterone affects absence seizure in two ways.

First, we examined the time course of absence seizures over the ovarian cycle in adult female WAG/Rij rats. In this way, we could establish the extent of physiological fluctuations of SWDs as a function of the fluctuations of the ovarian hormones progesterone and estradiol. These hormones are known to be elevated at specific days and hours of the ovarian cycle. The data of the long-term EEG recording of SWD in female WAG/Rij rats are presented in Figure 1.

These data show a consistent circadian pattern for the number of SWDs, with an acrophase during the first hours of the dark period and a nadir during the first hours of the light period. While this circadian distribution is in full agreement with earlier studies, it also shows a newly-observed additional increase in SWDs at the shift from the light to the dark phase of the proestrus day. The latter finding strongly suggests that a physiological increase in the concentration of plasma progesterone on the proestrus day enhances SWDs. The outcome of an acute pharmacological study pointed in the same direction. Progesterone rapidly enhanced, in a dose- and time-dependent manner, the number of SWDs. Similarly, an increase in SWDs during proestrus days was found in a rat model for atypical absences (adult rats show atypical SWDs after an injection of a cholesterol synthesis inhibitor AY9944), and an acute injection of progesterone increased SWDs in these animals. The relevance of these data is twofold: First, changes in progesterone in physiological concentrations affect the number of spontaneously occurring SWDs. Second, experimentally-administered progesterone increases SWDs in two different models of absence epilepsy – which is in agreement with a single case study in humans which showed increased absence occurrence in a woman when she was administered progesterone. The direction of the effect of progesterone is in contrast to the often found anticonvulsant action of progesterone on other seizure types, both in animal models and in catamenial seizures.

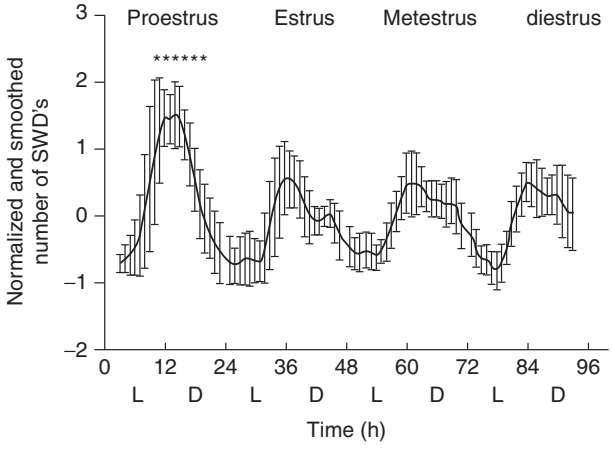

Figure 1 Hourly number of SWDs in the 4 days of the estrous cycle in WAG/Rij rats ($n = 8$). The hourly number (mean ± SD) of SWDs was normalized (mean, 0; variance, 1) per subject and smoothed by a centered moving averaging filter with span 4. Note the day effect at the first few hours of the dark period at proestrus. *Journal of Epilepsy Research*, with permission from Elsevier.

Subsequent research was designed to establish whether the effects of progesterone were due to the classical genomic mechanism or to receptor activation at the cell membrane. Finasteride, an inhibitor of 5α-reductase, which inhibits the synthesis of neurosteroids that have agonistic activity at $GABA_A$ receptors (e.g., allopregnanolone, tetrahydrodeoxycorticosterone (THDOC), androsterone), did not affect the number of SWDs in a 24 h recording period. However, finasteride did antagonize the increase in number of SWDs induced by progesterone in this rat model. In contrast, injection of RU 38486, an antagonist of intracellular progesterone receptors, had no effect on SWDs and did not block the stimulatory effect of progesterone. These findings demonstrate that progesterone has two types of effects: The normally-occurring SWDs during baseline periods were not affected by finasteride and RU 384886, and are most likely controlled by genomically mediated mechanisms. However, the SWDs induced by progesterone were blocked by finasteride, suggesting that this increase was due to nongenomic effects of progesterone, most likely those of allopregnanolone or 3α-OH-dihydroprogesterone, both potent endogenous positive modulators of CNS $GABA_A$ receptor function. Similar outcomes and conclusions have been presented by Persad and coworkers in the atypical absence seizure model. Interestingly, ovariectomy has little effects on SWDs; therefore it seems that the circadian rhythm of SWDs is not controlled by swings in plasma concentration but by central effects. The increase in SWDs during proestrus, however, coincides with increased plasma levels; how SWDs are specifically enhanced during the proestrus hours remains to be established.

Two neurosteroids, which are synthesized in the brain from cholesterol (pregnenolone sulphate) or from progesterone (allopregnanolone), have been tested. Allopregnanolone potently increased SWDs dose-dependently in WAG/Rij rats. The action is most parsimoniously explained by its action in stimulating the $GABA_A$ receptor. In support of this hypothesis is the recent report that isopregnanolone, an isomer of allopregnanolone, which is devoid of $GABA_A$ agonistic activity, when injected into the brains of WAG/Rij rat, has no effect on SWDs. Ganaxolone is a synthetic analogue of allopregnanolone. It is, like allopregnanolone, a potent positive allosteric

modulator of $GABA_A$ receptors. Ganaxolone has a robust anticonvulsant profile in a variety of animal models of epilepsy, is orally active and lacks hormonal side effects. Unlike diazepam, tolerance to the anticonvulsive action does not develop to ganaxolone following chronic therapy. However, ganaxolone has been found to increase SWDs when injected into some thalamic nuclei. Although the systemic effect of ganaxolone has not yet been tested in genetic animal models, we predict that it will aggravate SWDs and that ganaxolone should not be given to patients with absence seizures.

An increase in SWDs was also found after the highest dose of pregnenolone sulphate. This effect was explained by its agonistic effects on the NMDA receptor, although other mechanisms could not be excluded, such as an action through its conversion via progesterone to allopregnanolone.

Pregnancy is an interesting hormonal condition and epidemiological studies show an increase in seizure frequency in up to one-third of the woman with epilepsy because of hormonal and pharmacokinetic changes. Progesterone is chronically enhanced during pregnancy, to a concentration much higher than 17β-estradiol. However, in our study in WAG/Rij rats, SWDs were reduced during the first 18 days of pregnancy. Two days before delivery, progesterone decreases and SWDs increase significantly. These data demonstrate a negative relationship between plasma levels of progesterone and SWD in pregnant females, while the outcomes of the 96 h recording during the ovarian cycle and the acute pharmacological study demonstrate a positive relationship between plasma or brain concentrations of progesterone and absence seizures. The fact that these diametrically opposite relationships between absence seizures and progesterone have been demonstrated is a beautiful illustration of the fact that the relation between hormones and seizures may be completely opposite during different hormonal states (in this case, pregnancy).

Local vs. Systemic Injection of Progesterone in WAG/Rij Rats

The diametrically opposite relationship between progesterone and SWDs found during pregnancy versus the outcomes of the dose–response study and 96 h continuous recordings in female WAG/Rij rats has been a challenge for our further research. A first clue about how to understand these relationships comes from pharmacological studies in GAERS. In these studies, the effects of GABA-mimetic and antagonist, locally injected into the reticular thalamic nucleus, were opposite to the effects seen with injections of these drugs into the thalamic relay nuclei. Muscimol injected into the thalamic relay nuclei increased SWD frequency (the same as after systemic injections), but local injections in the RTN reduced SWDs.

A second clue comes after the demonstration of a cortical focus in absence epilepsy. This finding showed that SWDs are elicited in part of the somatosensory cortex, and the investigators predicted that local focal injections of GABA-mimetics (such as tiagabine) and modulators of the $GABA_A$ receptor should suppress SWD – in contrast to the effects of systemic studies of GABA-mimetic drugs (muscimol, THIP, SKF 89976, vigabatrin, tiagabine), which enhance SWDs. It quickly became clear that focal injection into this zone in the somatosensory cortex suppresses SWDs (compared with the effects of systemic injections), not only for GABA-mimetic drugs but also for antiepileptic drugs such as phenytoin. These results have led De Sarro and coworkers to compare the effects of local injections of neurosteroids into various regions in the thalamo-cortical loop (including the peri-oral region of the somatosensory cortex) in WAG/Rij rats. Allopregnanolone and ganaxolone, both with a potent enhancement of the GABA-response, injected in the thalamic VPM or VPL, increased SWD, similar to the systemic effects of allopregnanolone. The neurosteroid with a GABA antagonistic profile, pregnenolone sulphate, decreased SWDs after injections into the VPM, was ineffective in the VPL, and increased SWDs in the RTN. These regional differences are currently not well understood. Most interesting is that allopregnanolone and ganaxolone suppressed SWDs dose-dependently when administered into the peri-oral region of the somatosensory cortex. Pregnenolone sulphate showed the opposite effects of allopregnanolone and ganaxolone when it was administered into this region of cortex.

In all, the data show that neurosteroids like allopregnanolone, which modulate the $GABA_A$ receptor, can have different effects, depending on the location of the injection. Local cortical administration in the cortex blocks SWDs, while injection into thalamic relay nuclei enhances SWDs. Another example illustrating such differences is seen with local injections of progesterone and tiagabine (a GABA-reuptake inhibitor). Local hippocampal injections were effective in suppressing SWDs, while systemic injections of these drugs enhanced SWDs. Moreover, cortical injections outside the peri-oral cortical regions were without any effect. These data demonstrate that the same neuroactive steroid may have different consequences on seizure activity, dependent on the location of where the neurosteroids are active. They also suggest that the hippocampus, although not involved in the initiation and spread of absence seizures, may modulate absences seizure activity in the corticothalamic circuits.

17β-Estradiol

A second important neuroactive steroid hormone is 17β-estradiol. Beside an action via classical intracellular receptors on gene transcription, estrogen interacts with

specific receptors at the plasma membrane of neurons, and activation of these receptors activates intracellular signal transduction pathways. Estrogen has been shown to regulate the activation of some G-protein-coupled receptors (such as opioid, $GABA_B$ and dopamine D_2) and ionotropic receptors (such as 5-HT_3 and nicotinic). Estrogens also activate the *N*-methyl-D-aspartate (NMDA) excitatory neurotransmitter receptors in the hippocampus. It also affects the synthesis of DA. Considering the multiple action of estrogens, its action on absence seizures is difficult to predict.

We observed no difference in the number of SWDs during the first few hours of the light period between proestrus and the three other days of the cycle in female WAG/Rij rats in a 96 h EEG study, suggesting that 17β-estradiol has no effect on SWDs. Outcomes of pharmacological studies confirmed that 17β-estradiol does not affect absence seizures; in addition, tamoxifen, an antagonist of 17β-estradiol intracellular receptor, did not affect SWDs. In many other seizure models (e.g., kainic acid, ethyl chloride, kindling, and pentylenetetrazole), estrogens increase the number of seizures and decrease the threshold for electroshock-induced seizures. Interestingly, 17β-estradiol reduced absence seizures in the atypical absence seizure model.

Testosterone

There are no documented papers on the relationship between testosterone and absence epilepsy. Testosterone may have anti- or proconvulsant effects, depending on the dose, the animal's age, and the seizure type. The variable actions of testosterone can be partly explained by the metabolism of testosterone. Testosterone is metabolized via aromatization to 17β-estradiol (which is not effective, see above), and testosterone can also be reduced to 5α-dihydrotestosterone which is then converted to 3α-androstanediol; the latter is a powerful and positive modulator of the $GABA_A$ receptor. Therefore a relatively late increase in SWDs after systemic administration of testosterone can be predicted based on the GABA-mimetic effects of this metabolite. The first metabolite, 5α-dihydrotestosterone, is known to mimic the action of NMDA antagonists, it may reduce absence seizures considering that all NMDA antagonists reduce absence seizures. The results of systemic injections of testosterone in 6-months-old male WAG/Rij rats are presented in Figure 2.

The solvent cyclodextrine (CD) increased SWDs in the first hour, but this increase was not found for testosterone. Testosterone did not show the increase in SWDs in comparison with the solvent at the first hour post-drug administration, at post 2 and 3 testosterone showed a clear increase in number of SWDs while CD was no longer active. Considering these outcomes, we propose that testosterone is active through its metabolites 5α-dihydrotestosterone and 3α-androstanediol, which have anti- and pro-absence action on SWDs, respectively. The increase by the solvent might be due to the small injection stress or by intrinsic effects through sponging neuroactive steroids from endogenous resources that alters neuronal excitability and accounts for the increase of SWDs.

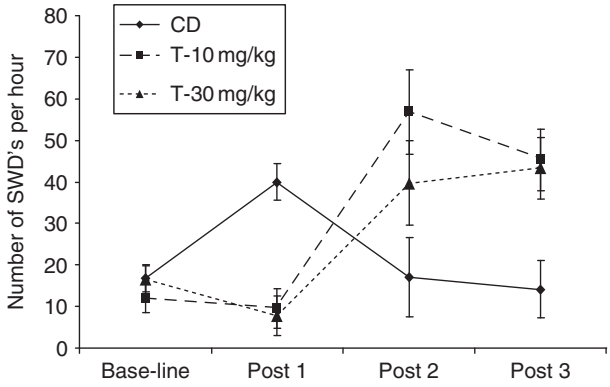

Figure 2 Effects of systemic injections of testosterone in WAG/Rij rats. Number and SEM of SWDs per hour during the baseline (preinjection), and in the first, second, and third hour following systemic injection with testosterone (10 or 30 mg kg^{-1}) of solvent CD (cyclodextrin). Note that in the first hour post-injection CD enhanced SWDs, and testosterone had less SWDs than CD alone, CD was no longer effective in the second and third hour post-administration, while both testosterone groups showed an increase in SWDs (courtesy of Alexandra Badura).

Hypothalamic–Pituitary–Adrenal Axis

Steroid hormones, secreted by the adrenal glands in response to stress, rapidly modulate brain function and behavior as well as cellular responses in general. The stress response in rats emerges within a few minutes after systemic injection of glucocorticoid. It modulates neurotransmission in the limbic system, e.g., the hippocampus, by a rapid and transient increase in the intracellular levels of inhibitory neurotransmitter GABA and the excitatory amino acids aspartate and glutamate. Systemic injections of corticosteroids in WAG/Rij rats produced a short decrease followed by an increase in SWDs. We have speculated that the short lasting decrease in SWDs is due to activation of peripheral adrenalin and to the enhancement of catecholamines in the central nervous system – known to accompany arousal and activation and suppress SWDs. We propose that the subsequent increase in SWDs might be explained by the increase of glutamate in the hippocampus, since opposite effects (reduced SWDs) were obtained after the administration of GABA-mimetics in the hippocampus. However, this possibility needs experimental verification. Interestingly, experiments with daily footshock presentation induced a similar

pattern – a short lasting suppression of SWDs was followed by a return to baseline or an increase. The data of our recent study are presented in Figure 3. The initial decrease in SWDs on day 1 after the footshock subsided over days, with a subsequent increase in SWDs that became larger over days. These data show that acute stress has a biphasic effects on SWDs and it is very likely that corticosteroids play a role in the increase of SWDs through their action in the hippocampus. These data show also that the increase in SWDs after repeated footshock exposure is elevated in ovariectomized rats. This observation has been attributed to the fact that ovarian and hypothalamic–pituitary–adrenal (HPA) axis hormones both contribute in the coping response to stress.

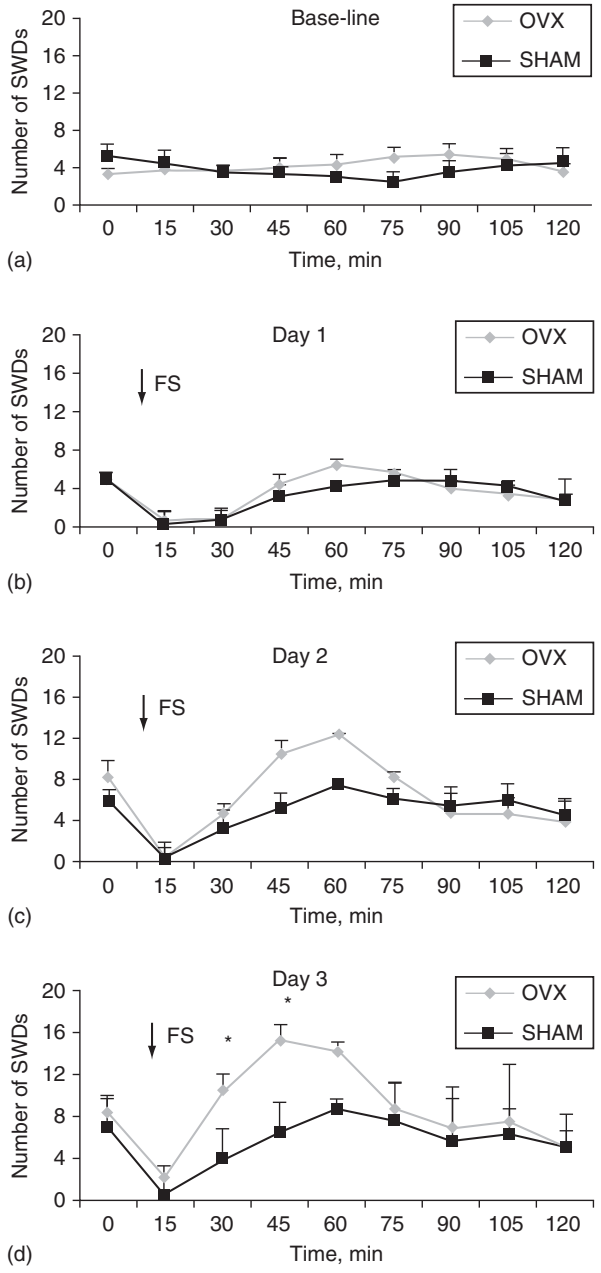

Figure 3 The effects of daily footshocks on the number of SWDs in a 2 h recording period. Note that the number of SWDs are immediately decreased after the shock and return to preshock levels, that the number of SWDs increase over days both pre and after footshocks, and that the increase over days (a)–(d) post-footshocks becomes larger over days. The latter effect is pronounced in ovariectomized females (OVX). Reproduced from Tolmacheva EA and van Luijtelaar G (2007) The role of ovarian steroid hormones in the regulation of basal and stress induced absence seizures. *Journal of Steroid Biochemistry and Molecular Biology* 104: 281–288, with permission from Elsevier.

Other Hormones, Peptides, and Absence Epilepsy

Although the thalamus is not the origin of absence seizures, it is definitely involved in the amplification and spread of these seizures. There are many neuropeptide hormones and peptides that can alter rhythmic thalamic activity, including somatostatin, cholecystokinin, neuropeptide Y, nociceptin/orphanin FQ, substance P, and vasoactive intestinal peptide. These peptides have all been localized within the thalamus, along with their respective receptors, and have been shown to alter the excitability of thalamic neurons by changing intrinsic properties of thalamic cells (such as resting membrane potential, input resistance, membrane conductance, action potential firing mode, and synaptic transmission). One peptide hormone, PrRP (prolactin-releasing peptide – which releases prolactin from pituitary cells), has been investigated in vivo and in vitro in experiments on GAERS. This peptide inhibits rhythmic activity in the RTN in the slice preparation, and it influences non-REM sleep and SWDs in intact animals. Both effects may emerge through action on receptors in the RTN; the mRNA for the receptor is expressed in the RTN and present on the GABAergic neurons in the RTN. Considering these effects on RTN neurons, one might predict that PrRP has anti-absence effects – and this effect has indeed been found. A second peptide hormone, TRH (thyrotropin-releasing hormone), administered i.c.v. decreased dose-dependently the number and mean duration of SWDs in WAG/Rij rats, and also has mild anti-absence effects.

Neuropeptide (NP) Y, a likely endogenous antiepileptic substance with possible antiepileptogenic effects, was shown to dose-dependently suppress SWDs in GAERS. Subsequent studies with specific NP Y receptor agonists showed that NP Y Y2 receptors are more important than Y1 and Y5 in mediating this effect, so that Y2 receptor agonists may represent targets for novel drugs against generalized epilepsies.

Future Challenges

In order to understand the relation between steroid hormones and absence seizures, it is necessary to find the

factors involved in the GABA hyperfunction responsible for SWDs as measured during baseline periods, and the changes that occur in SWDs during different hormonal states (such as pregnancy and various phases of the ovarian cycle). The hyperfunction and its changes can be due to elevated concentration of neuroactive steroid hormones in the cortex, thalamus and hippocampus, and/or to local concentrations of GABA-mimetic agents such as allopregnanolone, THDOC and 3α-androstanediol. These concentrations should also be determined and compared between WAG/Rij and control rats of different age, before the onset of seizures, and when the seizures are fully developed. Also the local concentration of enzymes that metabolize steroid hormones to the positive neurosteroid GABA modulators (e.g., 5α-reductase and 3α-hydroxysteroid dehydrogenase) should be compared in different hormonal conditions in WAG/Rij rats, and between WAG/Rij and control rats.

It would also be challenging to investigate whether the GABA hyperfunction is caused by action of GABA-mimetic neurosteroids (even at their unchanged level) on presynaptic, postsynaptic, or extrasynaptic $GABA_A$ receptors, the relevant receptor subunits, and the phosphorylation status of the receptors. These data should be compared between WAG/Rij and control rats. It is known that the ability of neurosteroids to affect GABA receptor function depends on the $GABA_A$ subunit expression. In some brain regions, extrasynaptic $GABA_A$ receptors, especially those containing delta subunits are more sensitive to neurosteroids than synaptic receptors. Also, phosphorylation of $GABA_A$ receptors regulates the interaction of neurosteroids with this receptor.

The changes that occur in childhood absence epilepsy, around puberty, are not understood. Therefore, it would be useful to develop a model for the transition from childhood absence epilepsy to other generalized (tonic–clonic) epilepsies.

It is challenging to study further the interaction between various hormones in the stress coping response. This response is relevant to our understanding of absence seizures, considering that the hormonal state changes dramatically in females – and that the way in which they cope with stress is highly dependent on these endocrinological changes. Moreover, acute stress increases the concentration of neuroactive steroids (allopregnanolone, THDOC) in plasma and brain, and neurosteroids in turn inhibit the release of both corticotropin-releasing hormone (CRH) and gonadotropin-releasing hormone (GnRH).

Allopregnanolone was shown to inhibit not only HPA axis activity but also glucocorticoid-mediated gene transcription. Interactions occurring among steroid hormones, neurosteroids, and glucocorticoids in response to stress (acute/chronic) should be compared between WAG/Rij and control rats.

Introduction

The interaction between hormones and seizures is complex. There is strong evidence that hormones influence seizures, particularly in women, and there is some evidence that seizures influence hormones in both men and women. This article will focus primarily on research investigating how the ovarian steroid hormones, estrogen and progesterone, influence seizures in women with epilepsy and in animal models of epilepsy. Understanding the mechanisms of hormone-sensitive seizures suggests targets for novel antiepilepsy therapies.

A relationship between seizures and the reproductive cycle in women with epilepsy has been recognized since the Greek era. In the mid to late nineteenth century, Locock and Gowers, separately, published the first clinical descriptions of seizures related to the menstrual cycle. In 1956, Laidlaw coined the term 'catamenial epilepsy' (from the Greek, *katamênios*, meaning monthly) to describe an exacerbation of seizures at various points in the menstrual cycle.

Typically, there are three times in the cycle in which increased seizure frequency is observed: around the time of menses, during ovulation, or in the second half of anovulatory cycles. Of these three, the perimenstrual seizure is the most common. A catamenial seizure pattern can occur in women with either generalized or focal epilepsy, and it has been reported that catamenial seizures are more resistant to control with antiepileptic drugs. For some women, the frequency or severity of their seizures also can be affected by reproductive life stage – for example, at puberty, during pregnancy, or after menopause. Seizure patterns related to these additional life stages have been less well studied than seizures related to the menstrual cycle.

The apparent prevalence of catamenial epilepsy depends heavily on the criteria used to define it. For example, as many as 78% of reproductive age women with epilepsy report a relationship between their menstrual cycle and their seizures. The number drops to about 30%, however, when a criterion of doubled average daily seizure frequency is applied, and to about 12% for a sixfold increase. At least a doubling of seizure frequency (during one of the three menstrual cycle points noted above) is generally accepted as the definition of catamenial epilepsy.

Although several nonhormonal causes of catamenial epilepsy have been suggested, there is strong evidence that catamenial seizure patterns are due, in large part, to fluctuating levels of ovarian steroid hormones across the menstrual cycle. Ovarian steroids do not cause seizures (except in very high doses), but they can make the neurons that support seizure activity more or less likely to fire action potentials, and particularly to fire synchronously. In this way, steroids alter susceptibility to the generation and/or propagation of seizure activity, and can influence seizure severity.

One characteristic that links the points in the menstrual cycle at which seizure frequency is increased in catamenial epilepsy is a high ratio of circulating estradiol to progesterone. The principal estrogen in reproductive age women who are not pregnant is estradiol; estriol dominates during pregnancy, and estrone after menopause. Laidlaw originally noted that elevated progesterone during the menstrual cycle is associated with reduced incidence of seizures, and so might be anticonvulsant. Subsequently, Bäckström observed that seizure frequency also can be increased during the preovulatory estradiol surge. In 1976, he modified Laidlaw's original hypothesis and suggested that the *ratio* of estradiol to progesterone is the most relevant factor in producing catamenial seizures. This view then developed into the relatively simple idea that estradiol is generally proconvulsant, whereas progesterone is generally anticonvulsant. Animal studies consistently support anticonvulsant effects of progesterone, primarily through modulation of inhibitory γ-aminobutyric acid $(GABA)_A$ receptors. There is also strong experimental evidence for proconvulsant effects of estradiol; however, the actions of estradiol are more diverse, and results of seizure studies with estradiol are more variable.

Introduction

The interaction between hormones and seizures is complex. There is strong evidence that hormones influence seizures, particularly in women, and there is some evidence that seizures influence hormones in both men and women. This article will focus primarily on research investigating how the ovarian steroid hormones, estrogen and progesterone, influence seizures in women with epilepsy and in animal models of epilepsy. Understanding the mechanisms of hormone-sensitive seizures suggests targets for novel antiepilepsy therapies.

A relationship between seizures and the reproductive cycle in women with epilepsy has been recognized since the Greek era. In the mid to late nineteenth century, Locock and Gowers, separately, published the first clinical descriptions of seizures related to the menstrual cycle. In 1956, Laidlaw coined the term 'catamenial epilepsy' (from the Greek, *katamênios*, meaning monthly) to describe an exacerbation of seizures at various points in the menstrual cycle.

Typically, there are three times in the cycle in which increased seizure frequency is observed: around the time of menses, during ovulation, or in the second half of anovulatory cycles. Of these three, the perimenstrual seizure is the most common. A catamenial seizure pattern can occur in women with either generalized or focal epilepsy, and it has been reported that catamenial seizures are more resistant to control with antiepileptic drugs. For some women, the frequency or severity of their seizures also can be affected by reproductive life stage – for example, at puberty, during pregnancy, or after menopause. Seizure patterns related to these additional life stages have been less well studied than seizures related to the menstrual cycle.

The apparent prevalence of catamenial epilepsy depends heavily on the criteria used to define it. For example, as many as 78% of reproductive age women with epilepsy report a relationship between their menstrual cycle and their seizures. The number drops to about 30%, however, when a criterion of doubled average daily seizure frequency is applied, and to about 12% for a sixfold increase. At least a doubling of seizure frequency (during one of the three menstrual cycle points noted above) is generally accepted as the definition of catamenial epilepsy.

Although several nonhormonal causes of catamenial epilepsy have been suggested, there is strong evidence that catamenial seizure patterns are due, in large part, to fluctuating levels of ovarian steroid hormones across the menstrual cycle. Ovarian steroids do not cause seizures (except in very high doses), but they can make the neurons that support seizure activity more or less likely to fire action potentials, and particularly to fire synchronously. In this way, steroids alter susceptibility to the generation and/or propagation of seizure activity, and can influence seizure severity.

One characteristic that links the points in the menstrual cycle at which seizure frequency is increased in catamenial epilepsy is a high ratio of circulating estradiol to progesterone. The principal estrogen in reproductive age women who are not pregnant is estradiol; estriol dominates during pregnancy, and estrone after menopause. Laidlaw originally noted that elevated progesterone during the menstrual cycle is associated with reduced incidence of seizures, and so might be anticonvulsant. Subsequently, Bäckström observed that seizure frequency also can be increased during the preovulatory estradiol surge. In 1976, he modified Laidlaw's original hypothesis and suggested that the *ratio* of estradiol to progesterone is the most relevant factor in producing catamenial seizures. This view then developed into the relatively simple idea that estradiol is generally proconvulsant, whereas progesterone is generally anticonvulsant. Animal studies consistently support anticonvulsant effects of progesterone, primarily through modulation of inhibitory γ-aminobutyric acid $(GABA)_A$ receptors. There is also strong experimental evidence for proconvulsant effects of estradiol; however, the actions of estradiol are more diverse, and results of seizure studies with estradiol are more variable.

Perimenstrual seizure exacerbation is likely due to the precipitous drop in progesterone that occurs just before menses, sometimes referred to as 'progesterone withdrawal.' Seizures that occur mid-cycle are most likely due to proconvulsant effects of estradiol, which surges just prior to ovulation. Seizures that increase during the second half of anovulatory cycles are also likely to be due to the actions of estradiol, together with a relative lack of progesterone. During ovulatory cycles, a corpus luteum forms from the follicle that releases its egg. The corpus luteum is the primary source of ovarian progesterone, which normally increases after ovulation – i.e., in the latter half of the cycle. In an anovulatory cycle, the corpus luteum fails to form (causing a condition sometimes referred to as 'inadequate luteal phase'). In these anovulatory cycles, progesterone levels do not rise and thus proconvulsant effects of estradiol are unopposed by anticonvulsant effects of progesterone. **Figure 1** depicts fluctuating estradiol and progesterone levels across the menstrual cycle, and the consequences for neuronal activity.

Background

Hormones and Seizures in Animal Models of Epilepsy

Animal research into the roles that progesterone and estradiol play in regulating seizure susceptibility began with the pioneering work of Selye in the case of progesterone, and D. E. Woolley, Teresawa, and Timiras in the case of estradiol. In 1942, 14 years before Laidlaw suggested that progesterone could be anticonvulsant during the menstrual cycle, Hans Seyle reported that progesterone had anticonvulsant effects in rats. Later, in the 1960s, Timiras *et al.* conducted the first animal studies investigating the effects of estradiol on seizures. Her group confirmed, again in rats, that progesterone is anticonvulsant. They further found that estradiol is proconvulsant in that seizure threshold is reduced both by exogenous estradiol treatment and during the high estradiol phase of the estrous cycle (analogous to the menstrual cycle in primates). These classic observations set the stage for the next six decades of research into the mechanisms by which ovarian steroids influence seizures through their effects on neuronal physiology. Given the importance of the hippocampus in temporal lobe epilepsy, the most common form of epilepsy in adulthood, the majority of these studies have focused on the hippocampus and related brain areas.

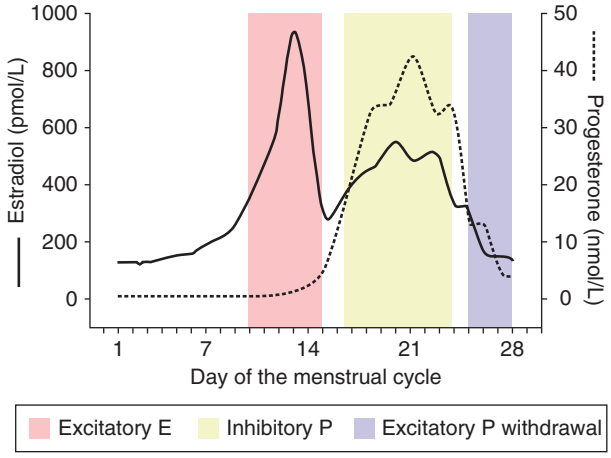

Figure 1 Median levels of estradiol (E) and progesterone (P) across the typical 28-day menstrual cycle in reproductive age women. Colored portions represent periods in the cycle during which estradiol and progesterone's effects on neuronal physiology in seizure-prone neural circuits alter seizure frequency. Ovulation typically occurs mid-cycle, and menses occurs at the end of the cycle. Estradiol and progesterone levels data are obtained from Table 1B in Stricker, R., Eberhart, R., Chevalilier M.C., *et al*. (2006) Establishment of detailed reference values for luteinizing hormone, follicle stimulating hormone, estradiol, and progesterone during different phases of the menstrual cycle on the Abbott ARCHITECT analyzer. *Journal of Clinical and Chemical Laboratory Medicine* 44, 883–887.

Progesterone and estradiol, like other steroid hormones, exert their effects in the brain through multiple mechanisms, with differing time courses. The classical (or genomic) mechanism of steroid action is through nuclear receptors. Steroid hormones secreted by peripheral endocrine glands are released into circulation, readily cross the blood–brain barrier, and diffuse into cells in the brain. In cells that contain the appropriate receptor(s), hormone–receptor complexes bind to hormone response elements in DNA and regulate gene expression. Owing to its dependence on gene expression, this mechanism produces effects with a delayed time course, on the order of hours to days.

In addition to this classical mechanism, steroid hormones also exert rapid, nonclassical effects that occur on a time scale of minutes to hours. That these rapid effects contribute to hormone regulation of seizures was predicted by the work of Selye. He found that the anticonvulsant effects of progesterone could occur within minutes. The nonclassical effects of steroids may be mediated by classical nuclear receptor proteins acting outside of the nucleus, by G-protein-coupled receptors and second messenger pathway activation, and/or by direct modulation of ion channels.

Methods

Most of the studies described here involve treating animals with estradiol and/or progesterone, and then either measuring some aspect of electrographic or behavioral seizures or making specific electrophysiological or anatomical measurements. Electrophysiological and anatomical studies give insight into the types of cellular or circuit

changes that parallel changes in behavioral seizures (and likely contribute to them). Most of the relevant measurements at the cellular and circuit level have been made in the hippocampus. In these experiments, typically, hormone levels first are normalized by removing an animal's ovaries; after a defined period, animals are then treated with known doses of estradiol and/or progesterone or vehicle, and analysis is performed after a known duration of hormone exposure.

Seizure studies typically involve measuring how animals treated with estradiol and/or progesterone respond (relative to controls) to a seizure-inducing stimulus. Responses are assessed to electrical stimulation of a specific pathway or brain area, or following treatment with a chemical convulsant (such as the glutamate analogue, kainic acid). Electrophysiological recordings have been carried out in vivo or, more typically, in vitro – in acute slices of the hippocampus or in dissociated hippocampal neurons. Some of these studies have involved comparing intrinsic or synaptic physiology in hippocampal slices from animals treated with hormones; other studies have focused on effects of direct application of hormones to slices, or to individual dissociated neurons, on intrinsic and synaptic physiology. Anatomical measurements have been made using light and/or electron microscopy in hippocampal tissue from animals treated with hormones. Electron microscopy has been particularly useful for studying hormone-induced structural plasticity of hippocampal circuitry, as this technique provides nanometer resolution of synaptic ultrastructure.

Results

Progesterone – Cellular Level

As noted earlier, progesterone appears to exert its anticonvulsant effects largely through regulation of the inhibitory GABAergic neurotransmitter system. There is ample evidence that alterations of GABAergic inhibition influence seizure susceptibility. Drugs that inhibit GABA synthesis or $GABA_A$ receptors (responsible for fast synaptic inhibition) cause seizures, whereas drugs that enhance GABAergic function are anticonvulsant. Some genetic forms of human epilepsy are associated with $GABA_A$ receptor mutations that impair receptor function. In animal models, mutation of the gene for the GABA synthesizing enzyme, glutamic acid decarboxylase (GAD), decreases GAD activity and GABA levels in the brain, and increases susceptibility to seizures.

Experimental studies have demonstrated two distinct and complementary mechanisms by which progesterone regulates GABAergic inhibition. Interestingly, in both cases, it appears that metabolites of progesterone, rather than progesterone itself, mediate the effects. In 1986, it was discovered that one metabolite of progesterone, allopregnanolone (3α-OH-5α-pregnan-one), is a powerful positive allosteric modulator of $GABA_A$ receptors. Allopregnanolone binds directly to the $GABA_A$ receptor, increases channel open time, and thus potentiates the inhibitory postsynaptic currents (IPSCs) mediated by this receptor.

Similar to other agents that increase GABAergic inhibition, allopregnanolone is anticonvulsant. Its immediate precursor, 5α-dihydroprogesterone, is anticonvulsant as well. Importantly, several groups have found that the anticonvulsant effects of progesterone depend upon its conversion to one or both of these metabolites. First, it was demonstrated that finasteride, an inhibitor of the enzyme that converts progesterone to 5α-dihydroprogesterone (5α-reductase), blocks progesterone's anticonvulsant effects on behavioral seizures. The importance of 5α-reductase was then confirmed in 5α-reductase knockout mice; progesterone is significantly less effective in inhibiting seizures in knock outs than in wildtype controls. The lack of involvement of the classical progesterone receptor was demonstrated using progesterone receptor knockout mice. Progesterone was similarly effective in inhibiting seizures in these mice as in wildtype mice, and finasteride similarly inhibited the effects of progesterone on seizures in these knockouts. Together, these studies make a very strong case that the progesterone metabolites, 5α-dihydroprogesterone and/or allopregnanolone, are critically important in mediating anticonvulsant effects of progesterone independently of the classical progesterone receptor.

A second mechanism of progesterone (or its metabolites) action was revealed using animal models designed to mimic the perimenstrual drop in progesterone levels during the menstrual cycle (i.e., progesterone withdrawal). As described earlier, this point in the cycle is associated with an increase in seizure frequency. In these studies, rats were treated chronically with progesterone or allopregnanolone and then the steroid was withdrawn. Shortly after withdrawal, expression of the α4 subunit of the $GABA_A$ increased markedly. This increased expression is relevant to seizures because $GABA_A$ receptor channels that contain α4 produce IPSCs with a relatively fast decay time, leading to less inhibition and greater neuronal excitability. As predicted, this progesterone withdrawal-induced increase in α4 was associated with greater hippocampal circuit excitability and increased behavioral seizure susceptibility/severity. The importance of α4 in progesterone withdrawal was confirmed by showing that suppression of α4 expression with antisense mRNA inhibits both the changes in IPSC decay time and in seizure behavior.

Given these two effects of progesterone metabolites on GABAergic inhibition, the perimenstrual phase of the menstrual cycle represents a 'double-hit' increase in neuronal excitability. At this point in the cycle, the direct GABA-potentiating effect of progesterone metabolites is lost and the GABA-suppressing progesterone withdrawal

effect is induced. Importantly, in the context of catamenial epilepsy, levels of allopregnanolone also rise in the second half of ovulatory menstrual cycles, in parallel with progesterone. Levels of allopregnanolone are also particularly high during pregnancy, which may explain why some pregnant women with epilepsy experience a decrease in their seizures during this time.

Estradiol – Cellular Level

In contrast to progesterone, which appears to have uniformly anticonvulsant effects mediated through the GABA system, estradiol's effects on seizures are considerably more complex. Estradiol regulates both the GABAergic system and the excitatory glutamatergic system, and its effects vary across brain regions. Additionally, estradiol's effects on inhibitory and excitatory neurotransmitter systems, even within the same brain region, occur with differing time courses. Thus, whether and how estradiol affects seizures depends on both duration of estradiol exposure and the brain regions involved in the type of seizure studied. This complexity was evident even in the earliest studies of estradiol's effects on seizures. For example, in their studies in the 1960s, Timiras' group found that estradiol decreased seizure threshold in the dorsal hippocampus and the medial amygdala, but at the same time, it increased seizure threshold in the lateral amygdala. The following discussion will focus on the hippocampus, in which most studies have been done.

Estradiol's effects on hippocampal physiology can be divided into three phases: potentiation of intrinsic excitability and excitatory synaptic transmission that occurs within minutes, transient suppression of GABAergic inhibitory synaptic transmission that occurs at ~24 h, and a secondary enhancement of excitatory synaptic transmission that occurs at 48–72 h. Each of these will be discussed separately below.

In 1980, Teyler *et al.* published the first paper demonstrating a rapid effect of estradiol to increase hippocampal excitability. Using hippocampal slices from rats, they found that 5–10 min of estradiol exposure potentiated the slope and amplitude of extracellularly recorded field excitatory postsynaptic potentials. The effects they observed could have been due to either an increase in intrinsic excitability and/or potentiation of excitatory synaptic transmission. Subsequently, both of these possibilities were shown to contribute. Several groups have reported that estradiol rapidly increases hippocampal excitability by modulating K^+ currents and suppressing the after-hyperpolarization (AHP) that follows an action potential. This effect is likely due to decreased Ca^{2+} influx through L-type Ca^{2+} channels. Because the AHP depends, in part, on Ca^{2+}-activated K^+ currents, suppression of Ca^{2+} influx suppresses the AHP. Estradiol also rapidly increases the amplitude of excitatory postsynaptic currents (EPSCs) in hippocampal neurons. As in many other brain regions, these EPSCs are mediated by glutamate. Reports in the 1990s indicated that the rapid increase in EPSC amplitude was due to greater postsynaptic responsiveness to glutamate (or glutamate analogues). More recent studies, however, point to increased probability of glutamate release as the mechanism for rapid EPSC potentiation.

These rapid excitatory effects of estradiol on hippocampal physiology lead to amplification of synaptic potentiation mechanisms, which likely contributes to increased seizure susceptibility or severity. Thus, if a high-frequency tetanus is delivered to a hippocampal slice in the presence of estradiol, the long-term potentiation (LTP) that results is significantly greater than the potentiation that occurs with the same tetanus given in the absence of estradiol. This enhanced excitatory mechanism can produce a vicious cycle of excitation in which intense excitatory synaptic activation – such as occurs with seizures – amplifies synaptic strength with a high gain, leading to more excitatory synaptic activation. Whether or how these rapid actions of estradiol, specifically, affect seizure susceptibility has not yet been investigated. However, a reasonable prediction is that rapid effects on intrinsic excitability and EPSC potentiation increase seizure susceptibility during the initial phase of the preovulatory estradiol surge.

With somewhat longer exposure, ~24 h in rats, estradiol suppresses GABAergic inhibition of hippocampal neurons. This effect is transient in that, by 72 h, inhibition recovers to control levels. In a series of studies, electrophysiology and electron microscopy have been used in my laboratory to show that estradiol suppresses inhibition by decreasing the probability of GABA release at inhibitory synapses. We found that estradiol decreases the amplitude of synaptically evoked IPSCs in hippocampal neurons, the frequency (but not amplitude) of miniature IPSCs, and paired-pulse depression of IPSCs. These changes are paralleled ultrastructurally by a decrease in the number of vesicles docked at inhibitory synapses, indicating fewer vesicles available for release. A decrease in vesicles available for release then translates into decreased probability of GABA release. Importantly, changes in GABAergic IPSCs occur in the absence of any effect on EPSCs; this effect leads to a disinhibition of hippocampal neurons, making them more likely to fire an action potential in response to synaptic input. As one would predict from this scenario, susceptibility to hippocampus-dependent behavioral seizures induced by kainic acid (KA) is increased with 24 h of estradiol treatment.

With an even longer exposure, 48–72 h, estradiol again enhances excitatory synaptic transmission in the hippocampus, but through a different mechanism than the rapid effects. This time range corresponds to the peak of estradiol levels during the estrous cycle in the rat and to the greatest hippocampal seizure susceptibility observed by

Timiras' group in the 1960s. Multiple studies indicate that this delayed enhancement of excitatory synaptic transmission is related, at least in part, to a physical increase in the number of dendritic spines and excitatory synapses on hippocampal neurons. Dendritic spines are small protrusions that cover the dendrites of many neuron types in the brain, and are the postsynaptic sites of excitatory synaptic input. In 1990s, Gould, C. S. Woolley, and McEwen published a series of papers demonstrating that the density and number of dendritic spines and excitatory synapses on hippocampal CA1 pyramidal cells is increased ~30% by 72 h of estradiol exposure. Progesterone given after estradiol counteracts the effect and decreases dendritic spine density. Importantly, spine and synapse density also fluctuate naturally as estradiol and progesterone levels rise and fall during the estrous cycle. Although these early studies were done in rats, subsequent work by other groups has replicated these studies in primates (both African Green monkeys and Rhesus macaques). Thus, it is highly likely that estradiol produces similar structural synaptic plasticity in women.

The estradiol-induced increase in hippocampal dendritic spine/synapse number is paralleled by increased sensitivity to excitatory synaptic input, specifically input mediated by the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. This enhanced sensitivity suggests that estradiol-induced synapses may be functionally different from preexisting synapses, which typically contain both NMDA and non-NMDA receptors. The greater sensitivity to NMDA receptor-mediated input is due to an increased contribution of receptors containing the NR2 subunit – a finding that has implications for LTP, since higher expression of NR2 is associated with greater LTP. Indeed, several groups have confirmed that LTP is enhanced by 48–72 h of estradiol treatment, both in vitro and in vivo. Similar to the rapid effect(s), longer exposure to estradiol also produces a situation in which excessive excitatory synaptic activity increases synaptic strength with a higher gain than in animals not exposed to estradiol. As predicted by the original Timiras studies, and consistent with its effects on hippocampal synaptic structure and function, estradiol treatment for 48–72 h increases susceptibility to behavioral seizures induced by KA.

However, it should be noted that not all studies that have investigated estradiol's effects on seizures have found that it is proconvulsant. As should be clear from the description above, the various durations of estradiol exposure produces various cellular changes that could underlie differences in seizure behavior. For example, although 72 h exposure to estradiol increases susceptibility to KA-induced seizures, longer treatment with estradiol may decrease susceptibility to seizures induced the same way. In addition, different methods of seizure induction, which engage different brain areas and/or cellular mechanisms, are likely to produce different results. For example, the same 72 h estradiol treatment that increases KA-induced seizure susceptibility has no effect on flurothyl-induced seizures. Similarly, estradiol promotes seizures induced by kindling in the dorsal hippocampus, but has no effect on kindling in the ventral hippocampus. Finally, it is important to distinguish between effects on seizure susceptibility, seizure severity, and neuroprotection from seizure-induced damage. Some investigators use the degree of seizure-related brain damage as a post hoc indication of seizure severity. However, because estradiol has neuroprotective effects irrespective of seizures, this indication can lead to confusing results.

In addition to the generally proconvulsant actions of estradiol described above, recent studies indicate that estradiol may have an anticonvulsant influence as well. This suggestion stems from the observation that estradiol can increase levels of the anticonvulsant neuropeptide, neuropeptide Y (NPY), in the hippocampus. NPY is thought to be released from hippocampal GABAergic neurons during intense seizure activity and it has been shown in many in vitro and in vivo studies to help terminate seizures. The consequences of estradiol's effects on hippocampal NPY for behavioral seizures are still somewhat controversial. Some groups report that with relatively long estradiol exposure (4 days) seizure susceptibility is reduced. Others find that shorter estradiol exposure decreases seizure severity through NPY. Thus, more work must be done to understand this NPY-mediated effect fully. And, as with estradiol's effects on the GABA and glutamate systems, understanding how estradiol/NPY interactions influence seizures will require careful attention to the duration of estradiol exposure, type of seizure analyzed, etc. Nevertheless, finding that estradiol can have a seizure mitigating effect suggests estradiol regulation of NPY as a promising avenue for development of novel antiseizure therapies.

Estradiol and Progesterone – Circuit Level

Estradiol's ability to increase the density/number of dendritic spines and synapses in the hippocampus not only increases excitatory drive onto hippocampal neurons, but also alters the pattern of hippocampal synaptic connectivity in a way that could promote seizures. Any useful understanding of how estradiol and progesterone influence seizures requires integration of their cellular level effects with their circuit level effects.

The effects of estradiol and progesterone at a circuit level involve changes in the relative proportions of different types of presynaptic axonal boutons. The majority of excitatory boutons in the hippocampus are in synaptic contact with one dendritic spine; these are termed single synapse boutons (SSBs). The remaining boutons form more than one synapse with more than one spine, and are termed multiple synapse boutons (MSBs). The

multiple spines in contact with an MSB may arise from the same postsynaptic neuron (forming a same-cell MSB), or from different postsynaptic neurons (forming a different-cell MSB). A series of detailed serial-section electron microscopic/3D reconstruction analyses of dendritic spines and axonal boutons in rats treated for 72 h with estradiol (compared with low estradiol controls) revealed that the new dendritic spines induced by estradiol form their synapses with preexisting boutons, transforming boutons that previously were SSBs into MSBs. Most importantly, the MSBs formed in this way are of the different-cell type. That is, the spines in contact with these MSBs arise from different postsynaptic cells. The effect of estradiol-induced dendritic spines to transform SSBs into different-cell MSBs is depicted in Figure 2.

The estradiol-induced transformation from few to many different-cell MSBs serves to increase the coupling of neighboring postsynaptic neurons through shared presynaptic input. Because different-cell MSBs are sites at which a single presynaptic input can simultaneously activate two or more postsynaptic cells, the increased proportion of different-cell MSBs is predicted to promote synchronous synaptically driven neuronal firing. Since seizures depend, in part, on synchronous firing, this structural plasticity is likely to be an important component of estradiol's proconvulsant effects. Furthermore, progesterone counteracts the spine/synapse-inducing effects of estradiol, so that progesterone (or its metabolites) would tend to return the pattern of hippocampal synaptic connectivity to an SSB-dominated state, decreasing synchronization of neuronal firing. Although still speculative, this hypothesis describes a mechanism that may be an additional source of progesterone's anticonvulsant effects.

Future Directions

Implications for Treatment Strategies

Understanding how hormones influence seizures has led to some therapeutic strategies that are being used now, and suggests other avenues for the future. One therapy being used now, though to a limited extent, is treatment with progesterone as a supplement to typical antiepileptic drug therapy. Several case histories in the literature indicate that this adjunctive treatment can be effective, particularly with a catamenial seizure pattern. The

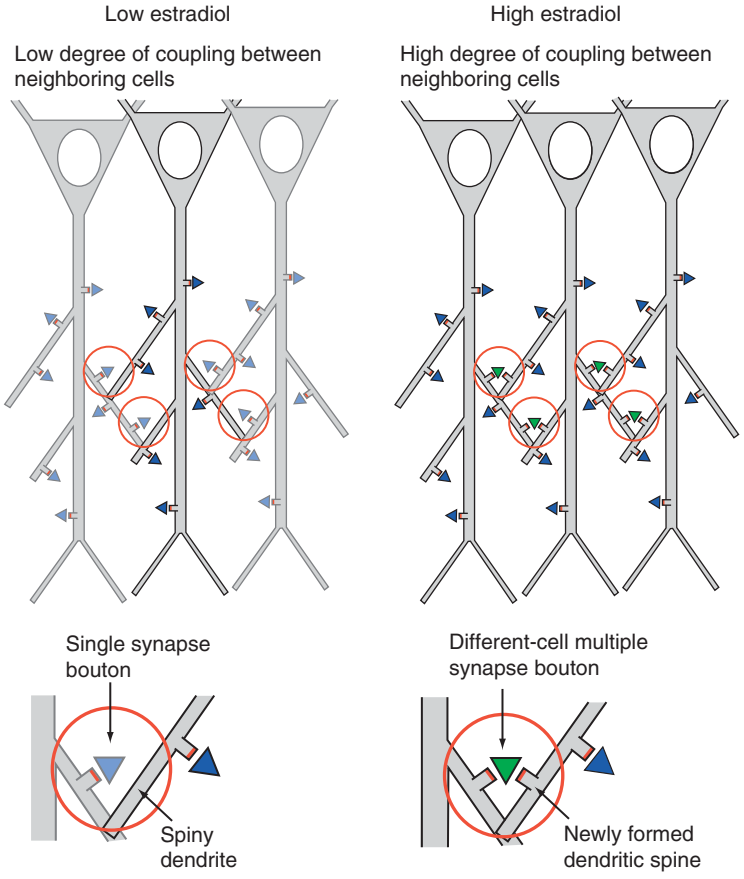

Figure 2 Schematic diagram of three hippocampal neurons showing how estradiol-induced dendritic spines transform single synapse boutons into different-cell multiple synapse boutons, increasing coupling between neighboring cells through shared presynaptic inputs. See text for details. Adapted from Yankova M, Hart SA, and Woolley CS (2001).

importance of progesterone metabolism in this treatment strategy is exemplified by the following case: A 34-year-old woman presented with intractable complex partial and secondary generalized seizures that increased in frequency and severity during the second half of each menstrual cycle. Hormone assays confirmed anovulatory cycles. The patient's seizures persisted despite trials with phenytoin, carbamazepine, valproate, and barbiturates. Adding progesterone to carbamazepine, however, reduced her seizure frequency from several per month to two per 6 months. Then, unbeknownst to her neurologist, a dermatologist prescribed finasteride for a different condition. Recall that finasteride inhibits conversion of progesterone to metabolites that positively modulate $GABA_A$ receptors. As predicted by animal studies, finasteride caused this patient's seizure frequency to increase dramatically (by 13-fold). As soon as her neurologist realized she was taking finasteride, it was discontinued, and her seizure frequency returned to two per 6 months. This case clearly demonstrates a therapeutic benefit of progesterone and, importantly, that its metabolism is essential to that benefit.

There are at least two avenues by which research on estradiol's effects on seizures may lead to new and better antiepilepsy therapies. One avenue is to study the molecular mechanisms by which cellular and circuit level effects of estradiol on the GABA and glutamate systems promote seizures. Greater understanding of the changes in seizure-prone circuits that lead to increased seizure occurrence, and particularly of how those changes come about, will point to ways of preventing those changes. A second avenue stems from the very recent discoveries that estradiol enhances the expression and/or actions of hippocampal NPY, which is anticonvulsant. With more study, knowledge of how estradiol regulates NPY could be used to target this anticonvulsant effect specifically, and avoid the proconvulsant effects of estradiol itself.

Hormones and Seizures

K K Borowicz, Lublin Medical University, Lublin, Poland

Introduction

It is widely accepted that nervous, immunological, and hormonal systems cooperate with each other. Furthermore, there is bidirectional interdependence in the relationship between hormones and seizures. That is, hormones affect seizure phenomena and seizures influence release of several hormones. Several types of seizures, for example in the course of temporal lobe epilepsy (TLE) or catamenial epilepsy, are positively correlated with the respective pattern of steroid hormones. Accurate knowledge about these relations may increase utility of hormones and their derivative neurosteroids in the treatment of epilepsy.

Background

Influence of Seizures on Hormone Release

A large number of studies of experimental seizures in rodents have revealed diverse hormonal changes. For instance, it is widely accepted that maximal electroshock, an animal model of generalized tonic–clonic convulsions, is associated with substantial and prolonged increases of thyrotrophin-releasing hormone (TRH) concentrations in such epilepsy-related brain regions as hippocampus, amygdala, piriform, and frontal cortices. Corticotrophin-releasing hormone (CRH), oxytocin (OXT), and vasopressin release is increased after kindled seizures (a model of complex partial seizures in humans), while significantly enhanced plasma concentrations of ACTH, glucagon, cortisol, vasopressin, and aldosterone are observed after pentylenetetrazole-evoked convulsions (an animal model of myoclonic epilepsy). Increased concentrations of OXT are also observed after kainate-induced convulsions.

An increased concentration of prolactin is a marker of generalized seizures, both in animals and humans, and may be viewed as part of an endogenous anticonvulsant system. Interestingly, this rise in prolactin is usually not seen after psychogenic seizures. Variability of baseline luteinizing hormone (LH) secretion, as well as in the frequency of transient hormonal 'pulses,' is observed in men with complex partial seizures. Acute seizures induce timing irregularity in LH secretion, whereas chronic epilepsy is associated with changes in LH pulse frequency and amplitude.

Increased concentrations of somatostatin (STS) may be found in the cerebrospinal fluid of epileptic patients and in children with febrile seizures. STS is considered to be a very early and long-term cerebrospinal seizure marker. There is a positive correlation between STS and CRH.

Influence of Hypothalamic Hormones on Seizures

Thyrotrophin-releasing hormone

In vitro studies have revealed that TRH inhibits pathological discharges in epilepsy-related brain structures. Acute treatment with TRH and its analogues (RGH 2202, DN-1417) results in an antiepileptic effect in several animal models of epilepsy, such as amygdala- or cortically-kindled seizures, maximal electroshock, audiogenic seizures, and glutamate-, kainate-, pentylenetetrazole-induced convulsions. A number of add-on human studies and case reports suggest an antiseizure effect of TRH in intractable epilepsies like infantile spasms, Lennox-Gastaut syndrome, myoclonic seizures, and other generalized and partial seizures. In Lennox-Gastaut syndrome, the hormone may benefit atypical absence seizures and electroconvulsive therapy-induced seizures more than tonic seizures. Undesired therapy side-effects during treatment for infantile spasms are significantly less in patients receiving TRH as compared with those treated with ACTH. The anticonvulsant action of TRH is probably mediated by two metabotropic receptors (TRH-R1, TRH-R2) activating phospholipase C. It has been hypothesized that hippocampal TRH inhibits seizure propagation, whereas striatal TRH reduces seizure susceptibility. The antiseizure action of TRH may be also due to attenuation of cholinergic and glutamatergic neurotransmission and simultaneous enhancement of the monoaminergic (noradrenaline, dopamine, serotonin) system. Decreased brain glutamatergic activity may result from decreased release of glutamate and aspartate into the synaptic cleft, as well as increased synthesis of kynurenine. Both processes are mediated by TRH.

Corticotrophin-releasing hormone

In the majority of neuronal circuits, CRH functions as an excitatory modulator. Amygdala and hippocampus, parts of the limbic system, are particularly rich in CRH receptors. Elevated brain concentrations of CRH may induce phenotypic 'limbic seizures,' resembling those produced by kainic acid or rapid amygdala-kindling, and eliminated by the administration of a selective CRH antagonist.

In vitro studies demonstrate that CRH amplifies excitatory stimuli in the network, and triggers neurodegeneration

process in areas involved in learning and memory. In animal studies, CRH augments the action of some proconvulsant substances like kainic acid. The hormone exacerbates, among others, cocaine-induced convulsions, as well as Shigella dysenteriae exposure-evoked seizures and lethality. Intracerebroventricular administration of CRH, at doses not affecting the plasma corticosterone concentrations, induces seizures in rodents. This demonstration excludes the possibility of glucocorticoid involvement in the initiation of CRH-induced seizures. The proconvulsant effect of CRH seems also to be independent of glutamatergic neurotransmission.

Proposed mechanisms of CRH action are widely attributed to two G-protein-coupled receptors for CRH (CRF1 and CRF2). Excitatory effects of CRH are mediated through activation of CRF1 receptors, leading to increased activity of GABA transporter 1 (GAT-1) in several strategic brain areas, including hippocampus, neocortex, piriform cortex, prepiriform cortex, and amygdala. Therapeutic effects of adrenocorticotrophin hormone (ACTH) and glucocorticoids in infantile spasms have been hypothesized to be because of a negative feedback system leading to suppressed CRH secretion.

Influence of Pituitary Hormones on the Course of Seizures

Adrenocorticotrophin

Both pro- and anticonvulsant action of ACTH has been observed in vitro. ACTH treatment reduces seizure susceptibility in immature rat brain slices and has no long-term deleterious effects on neuronal growth. In contrast, a proconvulsant effect of the hormone has been shown in neurons of adult rats.

In rodents, ACTH is entirely ineffective against the pentylenetetrazole-induced seizures or maximal electroshock. However, both acute and chronic treatment with ACTH slows the development of amygdala-kindled seizures. In contrast, proconvulsant effects of the hormone have been observed in seizures kindled from hippocampus.

The anticonvulsant effect of ACTH in humans is age dependent. The hormone is effective in children, but not in adults. ACTH has been successfully used for treating children with West or Lennox-Gastaut syndrome. Usefulness of adrenocorticotrophin for generalized seizures other than infantile spasms is limited by its transient efficacy. ACTH treatment is occasionally associated with serious adverse effects, including immunosuppression, body weight gain, and hypertension.

Most ACTH effects on the central nervous system have been attributed to increased glucocorticoid synthesis. However, ACTH also reduces CRH expression in amygdala neurons, which may be responsible for its anticonvulsant effect.

Gonadotrophin releasing hormone

Complex partial seizures may disrupt hypothalamic regulation of pituitary secretion in animals and in humans. There is a strong predominance of left-sided discharges in women with hypergonadotropic hypogonadism and right-sided discharges in those with hypogonadotropic hypogonadism. Gonadotrophin releasing hormone agonists and analogues (e.g., leuprolide acetate) may suppress catamenial seizures, and trigger atypical absence seizures in pediatric patients with diffuse brain damage.

Arginine vasopressin

Data on the influence of arginine vasopressin (AVP) on seizure phenomena are contradictory. The AVP-induced increment of ACTH release may contribute to a net anticonvulsant action. However, both intracerebroventricular and systemic administration of AVP can induce behavioral seizures in rodents. AVP also decreases the threshold of pentylenetetrazole-induced convulsions. However, the effect of AVP on the pilocarpine-induced seizures is far from clear; some reports show a proconvulsant action of AVP on pilocarpine-induced seizures, while other studies do not confirm such observations. AVP, through the activation of the V_2 receptors, may also be involved in the pathogenesis of febrile convulsions.

Oxytocin

OXT can influence seizure phenomena through its ability to stimulate ACTH release.

Somatostatin

Pharmacological studies show that STS affects electrophysiological properties of neurons, modulates classical neurotransmission, and has anticonvulsant activity in experimental models of seizures. The protective action of STS in hippocampus may depend on the activity of the inhibitory GABAergic neurons and STS_2 receptor activation, leading to the increment of hippocampal extracellular dopamine and serotonin concentrations. Activation of STS_2 receptors may play a role in the control of partial complex seizures and, therefore, it may be useful as a therapeutic target for TLE. STS may also exhibit antiepileptogenic effects in animal models of partial complex seizures. STS gene knockout animals have been shown to have a shorter average latency to experimental seizures of different types, higher average seizure score, and longer afterdischarge durations.

Influence of Thyroid Hormones on Seizures

On the level of cell membrane, thyroid hormones increase oxygen consumption and Na^+/K^+-ATPase activity (which controls the intracellular Na^+/K^+ ratio). In vitro, accumulation of triiodothyronine increases delayed excitability in several brain areas, for instance in the hippocampus and

visual cortex. In experimental studies, acute exposure to triiodothyronine has no effect on experimentally induced epileptiform activity; however, increased susceptibility to some convulsants (e.g., isoniazide, picrotoxin) has been observed after repeated administration of triiodothyronine. Thyroxin significantly lowers the seizure threshold in several animal models, including electroconvulsions and audiogenic seizures. Both pro- and anticonvulsant action of the hormone has been reported in lidocaine-induced convulsions. In clinical conditions, there have been two case reports of single tonic–clonic convulsions in a child after taking an overdose of levothyroxine.

Influence of Parathormone on Seizures

Hypocalcemia due to hypoparathyroidism may result in intractable seizures of nonepileptic origin, but there are no available data on the effect of parathormone on epileptic seizures.

Influence of Insulin on Seizures

In vivo, hypoglycemia is frequently associated with seizures. Nitric oxide may play a protective role in acute hypoglycemia-induced seizures. However, partial motor seizures are also common in severe nonketotic hyperglycemia. In vitro, decreases in extracellular glucose do not induce epileptiform discharges, and even attenuate preexisting low magnesium-induced epileptiform activity in the enthorinal cortex and hippocampal CA1 region.

Under normoglycemic conditions, insulin may directly inhibit the neural firing rate, increase resting membrane potential, and activate membrane ion transport. In normoglycemic animals (with additional glucose supplementation), insulin decreases incidence, intensity, and mortality rate of a variety of chemically-induced convulsions. It has been hypothesized that the antiseizure action of insulin may be realized via activation of the brain Na^+/K^+-ATPase.

Influence of Adrenal Hormones on Seizures

Glucocorticoids

Glucocorticoids can increase neuronal excitability and facilitate seizure development of kindled seizures. Moreover, when applied at supratherapeutic doses, glucocorticoids may aggravate electrically- and chemically-induced convulsions.

In human studies, ACTH-evoked hypercortisolemia is not associated with any interictal EEG changes, and cortisol therapy may be useful in the treatment of refractory tonic–clonic convulsions. In contrast, chronic hypercortisolemia, as a result of stress, anxiety, and depression, may facilitate the development and progression of epilepsy.

Corticosterone at physiologically relevant concentrations can aggravate absence seizures, possibly via a temporary increase of excitatory neurotransmitters. Simultaneously, the hormone also enhances the proconvulsant action of excitatory amino acids. Chronic exposure to high corticosterone concentrations accelerates experimental convulsions and increases spike amplitude in the CA1 hippocampal area. Corticosteroid receptors can modulate expression of some experimental seizures.

Deoxycorticosterone, an agonist of mineralocorticoid receptors and an antagonist of glucocorticoid receptors, plays a role in stress-related changes in seizure control. The hormone is metabolized by 5α-reductase to the inhibitory neurosteroid, allodeoxycorticosterone, a positive modulator of $GABA_A$ receptor. Deoxycorticosterone may exhibit anticonvulsant action against chemically- and electrically-induced convulsions.

Mineralocorticoids

Aldosterone, a selective agonist of mineralocorticoid receptors, may be anticonvulsant in developing rats, although they are rather proconvulsant in adult animals. In young rats, aldosterone has been shown to inhibit minimal and maximal pentylenetetrazole-induced convulsions, but appears to be ineffective against maximal electroshock- and hippocampal-kindled seizures.

Adrenal androgens

Dehydroepiandrosterone sulfate was reported to have both $GABA_A$-antagonistic and NMDA-agonistic properties. However, the net action of the hormone in experimental seizures is anticonvulsant.

Influence of Gonadal Hormones on Seizures

Estradiol/progesterone

Clinical and animal data show that estrogens may be ineffective or present both proconvulsant and anticonvulsant effects. The action of estrogens depends on various factors, such as the dose, treatment duration, latency prior to the seizure testing, hormonal status, the region/neurotransmitter system involved, the seizure type/model, and sex of subjects. Estradiol at physiological concentrations decreases the threshold, increases seizure activity, may trigger status epilepticus, and accelerates kindled seizures in female animals. However, the opposite (anticonvulsant) effects are observed after chronic treatment with estrogen. It has been hypothesized that estrogens may confer anticonvulsant and neuroprotective effects by enhancing formation of progesterone and allopregnanolone. According to another hypothesis, estrogens can be proconvulsant in adult animals, but ineffective in immature animals. It is interesting that in ovariectomized female rats, both estradiol and progesterone prolong seizure duration. In gonadectomized male rats, estrogen may have either

proconvulsant or anticonvulsant effects, depending on the dose of the chemoconvulsant used to induce seizures. Generally, hormonal changes during puberty, menopause, or hormonal contraception do not influence seizure frequency. However, estrogen may trigger catamenial seizures and contribute to pregnancy-related changes in seizures. Mid-cycle exacerbation of seizure activity is usually attributed to the preovulatory surge of estrogen that is unaccompanied by a significant rise in progesterone.

Progesterone is transformed by 5α-reductase to the neurosteroid, allopregnanolone, a potent positive modulator of $GABA_A$ receptors. Moreover, the hormone may potentiate the effect of endogenous anticonvulsant adenosine. In vitro studies have shown that the action of progesterone may depend on brain region; the hormone inhibits the development of epileptiform activity in the enthorinal cortex, but accelerated it in the CA1 hippocampal region.

In animal models, progesterone at physiologically relevant concentrations inhibits seizure susceptibility in various models of epilepsy, including focal cortical spikes, kindled and audiogenic seizures, as well as convulsions induced by kainic acid and pentylenetetrazole. Progesterone increases the threshold and reduces the magnitude of seizure activity in female, male, and gonadectomized animals. Withdrawal from chronic therapy with progesterone has proconvulsant effects. The hormone can also slow both amygdala and hippocampal seizure development, thus demonstrating antiepileptogenic activity.

In women, progesterone concentrations are significantly lower in patients with catamenial epilepsy. Premenstrual exacerbation of seizures is often attributed to withdrawal of the antiseizure effects of progesterone. In fact, progesterone administration can suppress epileptiform spikes in epileptic patients. In contrast to generalized seizures, progesterone exacerbates absence seizures in humans.

Androgens

Effects of testosterone on seizures depend on the metabolic route in which this androgen is involved. Testosterone is metabolized by 3α-reductase to 3α-androstanediol, a positive modulator of $GABA_A$ receptors. Aromatase is the enzyme for the conversion of testosterone to 17β-estradiol, a hormone with proconvulsant properties mediated via glutamate NMDA receptors. In animals, the proconvulsant action of both acute and chronic treatment with testosterone has been shown in the pentylenetetrazole-induced and electrically-kindled seizures models. It is interesting that this effect may be accompanied by increased plasma concentrations of 17β-estradiol. Also, androstanediol and dihydrotestosterone have proved to exhibit anticonvulsant and neuroprotective activity in chemically-induced convulsions in rodents. It worth mentioning that gonadectomy increases susceptibility of male rats to generalized tonic–clonic convulsions.

In humans, testosterone administration reduces seizures in the course of posttraumatic epilepsy. Furthermore, male epileptic patients usually have higher levels of dihydrotestosterone than do men without seizure disorders.

Methods

In our laboratory, we have studied the influence of steroid hormones on the basic experimental models of epilepsy: maximal electroshock- and pentylenetetrazole-induced convulsions in mice, as well as amygdala-kindled seizures in rats. The three models are required screening tests for potential anticonvulsant drugs. Maximal electroshock reflects generalized tonic–clonic seizures, pentylenetetrazole-evoked convulsions are an equivalent of myoclonic epilepsy, while amygdala-kindled seizures resemble complex partial seizures in humans.

Electroconvulsions are produced by an alternating current (50 Hz, 0.2 s, fixed current intensity of 25 mA, and maximum stimulation voltage of 500 V) delivered via ear-clip electrodes. Tonic hindlimb extension (the hind limbs of animals outstretched 180° to the plain of the body axis) is taken as the endpoint. Results are expressed as CS_{50} values for the hormones tested, where CS_{50} is current strength (in mA) necessary to induce tonic convulsions in 50% of animals.

In the pentylenetetrazole-induced convulsions model, the chemoconvulsant is injected at its CD_{50} dose, defined as a dose producing clonic convulsions in 50% of tested animals. Subsequently, the influence of steroid hormones on the CD_{50} value of pentylenetetrazole is determined and interpreted as an effect on the seizure threshold.

Kindled seizures are evoked electrically from basolateral amygdala. Each stimulus consists of a 1-s train of 50 Hz, 1 ms biphasic square-wave pulses, with pulse amplitude of 500 μA, delivered every 24 h. Stimuli are delivered until at least 10 sequential fully kindled seizures are generated. At that point, four parameters are measured: (1) the seizure threshold, (2) seizure severity, assessed according to a modified Racine's system, (3) duration of limbic seizures (stage 1–2) and motor seizures (stage 3–5), and (4) EEG afterdischarge duration defined as spikes with a frequency of at least 1 Hz and amplitude at least twice greater than the prestimulation baseline. The after-discharges from the amygdala are recorded prior to and after the stimulation. After-discharge threshold (ADT) is determined after administration of a test drug (or vehicle control) by administering a series of stimulations at intervals of 3 min, increasing stimulus amplitude in steps of about 20% over the previously applied current until an after-discharge (duration of at least 3 s) is evoked. At this ADT current, seizure severity, seizure duration, and after-discharge duration are

recorded and the data analyzed. Control readings are made 2 days before and 2 days after respective treatments.

Results

Steroid hormones administered intraperitoneally, but only at supratherapeutic doses, affect seizures in all three animal models of epilepsy. The revealed relationship is markedly dose-dependent. Testosterone (5–7.5 mg kg^{-1}) and progesterone (4.5–6 mg kg^{-1}) significantly increase the electroconvulsive and pentylenetetrazole threshold in mice. In contrast, estradiol (1.125–3.375 mg kg^{-1}) decreases the threshold of pentylenetetrazole-induced convulsions, but does not influence the electroconvulsive threshold. In amygdala-kindled rats, estradiol (3.375–4.5 mg kg^{-1}) decreases the ADT and prolongs the seizure duration. Seizure duration is shortened by progesterone and testosterone, but prolonged by estradiol. Progesterone (6–12 mg kg^{-1}) significantly decreases seizure severity and shortens the seizure and after-discharge durations. However, testosterone (5–10 mg kg^{-1}) does not affect any seizure parameter in this model. Cortisol (hydrocortisone; 25–50 mg kg^{-1}) decreases the threshold in pentylenetetrazole- and maximal electroshock-induced convulsions, but is ineffective in the amygdala-kindled seizures model. Finally, aldosterone (1–10 mg kg^{-1}) does not seem to affect seizures in animal models used in our studies.

These results support the hypothesis that among all steroid hormones, the gonadal hormones exert the most powerful influence on seizure phenomena. Estrogens are generally proconvulsant, while progestins and androgens present anticonvulsant activity.

Future Goals

A major challenge for this area of research is to determine accurate hormonal influences – i.e., at physiological, therapeutic, and supratherapeutic plasma concentrations – on seizure generation and propagation in primates, including humans. Exceptionally important in such an analysis is a focus on the synthesis of hormone derivatives that preserve, or even exceed, the anticonvulsant activity of their precursors. Ideally, such derivatives would not exhibit hormonal actions, the most frequently undesirable side-effects in hormonal treatments of epilepsy. To date, only few synthetic inhibitory neurosteroids meet these criteria – for instance, ganaxolon, which is presently in phase III clinical trials.

Introduction

Gonadal steroid hormones have profound effects on the growth and differentiation of the central nervous system. Male-typical steroids, androgens, which are secreted from the testes into the circulatory system, have long been understood to maintain reproductive behavior. Emerging evidence indicates that androgens also exert trophic effects on the brain, which may influence the processing, storage, and retrieval of information, and may underlie the positive effects of androgens on cognitive performance and/or mood state. Changes in androgens may also influence the incidence and/or expression of certain types of neurodegenerative disorders, such as Alzheimer's disease, which are characterized by reduction in androgen levels. Seizure disorder is the most common neurological condition among children, and for adults only Alzheimer's disease and stroke are more prevalent. As such, the role of androgens in epilepsy is of great interest.

Research from our laboratory focuses on the effects and mechanisms by which steroids mediate variations in social, cognitive, and affective behavior in both normative and pathophysiological conditions. To examine neuroprotective effects and mechanisms of androgens, we have primarily used animal models of seizure disorders. Our findings to date suggest that androgens have robust antiseizure effects in a number of different animal models using chemoconvulsants. Seizures and/or antiepileptic drugs (AEDs) can also alter sexual, cognitive, or anxiety behaviors, as well as bioavailability of androgens. As such, whether androgen deficiencies in epilepsy contribute to, or are a consequence of, some seizure disorders and/or its treatments is of great interest.

One of the challenges to understanding androgens is the broad spectrum of activity they influence. Although a comprehensive discussion of androgens' mechanisms is beyond the scope of this article, it is generally accepted that androgens exert their effects through 'genomic' actions at intracellular androgen receptors (ARs) to modulate gene expression. Testosterone, the principal androgen, and its metabolite 5-dihydrotestosterone (DHT) produce some of their effects through binding to intracellular ARs, members of the nuclear receptor superfamily. ARs, and other nuclear steroid receptors, act as ligand-inducible transcription factors to modulate target genes. These actions via ARs involve protein synthesis and take hours or days to occur. However, there are also rapid effects of androgens, which occur too quickly to be explained by the classical AR mechanisms. These rapid androgen effects occur within seconds to minutes, significantly faster than androgen-enhanced protein synthesis. These 'nongenomic' effects of androgens can occur when androgens act at cell membranes or in systems lacking ARs. Further, they are not abolished by inhibition of transcription or translation. Nongenomic actions of hormones are now generally accepted to contribute to the physiological effects of steroids. Given that rapid actions of androgens may ultimately have downstream effects to modulate transcriptional activity of ARs or other factors, the term 'nonclassical,' rather than nongenomic, has been used more recently to describe these effects. This review summarizes some of the effects and mechanisms by which androgens, seizures, and AEDs influence reproductive, cognitive, or affective behaviors.

Background

Androgens and Reproductive Function

Testosterone, the primary androgen secreted by the testes, probably mediates male sexual development, maturation, and maintenance of male reproductive organs through both genomic and nonclassical actions. One well-investigated, androgen-mediated reproductive function is for testosterone to regulate spermatogenesis through its actions on Sertoli cells in seminiferous tubules. Using an organotypic approach to investigate testosterones effects on Sertoli cells, investigators have revealed novel actions of testosterone. Application of free testosterone or testosterone conjugated to bovine serum albumin (T-BSA), which does not permeate cell membranes, produces rapid and prolonged increases in intracellular Ca^{2+} inhibitors, indicating a plasma membrane action of testosterone. Testosterones membrane effects on Sertoli cells may involve rapid activation of Gq protein-mediated phospholipase C signaling to inhibit ATP-sensitive K^+ current to produce membrane depolarization, which in turn activates L-type Ca^{2+} channels and thereby Ca^{2+} influx. These increases in Ca^{2+} may influence cytoskeleton and/or cell–cell junctions to regulate metamorphosis, gene transcription, and/or secretions in Sertoli cells. In addition to these nonclassic actions of testosterone, AR-mediated actions of testosterone may also be involved in this system. For example, testosterone rapidly regulates transcription factors, such as cAMP response element binding protein (CREB), via mitogen-activated

protein kinase (MAPK) and ERK1/2 signaling pathways in Sertoli cells. However, the rapid effects of testosterone to induce ERK and CREB phosphorylation are not seen in testicular feminized (tfm) rats, which lack functional ARs. Furthermore, these effects are blocked by AR antagonists or interference RNAs. These insights from this system clearly demonstrate that nonclassical actions of testosterone on Sertoli cells may also involve ARs; whether these mechanisms are relevant for the etiology or the therapeutic treatment of androgen-relevant dysfunctions is of interest.

The neural control of reproductive behavior in laboratory rodents involves both genomic and nonclassical actions of androgens in an area of the hypothalamus referred to as the medial preoptic area (MPOA). Stimulation of the MPOA can elicit sexual behavior, and ablation can abolish reproductive behavior. There are many ARs in the MPOA. Castration inhibits male sexual behavior, but application of testosterone or T-BSA to the MPOA is sufficient to reinstate reproductive responses. Also, application of testosterone to brain regions such as the central tegmental field or medial amygdala (that project to the MPOA) can reinstate androgen-mediated sexual behavior. The precise downstream substrates through which androgens mediate reproductive behavior remain to be elucidated, but likely targets to be investigated are those identified above for peripheral actions of androgens.

Androgens and the Hippocampus

Androgens can also have profound effects on nonreproductive behaviors that are mediated in part through nonclassic actions in the hippocampus. The hippocampus is an important site of androgen action. Tritiated testosterone is taken up in the hippocampus of rats. Excitability of hippocampal tissue of male mice is altered following castration and in vivo or in vitro androgen administration restores it to levels of intact males. Similarly, castration of rats or vervet monkeys reduces the density of synaptic contacts on dendritic spines of CA1 pyramidal neurons. Administration of androgens that are potent modulators of ARs, such as testosterone or the nonaromatizable androgen DHT, and androgens that are only weakly active at ARs similarly reverse the effect of castration. These effects of androgens are not blocked by coadministration of an AR antagonist. The androgen-stimulated increase of hippocampal spine synapse density does not require ARs. Interestingly, the effects of androgens to enhance cognitive function and mood state, processes that are mediated in part by the hippocampus, also do not seem to require actions through ARs. Thus, it has been proposed that androgens' mnemonic and/or antianxiety effects may result, at least in part, from androgens' hippocampal neurotrophic responses.

Actions of androgens on the hippocampus are of particular interest because maintenance of androgen levels in this region may minimize the risks of neurodegeneration. Patients with Alzheimer's disease, characterized by damage in the hippocampus, have demonstrated a reduction in circulating concentrations of androgens in comparison to normal controls. Androgens also have protective effects in other models of neurodegeneration. Androgen administration reduces cell death in the granule cell layer of the hippocampus of male rats following adrenalectomy. Notably, the decrease in cell death following androgen administration is associated with functional effects as well. Androgen-administered rats that had less cell death in the hippocampus performed better in a hippocampally mediated memory task than did their vehicle-administered counterparts with more cell death. Thus, the hippocampus, a brain area involved frequently in partial and predominantly in generalized seizures, may be an important target of androgens' antiseizure actions.

Androgens and Seizures

Evidence from clinical and basic research studies also suggests that androgens can have antiseizure effects. In support of this view, alcohol withdrawal-induced seizures are less likely in men who have higher endogenous levels of testosterone. Androgens also reduce trauma-induced or epileptic seizures among men. In animal models, male (compared with female) rodents are less susceptible to allylglycine-, flumazenil-, or picrotoxin-induced seizures. There are developmental changes in seizure susceptibility which are related to androgen secretion. Intact, adult male rats, with high endogenous androgen levels, have fewer seizures than do either intact juvenile (30 days old) or middle-aged (13 months old) male rats, both of which have lower endogenous androgen levels. In adult rats, castration increases ictal activity and abrogates sex differences in seizure susceptibility, but androgen administration ameliorates the enhanced sensitivity to chemoconvulsants caused by castration.

AR-Mediated Antiseizure Effects

Temporal lobe epilepsy, one of the most prevalent classes of epilepsy, also involves the hippocampus. Actions of androgens in this region are antiepileptic. Administration of androgens directly to the hippocampus of castrated rats reduces pentylenetetrazol (PTZ)-induced seizures. The antiseizure effects of androgens delivered directly into the hippocampus are similar to the effects of systemic testosterone administration (**Figure 1**, top).

Notably, blocking androgen's actions in this region by administering flutamide, an AR antagonist, has proconvulsant effects; this effect can be produced with androgen injection either systemically or directly to the hippocampus of gonadally-intact male rats (**Figure 1**, bottom). Lifelong deletion of ARs, as occurs among tfm mice, is also

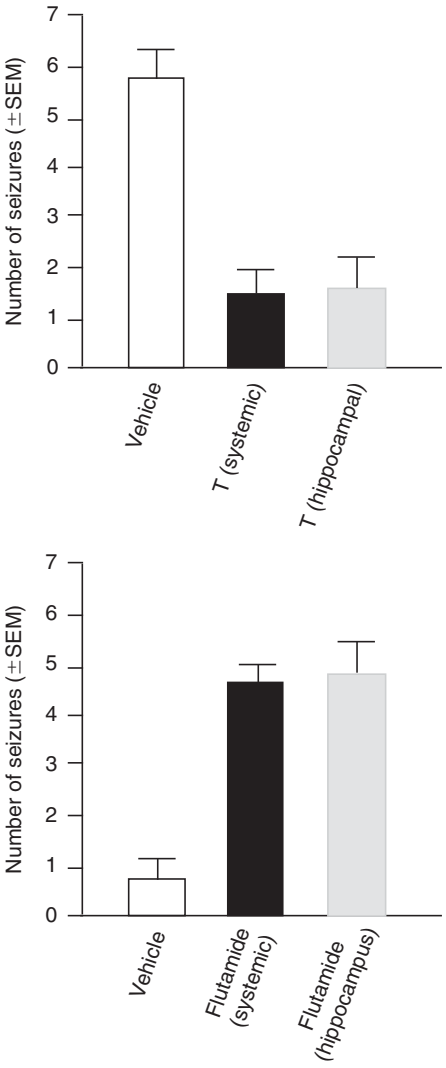

Figure 1 Top panel represents average (±SEM) seizure incidence of gonadectomized rats administered vehicle (white bar), systemic testosterone (black bar), or intrahippocampal testosterone (gray bar). Bottom panel represents average (±SEM) seizure incidence of intact rats administered vehicle (white bar), systemic flutamide (black bar), or intrahippocampal flutamide (gray bar).

deleterious. Tfm mice do not demonstrate the antiseizure effects of androgens that are produced in their wildtype counterparts when androgen is administered (**Figure 2**).

Thus, some antiseizure effects of androgens may occur through actions at ARs.

AR-Independent Antiseizure Effects

In addition to AR-mediated antiseizure effects, nonclassical actions of androgens may also underlie some anticonvulsant effects of androgens. Indeed, a large body of research suggests that some of testosterones antiseizure effects may be due, in part, to its metabolism to DHT, and

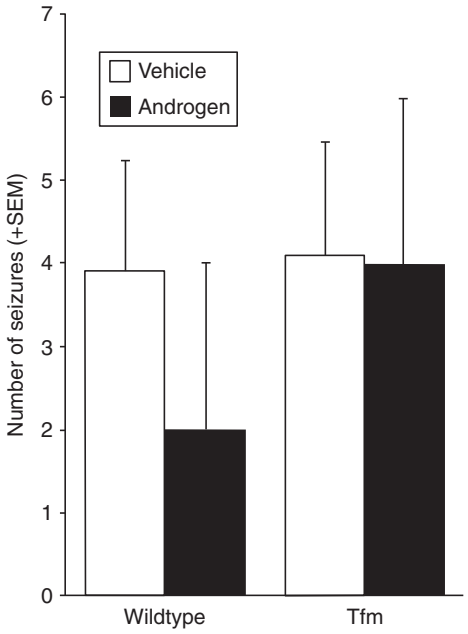

Figure 2 Average (±SEM) seizure incidence of gonadectomized wildtype (left) or tfm (right) mice administered vehicle (white bars) or systemic testosterone (black bars).

its subsequent conversion to 3α-androstanediol (3α-diol) by 3α-hydroxysteroid dehydrogenase. In support, testosterone, DHT, and 3α-diol all similarly reduce seizures in male rodents. Blocking formation of 3α-diol from DHT or testosterone, either systemically or in the hippocampus, attenuates antiseizure effects (**Figure 3**, top).

Administration of testosterone to mice that are genetically unable to metabolize testosterone to 3α-diol is not effective at reducing seizures. Further, concentrations of 3α-diol, but not testosterone, are reduced among aged male rats that have more seizures compared to their younger counterparts. These data, together with those presented earlier, suggest that androgens have antiseizure effects and that these effects are due, at least in part, to actions of testosterones metabolite, 3α-diol.

Testosterones and its metabolites, DHT and 3α-diol, may have multiple mechanisms in the hippocampus for antiseizure effects. Notably, testosterone and DHT bind with a very high affinity for ARs; however, at physiological concentrations, 3α-diol does not bind ARs. Instead, 3α-diol typically has its actions through membrane ionotropic neurotransmitter receptors, such as $GABA_A$ and *N*-methyl-D-aspartate (NMDA) receptors. Both $GABA_A$ and NMDA receptors occur at high levels in the hippocampus. Blocking $GABA_A$ receptors in the hippocampus attenuates antiseizure effects of 3α-diol (**Figure 3**, bottom). Blocking NMDA receptors also inhibits the anticonvulsant effects of androgens. Thus, antiseizure effects of testosterone metabolites, such as 3α-diol, may involve nonclassical actions of androgens in the hippocampus.

Bottom panel represents average (±SEM) seizure incidence of intact rats administered vehicle (white bar) or bicuculline (black bar).

Epilepsy and Reproductive Function

People with seizure disorders, particularly those with temporal lobe epilepsy, have an increased likelihood of reproductive dysfunction relative to the general population. Sexual dysfunctions, such as reduced potency or fertility, erectile dysfunction, hyposexuality, impotency, and reduced libido, are more prevalent among men with epilepsy. These effects may be due in some cases to hypogonadotropic hypogonadism, which is associated with reductions in the secretion of gonadal hormones because of dampened feedback from the hypothalamus and/or pituitary. However, neuroendocrine dysfunction could occur at multiple levels of the hypothalamic–pituitary gonadal axis.

Some AEDs may influence the neuroendocrine system and thereby alter the production, secretion, and bioavailability of steroid hormones. Some AEDs, such as phenytoin, carbamazapine, and barbiturates, can induce cyctochrome P450 enzymes; this action can enhance production of sex hormone-binding globulin and increase the metabolism of androgens, thereby reducing bioavailable androgens. In contrast, valproate inhibits steroid hormone metabolism, and can thereby increase androgen levels (due to reduced hepatic metabolism) and produce associated sexual dysfunction. Comparison of newer and classical AEDs, with respect to their effects on sexual function, suggests promising advantages of the newer generation of drugs. Gabapentin is associated with reversible sexual dysfunction. Men with epilepsy using lamotrigine had sexual function and androgen levels that were comparable to those of untreated males and control men without epilepsy.

Methods

The majority of the earlier data from our laboratory was collected using the PTZ model of generalized seizures. The seizure progression produced with our PTZ regimen ($70\,mg\,kg^{-1}$ for rats, $85\,mg\,kg^{-1}$ for mice) is consistent, and reliably observed and quantified, using a modification of the scale devised by Racine (mouth and facial movements, head nodding, forelimb clonus, rearing, and rearing and falling). Further, we observe similar effects of androgens on each stage of seizure progression (myoclonus, tonic clonic seizures, and survival). As evidenced by the studies described earlier, this PTZ protocol allowed us to characterize androgens' effects and mechanisms with respect to seizures. To address the acute effects of seizures on androgen-mediated behavior, the chronic effects of epilepsy on these behaviors, and the use of AEDs on androgen-mediated behavior, we have recently employed a chronic pilocarpine model of temporal lobe epilepsy. Brain damage associated with pilocarpine-induced status epilepticus involves the hippocampus and amygdala, areas that are typically damaged in patients with temporal lobe epilepsy. As discussed earlier, there is some evidence that seizures can alter cognitive, affective, reproductive, and neuroendocrine processes. Hence, we have begun to extend our prior studies by using this model to examine effects of chronic seizures on these endpoints. In this pilocarpine model, rats are administered pilocarpine ($60\,mg\,kg^{-1}$, i.p.) on postnatal day 10 and observed for the occurrence of status epilepticus. Rats are then allowed to grow-up and are tested for affective behavior and reproductive function. After completing these behavioral tests, rats are readministered pilocarpine ($100\,mg\,kg^{-1}$) and scored for seizure severity. In the subsequent weeks, differences in androgen-dependent behaviors and hormones levels are examined.

Table 1 Reproductive, cognitive, and affective behaviors and 3α-diol levels of control rats and rats exposed to pilocarpine-induced seizures perinatally, in adulthood, or both

	Control	*Perinatal seizures*	*Adult seizures*	*Both*
Number of sexual contacts	15 ± 1	9 ± 1	12 ± 1	7 ± 1
Latency to cross-over	298 ± 15	222 ± 33	252 ± 21	214 ± 34
Central square entries	28 ± 8	15 ± 3	10 ± 2	6 ± 2
Hypothalamic 3α-diol (ng g^{-1})	3.9 ± 0.1	2.6 ± 0.2	3.1 ± 0.3	2.3 ± 0.2
Hippocampal 3α-diol (ng g^{-1})	4.0 ± 0.2	2.1 ± 0.4	2.5 ± 0.4	2.3 ± 0.2

Recent Results

Hypothalamic- and hippocampally mediated androgen-dependent behaviors are altered by pilocarpine when administered perinatally or in adulthood. Pilocarpine-induced seizures produce deficits in reproductive, cognitive, and affective function. Rats that experienced pilocarpine-induced seizures, either early in development or during adulthood, engaged in significantly fewer sexual contacts than did rats that did not have seizures (Table 1). Rats exposed to pilocarpine, either perinatally or in adulthood or at both times, had shorter latencies to shock-avoidance (indicating poorer cognitive performance) and entered fewer central squares in the open field (more anxiety behavior) than did rats that were never exposed to pilocarpine (Table 1). Levels of 3α-diol, but neither testosterone nor DHT, in the hypothalamus and hippocampus, were reduced among pilocarpine-treated rats compared to controls (Table 1). These data suggest that pilocarpine-induced seizures can produce decrements in androgen-mediated social, cognitive, and affective behavior that may be due, in part, to reductions in 3α-diol in the hypothalamus and hippocampus.

We have begun to investigate effects of different classes of AEDs on reproductive, cognitive, affective behaviors, as well as androgen levels of male rats. Adult intact male rats were administered valproate (325 mg kg^{-1}, i.p., b.i.d.) (a nonenzyme-inducing AED), phenytoin (50 mg kg^{-1}, i.p., b.i.d.) (an enzyme-inducing AED), or vehicle (saline, b.i.d.) for 30 days. On the last day of drug administration, rats were tested for sexual behavior (with a stimulus female), anxiety (open field), or cognitive behavior (object recognition), and observed for ictal activity. Phenytoin administration, compared to vehicle or valproate, significantly decreased the incidence of sexual contacts, reduced the amount of time investigating a novel object, and decreased central entries in the open field (Table 2). Concomitant with these behavioral changes, phenytoin-administered rats had significantly-decreased levels of 3α-diol (but not estradiol or testosterone levels), in the hippocampus and hypothalamus. We next examined whether coadministration of 3α-diol could attenuate these effects of phenytoin. Rats with silastic implants of 3α-diol or vehicle were administered phenytoin or vehicle for 30 days and then tested as above. Rats that had empty silastic implants in conjunction with phenytoin showed deficits in sexual, cognitive, and affective behavior,

Table 2 Reproductive, cognitive, and affective behaviors and 3α-diol levels of rats administered vehicle, valproate, and phenytoin

	Vehicle	*Valproate*	*Phenytoin*
Number of sexual contacts	24 ± 6	27 ± 9	11 ± 11
Time with novel object	71 ± 11	69 ± 9	49 ± 6
Central entries	38 ± 6	37 ± 7	23 ± 9
Number of seizures	11 ± 1	5 ± 2	4 ± 1
Hypothalamic 3α-diol (ng g^{-1})	3.9 ± 0.6	4.0 ± 0.9	1.8 ± 0.7
Hippocampal 3α-diol (ng g^{-1})	2.8 ± 1.1	3.1 ± 1.3	0.9 ± 0.8

and lower 3α-diol concentrations in the hippocampus and hypothalamus, as described earlier. These effects were abolished in the rats that were administered phenytoin but had silastic implants of 3α-diol (Table 3). Together, these data suggest that enzyme-inducing AEDs can have negative effects on reproductive, cognitive, and affective processes, and that these effects may be due in part to 3α-diol.

Summary and Future Goals

Research described and discussed here supports a relationship between androgens, androgen-mediated behaviors, and ictal activity. First, testosterone and 3α-diol reduce seizures, in part through actions at ARs and $GABA_A$ receptors in the hippocampus, respectively. Second, ictal activity has reciprocal effects on androgen levels in the brain. Seizures, either early in development or in adulthood or at both time points, reduce 3α-diol levels in the hypothalamus and hippocampus and produce decrements in sexual, cognitive, and affective behaviors. Third, enzyme-inducing AEDs decrease 3α-diol levels in the hippocampus and hypothalamus concomitant with deficits in reproductive, cognitive, and affective processes; these decrements are ameliorated by 3α-diol administration. Together, these data suggest a unique relationship between ictal activity and androgens (Figure 4). Further investigation of this relationship is necessary to capitalize on the putative therapeutic effects of androgens while reducing negative side effects of seizures and AEDs.

Table 3 Reproductive, cognitive, and affective behaviors and 3α-diol levels of rats administered vehicle or phenytoin with or without 3α-diol silastic implants

	Vehicle		*Phenytoin*

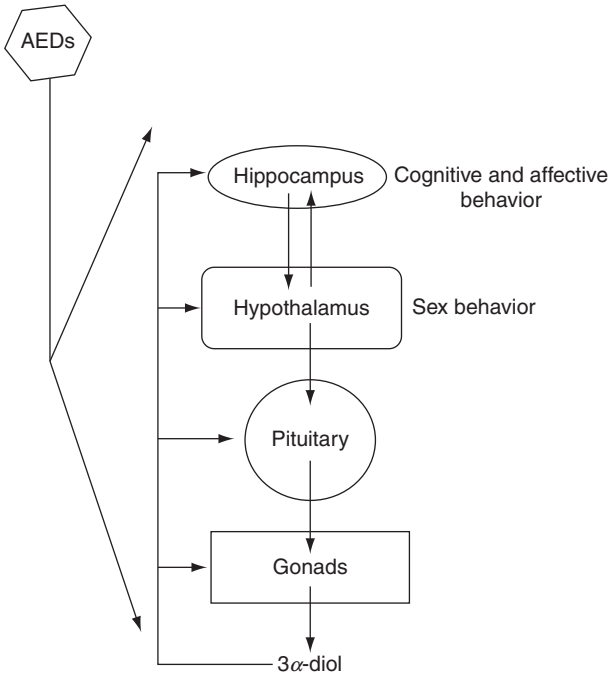

Figure 4 Schematic representation of putative effects of antiepileptic drugs on neuroendocrine and behavioral processes.

There are two major goals for future research in this area. First, it is critical to further identify membrane targets through which androgens may exert nonclassical effects to decrease seizures. Although testosterone can bind to plasma membrane in different models, a specific membrane protein through which testosterone has nonclassical actions has not yet been identified. There are, however, several possibilities. Testosterone bound to sex hormone binding globulin (SHBG) can act through a G-protein coupled SHBG receptor that has yet to be cloned. Testosterone may also bind a membrane-associated classical AR, which may anchor to caveolae or lipid rafts that are enriched with signaling proteins. Alternatively, a membrane AR distinct from the classic AR may exist; however, a specific membrane protein through which testosterone has nonclassical actions has not yet been cloned. Despite the lack of identification of discrete target sites to date, there is evidence that dynamic minute-to-minute changes in local androgen concentrations in various brain areas may explain some of the rapid physiological responses via membrane associated receptors in target cells. Second, the relationship between androgens, ictal activity, and AEDs needs to be better understood. Reductions in androgen levels of men with epilepsy, on some AED therapies, are associated with decreased sexual functioning and may also alter other androgen-dependent behaviors. Our initial data are intriguing and suggest androgens, ictal activity, and AED therapies interact with, and influence, one another. Given the challenge of addressing the relative contributions of each of these factors in a clinical population, we will continue to develop this line of research using animal models. It is vital to understand each of the putative mechanisms through which androgens may have their effects, and the relationship between androgens, seizures, and AEDs, in order to enhance the therapeutic options for those with seizure disorders.

Neurosteroid Modulation of $GABA_A$ Receptor-Mediated Synaptic Transmission in an Animal Model of Temporal Lobe Epilepsy

K Rajasekaran, Z Mtchedlishvili, C Sun, and J Kapur, University of Virginia Health Sciences Center, Charlottesville, VA, USA

Introduction and Background

Temporal lobe epilepsy (TLE) is a common form of epilepsy in adults; in many patients, it is medically refractory. Patients with TLE have a characteristic neuropathology, which most significantly affects the hippocampus. Removal of the hippocampus and amygdala leads to the remission of seizures in over 70% of patients. Women with temporal lobe epilepsy frequently suffer from seizure exacerbations during menstruation – a condition often referred to as catamenial epilepsy. In 1957, Sir Charles Locock provided the first documented evidence for seizures in the 'catamenial period' (Gk. *kata*, by; *men*, month), suggesting a hormonal modulation of seizures. Subsequent studies have demonstrated that steroid hormones are precursors to the generation of neuroactive steroids that critically modulate seizure activity. The term *neurosteroids* refers to a group of compounds synthesized in the brain (largely by glia) from circulating steroid hormones and de novo from cholesterol, which exert their actions in the CNS via actions on neurotransmitter receptors.

Studies over the past few decades have identified that the $GABA_A$ receptor-mediated inhibitory system is a critical target for neurosteroids. Physiological concentrations of neurosteroids are known to modulate $GABA_A$ receptors and inhibitory neurotransmission, and reduction in endogenous neurosteroid levels is associated with increased seizure frequency.

Hippocampal seizures consist of synchronized tonic–clonic bursts of action potentials riding on a prolonged wave of depolarization in a network of neurons. Within the normal hippocampus, pyramidal CA1 and CA3 neurons can generate bursts, but the dentate gyrus resists their spread into other regions. Thus, the dentate gyrus has been proposed to act as a 'gate' that filters the flow of information from the entorhinal cortex to the hippocampus proper. A breakdown of this gating function of the dentate gyrus is considered crucial for the occurrence of seizures. Many investigators have proposed – and tested – the hypothesis that this breakdown of the filtering function of the dentate gyrus is due to reduced $GABA_A$ receptor-mediated inhibition. Both pre- and postsynaptic mechanisms of plasticity have been proposed. The presynaptic changes include (1) loss of GABAergic interneurons, which would lead to decreased frequency of inhibitory postsynaptic currents received by DGCs, (2) increased recurrent connectivity among granule cells due to mossy fiber sprouting, and increased neurogenesis and aberrant connectivity of newly born neurons.

Changes in the postsynaptic properties of the $GABA_A$ receptors may also contribute to the breakdown of the gating function of the DGCs. The plasticity of $GABA_A$ receptors on DGCs of epileptic animals was first reported in the kindling model, and subsequently confirmed using the lithium/pilocarpine model of TLE. In the DGCs from epileptic animals, there was a diminished expression of the $\alpha 1$ and δ subunit of the $GABA_A$ receptor, together with an increase in the expression of $\alpha 4$ subunit mRNA and protein. These electrophysiological, mRNA, and protein expression studies demonstrated clearly that $GABA_A$ receptors on DGCs were altered in animal models of epilepsy.

The neurosteroid sensitivity of $GABA_A$ receptors depends in large part on their subunit composition. It has been suggested that while the δ subunit confers neurosteroid sensitivity, an increase in the expression of one of its partnering subunits, the $\alpha 4$ subunit, diminishes

Introduction and Background

Temporal lobe epilepsy (TLE) is a common form of epilepsy in adults; in many patients, it is medically refractory. Patients with TLE have a characteristic neuropathology, which most significantly affects the hippocampus. Removal of the hippocampus and amygdala leads to the remission of seizures in over 70% of patients. Women with temporal lobe epilepsy frequently suffer from seizure exacerbations during menstruation – a condition often referred to as catamenial epilepsy. In 1957, Sir Charles Locock provided the first documented evidence for seizures in the 'catamenial period' (Gk. *kata*, by; *men*, month), suggesting a hormonal modulation of seizures. Subsequent studies have demonstrated that steroid hormones are precursors to the generation of neuroactive steroids that critically modulate seizure activity. The term *neurosteroids* refers to a group of compounds synthesized in the brain (largely by glia) from circulating steroid hormones and de novo from cholesterol, which exert their actions in the CNS via actions on neurotransmitter receptors.

Studies over the past few decades have identified that the $GABA_A$ receptor-mediated inhibitory system is a critical target for neurosteroids. Physiological concentrations of neurosteroids are known to modulate $GABA_A$ receptors and inhibitory neurotransmission, and reduction in endogenous neurosteroid levels is associated with increased seizure frequency.

Hippocampal seizures consist of synchronized tonic–clonic bursts of action potentials riding on a prolonged wave of depolarization in a network of neurons. Within the normal hippocampus, pyramidal CA1 and CA3 neurons can generate bursts, but the dentate gyrus resists their spread into other regions. Thus, the dentate gyrus has been proposed to act as a 'gate' that filters the flow of information from the entorhinal cortex to the hippocampus proper. A breakdown of this gating function of the dentate gyrus is considered crucial for the occurrence of seizures. Many investigators have proposed – and tested – the hypothesis that this breakdown of the filtering function of the dentate gyrus is due to reduced $GABA_A$ receptor-mediated inhibition. Both pre- and postsynaptic mechanisms of plasticity have been proposed. The presynaptic changes include (1) loss of GABAergic interneurons, which would lead to decreased frequency of inhibitory postsynaptic currents received by DGCs, (2) increased recurrent connectivity among granule cells due to mossy fiber sprouting, and increased neurogenesis and aberrant connectivity of newly born neurons.

Changes in the postsynaptic properties of the $GABA_A$ receptors may also contribute to the breakdown of the gating function of the DGCs. The plasticity of $GABA_A$ receptors on DGCs of epileptic animals was first reported in the kindling model, and subsequently confirmed using the lithium/pilocarpine model of TLE. In the DGCs from epileptic animals, there was a diminished expression of the $\alpha 1$ and δ subunit of the $GABA_A$ receptor, together with an increase in the expression of $\alpha 4$ subunit mRNA and protein. These electrophysiological, mRNA, and protein expression studies demonstrated clearly that $GABA_A$ receptors on DGCs were altered in animal models of epilepsy.

The neurosteroid sensitivity of $GABA_A$ receptors depends in large part on their subunit composition. It has been suggested that while the δ subunit confers neurosteroid sensitivity, an increase in the expression of one of its partnering subunits, the $\alpha 4$ subunit, diminishes

neurosteroid sensitivity of $GABA_A$ receptors. In our studies, we tested whether mechanisms mediating neurosteroid sensitivity of synaptic $GABA_A$ receptors on DGCs are altered in a rat model of temporal lobe epilepsy.

Methods

Our experiments were performed on DGCs from animals made epileptic using the continuous hippocampal stimulation protocol. Briefly, rats were anesthetized with ketamine ($50\,mg\,kg^{-1}$) and xylazine ($40\,mg\,kg^{-1}$) and implanted with a pair of bipolar stimulating electrodes in the left posterior ventral hippocampus (AP 3.6, ML 4.0, DV 5.0 from the dura, incisor bar at +5.0). After 1 week of recovery, the left hippocampus was stimulated with 10-sec trains of 50 Hz, 1 ms, 400-mA biphasic square wave current pulses, delivered every 13 s for 90 min, to induce status epilepticus (SE). Approximately 4–6 weeks after the stimulation, the rats developed spontaneous limbic seizures with the typical tonic–clonic motor component. The seizures were documented either by continuous EEG recording or by direct observation of the spontaneous seizures. For all experiments, age-matched control animals were used.

Whole-cell patch clamp recordings of $GABA_A$ receptor-mediated currents were performed on acutely isolated DGCs. Rats were decapitated under halothane anesthesia, and the brains were dissected free and chilled to 4 °C for 1 min in a piperazine-*N*,*N*′-bis(2-ethanesulphonic acid) (Pipes) buffer solution composed of (mM): NaCl 120, KCl 5, $CaCl_2$ 1.5, $MgCl_2$ 1, D-glucose 25, Pipes 20 (pH 7.0) (all chemicals from Sigma, St. Louis, MO, USA, unless noted otherwise). The region containing the hippocampus was blocked. The brain was blot-dried, mounted on a vibratome (Camden Instruments, UK) stage with the caudal part facing up, and 400–500 µm coronal slices containing hippocampus were cut. The slices were allowed to recover for at least 1 h in Pipes solution before being transferred to an enzyme solution. The slices were incubated in continuously oxygenated Pipes solution, containing $3\,mg\,ml^{-1}$ type XXIII protease enzyme from *Aspergillus oryzae*, at 32 °C for 45 min. The enzyme incubation was terminated by transferring the slice into enzyme-free Pipes solution; after a minimum of 30 min of recovery, DGCs were isolated from caudal parts of both left and right ventral hippocampi. The dentate gyrus was dissected from the rest of the slice under a microscope and cut into $0.5\text{-}mm^3$ chunks. These chunks were triturated through 0.5- and 0.3-mm diameter fire-polished glass pipettes, and the isolated neurons were plated on 35-mm plastic Petri dishes. DGCs were identified by their typical oval shape and single process.

Horizontal hippocampal sections of 300-µm thickness were used for patch clamp recordings of $GABA_A$ receptor-mediated currents in brain slices. The ACSF consisted of the following (in mM): 127 NaCl, 2 KCl, 1.5 $CaCl_2$, 1.5 $MgSO_4$, 25.7 $NaHCO_3$, 1.1 KH_2PO_4, and 10 glucose (osmolarity, 300–305 mOsm), and was continuously oxygenated with 95% O_2–5% CO_2. The internal pipette recording solution consisted of the following (in mM): 153.3 CsCl, 1.0 $MgCl_2$, 10.0 HEPES, and 5.0 EGTA, pH 7.2 (with CsOH) (osmolarity, 285–295 mOsm). The electrode shank contained the following (in mM): 3 ATP Mg^{2+} salt and 0.1 GTP Na^+ salt. Visualized patch clamp recordings of $GABA_A$ receptor-mediated chloride currents were performed at room temperature in a symmetrical chloride environment. The neurons were voltage clamped to −65 mV. Currents reversed at 0 mV and were blocked by bicuculline, indicating that they are $GABA_A$-receptor mediated. The recordings were analyzed with Mini Analysis software. In parallel, anatomical studies, including light, confocal, and electron microscopy, were performed.

Results

We first studied neurosteroid modulation of $GABA_A$ receptor-mediated whole cell currents in acutely dissociated DGCs. DGCs obtained from epileptic rats will be hereafter referred to as 'epileptic DGCs' and those isolated from control animals will be hereafter referred to as 'control DGCs.'

We observed that $GABA_A$ receptors on epileptic DGCs were less sensitive to the neurosteroid allopregnanolone than those of controls. Allopregnanolone (10 and 30 nM) enhancement of 10 µM GABA-evoked currents in epileptic DGCs was significantly diminished compared to that in control DGCs. While the efficacy remained unaltered, the potency (EC_{50}) of allopregnanolone enhancement of GABA-evoked currents was markedly diminished in epileptic DGCs compared to that in control DGCs. In epileptic DGCs, there was a significant right shift of the allopregnanolone concentration-response curve (**Figure 1**).

In addition, we found that in epileptic DGCs, there was a loss in the sensitivity of diazepam, whereas the sensitivity to Zn^{2+} was enhanced. Since whole-cell $GABA_A$ receptor currents comprise currents from synaptic and extrasynaptic receptors, and because synaptic and extrasynaptic currents have distinct properties, we then studied neurosteroid modulation of synaptic inhibition in acute hippocampal slices.

The neurosteroid sensitivity of synaptic $GABA_A$ receptors in control and epileptic DGCs was compared by bath application of allopregnanolone (10 nM) in slices from control and epileptic animals. Allopregnanolone (10 and 30 nM) prolongation of mIPSC decay time constant (**Figure 2(a)** and **2(c)**) was lost in epileptic DGCs (**Figure 2(b)** and **2(b)**). This loss of neurosteroid sensitivity of synaptic currents raised the possibility

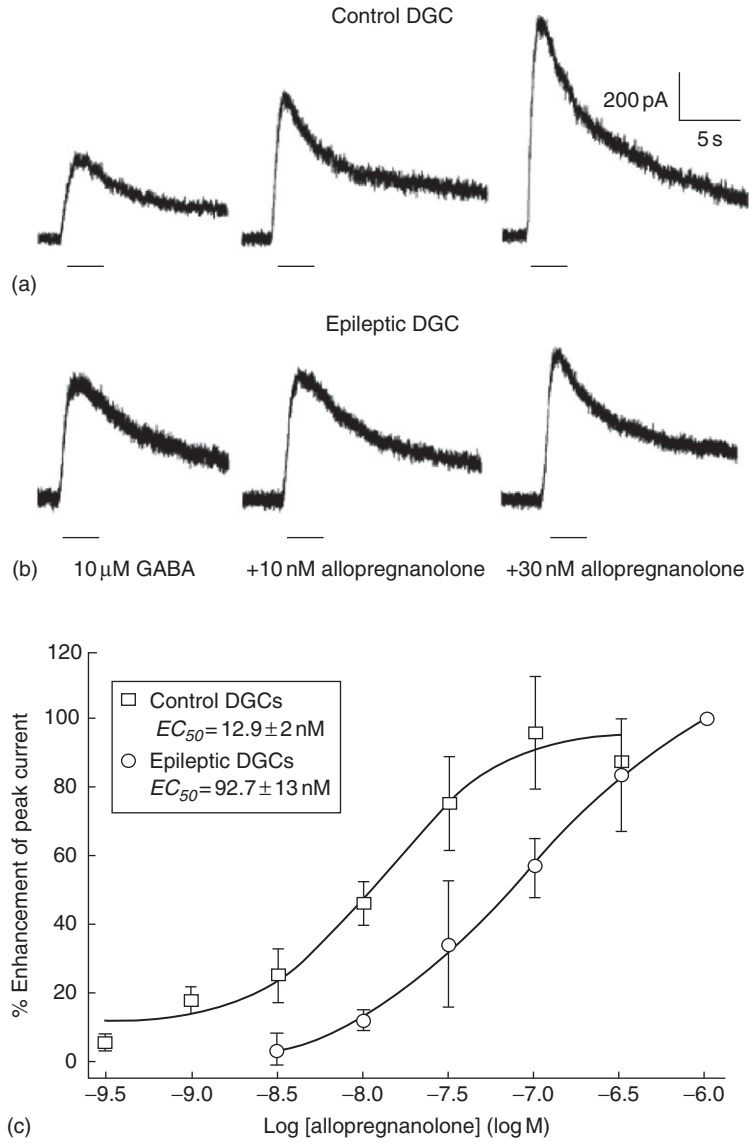

Figure 1 The peak current elicited by GABA was robustly enhanced by 10 and 30 nM allopregnanolone (a). In contrast, the same concentrations of allopregnanolone poorly enhanced $GABA_A$ receptor currents in an epileptic DGC (b). There was a right shift in the allopregnanolone concentration-response curve of epileptic DGCs than in the controls (c). Reproduced from Mtchedlishvili Z, Bertram EH, and Kapur J (2001) Diminished allopregnanolone enhancement of GABA(A) receptor currents in a rat model of chronic temporal lobe epilepsy. *Journal of Physiology* 537: 453–465, with permission from Wiley-Blackwell.

that α4 subunit-containing $GABA_A$ receptors were present on postsynaptic membrane of epileptic but not control DGCs. The α4 subunit-containing receptors have unique benzodiazepine pharmacology. They are insensitive to the classical, broadly active benzodiazepine, diazepam. However, the imidazobenzodiazepine, RO 15-4513, is a partial agonist at the benzodiazepine insensitive, α4 and γ2 subunit-containing receptors and acts as an inverse agonist at receptors with classical benzodiazepine pharmacology (α1βxγ2, α2βxγ2, and α5βxγ2). Therefore, we compared the actions of diazepam and RO 15-4513 on mIPSCs recorded from control and epileptic animals.

We found that the sensitivity of synaptic currents to diazepam was lost in epileptic DGCs. Diazepam (30 nM) prolonged the mIPSC decay time constants, and enhanced the amplitude of mIPSCs in control (**Figure 3(a)** and **3(c)**), but not epileptic DGCs (**Figure 3(b)** and **3(d)**). We then tested whether the response to RO 15-4513 had also changed. RO 15-4513 (300 nM) inhibited mIPSCs amplitude but had no effect on the decay time constant in control DGCs (**Figure 4(a)**); however, it potentiated the amplitude and decay of mIPSCs in epileptic DGCs (**Figure 4(b)**).

These observations suggested the presence of synaptic $GABA_A$ receptors containing the α4 and γ2 subunit of

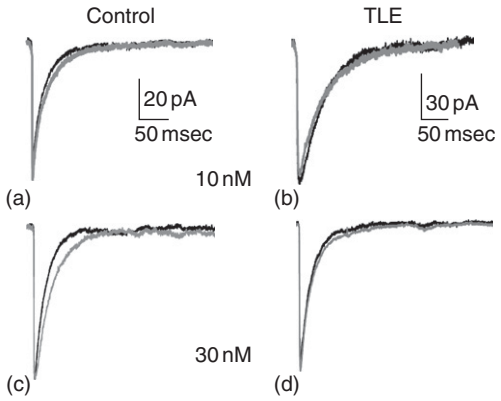

Figure 2 Allopregnanolone (10 and 30 nM) prolonged decay of mIPSCs recorded from control DGCs (a, c) but did not alter decay of mIPSCs recorded from epileptic DGCs (b, d). In this and subsequent figures, the black trace of averaged mIPSCs represent recordings in ACSF, and gray trace represents recordings after bath application of drug. Reproduced from Sun C, Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of $GABA_A$ receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

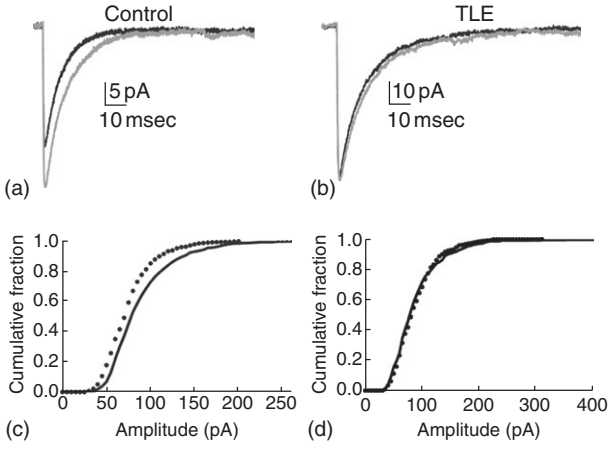

Figure 3 Diazepam (30 nM) strongly potentiated amplitude and decay of mIPSCs recorded from control DGC (a), whereas it had no effect on mIPSCs recorded from an epileptic DGC (b). Cumulative fraction plots of distribution of mIPSC amplitudes derived from six control and six epileptic DGCs before (black line) and after (dotted lines) application of drug indicate that diazepam caused a leftward shift in control (c) but not in epileptic (d) DGCs. Reproduced from Sun C, Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of $GABA_A$ receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

the receptor. We further confirmed the presence of the α4 subunit, by studying the sensitivity of the synaptic currents to furosemide, which inhibits α4 subunit-mediated $GABA_A$ currents with a high affinity. In control

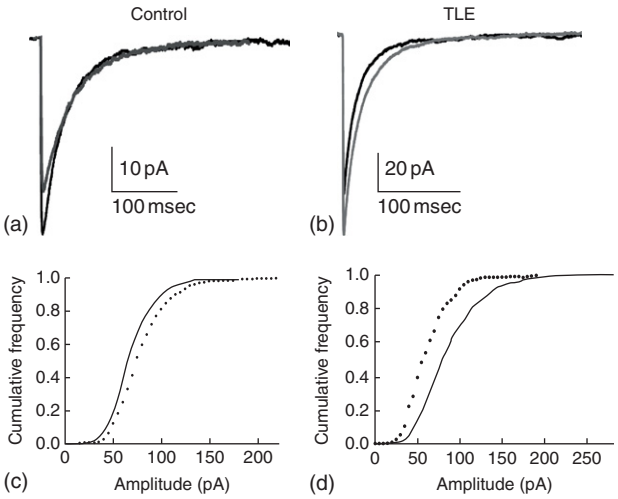

Figure 4 Averaged trace of mIPSCs recorded from a control (a) and an epileptic (b) DGC before and after bath application of 300-nM RO 15-4513. RO 15-4513 did not alter decay time constants, and the median amplitude decreased slightly in control DGC (a), whereas in an epileptic DGC (b), it significantly prolonged slow decay time constant and increased peak amplitude. Cumulative fraction plots of mIPSC amplitude data from seven control DGCs (c) and eight epileptic DGCs (d) before (black line) and after (dotted line) application of 300-nM RO 15-4513; the drug reduced mIPSC amplitude in control DGCs but increased it in epileptic DGCs. Reproduced from Sun C,Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of $GABA_A$ receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

DGCs, furosemide (100 μM) did not have any inhibitory effect on mIPSCs. There was a slight, but statistically insignificant, increase in the amplitude of mIPSCs; decay of mIPSCs was not affected (**Figure 5(a)** and **5(c)**). However, in epileptic DGCs, furosemide inhibited mIPSCs as demonstrated by a faster decay (**Figure 5(b)**) and a significant reduction in amplitude (**Figure 5(d)**).

The results of these pharmacological studies suggested that the loss of neurosteroid sensitivity in epileptic DGCs may be due to the presence of α4 subunit-containing $GABA_A$ receptors on the postsynaptic membrane. Indeed, it has been previously reported that there is an increase in α4 subunit-containing $GABA_A$ receptors following progesterone withdrawal, and that this change predisposes to an increase in seizure susceptibility. We employed anatomical methods, therefore, to determine the presence of α4 subunit containing receptors at the inhibitory synapses of the epileptic DGCs. Using double-label immunohistochemistry and confocal laser microscopy, we found that in epileptic DGCs, there was an increased colocalization of the α4 subunit with GAD65, the presynaptic marker of GABAergic synapses (**Figure 6**). GAD65 labels synapses; hence, the association of α4 colocalization with GAD65 suggested the presence of the α4 subunit in the synapse.

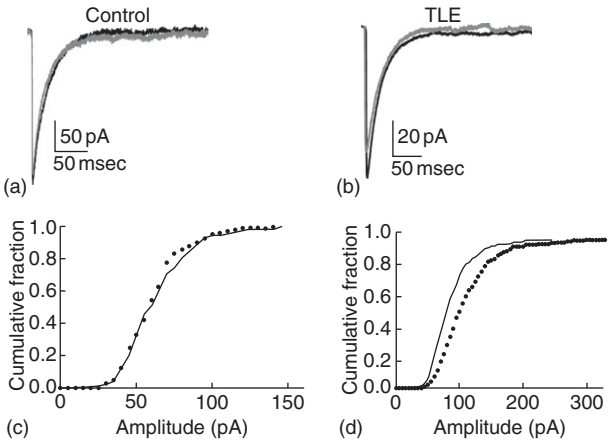

Figure 5 Averaged mIPSC traces demonstrate that furosemide (100 μM) had no effect on mIPSCs recorded from control DGCs (a), but it inhibited mIPSCs recorded from epileptic DGCs (b). Cumulative fraction plot of mIPSC amplitudes recorded from eight control (c) and seven epileptic (d) DGCs before (black line) and after (dotted line) drug application. Reproduced from Sun C, Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of $GABA_A$ receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

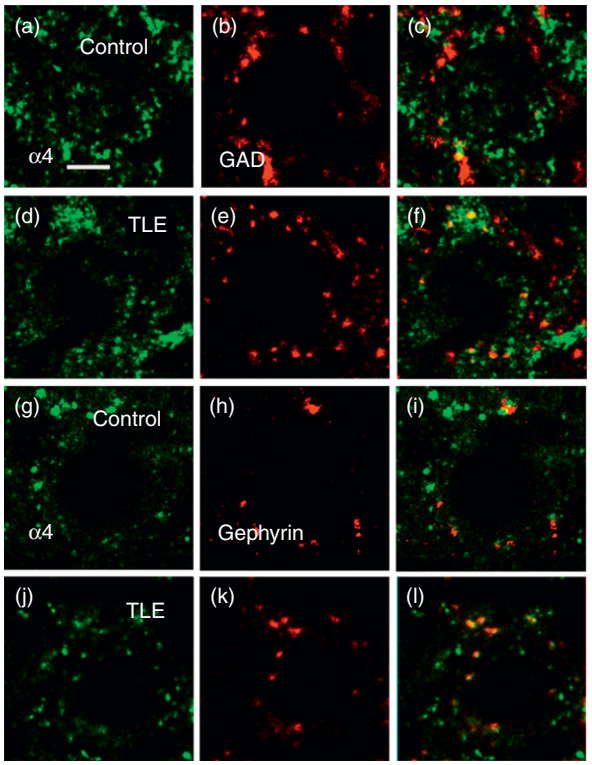

Figure 6 There were more clusters of the α4 subunit of the $GABA_A$ receptor colocalized with synaptic makers (GAD65 and gephyrin) in epileptic DGCs than in controls. The DGCs were double labeled with the α4 subunit of the $GABA_A$ receptor (a, d, g, j) and the presynaptic marker GAD65 (b, e) or the postsynaptic marker gephyrin (h, k). The subunit was visualized by secondary antibody conjugated with Alexa Fluor 488 (green), and synaptic markers were visualized with Alexa Fluor 594 (red). Parts (c), (f), (i), and (l) are merged images of the subunit and synaptic markers. Scale bar, 5 μm. Reproduced from Sun C, Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of $GABA_A$ receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

To further confirm the location of the α4 subunit of the $GABA_A$ receptor, we used postembedding immunogold electron microscopy. Quantitative analysis was performed on randomly selected grids of α4 subunit-labeled synaptic profiles within the granule cell layer, and the synapses were considered labeled with α4 immune particles only if two or more gold particles were present at or around a synapse. The synapse was defined as the area where the pre- and postsynaptic membranes remained parallel to each other and were separated by a synaptic cleft. The distribution of α4 immunogold particles was classified as one of the following: (1) within the central third of the synapse (**Figure 7**, label 1), (2) within the outer third of the synapse (**Figure 7**, label 2), (3) within 40 nm of the ends of synapses (considered to be perisynaptic) (**Figure 7**, label 3), and (4) extrasynaptic, located 40–100 nm from the end of synapses along the adjacent membrane (**Figure 7**, label 4). Gold particles within the center third and outer third were classified as synaptic labeling, whereas those within perisynaptic and extrasynaptic were classified as extrasynaptic labeling.

In epileptic DGCs, the α4 subunit immunogold particles redistributed from the extrasynaptic membrane to the synapses as shown in **Figure 7**. The number of gold particles per synapse in control and epileptic animals was similar (control 3.38 ± 0.27 vs. epileptic 4.04 ± 0.31, unpaired t-test $p > 0.05$). However, in epileptic DGCs, the fraction of gold particles in the center of the synapse was increased from 12.9% in controls to 23.5% in epileptic DGCs, and from 16.9% in controls to 32.8% in the outer third synaptic membrane. Also, there was a clear reduction in the number of gold particles in the extrasynaptic region in epileptic DGCs (25.5%) than in controls (45.5%). Thus, compared with controls, a larger faction of α4 subunit labeling was found within the perisomatic symmetric synapses on epileptic DGCs. Further analysis of the symmetric synapses on proximal dendrites of DGCs revealed that compared with controls, epileptic DGCs had a larger faction of α4 subunits within synapses, and a smaller fraction in the extrasynaptic and perisynaptic regions of the synapses.

Our physiological and anatomical studies thus demonstrated a loss of neurosteroid sensitivity of synaptic currents in epileptic DGCs. Other studies have suggested the presence of the γ2 subunit in the peri- and extrasynaptic sites. Together, these results suggest that a potential

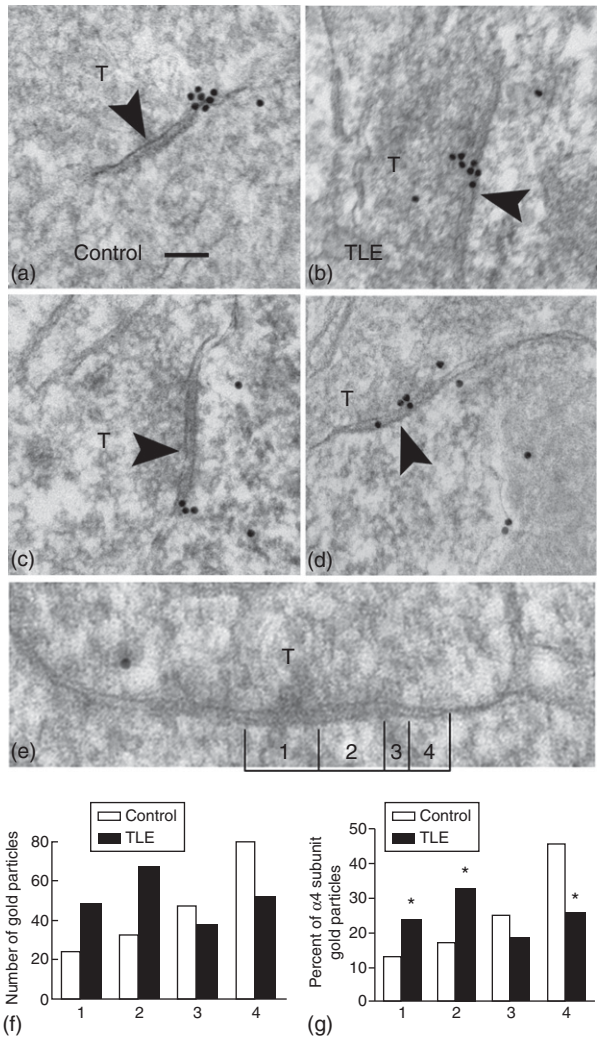

Figure 7 While α4-immunoreactive gold particles were found close to or at the end of symmetric axosomatic synapses in the hippocampal DGC layer from control animals (a, c), they were also found at the symmetric synapses in hippocampal DGC layer from epileptic animals (b, d). Terminals are indicated by T, and the arrowheads in (a–d) indicate the center of synapses. Scale bar: (a–d), 100 nm. (e) A representation of the classification of subdivisions of the synaptic and extrasynaptic regions. (f) More number of immunogold particles were found in center and outer third of synapses, and less in the peri and extrasynaptic regions in epileptic DGCs. (g) Immunogold particles in regions 1–4 expressed as a percentage fraction of total number of gold particles in symmetric synapses in control and epileptic DGCs. *$p < 0.05$, χ^2 test. Reproduced from Sun C, Mtchedlishvili Z, Erisir A, Kapur J (2007) Diminished neurosteroid sensitivity of synaptic inhibition and altered location of the a4 subunit of GABA-A receptors in an animal model of epilepsy. *Journal of Neuroscience* 27(46): 12641–12650, with permission from Society for Neuroscience.

mechanism underlying the loss of neurosteroid sensitivity may be the presence of novel $GABA_A$ receptors with pharmacological properties similar to those containing the α4 and γ2 subunits in the postsynaptic membrane.

Future Goals

Altered neurosteroid modulation of $GABA_A$ receptors on DGCs in temporal lobe epilepsy may have consequences in the precipitation of seizures or catamenial exacerbation of seizures. It is possible that this diminished sensitivity results in increased vulnerability to seizures. Further studies are underway to confirm if similar changes in neurosteroid sensitivity and $GABA_A$ receptor assembly occur in an animal model of catamenial epilepsy. An important question that remains to be answered is whether the loss of neurosteroid sensitivity occurs after the establishment of epilepsy, or during the latent period (epileptogenesis) after *status epilepticus*. The loss of sensitivity in the latent period would suggest that loss of neurosteroid sensitivity may predispose to the development of epilepsy.

Sex and Seizure Sensitivity

Introduction

Animal studies have revealed that subtle sex differences in basal seizure susceptibility exist between males and females. It has been hypothesized that the distal portion of chromosome 1 in mice harbors a gene that has a fundamental role in regulating seizure susceptibility (Ferraro *et al.*, 2001). During early ontogenetic development, gonadal hormones regulate the process of sexual differentiation and are involved in the maturation of many brain structures such as the hypothalamus, hippocampus, and substantia nigra. Sex differences in seizure susceptibility are not restricted to hormonal modulation of receptor activity. Alterations in the concentration of neurotransmitters, especially glutamate and γ-aminobutyric acid (GABA), may contribute to the variations in the susceptibility to seizures. It should also be emphasized that hormones and their neurosteroid derivatives modulate a variety of ionotropic receptors, including $GABA_A$, and *N*-methyl-D-aspartate (NMDA) receptor complexes.

Hippocampus and substantia nigra are two main subcortical structures essential for seizure generation and propagation. Substantia nigra is, furthermore, involved in the expression of movement disorders. Within this area, sex-specific differences in functionality of the GABAergic system have been determined in a variety of animal studies. In mature male rats, there are two distinct regions mediating opposite effects on seizure phenomena. In females, in contrast, only one region that can affect seizures has been confirmed. Testosterone seems to be responsible for the development of 'proconvulsant' region of substantia nigra in male rats. In infantile rats, neural depolarization and intracellular Ca^{2+} increases are participants in the pathways that regulate gene expression differently in male and female substantia nigra, thus promoting their sexual differentiation. Moreover, sex differences in the expression of cation-chloride cotransporters may underlie the GABA-mediated sexual differentiation of certain brain structures.

The pattern of gonadal steroids contributes to seizure susceptibility in adult males and females. Testosterone, which is predominant in males, is generally metabolized by 5α-reductase to 5α-dihydrotestosterone, which is converted to 3α-androstanediol, a powerful positive modulator of $GABA_A$ receptors, thus yielding anticonvulsant properties. Nevertheless, testosterone in the presence of aromatase is converted to 17β-estradiol, exhibiting some proconvulsant action, probably via glutamatergic NMDA receptors. Therefore, testosterone may increase seizure susceptibility in females and decrease it in males. In females, estrogen enhances, but progesterone and its metabolite allopregnanolone diminish, the convulsive threshold. Allopregnanolone, as a very potent positive modulator of $GABA_A$ receptor, decreases sensitivity to most seizures, with the exception of absence epilepsy. In a model of absence epilepsy (rats treated during development with a cholesterol synthesis inhibitor, AY9944), progesterone and allopregnanolone exacerbated, while 17β-estradiol attenuated seizure severity.

Steroid hormones and other factors may differentially affect the response of $GABA_A$ receptors to various ligands. For instance, acute restraint stress selectively decreases the potency of GABA to modulate $GABA_A$ receptors. Chronic ethanol consumption decreases α1 subunit expression in male rat, but not female rat cortex.

The effect of sex and gonadal hormones on seizure susceptibility is observed also in humans. One obvious example is the influence of the menstrual cycle on catamenial seizures in women. Moreover, childhood absence epilepsy affects more girls than boys, in contrast to myoclonic epilepsy, which affects more boys than girls. The existing data suggest that sex differences in seizure

Introduction

Animal studies have revealed that subtle sex differences in basal seizure susceptibility exist between males and females. It has been hypothesized that the distal portion of chromosome 1 in mice harbors a gene that has a fundamental role in regulating seizure susceptibility (Ferraro *et al.*, 2001). During early ontogenetic development, gonadal hormones regulate the process of sexual differentiation and are involved in the maturation of many brain structures such as the hypothalamus, hippocampus, and substantia nigra. Sex differences in seizure susceptibility are not restricted to hormonal modulation of receptor activity. Alterations in the concentration of neurotransmitters, especially glutamate and γ-aminobutyric acid (GABA), may contribute to the variations in the susceptibility to seizures. It should also be emphasized that hormones and their neurosteroid derivatives modulate a variety of ionotropic receptors, including $GABA_A$, and *N*-methyl-D-aspartate (NMDA) receptor complexes.

Hippocampus and substantia nigra are two main subcortical structures essential for seizure generation and propagation. Substantia nigra is, furthermore, involved in the expression of movement disorders. Within this area, sex-specific differences in functionality of the GABAergic system have been determined in a variety of animal studies. In mature male rats, there are two distinct regions mediating opposite effects on seizure phenomena. In females, in contrast, only one region that can affect seizures has been confirmed. Testosterone seems to be responsible for the development of 'proconvulsant' region of substantia nigra in male rats. In infantile rats, neural depolarization and intracellular Ca^{2+} increases are participants in the pathways that regulate gene expression differently in male and female substantia nigra, thus promoting their sexual differentiation. Moreover, sex differences in the expression of cation-chloride cotransporters may underlie the GABA-mediated sexual differentiation of certain brain structures.

The pattern of gonadal steroids contributes to seizure susceptibility in adult males and females. Testosterone, which is predominant in males, is generally metabolized by 5α-reductase to 5α-dihydrotestosterone, which is converted to 3α-androstanediol, a powerful positive modulator of $GABA_A$ receptors, thus yielding anticonvulsant properties. Nevertheless, testosterone in the presence of aromatase is converted to 17β-estradiol, exhibiting some proconvulsant action, probably via glutamatergic NMDA receptors. Therefore, testosterone may increase seizure susceptibility in females and decrease it in males. In females, estrogen enhances, but progesterone and its metabolite allopregnanolone diminish, the convulsive threshold. Allopregnanolone, as a very potent positive modulator of $GABA_A$ receptor, decreases sensitivity to most seizures, with the exception of absence epilepsy. In a model of absence epilepsy (rats treated during development with a cholesterol synthesis inhibitor, AY9944), progesterone and allopregnanolone exacerbated, while 17β-estradiol attenuated seizure severity.

Steroid hormones and other factors may differentially affect the response of $GABA_A$ receptors to various ligands. For instance, acute restraint stress selectively decreases the potency of GABA to modulate $GABA_A$ receptors. Chronic ethanol consumption decreases α1 subunit expression in male rat, but not female rat cortex.

The effect of sex and gonadal hormones on seizure susceptibility is observed also in humans. One obvious example is the influence of the menstrual cycle on catamenial seizures in women. Moreover, childhood absence epilepsy affects more girls than boys, in contrast to myoclonic epilepsy, which affects more boys than girls. The existing data suggest that sex differences in seizure

susceptibility are intimately related to the modulation of the activity of the $GABA_A$ receptor complex by sexual hormones.

Background

Pentylenetetrazole-Induced Seizures

Female rats, having higher threshold than males, are less susceptible to seizures induced by pentylenetetrazole. Since ovariectomy reduces the threshold of females to approximately that of the males, it is believed that progesterone and allopregnanolone are responsible for this discrepancy between intact female and male rats. In contrast, female mice seem to be more susceptible to pentylenetetrazole than do males; however, this effect appears only when the chemoconvulsant is applied at a dose range of 50–60 mg kg^{-1} Qualitative differences of convulsion expression are also observed. Females most frequently display running clonus, while males often present with myoclonus.

It is interesting that L-NAME, an inhibitor of nitric oxide synthase, completely prevents the pentylenetetrazole-induced convulsions in male rats, but increases the seizure severity, frequency, and duration, as well as shortens the latency in female rats. A nitric oxide precursor, sodium nitroprusside, increases these seizure parameters in male rats, while decreases them in female rats. Given these data, the effect of nitric oxide on the seizure susceptibility appears to be clearly sex-dependent. It is also interesting that morphine, administered at relatively low doses (0.5–3 mg kg^{-1}), exhibits anticonvulsant effects against pentylenetetrazole-evoked convulsions in males and estrus females, but not in diestrus females. However, at higher doses (30 and 60 mg kg^{-1}), morphine decreases the seizure threshold in males and diestrus females, with relatively little effect in estrus mice. This result suggests that the net effect of morphine on seizure susceptibility in female mice depends on the administered dose of the opioid.

Bicuculline-Induced Convulsions

Bicuculline is a widely known antagonist of the $GABA_A$ receptor. In female rats, a higher concentration of progesterone is correlated with a heightened seizure threshold to bicuculline-induced convulsions (when compared with intact males and gonadectomized animals of both sexes). However, there are also reports that rats of both sexes are equally sensitive to the convulsant. Bicuculline has been used to investigate seizure susceptibility in pre- and peripubertal rats of both sexes, exposed prenatally to morphine. Males show increased susceptibility at the prepubertal ages and decreased susceptibility at peripubertal ages.

Picrotoxin-Induced Convulsions

In the model of picrotoxin-induced seizures, there is no significant sex difference in mean latencies to first convulsions. However, this effect may depend on the dose of the convulsant. Female rats treated with picrotoxin at low doses (4 mg kg^{-1}) have significantly shorter latencies to myoclonic seizures, and higher incidence of generalized tonic-clonic seizures than males do. Higher doses of picrotoxin (8 and 10 mg kg^{-1}) shorten relative latencies to myoclonic seizures in male individuals. No sex differences have been observed in the incidence of or latency to picrotoxin-induced focal or akinetic seizures.

There is evidence showing that sex differences in the sensitivity to picrotoxin are age-dependent. Picrotoxin is equipotent in producing convulsions in male and female 20-day-old rats. In contrast, adult females tend to be more, while adult males are considerably less sensitive to picrotoxin than young individuals. These observations suggest that gonadal hormones affect the seizure threshold for picrotoxin during maturation processes. Moreover, lower rates of synthesis of GABA in substantia nigra and, in consequence, the less effective GABA system in female rats may be responsible for their greater susceptibility to picrotoxin-induced convulsions. Nevertheless, the prior treatment of octreotide (a somatostatin analogue with $GABA_A$ receptor antagonistic activity) increases susceptibility for picrotoxin-induced seizures in male, but not female rats.

Ethanol Withdrawal-Induced Convulsions

Ethanol withdrawn female, but not male rats are more responsive to the anticonvulsant effects of the neurosteroid 3α-hydroxy-5α-pregnan-20-one. These findings show that sex has an effect on receptor adaptations elicited by ethanol. Proposed mechanisms for the development of ethanol dependence involve alterations in $GABA_A$ and NMDA receptors.

Pilocarpine-Induced Convulsions

Male rats appear to be more susceptible to the proconvulsant effects of pilocarpine, presenting a greater degree of full limbic convulsions when compared with female individuals. Rats of both sexes have similar latencies to onset of pilocarpine-evoked status epilepticus, but the status epilepticus-induced mortality is markedly higher in male rats. Ovariectomy shortens the latency to pilocarpine-induced status epilepticus, and increases the status epilepticus-related mortality.

Excitatory Amino Acid-Induced Convulsions

Male rats are more prone to kainate-induced seizures than females. Testosterone enhances the occurrence and

severity of seizures, and there is a reciprocal relationship between kainate-induced seizures and plasma testosterone level. Octreotide, acting as a $GABA_A$ receptor antagonist, decreases the number of kainate-evoked convulsions in animals of both sexes, but this effect is more pronounced in males. Onset of kainate-induced seizures is quicker in females than males; however, there is no effect of octreotide on the seizure latency.

NMDA-induced seizure activity is more severe in males when compared to female rats. Anticonvulsant effects of magnesium sulfate on the NMDA seizures are greater in males than females.

Maximal Electroshock

According to available data, female rats have a lower seizure threshold for electroshock-induced seizures than males.

Kindled Seizures

In the in vitro slice kindling model of epileptogenesis, some investigators have shown that the hippocampal CA1 shows larger excitatory postsynaptic potential amplitudes in males than in females. However, other authors have found that the natural changes in sex hormone levels during the estrous cycle in rats do not affect seizure susceptibility, at least in the amygdala kindling model; no sex differences were observed either in seizure parameters or in effectiveness of conventional antiepileptic drugs.

Methods

In our laboratory, we have studied the influence of steroid hormones on the basic experimental models of epilepsy: maximal electroshock- and pentylenetetrazole-induced convulsions in mice, as well as amygdala-kindled seizures in rats. The three models are required screening tests for potential anticonvulsant drugs. Maximal electroshock reflects generalized tonic–clonic seizures, pentylenetetrazole-evoked convulsions are an equivalent of myoclonic epilepsy, while amygdala-kindled seizures resemble complex partial seizures in humans.

Electroconvulsions are produced by an alternating current (50 Hz, 0.2 s, fixed current intensity of 25 mA, and maximum stimulation voltage of 500 V) delivered via ear-clip electrodes. Tonic hindlimb extension (the hind limbs of animals outstretched 180° to the plain of the body axis) is taken as the endpoint. Results are expressed as CS_{50} values for the hormones tested, where CS_{50} is current strength (in mA) necessary to induce tonic convulsions in 50% of animals.

In the pentylenetetrazole-induced convulsions model, the chemoconvulsant is injected at its CD_{50} dose, defined as a dose producing clonic convulsions in 50% of tested animals. Subsequently, the influence of steroid hormones on the CD_{50} value of pentylenetetrazole is determined and interpreted as an effect on the seizure threshold.

Kindled seizures are evoked electrically from basolateral amygdala. Each stimulus consists of a 1-s train of 50 Hz, 1 ms biphasic square-wave pulses, with pulse amplitude of 500 μA, delivered every 24 h. Stimuli are delivered until at least 10 sequential fully kindled seizures are generated. At that point, four parameters are measured: (1) the seizure threshold, (2) seizure severity, assessed according to a modified Racine's system, (3) duration of limbic seizures (stage 1–2) and motor seizures (stage 3–5), and (4) EEG after-discharge duration defined as spikes with a frequency of at least 1 Hz and amplitude at least twice greater than the pre-stimulation baseline. The after-discharges from the amygdala are recorded prior to and after the stimulation. After-discharge threshold (ADT) is determined after administration of a test drug (or vehicle control) by administering a series of stimulations at intervals of 3 min, increasing stimulus amplitude in steps of about 20% over the previously applied current until an after-discharge (duration of at least 3 s) is evoked. At this ADT current, seizure severity, seizure duration, and after-discharge duration are recorded and the data analyzed. Control readings are made 2 days before and 2 days after respective treatments.

Results

Our results demonstrate that male and female animals do not differ in susceptibility to seizures evoked in three basic models of experimental epilepsy described above. Estradiol administered intraperitoneally at the dose range of 1.125–3.375 mg kg^{-1} does not change the electroconvulsive threshold, but significantly decreases the threshold for the pentylenetetrazole-induced convulsions in mice of

Table 1 Effect of steroid hormones on the threshold of experimental seizures

	ECT		*PTZ*		*AKS*	
Hormone	*F*	*M*	*F*	*M*	*F*	*M*
Estradiol	–	–	↓↓	↓	↓	↓
Testosterone	↑	↑↑	↑	↑↑	–	–
Progesterone	↑↑	↑	↑↑	↑	–	–
Cortisol	↓	↓	↓	↓	–	–
Aldosterone	–	–	–	–	–	–

ECT, the electroconvulsive threshold; PTZ, the threshold for pentylenetetrazole-induced convulsions; AKS, the after-discharge threshold for amygdala-kindled seizures; –, lack of effect; F, females; M, males; ↓, proconvulsant effect; ↓↓, more intensified proconvulsant effect; ↑, anticonvulsant effect; ↑↑, more intensified anticonvulsant effect.

both sexes. However, the antiseizure effect is more distinct in females. Testosterone ($5\,mg\,kg^{-1}$) increases the electroconvulsive threshold only in males, but when applied at $10\,mg\,kg^{-1}$, it raises the threshold in animals of both sexes. Progesterone ($4.5\,mg\,kg^{-1}$) raises this seizure parameter only in females, while at $6\,mg\,kg^{-1}$, the hormone increases the threshold in female and male mice. In the pentylenetetrazole model of epilepsy, testosterone ($5–10\,mg\,kg^{-1}$) and progesterone ($4.5–6\,mg\,kg^{-1}$) decrease the 50% convulsive dose of pentylenetetrazole – testosterone more dramatically in males, while progesterone more dramatically in female individuals. Cortisol (hydrocortisone; $25–50\,mg\,kg^{-1}$) decreases the electroconvulsive and pentylenetetrazole threshold similarly in mice of both sexes. Aldosterone does not influence the seizure susceptibility in the two epilepsy models.

Among all applied steroid hormones, only estradiol (3.375–4.5 mg) decreases the ADT, and does so similarly in rats of both sexes. Progesterone ($6–12\,mg\,kg^{-1}$) reduces the seizure severity and duration, but does not affect the ADT.

In conclusion, steroid hormones certainly modulate seizure susceptibility, and this effect is particularly distinct in the case of gonadal hormones in animals of the respective sex. However, it should be emphasized that effective doses of hormones used in these studies significantly exceed the therapeutic range (for review see **Table 1**).

Future Goals

The most critical immediate goal is to determine the influence of these hormones on seizure susceptibility in humans. Relatively little is known about the role of hypothalamic and pituitary hormones in epileptogenesis, seizure generation, and seizure propagation.

Sex Differences in Seizure Sensitivity

J Velíšková, Albert Einstein College of Medicine, Bronx, NY, USA

Introduction

Similar to other neurological diseases, epilepsy shows sex differences in incidence, progression and severity, as well as in responsiveness to therapy. Clinical data suggest that incidence of seizures and epilepsy is slightly higher in males than in females. These data are supported by animal studies, which also demonstrate higher seizure susceptibility in males than in females, using several seizure models. Many factors are involved in determining sex differences in seizure susceptibility, including the presence of sexual dimorphism in brain structures involved in seizure generation and control, in regional connectivity, sensitivity of neurotransmitter systems, receptor distribution, dependence on hormonal milieu and on changes in sex hormone levels during the life span. For example, some epileptic syndromes may either remit (benign rolandic epilepsy, childhood absence) or have their onset (juvenile myoclonic epilepsy) in adolescence, indicating the likely influence of hormonal changes occurring around puberty. Sex differences have been described in patients with temporal lobe epilepsy, with respect to distinct regional distribution of brain dysfunction during interictal periods as well as to the extent of neuronal damage. Women tend to have less structural atrophy than men, regardless of the seizure rate.

Background

Hormones influence neuronal development and neuronal circuit formation in the brain, and modulate its activity either through excitatory or inhibitory mechanisms. During embryonic and postnatal development, steroid hormones induce differentiation of discrete brain regions by modulation of specific neuronal and glial components directly involved in synaptogenesis and myelinogenesis. At the cellular level, sex differences in the nervous system include the size of nucleus and nucleolus in neurons, size of synaptic vesicles and terminals, and dendritic branching pattern – all leading to differences in gross structural volume, connectivity, and neurotransmitter distribution. These steroid hormone-dependent sex differences include many areas in the CNS, such as preoptic area, amygdala, hippocampus, hypothalamus, cortex, substantia nigra, striatum and lumbar spinal cord.

Many of these sexual differences develop during the 'critical period' for sexual differentiation. During this developmental period, the CNS is more sensitive to the permanent effects of gonadal hormones. There are several generally accepted assumptions in the current theory about the development of sexual dimorphism:

1. Every individual, whatever its 'chromosomal sex' (XX or XY), is programmed to develop complete feminine features;
2. Testosterone or its metabolites, estradiol and dihydrotestosterone, determine the male-type of brain organization, irrespective of the genetic sex; and
3. The organizing effect that occurs during the 'critical period' is irreversible ('imprinting effect').

In the male developing rat, the surge of testosterone from the fetal testes starts in the last part of gestation (embryonic day 18–22) and starts again at the early neonatal period (postnatal day: PN 0–6). These periods of secretion are responsible for the masculinization and defeminization of the developing rat brain. Recently, however, some exceptions to these postulates have been discovered. New studies show that some sex differences exist prior to the surge in sex hormones, presumably due to the genetic influence. Finally, some sex differences are maintained, but depend on the continued presence of sex hormones.

Our interest in sex differences in the substantia nigra pars reticulata (SNR) has led to extensive studies. The SNR contains mainly GABAergic neurons and serves as a main output of the basal ganglia. The SNR belongs to an endogenous seizure-controlling system, and especially activation of its $GABA_A$ receptor system seems to play an important role in seizure control. In adult rats, pharmacological manipulations of the $GABA_A$ergic system revealed that the role of the SNR in control of flurothyl seizures is region-specific. In contrast, in rat pups there is no regional compartmentalization within the SNR with respect to seizure control.

Methods

Male and female Sprague Dawley rats have been used at different developmental stages.

Development of Sex Differences in SNR-Mediated Seizure Control

Male and female pups were kept with their dams. The day of birth was considered postnatal day (PN) 0. To determine

development of sexual differentiation of the SNR seizure control system, we used following groups of rats: (1) Naïve males; (2) Naïve females; (3) Neonatally castrated males (castration at PN 0); (4) Females injected with testosterone or its metabolites (estrogen and dihydrotestosterone) at PN 0–2; (5) Neonatally castrated males injected with testosterone or its metabolites (estrogen and dihydrotestosterone) at PN 0–2; (6) Males castrated at PN 3.

Neonatal castration (at PN 0) prevents the postnatal testosterone surge, which starts several hours after the birth. This testosterone surge leads to development of sex differences in many brain regions. Although the critical period extends till PN 6, the sensitivity of brain regions to testosterone or its metabolites decreases with age. Thus, the most pronounced differences in the majority of the brain structures develop within the first two days after the birth.

The hormones were injected daily subcutaneously in the following doses: testosterone propionate – 0.1 mg per 0.02 ml; diethylstilbestrol (a synthetic estrogen, which in contrast to β-estradiol does not bind to α-fetoprotein and thus can reach the brain tissue)-2 μg per 0.02 ml; 5α-androstan-17b-ol-3-one (5α-dihydrotestosterone)-100 μg per 0.02 ml.

At PN 13, rats were placed in a stereotaxic apparatus and equipped with bilateral cannulae (Plastics One, Roanoke, VA, USA) in the SNR under ketamine (70 mg kg^{-1}) – xylazine (10 mg kg^{-1}) anesthesia. The incisor bar was positioned 3.5 mm below the interaural bar. The cannulae were inclined at an angle of 15° from the sagittal plane. The stereotaxic coordinates for the SNR were: anterior-posterior = 5.3 mm from bregma, medial-lateral = 3.5 mm from midline, dorsal-ventral = 6.0 mm below the skull. Pups were allowed to recover after the surgery for 2 days with their dams.

At PN 15, muscimol, an agonist to $GABA_A$ receptors (100 ng per 0.25 μl saline), was injected in the SNR bilaterally 30 min prior to seizure testing. Controls were infused with saline. The volume injected into each SNR was 0.25 μl (using a Hamilton syringe) over a 2-min period. After the infusion was completed, the infusion cannulae remained inserted in the guide cannulae for an additional minute.

Permanent Presence of Sex Differences in the SNR-Mediated Seizure Control

Adult (PN 60) male and female rats were used. Rats were divided into groups of animals with symmetrical cannula placements in the anterior part of the SNR (SNRanterior) and animals with symmetrical cannula placements in the posterior part of the SNR (SNRposterior). Cannulae were stereotactically implanted bilaterally in the SNR as described above. The stereotaxic coordinates for the SNRanterior were: anterior-posterior = 5.2 mm from bregma, medial-lateral = 4.0 mm from midline, dorsal-ventral = 7.0 mm below the skull. The stereotaxic coordinates for the SNRposterior were: anterior-posterior = 6.0 mm from bregma, medial-lateral = 4.0 mm from midline, dorsal-ventral = 7.0 mm below the skull. Rats were allowed to recover after the surgery for 2 days and muscimol (100 ng per 0.25 μl per SNR) was infused the same way as in the pups. Controls received SNR saline infusions (0.25 μl per SNR).

Flurothyl-induced seizures were used to determine seizure susceptibility. The rat was placed in a chamber where flurothyl was infused by a pump at a constant rate. Inhalation of flurothyl vapors induces generalized clonic seizures followed by tonic-clonic seizures. In these studies, we monitored the onset of first clonic seizure following muscimol SNR infusions. Flurothyl seizure threshold was calculated as the amount of flurothyl (in μl) necessary to elicit the seizure. Clonic seizures were characterized by facial and forelimb clonus with preserved righting reflex.

At the end of the experiment, the rats were sacrificed, and their brains were collected and snap frozen in 2-methylbutane at −35° C. Coronal sections were cut and stained with thionin for histological examination of the cannulae placements. Only rats with bilateral symmetrical SNR placements of both cannulae entered statistical analysis. In this experiment, effects of SNR muscimol infusions were compared to saline-infused controls within each experimental group using Student's t-test.

Results

Development of Sex Differences in SNR-Mediated Seizure Control (Table 1)

Activation of $GABA_A$ receptors in the SNR by microinfusion of muscimol had sex-specific effects on flurothyl-induced seizure threshold. At PN 15, muscimol infusions in males had a proconvulsant effect on the

Table 1 Development of sex differences in the SNR-mediated seizure control in response to muscimol infusions

	Male type	*Female type*
Naïve rats	Proconvulsant	No effect
Males castrated PN 0		No effect

onset of clonic and tonic-clonic seizures compared to saline-infused controls ('male phenotype' of SNR responses to muscimol infusions). In contrast, in female pups, muscimol had no effect on the seizure threshold compared to saline-infused controls ('female phenotype' of SNR responses to muscimol infusions). The role of the postnatal testosterone surge in the proconvulsant muscimol effects in the SNR on flurothyl seizures in PN 15 males was confirmed using males castrated at PN 0. In neonatally castrated males, SNR muscimol infusions at PN 15 had no effect on flurothyl seizure threshold compared to saline-infused controls; a similar absence of effect was found in female rat pups.

We further explored the role of the early postnatal testosterone surge in the 'male phenotype' of SNR responses to muscimol infusions by injecting testosterone during the early postnatal period (PN 0–2) in females. This manipulation resulted in the loss of the 'female phenotype' of SNR responses; that is, muscimol infusions into the SNR in females treated with testosterone had proconvulsant effects on flurothyl seizure threshold compared to saline controls. Similarly, the males castrated at PN 0 regained the 'male phenotype' of SNR responses (i.e., muscimol infusions had proconvulsant effects compared to saline-infused controls) when injected with testosterone. In males castrated at PN 3, and therefore exposed to endogenous testosterone at the early neonatal period (PN 0–2), muscimol infusions had proconvulsant effects compared to saline controls, further demonstrating the importance of early postnatal testosterone in the development of the 'male phenotype' of SNR responses to muscimol infusions.

Finally, administration of either testosterone metabolite (estradiol or dihydrotestosterone) at PN 0–2 to females or males castrated at PN 0 leads to the 'male type' proconvulsant SNR muscimol responses when tested at PN 15. Thus, testosterone or its metabolites organize the SNR seizure-controlling network during the early postnatal period into the 'male type' effects of $GABA_A$ receptor system activation on seizures.

Permanent Presence of Sex Differences in SNR-Mediated Seizure Control (Table 2)

In adult female rats, flurothyl-induced seizure threshold did not depend on a stage of the estrous cycle, so we combined the data from all females regardless of estrous cycle stage. In adult rats, muscimol infusions in the SNR had region- and sex-specific effects. Muscimol infusions in the SNRanterior had an anticonvulsant effect on flurothyl seizure threshold compared to saline-infused rats in both sexes. However, infusions of muscimol in the SNRposterior had a proconvulsant effect in males – but no effect on flurothyl-induced seizure threshold in females compared to saline-infused rats. These data show that the sex-specific features of SNR-mediated seizure control remains into adulthood.

Future Goals

Many epileptic syndromes show gender-related prevalence. Here we illustrate that point using the example of the SNR, where the presence of sexual dimorphism in the brain influences how seizures are controlled. More studies need to be designed to understand the underlying mechanisms of the sex differences in the SNR seizure-controlling network, and to determine whether the seizure-controlling properties of the SNR are changing in animals with previous history of seizures or in a previously compromised brain (e.g., as a result of pre/postnatal stress, in models of migrational disorders, traumatic injury, etc.). At present, there are no similar studies of sexually dimorphic effects in other regions known to be involved in seizure initiation or suppression (i.e., amygdala, hippocampus, cortex). It would be important to initiate such studies of sex-specific roles of these structures in seizures and epilepsy.

The main goal for the future is to increase the awareness regarding sex differences in the brain. Sex differences may influence epileptic syndrome outcome, responsiveness to treatment, and also adverse effects of therapy. Thus, it is important to study the brain functionality separately in males and females. Sex differences are present from early development, so data from males and females in any age group should not be combined – at least not without determination that sex differences do not exist in the system studied.

Better knowledge of how sex differences influence brain function and neuronal activity may bring new insights in the mechanisms of sex-dependent seizure disorders and can help to design sex-specific treatments.

Introduction

Sex difference in seizure susceptibility is one of the long-standing issues in epilepsy research, at both the basic and clinical levels. Clinical evidence shows gender- and age-related expression in many seizure syndromes. The incidence of epilepsy is generally higher in men than in women. More women rather than men are diagnosed with idiopathic generalized epilepsy, but localization-related symptomatic epilepsies are more frequent in men, and cryptogenic localization-related epilepsies are more frequent in women. Overall, considerable evidences indicate that men are highly susceptibile to seizures than women. Many women exhibit greater fluctuations in susceptibility to seizures, including ovarian cycle-related changes in seizure activity.

During brain development, sex hormones have organizational effects leading to permanent differences between males and females in distinct brain regions. The presence or absence of testosterone determines the male or female brain phenotype. However, the precise mechanisms underlying the sex-dependent differentiation of the specific neuronal circuits, particularly brain regions involved in seizure control, are not clear. Sex-specific differences in the development of seizure suppressing neuronal networks may partly account for sex related susceptibility to seizures.

Sex-based differences in seizure sensitivity may arise from variations between men and women in factors such as body weight, steroid hormones, cytochrome P450 activity and biologic differences in neuronal networks in the brain. The intricate relationship between reproductive hormones and epilepsy suggests that seizures affect hormones and vice versa. Age-related gender differences in seizure sensitivity could be due to developmentally specific changes in neurotransmitters and receptor systems in the brain. For example, changes in seizure sensitivity are

Introduction

Sex difference in seizure susceptibility is one of the long-standing issues in epilepsy research, at both the basic and clinical levels. Clinical evidence shows gender- and age-related expression in many seizure syndromes. The incidence of epilepsy is generally higher in men than in women. More women rather than men are diagnosed with idiopathic generalized epilepsy, but localization-related symptomatic epilepsies are more frequent in men, and cryptogenic localization-related epilepsies are more frequent in women. Overall, considerable evidences indicate that men are highly susceptibile to seizures than women. Many women exhibit greater fluctuations in susceptibility to seizures, including ovarian cycle-related changes in seizure activity.

During brain development, sex hormones have organizational effects leading to permanent differences between males and females in distinct brain regions. The presence or absence of testosterone determines the male or female brain phenotype. However, the precise mechanisms underlying the sex-dependent differentiation of the specific neuronal circuits, particularly brain regions involved in seizure control, are not clear. Sex-specific differences in the development of seizure suppressing neuronal networks may partly account for sex related susceptibility to seizures.

Sex-based differences in seizure sensitivity may arise from variations between men and women in factors such as body weight, steroid hormones, cytochrome P450 activity and biologic differences in neuronal networks in the brain. The intricate relationship between reproductive hormones and epilepsy suggests that seizures affect hormones and vice versa. Age-related gender differences in seizure sensitivity could be due to developmentally specific changes in neurotransmitters and receptor systems in the brain. For example, changes in seizure sensitivity are

evident at puberty, at which marked changes in reproductive hormones and behavioural patterns occurs. Steroid hormones and endogenous neurosteroids, including those derived from adrenal steroids and androgens, substantially influence seizure susceptibility (Figure 1). This article examines the biological basis of sex-based differences in seizure susceptibility and summarizes studies that have focused on steroid hormones and sexually dimorphic brain circuits.

Background

Sex Differences in Seizure Susceptibility

In general, men are more susceptible to injury-induced seizures than women. Higher frequency of infantile spasm, an age-specific epileptic syndrome in infants and young children, is more frequently observed in boys than girls. Recent findings have shown that in early-onset temporal lobe epilepsy, women show greater functional plasticity for verbal memory than men. The relationship between menstrual cycle and seizure sensitivity in women is well known and is greatly influenced by hormonal fluctuations associated with menstrual cycle phases. Considering the first day of menstrual bleeding as the first day of the cycle, we can divide the menstrual cycle into four phases: (a) *menstrual phase*, days −3 to +3; (b) *follicular phase*, days +4 to +9; (c) *ovulatory phase*, days +10 to +16; and (d) *luteal phase*, days +17 to −4. Analysis of seizure diaries shows that seizure frequency is greater during perimenstrual and periovulatory phases than at luteal phase. Women with epilepsy are at increased risk for polycystic ovary syndrome. Sexual dysfunction is common among patients with epilepsy, and studies have found reduced fertility rates among women with epilepsy.

Numerous studies on gender-related sensitivity in animal models of epilepsy characterizes male/female differences in severity of response to seizure stimuli and drug protection. In most animal models of induced seizures, male mice or rats are more seizure-prone than females. For example, our experimental results show male adult mice to have a lower seizure threshold than females in the pentylenetetrazol (PTZ) test (Figure 2). Sex differences in the occurrence or severity of seizures are found for both GABAergic and glutamatergic compounds. The most marked differences are observed with ovariectomy, gonadectemy, and pharmacological manipulations of reproductive milieu. In experimental animals, estrous cycle-related changes in seizure susceptibility are widely reported in the literature. As is seen clinically, the hormonal milieu present during estrus or proestrous phase reduces seizure susceptibility, but animals are more vulnerable to seizures during the metestrous or diestrous phase. In contrast, the chronic absence of an estrous cycle, such as that induced by ovariectomy, leads to a greater chronic susceptibility to seizures. In a recent study, late diestrous phase has been shown to be associated with enhanced expression of $GABA_A$ receptor δ subunit (a molecular signal for increased tonic inhibition) and thereby reduces seizure susceptibility.

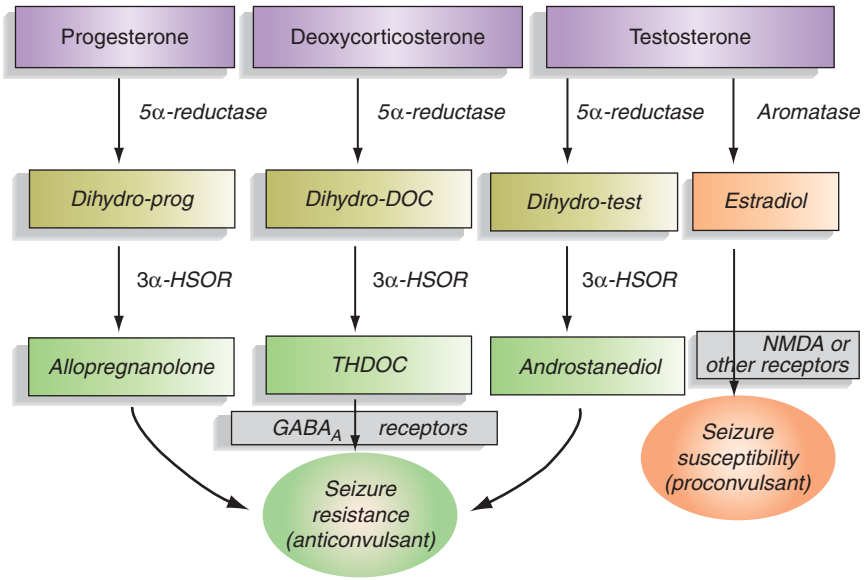

Figure 1 Biosynthetic pathways of steroid hormone metabolism and their influence on seizure susceptibility. 5α-Reductase converts progesterone, testosterone and deoxycorticosterone (DOC) into 5α-dihydro reduced steroids, which are then reduced further to 3α-hydroxylated neurosteroids by 3α-HSOR. Testosterone is converted into 17β-estradiol by the aromatase enzyme. The three enzymes are present in the brain.

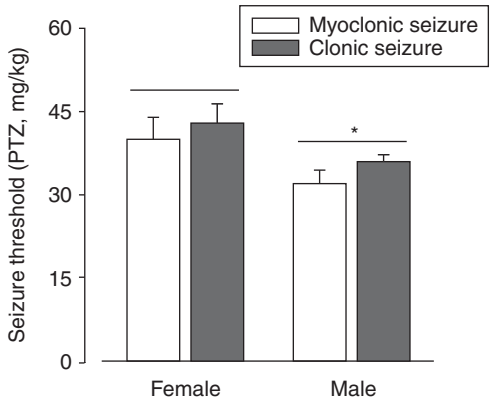

Figure 2 Seizure threshold in adult male and female mice. Seizure-threshold determinations were made by constant intravenous infusion of pentylenetetrazol (PTZ, 5 mg ml^{-1}). The times between the start of infusion and onset to myoclonic seizure and forelimb clonic seizure were recorded in seconds and subsequently converted to threshold convulsant dose in milligrams of PTZ per kilogram of body weight. Data represent mean ± SEM (n = 6–8 per group). *$p < 0.05$ vs. female group (Students' t-test).

Sexual Dimorphism in Brain Circuits and Seizure Susceptibility

The substantia nigra pars reticulata (SNR), a midbrain structure populated largely by GABAergic neurons, plays an important role in seizure control, in an age- and sex-dependent manner. In particular, GABAergic activation of SNR at P15 has sex-specific features on seizure control. Bilateral SNR microinjections of the $GABA_A$ receptor agonist muscimol have been associated with proconvulsant effects on flurothyl-induced seizures in male animals but not in female animals. Further studies have revealed that the postnatal testosterone is responsible for the male proconvulsant phenotype of SNR muscimol effects on seizures. In many neuronal types, GABAergic synaptic transmission is excitatory early in development and later switches to the mature hyperpolarizing type. This switching occurs in males around postnatal day (PN) 17 and in females around PN10. This sexual dimorphism may play a role in several other recognized sex differences in the development of SNR and in its regulatory role in seizures. Because the substantia nigra is an important brain nucleus involved in the expression of movement disorders, the two most common movement disorders affecting the substantia nigra – Parkinson's disease and Tourette syndrome – also show gender differences and age-related onset.

The central nervous system is an important target for steroid hormones such as progesterone and testosterone. These steroid acts in discrete regions of the female brain to regulate sexual behavior and other aspects of reproduction through classical genomic actions mediated by steroid receptors. Many of the biological actions of steroid hormones are mediated through intracellular receptors, which act as nuclear transcription factors. In steroid hormone-responsive target cells, steroid hormone binds to specific cytoplasmic receptors and the hormone-nuclear receptor complexes translocate to the cell nucleus where they activate or silence the transcription of downstream gene networks – thus affecting the physiological response of the target cell. The differential distribution of steroid hormones could account for sex differences in seizure susceptibility. It is well known that female mice and rats are more sensitive to the central nervous system actions of progesterone than are males. For example, our recent finding that wild-type, heterozygous and progesterone receptor knockout (PR-KO) female mice are more sensitive to the anticonvulsant effects of progesterone than males is consistent with the above viewpoint. Moreover, the fact that female PR-KO animals exhibit greater progesterone sensitivity demonstrates that known differences in the density or distribution of the progesterone receptors in the female and male brain are not responsible for the sexual dimorphism. Overall, the emerging evidence clearly supports the notion that although the hormonal milieu influences seizures, innate differences in brain structure between the sexes also contribute to sex differences in seizure sensitivity.

Methods

Animal Models of Epilepsy and Seizures

In our laboratory, a number of animal models are used to assess seizure susceptibility, seizure threshold, and anticonvulsant drug effects in rodents. Seizure susceptibility is determined by measuring the animal's response to a chemoconvulsant such as PTZ or other GABAergic antagonists (such as biculline or picrotoxin). The seizures induced by these chemoconvulsants are thought to resemble seizures in human partial epilepsies. PTZ (85 mg kg^{-1}, s.c.) is administered 15 to 30 min after administration of test drugs. Animals failing to show clinical seizure behavior lasting >5 s are scored as 'protected' by the drug of interest. Because the s.c. PTZ test provides only an all-or-none measure of seizure presence (at a given dose of PTZ), we have also adopted the intravenous PTZ test for a quantitative determination of changes in seizure threshold. In this test, 20 mg ml^{-1} PTZ solution (in sterile saline) is infused via a tail vein at a rate of 0.5 ml min^{-1} using a syringe pump. Three convulsion signs (myoclonic twitch, forelimb clonus, and tonic hindlimb extension), which are typically observed in sequence, are used as end points in the PTZ threshold test. This test allows us to evaluate agents or conditions that alter seizure threshold. In addition, maximal electroshock (MES), which stimulates large portions of the brain and is a suitable model for generalized tonic-clonic seizures, is also used to evaluate drug efficacy. In the MES test, animals are usually subjected to a 50 mA, 0.2 s, 60 Hz electrical

stimulus via corneal electrodes. Animals failing to show tonic hindlimb extension are scored as protected.

Kindling is a widely used model for epileptogenesis and seizure expression, and has been used to model complex partial seizures. Brief electrical stimulus trains (1-ms sine- or square-wave pulses, at a frequency of 60 Hz, for one second) are typically delivered via bipolar electrodes to a limbic structure (e.g., hippocampus or amygdala), to trigger after-discharge. With repeated stimulations, there is a progressive intensification of electrographic and behavioural seizures. In kindling studies, we measures the rate of kindling (number of stimuli required to reach a stage-5 seizure), after-discharge durations, and seizure stage. The kindled state is permanent, but may be altered by test compounds or experimental conditions.

Animal Models of Gender-Specific Epilepsy

There are few gender-specific models of epilepsy. Overiectomized or gonadectomized animals are commonly used to study the influence of gonadal hormones. Conventional models based on acute seizure induction are not suitable for studies on gender-specific forms of epilepsy such as catamenial seizures. There are two new types of models systems that partially represent catamenial epilepsy. The first simulates the rise and fall of estrogen and progesterone at the point in the estrous cycle associated with increased seizure susceptibility. Some examples of this type of model are: pseudopregnancy, chronic progesterone treatment, and a progesterone (or neurosteroid) withdrawal. The second category is based on the naturally-occurring estrous cycle or administration of exogenous hormones that simulate the specific stages of the estrous cycle in rats whose ovaries have been removed. We are using a rat model of perimenstrual catamenial epilepsy that was developed based on the premise that perimenstrual seizures are due to withdrawal of neurosteroids such as allopregnanolone. To assess the potential of drugs for treating catamenial epilepsy, a state of persistently high serum progesterone (pseudopregnancy) is induced in female rats with gonadotropins, and neurosteroids are withdrawn after 10 days with finasteride, a 5α-reductase inhibitor that blocks the conversion of progesterone to allopregnanolone. Finasteride treatment results in a reduction in the seizure threshold, and hence mimics perimenstrual seizure exacerbation. Plasma progesterone and neurosteroid levels are measured by liquid or gas chromatography and mass spectrometry.

Results

Hormonal Basis of Sex Differences in Seizure Susceptibility

Steroid hormones play vital roles in the neuroendocrine control of brain function. Adrenal-derived steroid hormones (glucocorticoids and mineralocorticoids), ovarian hormones (progesterone and estrogen), and hormones synthesized in the testis (testosterone and androgens) are essential for life. Steroid hormones play a key role in the gender-related differences in susceptibility to seizures. However, the precise mechanism underlying such sexual dimorphism is obscure. Studies have suggested that these sex differences in seizure sensitivity are due to gender-specific distribution of steroid hormones or other sexually dimorphic characteristics in specific brain areas relevant to epilepsy. Cyclical changes of ovarian hormones – estrogens and progesterone – are now widely believed to be important factors in fluctuations in seizure susceptibility observed in female cycling animal (**Figure 1**). Generally, progesterone has antiseizure effects, while estrogens have been generally shown to cause proconvulsant effects. There is emerging evidence that circulating steroid hormones serve as precursors for the synthesis of 'neurosteroids' – a term (coined by the French physiologist Etienne Baulieu) that refers to steroids that are synthesized de novo in the brain. Neurosteroids are endogenous modulators of neuronal excitability, and thus could play a vital role in gender-related differences in seizure susceptibility. Current experimental evidence indicates that progesterone- and testosterone-derived neurosteroids could be involved in sexual dimorphism in neural excitability and seizure susceptibility. For example, the progesterone-derived neurosteroid allopregnanolone is a powerful $GABA_A$ receptor-modulating agent with anticonvulsant properties. This neurosteroid shows a dose-dependent protection against PTZ seizures in both male and female mice lacking progesterone receptors. However, female mice exhibit significantly enhanced sensitivity to the protective activity of allopregnanolone as compared to males. In the pilocarpine seizure test, 3α-androstanediol has similar increased potency in female mice. Significant sex differences in responses to neurosteroids are also evident during alcohol withdrawal. These results underscore the possible role of GABAergic neurosteroids (such as allopregnanolone and 3α-androstanediol) in gender-related differences in seizure susceptibility and protection.

Progesterone, Neurosteroids and Catamenial Epilepsy

Progesterone plays a critical role in gender-related differences in seizure susceptibility. Progesterone is an anticonvulsant hormone. It has long been known to have antiseizure activity in animal models, and in clinical studies has also been found to reduce seizures. In many women with epilepsy, natural variations in progesterone levels during the menstrual cycle may influence seizure susceptibility. Seizures decrease in the mid-luteal phase when serum progesterone levels are high, and increase

premenstrually when progesterone levels fall (and decrease the serum progesterone to estrogen ratio). There is strong evidence that 'withdrawal' of progesterone is at least partly responsible for seizure exacerbation in the perimenstrual period.

There are two mechanisms by which progesterone affects reproduction and seizure susceptibility: binding to progesterone receptors and metabolism to the neurosteroid allopregnanolone. Neurosteroids such as allopregnanolone are synthesized from progesterone by two sequential A-ring reductions (**Figure 1**). Allopregnanolone is a potent, broad-spectrum anticonvulsant neurosteroid – a 'neurosteroid' that rapidly modulates neural excitability. Recently it has been discovered that allopregnanolone is a potent positive modulator of $GABA_A$ receptors. Structurally, $GABA_A$ receptors are believed to be pentameric, with five protein subunits that form the chloride ion channel pore. Allopregnanolone has distinct binding sites on $GABA_A$ receptors that are separate from those for benzodiazepines and barbiturates. Allopregnanolone binding to 'neurosteroid' sites on the $GABA_A$ receptor causes massive influx of chloride ions into the neuron, leading to postsynaptic hyperpolarization. This inhibitory mechanism almost certainly underlies allopregnanolone's protective actions against seizures.

To understand the gender-related antiseizure effects of neurosteroids, we examined the ability of progesterone and neurosteroids to protect against PTZ-induced seizures in male and female mice. In both male and female mice, progesterone and allopregnanolone protected against PTZ-induced seizures in a dose-dependent fashion (see **Table 1** for ED_{50} values). However, in male mice, the antiseizure ED_{50} value of progesterone as well as allopregnanolone was significantly higher than that of female mice, indicating an increase in the antiseizure potency of progesterone in female mice. These findings are consistent with previous reports that female animals are more sensitive to the central nervous system actions of progesterone than are males. The gender-related difference in antiseizure activity of neurosteroids is not due to known differences in the density or distribution of the PR in the female and male brain. However, it is not clear if sex differences in bioavailability or pharmacokinetics of drugs could contribute to such gender differences in neurosteroid actions.

Table 1 The antiseizure ED_{50} values (mg kg^{-1}) of progesterone and allopregnanolone in the PTZ test in male and female mice

Drug	*Male*	*Female*
Progesterone	106 (84–133)	70 (55–89)*
Allopregnanolone	15 (6–37)	7 (4–12)**

*$p < 0.05$ vs. male group (Litchfield and Wilcoxon X^2 test).
**$p < 0.05$ vs. male group (Fisher's exact test).
ED_{50} value (the dose at which 50% of tested mice are protected from seizures) with 95% confidence limits (CL) were determined by Litchfield and Wilcoxon procedure (N = 6–8 mice per group at each dose level).

A hallmark of epilepsy is the unpredictable occurrence of seizures. However, in many women with epilepsy, seizures do not occur randomly but cluster in association with the menstrual cycle, most frequently during perimenstrual and periovulatory phases. Recent studies indicate that 'catamenial' epilepsy affects from 39 to 60% of the women with epilepsy. Diagnosis of catamenial epilepsy is mainly based on the assessment of menstruation and seizure records for at least two cycles. The number of seizures in each phase is counted and a two-fold or greater increase in frequency is used as the criterion for diagnosis. There appear to be three patterns of catamenial epilepsy: perimenstrual, periovulatory and inadequate luteal-phase catamenial seizures, with the perimenstrual pattern most commonly observed. Currently, there is no specific drug therapy for catamenial epilepsy; a detailed understanding of the patterns and pathophysiology is essential for the development of rational approaches for the prevention and treatment of catamenial epilepsy.

Catamenial epilepsy is observed in women with ovulatory or anovulatory cycles. A variety of mechanisms, such as fluctuations in antiepileptic drug (AED) levels, changes in water and electrolyte balance, and physiological variation in ovarian hormone secretion are thought to contribute to catamenial epilepsy, with hormonal changes (in the circulating levels of estrogens and progesterone) during the menstrual cycle certainly playing a large role in the increased seizure susceptibility. There is emerging evidence that endogenous neurosteroids, including those derived from adrenal steroid hormones and circulating androgens, substantially influence seizure susceptibility. Because progesterone is a powerful anticonvulsant hormone, decreasing levels of progesterone (or neurosteroids) during the perimenstrual period could result in catamenial seizure exacerbation. Withdrawal from chronic progesterone or allopregnanolone has been shown to be associated with enhanced expression of $GABA_A$ receptor $\alpha 4$ subunit, a molecular signal for increased neuronal excitability and seizure susceptibility.

Several conventional AEDs are used in catamenial epilepsy therapy. However, catamenial seizures are often not successfully treated with these AEDs. Hormonal agents, such as progesterone and neurosteroids, may provide rational therapy for catamenial epilepsy. Progesterone supplementation has been shown to reduce catamenial seizure frequency in women with epilepsy. Using the catamenial epilepsy model, we evaluated the hypothesis that neurosteroid 'replacement' is an effective and rational therapy for catamenial epilepsy. Our results show that neurosteroids that positively modulate $GABA_A$ receptors have significant anticonvulsant potency in our

model, providing support for a neurosteroid 'replacement' approach to the treatment of catamenial epilepsy. Pilot clinical studies indicated beneficial effect with ganaxolone, but it is not yet evaluated in controlled clinical trials.

Estrogens, Aromatase and Seizure Susceptibility

Estrogens play an important role in seizure susceptibility. There are three biologically active forms of estrogen: 17β-estradiol, dominant in pre-menopausal women; estriol, the major form of estrogen during pregnancy; and estrone, which is prevalent after menopause. Estradiol has been shown in many studies to have significant proconvulsant effects. It facilitates various forms of induced seizures, and has been shown to worsen seizures in women with epilepsy. On a cellular level, estradiol, aside from its normal reproductive effects, enhances neural excitation and suppresses inhibition. It also leads to changes in the physical properties of some neurons – such as increase in excitatory dendritic spine density in the hippocampus – which are consistent with an increased potential for seizures. Therefore, the periovulatory catamenial exacerbation has been attributed to the midcycle surge of estrogen that is relatively unopposed by progesterone until early luteal phase. An increase in the ratio of estrogen-to-progesterone levels during perimenstrual period might at least partly contribute to the development of perimenstrual seizure exacerbation.

The effect of estrogens on cortical excitability and on seizure frequency, however, is controversial. There are also studies that support an inhibitory effect of estrogens on cortical excitability and an estrogen protection from cortical or hippocampal injury. Estradiol regulation of the hippocampal expression of glutamic acid decarboxylase (GAD), the principal enzyme for the synthesis of inhibitory neurotransmitter GABA, could lead to a decrease in seizure susceptibility. Moreover, estradiol reduces seizure-induced hippocampal injury in ovariectomized female but not in male rats, suggesting that the effects of estradiol on seizure threshold and damage may be determined by sex-related differences in the hormonal environment.

Aromatase is the key enzyme for the conversion of testosterone to 17β-estradiol, a neuroactive steroid that promotes seizures (**Figure 1**). The aromatase enzyme is expressed in discrete areas in the brain, such as hippocampus and neocortex, that are involved in epileptogenesis. Aromatase inhibitors could decrease brain excitability by decreasing local estradiol levels and, therefore, could be beneficial for the treatment of epilepsy. Consequently, three different aromatase inhibitors have been tested in men with epilepsy: testolactone, letrozole and anastrazole; preliminary data suggests a beneficial effect.

Testosterone, Androgenic Neurosteroids and Seizure Susceptibility

Testosterone is the primary circulating androgen, and it produces rapid modulation of neuronal excitability. Experimental studies with testosterone have shown both pro- and anticonvulsant effects, depending on the animal model and the seizure type. Epidemiological data indicate that the occurrence of epileptic seizures is ~50% higher in intact than in castrated animals. The incidence of epilepsy is ~15% higher in men than in women, and men with epilepsy exhibit testosterone deficiency. Consistent with this notion of testosterone involvement in seizure propensity, experimental studies with kainic acid and pilocarpine – two widely used convulsants for induction of chronic temporal lobe-like epilepsy – indicate that the males are more susceptible to the convulsant effects than females. The presence of testosterone, in intact and in gonadectomized males with testosterone replacement, increased the susceptibility to seizures. In contrast, testosterone and related androgens appear to have protective effects against seizures induced by chemoconvulsants. Moreover, studies in orchidectomized or castrated animals have shown that decreased testosterone is associated with higher incidence of seizures, and that replacement of testosterone in these animals attenuates seizures. Alterations in testosterone levels, therefore, may possibly contribute to exacerbation of seizures. However, the cellular mechanisms by which testosterone causes such bimodal effects on seizure susceptibility are unclear.

There are two potential mechanisms by which testosterone exert neuroendocrine control of brain function: binding to intracellular androgen receptors (genomic) and metabolism to neurosteroids (non-genomic). Testosterone-derived 'androgenic neurosteroids' could be involved in mediating the testosterone effects on neural excitability (**Figure 1**). However, very little is known about the potential role of androgenic neurosteroids in gender-related differences in seizure sensitivity. Testosterone is metabolized to neurosteroids via two distinct pathways, an 'androgen pathway' and an 'estrogen pathway' (**Figure 1**). In the androgen pathway, 3α-androstanediol is synthesized from testosterone by two sequential A-ring reductions. 5α-reductase enzyme first converts testosterone to the intermediate 5α-dihydrotestosterone, which is then further reduced by 3α-HSOR to form 3α-androstanediol. 3α-Androstanediol has been shown to be a positive modulator of $GABA_A$ receptors, with powerful anticonvulsant and protective effects. Thus, 3α-androstanediol could play a key physiological role in mediating the effects of testosterone on cortical excitability, seizure activity, and neuroprotection. In the estrogen pathway, testosterone is converted into 17β-estradiol by the aromatase enzyme (see above).

Testosterone modulation of seizure susceptibility is thought to occur through its conversion to neurosteroids

with 'anticonvulsant' and 'proconvulsant' actions, and hence the net effect of testosterone on neural excitability and seizure activity depends on the levels of distinct testosterone metabolites. Changes in brain androgenic neurosteroid biosynthesis could affect not only seizure susceptibility, but also conditions such as cognitive dysfunction. Since aging is associated with low levels of testosterone, the loss of testosterone may contribute to increased seizure propensity in the elderly. However, despite the antiseizure effects of testosterone-derived 3α-androstanediol (as seen in animal models), testosterone itself has not been reported to improve seizures clinically. One possible explanation is that AEDs that induce enzyme synthesis may enhance the conversion of testosterone to 17β-estradiol, and presumably reduce the net availability of testosterone for the synthesis of 3α-androstanediol. This conjecture is supported by the improved seizure control achieved with testosterone therapy when testosterone was used along with an aromatase inhibitor (testolactone) that inhibits 17β-estradiol synthesis.

Deoxycorticosterone, Stress and Seizure Susceptibility

Stress affects seizure susceptibility in both genders. Acute stress causes increased production of hypothalamic corticotrophin-releasing hormone (CRH), which increases both adrenocorticotropic hormone (ACTH) synthesis and secretion. Major physiological effects of ACTH result from its action on the adrenal cortex to increase the circulating levels of corticosteroids, principally cortisol. The adrenal cortex contains two anatomically and functionally distinct compartments: the outer zona glomerulosa, which secretes the mineralocorticoid aldosterone; and the inner zonae fasciculata/reticularis, which secrete the glucocorticoids cortisol as well as the adrenal androgens. Deoxycorticosterone (DOC), a mineralocorticoid precursor with anesthetic and antiseizure properties, is also produced in the adrenal zona fasciculata. Recent studies indicate that the antiseizure activity of DOC requires its enzymatic conversion to 3α,5α-allotetrahydrodeoxycorticosterone (THDOC), a neuroactive steroid that lacks classical hormonal properties but acts as a powerful positive allosteric modulator of the $GABA_A$ receptors (**Figure 2**).

It has been proposed that THDOC play a role in mediating DOC function in stress and related neuroendocrine conditions in males and females. Stress increases plasma and brain concentrations of corticosteroids and neuroactive steroids. Cortisol is the most important stress hormone in the hypothalamic pituitary adrenocortical system. However, a significant amount of DOC is also released during stress (which subsequently undergoes biotransformation to THDOC). Although the role of THDOC within the brain is undefined, recent studies indicate that stress induces THDOC to levels that can activate $GABA_A$ receptors. These findings have obvious implications for stress-sensitive conditions such as epilepsy and post-traumatic stress disorder. Moreover, it is widely believed that emotional factors can affect seizure control. In general, stressful events are associated with more frequent epileptiform discharges and seizures. However, acute stress has anticonvulsant-like effects in animals. Therefore, the exact pathophysiology of possible seizure facilitation by stress is unclear, but there are certainly many neural and endocrine pathways through which stress can alter excitability and thereby affect seizure susceptibility. The extent of seizure susceptibility during stress, in both males and females, is likely to reflect the balance between endogenous anticonvulsants (such as neurosteroids) and proconvulsant factors (such as glucocorticoids). Gender differences in stress-induced seizures may arise due to differences in the secretion of anticonvulsant or proconvulsant steroid hormones.

Directions for Future Research

Gender-related differences in epileptogenesis and AED therapy are not well studied. The major goal of epilepsy research is to characterize the biological basis of sex differences in susceptibility to seizure disorders and to develop rational therapeutic strategies for gender-specific epilepsies. Although steroid hormones and sexually dimorphic brain structures play an important role in gender-related seizure susceptibility, the precise neuroendocrine mechanisms underlying such sex differences in seizure occurrence and antiseizure drug actions remain unclear. Understanding the fluctuations in steroid hormones in men and women, and their influence on seizure susceptibility, is fundamental for developing gender-specific strategies for epilepsy therapy.

The effects of steroid hormones on neuronal plasticity are complex. Estrogens and testosterone have largely excitatory effects, while progesterone, DOC and neurosteroids are powerful anticonvulsants. There is emerging evidence on the role of neurosteroids in the regulation of GABAergic inhibition. Neurosteroid-based treatments are being developed for gender-specific conditions such as catamenial epilepsy. An NIH-funded study is evaluating the effects of progesterone in women with epilepsy. Future studies should focus on uncovering short- and long-term molecular changes in GABAergic and glutamatergic receptor systems in relation to natural fluctuations in steroid hormones. A major challenge in the field of neurosteroids is to develop specific antagonists for neurosteroid sites on GABA-A receptors. Further studies are, therefore, clearly warranted to uncover the molecular mechanisms of neurosteroid actions and the role of neurosteroids in men and women with epilepsy.

Introduction

Epilepsy is a paroxysmal neurological disorder characterized by synchronous high voltage discharges arising from a population of hyperexcitable neurons. Approximately 0.5–3% of the world population suffers from epilepsy. In most patients with epilepsy, the prognosis for seizure control is good. However, 20–30% of epileptic patients develop intractable epilepsies that are unresponsive to treatment, despite the advent of new antiepileptic drugs and development of intensive monitoring. Advances in brain imaging and seizure mapping techniques have made surgery an option for patients in whom a clearly defined, surgically approachable epileptic focus can be identified. The interest in surgical treatment for epilepsy over the past decades has been accompanied by an increasing opportunity for basic neuroscientists to perform research on epileptic patients (and tissue resected from these patients), not only to validate observations made in animal investigations but also to characterize specific aberrant phenomena in human epileptic brain. Surgical resection provides tissue that can be used for electrophysiological, morphological, biochemical, and molecular biological investigations. The availability of human brain tissue resected from patients undergoing neurosurgical treatment for refractory epilepsy has provided investigators with the opportunity to identify abnormalities promoting hyperexcitability in epileptic tissues, and to develop hypotheses regarding the underlying pathophysiological mechanisms of epilepsy. Such phenomena can then also be modeled in animals, and studied at a mechanistic level in order address specific novel hypotheses.

Background

Revealing the three-dimensional functional organization of a given cortical area is a key step towards understanding the mechanisms of information processing in that area. Thus, experimental methods that allow the visualization of functional organization across large areas of cortex are of special importance. Voltage-sensitive dye imaging provides the possibility for recording neuronal activity with adequate temporal and spatial resolution. Optical techniques, using a multiple-element photodiode array, have facilitated simultaneous multiple site recordings of

electrical activity in a given preparation. Optical imaging with voltage-sensitive dyes permits the visualization of cortical activity with a sub-millisecond time resolution and a spatial resolution of 50–100 μm. Other advantages of this method are: (i) the direct recording of the summed intracellular activity of neuronal populations, including fine dendritic and axonal processes; (ii) the possibility of repeated measurements from the same cortical region under different experimental and/or stimulus conditions over an extended period of time; and (iii) selective visualization of neuronal assemblies (**Figure 1**).

Methods

Our studies were carried out on slices of human neocortical tissue, excised for treatment of pharmacoresistant temporal lobe epilepsy. From a 1-cm^3 block of the inferior temporal gyrus, 450-μm coronal sections were made with a vibratome within 5 min after resection. These slices were placed in a portable incubation chamber with oxygenated (95% O_2–5% CO_2) and warmed (28 °C) artificial cerebrospinal fluid (ACSF) containing (in mM): 124 NaCl, 4 KCl, 2 $CaCl_2$, 1.24 NaH_2PO_4, 1.3 $MgSO_4$, 26 $NaHCO_3$, and 10 glucose (pH 7.35–7.45). Slices were stained with 12.5 μg ml^{-1} of the voltage-sensitive dye RH795 1 h prior to the experiment, and washed for 1 h before they were transferred to a submerged-type recording chamber (32 °C) mounted on an inverted microscope. Field potentials were recorded from cortical layers II/III and V using conventional glass micropipettes filled with ACSF. Slices were scanned electrophysiologically for spontaneous rhythmic epileptiform sharp waves (SRSW), by repositioning field potential electrodes to at least six different sites, distributed roughly equally across the slice.

Dye-related fluorescence signals were detected by a 464-element honey-comb-shaped photodiode array, at a rate of 785 frames per second; images were obtained via 10× and 20× objective lenses, yielding total fields of view of 1500 and 750 μm diameter, respectively. Xenon lamp illumination was allowed for a maximum of 4 s per single detection period, and detection periods were separated by at least 5 min each. Optical data were assessed as fluorescence changes relative to resting light intensity (dI/I) using NeuroPlex software (RedShirt Imaging, LLC, Fairfield, CT), precluding signal variability due to inhomogeneous illumination or differences in lens properties. For trace illustrations, optical and field potential signals were low-pass-filtered (Butterworth filter, 30 or 50 Hz). Unfiltered fluorescence changes were converted to pseudocolor images scaled to the center diode. The fluorescence change dI/I for typical event was 0.05–0.3% of resting light intensity. The correlation of the dye signal and bioelectrical neuronal activity is explained in **Figure 1**.

Results

Voltage-Sensitive Dye Imaging

In previous studies, spontaneous rhythmic epileptiform sharp waves (SRSW) were found to occur spontaneously in 20–30% of human epileptic neocortical slices. Such spontaneous potentials are characteristic of chronically epileptic human brain tissue, as these potentials cannot be observed in animal tissue, nor in human brain slices obtained from tumor resections from patients without clinical signs of seizures. Although synchronous rhythmic waves do not resemble typical ictal activity (as elicited in different in vitro models), these potentials reflect a heightened propensity of network synchronization. Spontaneous rhythmic potentials are accompanied by extended focal neuronal hyperpolarization and depolarization. As these potentials reflect a state of increased neuronal synchronization, it was suggested that spontaneous sharp waves might facilitate initiation or spread of seizures under certain conditions.

The epileptiform activity pattern in human tissue differed considerably across tissue samples. Localized and spatially inhomogeneous neuronal depolarizations, as determined by voltage-sensitive dye recordings, were found to underlie these sharp waves. Hot spots of neuronal depolarizations were spatially dynamic. With gradual build-up of the SRSW, an increasing number of photodiodes detected depolarizations, reaching a maximum at ~14 ms after the peak of the SRSW. Depolarizations at individual diodes could be distinguished at all times during the recording, creating dynamic activation patterns of activity: only rarely, at the peak of the sharp wave event, did some diodes with maximal activity converge to cover larger fields. Other diodes showed a decrease of noise instead of a clear-cut signal, possibly a sign of disfacilitation. Although maximal neuronal depolarizations were thus inhomogeneously distributed, SRSW-associated depolarizations were a population phenomenon. Before the SRSW, only 2% of the total area of the optical recording field showed maximal depolarization changes, possibly reflecting asynchronous spontaneous action potentials of single neurons or small neuronal clusters.

In experiments on brain slices from human epileptic cortex, we attempted to increase tissue excitability by superfusion of low Mg^{2+} solution. This treatment had no significant effect on the spatiotemporal distribution of epileptiform discharge in 70% of tissue samples. However, in 30% of these slices, the activity pattern appeared atypical with respect to the extent of spread of activity (both vertically and horizontally). Maximal stimulation in white matter evoked depolarizations of high amplitude, both in infragranular and in supragranular layers of the temporal neocortex – a pattern not normally seen in nonsensory neocortex. In addition, stimulation in layer

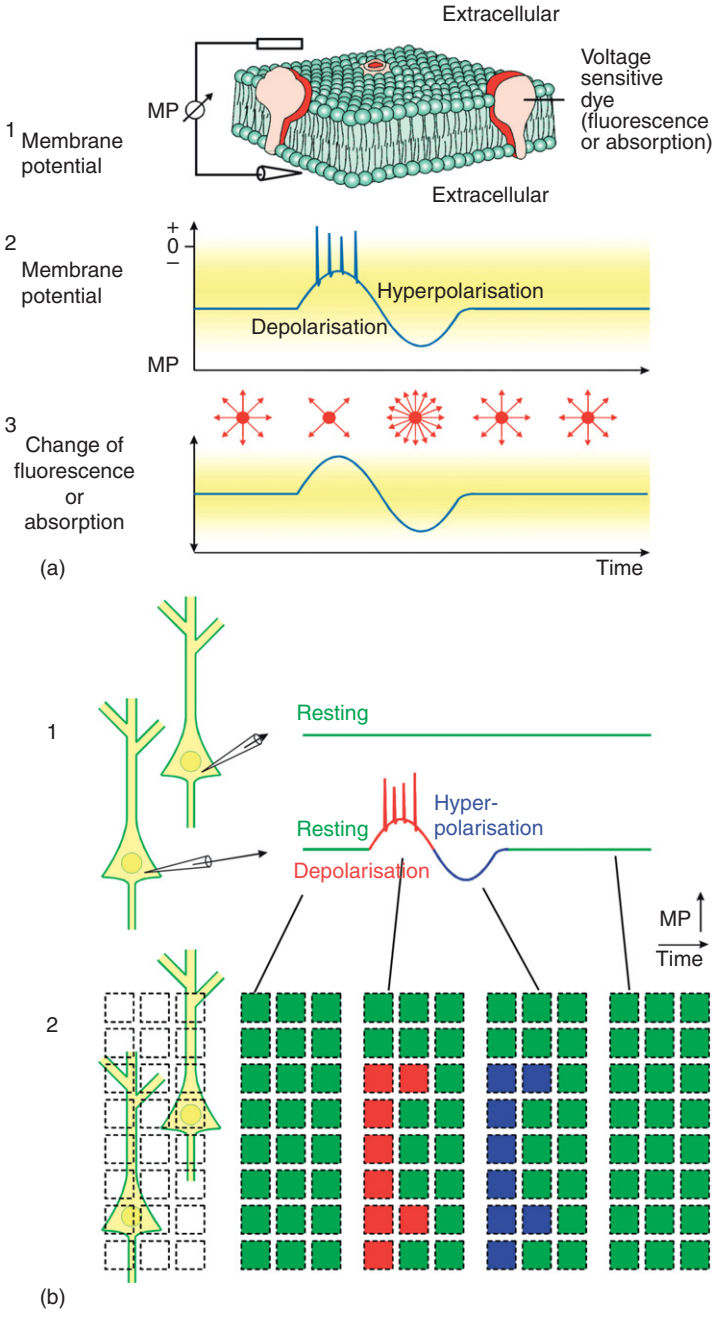

Figure 1 Recordings of neuronal membrane potentials using voltage-sensitive dye imaging. (a) 1 – the dye binds to the lipid bilayer of the membrane and changes in transmembrane potential are reflected in the spectral properties of the dye. Simultaneously, the membrane potential is recorded with an intracellular microelectrode. The voltage sensitive dye produced fluorescence changes when excited at the proper wavelengths. 2 – Changes of the membrane potentials from resting levels by an initial depolarization followed by hyperpolarization. 3 – Corresponding to the changes of the membrane potentials the fluorescence or absorption of the dye varied. With fluorescence dyes depolarization leads to a decrease and hyperpolarization to an increase of radiation (marked by symbols). (b) 1 – Schematic diagram of two neurons; one of which is in the resting state, the other one shows changes in the membrane potentials in depolarizing and hyperpolarizing direction. 2 – With the aid of microscope coupled with matrix photodiodes the different bioelectrical activities of the two neurons can be recorded via different optical behavior. I evoked activity in all supragranular layers during control condition. However, in some human slices, activity evoked during superfusion with Mg^{2+} free solution was limited to the region in the direct neighborhood of the stimulation electrode in layers I/II. In these slices, the evoked activity pattern typically seen during Mg^{2+}-free superfusion was already apparent under control conditions. Furthermore, in other slices, layer I stimulation evoked 'islands' of

Münster: Daedalus Verlag.

excitation, which were inhomogeneously scattered over the whole slice. Clear boundaries usually found around layer IV were missing. The described activity pattern correlates in principle with the neuropathological diagnosis of laminar disorders, as in fact was found for the demonstrated case. These data show that dye imaging can be quite effective in demonstrating abnormal organization and intrinsic epileptiform properties of some resected tissues from epilepsy surgery (Figure 2).

Directions for Future Research

Important future discoveries in this field will require further development of imaging techniques. These techniques should be capable of comparing data obtained from epileptic brain before the surgical intervention (preoperative studies), on the intervention itself (intraoperative studies), and on the period when the part of the brain that has to be removed (postoperative studies). Such technical advances may lead to a better diagnosis and treatment of medically refractory epilepsy.

Introduction

Functional neuroimaging encompasses several important techniques used to approximate neuronal activity throughout the brain during normal and pathophysiological states. These techniques have proven useful particularly in the study of epileptic seizures, which often involve significant alterations in activity affecting widespread networks throughout the brain. Although functional imaging studies of seizures in animal models have lagged considerably behind investigations of human patients with epilepsy, the recent burgeoning of functional magnetic resonance imaging (fMRI), as well as technological advances in other neuroimaging methods, has resulted in an increase in basic imaging studies of epileptic states. These developments provide a novel and exciting opportunity for epilepsy researchers, as unlike human imaging studies, animal models allow experimenters to control seizures onset and type as well as employ various therapeutic interventions. Furthermore, functional neuroimaging can serve to complement invasive electrophysiological techniques (which possess excellent temporal resolution but limited spatial sampling), as well as histological studies (which permit detailed spatial sampling and resolution but are limited to a single point in time), to allow dynamic mapping of activity in the epileptic brain.

Epilepsy represents a heterogeneous group of chronic disorders associated with intermittent pathophysiological neuronal activity. Thus, one major goal of functional imaging studies of epilepsy is to obtain accurate characterization of neuronal activity within focal brain regions and related networks, as they are affected by each different type of seizure. Knowledge of which brain areas are involved in specific kinds of seizures may facilitate the discovery of targeted pharmacological, surgical, or genetic therapies aimed at interfering with the development or progression of epilepsy. Finally, in addition to mapping seizure origin and propagation, functional neuroimaging can provide a useful tool for understanding the effects of epilepsy on brain networks outside the seizure focus – information that may be relevant to functional brain impairment and cognitive dysfunction during ictal and interictal periods.

The major functional imaging techniques currently employed in animal studies to address these issues include fMRI, positron emission tomography (PET), and magnetic resonance spectroscopy (MRS). Given that each major neuroimaging technique employed in basic epilepsy research measures a different aspect of neurophysiology, the best method to utilize in a particular study is heavily dependent on the nature of the research question. For instance, while most PET and MRS measurements have relatively low temporal resolution, fMRI images can be acquired sequentially in the same experiment, up to a frequency of several per second. Thus, fMRI is a useful tool for tracking changes in neuronal activity during individual epileptic events with relatively high temporal and spatial resolution. In contrast, although PET experiments typically require serial acquisitions over longer time, the increasing availability of novel tracers allows investigation into specific biomolecular changes across multiple

Introduction

Functional neuroimaging encompasses several important techniques used to approximate neuronal activity throughout the brain during normal and pathophysiological states. These techniques have proven useful particularly in the study of epileptic seizures, which often involve significant alterations in activity affecting widespread networks throughout the brain. Although functional imaging studies of seizures in animal models have lagged considerably behind investigations of human patients with epilepsy, the recent burgeoning of functional magnetic resonance imaging (fMRI), as well as technological advances in other neuroimaging methods, has resulted in an increase in basic imaging studies of epileptic states. These developments provide a novel and exciting opportunity for epilepsy researchers, as unlike human imaging studies, animal models allow experimenters to control seizures onset and type as well as employ various therapeutic interventions. Furthermore, functional neuroimaging can serve to complement invasive electrophysiological techniques (which possess excellent temporal resolution but limited spatial sampling), as well as histological studies (which permit detailed spatial sampling and resolution but are limited to a single point in time), to allow dynamic mapping of activity in the epileptic brain.

Epilepsy represents a heterogeneous group of chronic disorders associated with intermittent pathophysiological neuronal activity. Thus, one major goal of functional imaging studies of epilepsy is to obtain accurate characterization of neuronal activity within focal brain regions and related networks, as they are affected by each different type of seizure. Knowledge of which brain areas are involved in specific kinds of seizures may facilitate the discovery of targeted pharmacological, surgical, or genetic therapies aimed at interfering with the development or progression of epilepsy. Finally, in addition to mapping seizure origin and propagation, functional neuroimaging can provide a useful tool for understanding the effects of epilepsy on brain networks outside the seizure focus – information that may be relevant to functional brain impairment and cognitive dysfunction during ictal and interictal periods.

The major functional imaging techniques currently employed in animal studies to address these issues include fMRI, positron emission tomography (PET), and magnetic resonance spectroscopy (MRS). Given that each major neuroimaging technique employed in basic epilepsy research measures a different aspect of neurophysiology, the best method to utilize in a particular study is heavily dependent on the nature of the research question. For instance, while most PET and MRS measurements have relatively low temporal resolution, fMRI images can be acquired sequentially in the same experiment, up to a frequency of several per second. Thus, fMRI is a useful tool for tracking changes in neuronal activity during individual epileptic events with relatively high temporal and spatial resolution. In contrast, although PET experiments typically require serial acquisitions over longer time, the increasing availability of novel tracers allows investigation into specific biomolecular changes across multiple

imaging sessions. This capability makes small animal PET (saPET) a particularly useful tool for studying the slower biophysiological changes inherent to epileptogenesis. Furthermore, MRS can be used to detect subtle metabolic and neurochemical differences in epileptic tissue with high sensitivity and specificity.

The remainder of this article will focus on the use of fMRI in epilepsy research; other articles will discuss other imaging modalities in more detail.

Background

Neuroimaging Signals are Indirectly Related to Neuronal Activity

Although functional neuroimaging studies are used to assess neuronal activity during various states, all neuroimaging signals are only indirectly related to neuronal activity. Neuronal activity encompasses several energy-requiring processes, including presynaptic action potentials, Ca^{2+} currents, neurotransmitter release and repackaging, and postsynaptic potentials. However, functional imaging techniques such as fMRI, PET, and MRS measure changes in cerebral oxygenation, cerebral metabolism and blood flow, and brain metabolite and neurotransmitter concentrations, respectively. Thus, interpretation of functional neuroimaging studies depends on the assumption that alterations in neuronal activity are highly correlated with changes in these neurophysiological parameters, and the inherent limitations of this assumption must be considered carefully.

The Biophysical Basis of the BOLD Signal

In 1936, the Nobel laureate chemist Linus Pauling and his student Charles Coryell discovered that the hemoglobin molecule has magnetic properties that differ depending on whether it is bound to oxygen. While oxygenated hemoglobin is diamagnetic, having no unpaired electrons and zero magnetic moment, deoxygenated hemoglobin has a significant magnetic moment. In the late 1980s, Seiji Ogawa correctly hypothesized that the magnetic susceptibility of deoxyhemoglobin would cause nuclear spin dephasing upon its introduction into the magnetic field of an MRI machine, resulting in a decay of transverse magnetization that depends on the time constant T_2^*. Thus, by inducing a decrease in T_2^*, deoxyhemoglobin acts as an endogenous paramagnetic contrast agent. As a result, the blood oxygen level dependent (BOLD) fMRI signal intensity reflects net oxygen delivery to the brain, which in turn depends on a balance between cerebral blood flow (CBF), cerebral blood volume (CBV), and the cerebral metabolic rate of oxygen consumption ($CMRO_2$).

Interpreting fMRI Results

A well supported theory in the study of neurovascular responses is that an increase in neuronal activity results in enhanced cerebral metabolism, and a compensatory increase in CBF. The increase in CBF usually exceeds metabolic need, resulting in a net increase in oxygenation. Therefore, an increase in neuronal activity typically results in an overall increase in oxygenation and a BOLD activation. The implications of this finding have allowed fMRI to emerge as a powerful tool in the study of both physiological and pathophysiological brain states, such as epilepsy. However, a more controversial question in fMRI has been whether diminished neuronal activity will produce an overall decrease in oxygenation and a BOLD deactivation, and whether fMRI deactivations always represent decreased neuronal activity. Although commonly reported, negative BOLD signals have been less thoroughly studied and controversy over their origin has led to some uncertainty in their interpretation.

Methods

To date, human fMRI studies of epilepsy have far outnumbered basic animal studies of the disease. However, because of issues related to movement artifact, investigations in humans have predominantly been restricted to recordings of nonconvulsive absence (spike-wave) seizures and interictal events. For this reason, anesthetized and paralyzed animal models provide a unique opportunity to study various seizure types in a controlled environment with high-field fMRI. An additional advantage of using animal seizure models in fMRI investigations is the ability to corroborate changes observed in the BOLD signal using invasive electrophysiological techniques in the same or similar preparation. This benefit is particularly useful given controversy in directly relating BOLD signal changes to alterations in neuronal activity.

Using anesthetized and paralyzed rat models, our laboratory has successfully collected high-field fMRI and simultaneous electroencephalogram (EEG) recordings of both convulsive and nonconvulsive seizures, including models of both generalized and partial epilepsy. Previous human neuroimaging studies have examined absence (petit mal) epilepsy, a generalized seizure disorder characterized by 5–10 s episodes of unresponsiveness that are associated with spike-wave discharges (SWD) on EEG. However, these studies have produced inconsistent results regarding whole-brain energetics, and have not clearly identified which specific brain areas are involved. To begin to clarify these discrepancies, we have performed both 7 T and 9.4 T fMRI with simultaneous EEG recordings of SWD in the Wistar Albino Glaxo rat of Rijswijk

(WAG/Rij) rat, an established model of absence epilepsy in which animals display frequent, spontaneous spike-wave seizures.

All fMRI studies of SWD to date have been performed in WAG/Rij rats, genetic absence epilepsy rats from Strasbourg (GAERS), or through chemically-induced spike-wave seizures induced using gamma-butyrolactone (GBL) in normal rats. For simultaneous fMRI/EEG studies of SWD, animals are anesthetized with fentanyl and haloperidol injections every 45 min, paralyzed with tubucurarine to prevent movement, and artificially ventilated. The fentanyl/haloperidol regimen is a drug combination that provides reliable anesthesia without suppressing SWD. A 30 min run of simultaneous EEG (using carbon filament electrodes under the scalp) and fMRI typically allows sufficient time to record 20–50 SWD. Imaging 10–12 coronal slices of 1-mm thickness over 1 s with a 5 s break in between each acquisition permits ample artifact-free EEG recordings to conveniently distinguish images corresponding to 'seizure' versus nonseizure 'baseline.' Generating t-maps comparing images between these two states then allows the identification and quantification of fMRI signal differences in brain regions involved in the SWD.

In contrast to nonconvulsive absence epilepsy, no human fMRI recordings have been collected during generalized tonic–clonic (grand mal) seizures. This gap provides a particularly important opportunity for animal studies of this form of epilepsy. While investigations of spontaneous generalized tonic–clonic seizures have not yet been performed, fMRI studies of seizures induced by chemoconvulsant agents have been completed by several laboratories. For instance, our laboratory has collected recordings of tonic–clonic seizures in anesthetized–paralyzed rats induced acutely by bicuculline administration. After fMRI and EEG recordings of 5 min baseline period, an intravenous injection of bicuculline produces generalized seizures within several minutes. Comparing functional images acquired during baseline with those collected continuously throughout the ictal and postical periods allows the tracking fMRI signal changes throughout the brain during and after these tonic–clonic seizures.

Recent Results

WAG/Rij rats display frequent spontaneous spike-wave seizures that are not blocked by fentanyl/haloperidol anesthesia, thus providing a convenient model to study SWD using simultaneous fMRI and EEG recordings. During these SWD in anesthetized/paralyzed animals, our laboratory observed BOLD signal increases (compared with baseline) in several cortical and subcortical regions, most prominent in the somatosensory cortex, motor cortex, thalamus, and brainstem (**Figure 1(a)**). Recent studies from our laboratory, and work by others, have suggested that fMRI decreases occur in the basal ganglia during SWD in rats. Notably, fMRI signal changes did not involve the whole brain uniformly, as occipital regions were largely unaffected (**Figure 1(a)**). Thus, although SWD are considered generalized epileptic events, these experiments suggest focal involvement of specific brain regions with relatively sparing of other areas. Bench-top experiments have also been performed on animals under the same conditions to measure both electrophysiological signals and CBF (using laser Doppler flowmetry probes). We have observed that recordings in regions showing increased fMRI signals during SWD, such as the barrel somatosensory cortex, display increased CBF, and neuronal firing (**Figure 1(b)**). In contrast, little (if any) change in neuronal firing and CBF was seen in areas lacking BOLD signal changes, such as the primary visual cortex (V1M) (**Figure 1(b)**).

Using anesthetized, paralyzed rats, our laboratory recently completed a multimodal fMRI and electrophysiology study of generalized tonic–clonic seizures induced by intravenous administration of the proconvulsive agent bicuculline. During seizures, large BOLD signal increases were seen in thalamic and widespread cortical regions (**Figure 2(a)**). These changes resembled those recently reported by others during generalized tonic–clonic seizures induced by the drug pentylenetetrazole. Interestingly, however, we also observed ictal fMRI decreases in the hippocampus during several of the recorded events (**Figure 2(a)**). These hippocampal decreases seemed perplexing, as limbic structures, such as the hippocampus are often intensely involved in generalized tonic–clonic seizures. To clarify this unexpected finding, we directly measured neuronal activity and CBF during seizures in this model, in both the hippocampus and cerebral cortex, using microelectrodes and laser Doppler flowmetry probes. These recordings showed that despite opposite BOLD signal changes in the hippocampus and the cortex, both regions showed large increases in CBF, local field potentials (LFP), and multiunit activity (MUA) during seizures (**Figure 2(b)**). Furthermore, whereas the ictal elevations in CBF in both regions were of similar magnitude, MUA showed significantly greater increases in the hippocampus than in the cortex. These results suggest an uncoupling of the BOLD signal from CBF and neuronal activity in the hippocampus of this seizure model, likely resulting from an abnormally elevated metabolic rate ictally that exceeds the delivery of oxygen. This observation serves as an important cautionary reminder that BOLD signal changes may not directly represent similar alterations in neuronal activity. Thus, while fMRI studies can provide significant useful information regarding network involvement of various seizure types, results should be corroborated using alternate means.

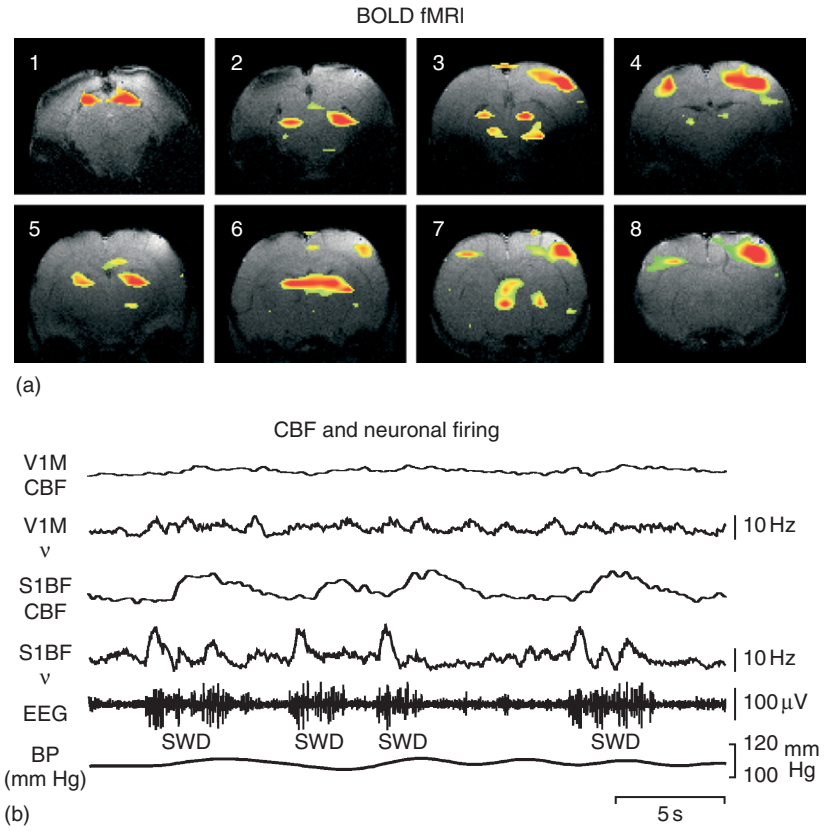

Figure 1 fMRI and electrophysiology recordings during spike-wave discharges (SWD). (a) Example of BOLD fMRI activations during spike-wave discharges. fMRI signal increases during SWD in a WAG/Rij rat under fentanyl-haloperidol anesthesia. t-maps were calculated from 23 SWD pairs recorded during one uninterrupted experimental run and were overlaid onto corresponding high-resolution anatomic images. Eight coronal slices were acquired from back to front (numbered 1–8) at 1-mm intervals, with the first slice at approximately −7.04 and the last slice at +0.40 mm relative to bregma. Bilateral and relatively symmetrical increases in BOLD signal were present mostly in frontoparietal cortex, thalamus, and brainstem nuclei, whereas occipital regions did not show significant changes. (b) Dynamic recordings of CBF and neuronal activity during SWD. Changes in CBF and neuronal activity were recorded by combined Doppler flowmetry and extracellular multiunit recordings obtained simultaneously during multiple episodes of SWD, along with EEG and arterial blood pressure (BP) monitoring in a WAG/Rij rat under fentanyl/haloperidol anesthesia. Spontaneous SWD induce parallel increases in CBF and neuronal firing rate (ν) in barrel cortex (S1BF), and no or very small increases in primary visual cortex (V1M). CBF variations are independent of arterial BP fluctuations. **Figure 1(a)**: reproduced with permission from Nersesyan *et al*. (2004a); **Figure 1(b)**: reproduced with permission from Nersesyan *et al*. (2004b).

To date, most fMRI reports of basic animal epilepsy models have focused on generalized epilepsy, although researchers in our laboratory and others elsewhere have begun to investigate partial seizures. Such studies of partial epilepsy are particularly important, as temporal lobe epilepsy, one of the most common seizure disorders in humans, most frequently presents as a partial seizure disorder. Furthermore, fMRI studies of partial seizures will not only allow insight into the focal regions involved in the seizure, but also provides an opportunity to study the effects of partial seizures on distant uninvolved brain networks. Recent work in our laboratory in a limbic seizure model has demonstrated that during focal seizures, there are fMRI signal increases in the hippocampus, but decreases in the frontal association cortex. Electrophysiology recordings in the frontal association cortex during seizures revealed cortical slow oscillations, resembling those seen in states of deep sleep or anesthesia. These remote network effects of focal seizures may explain behavioral impairment such as loss of consciousness during limbic seizures.

Future Goals

Rapid advances in magnetic resonance technology, including the production of faster and higher field strength hardware, and the development of improved analysis software, have led to increased opportunity for basic fMRI investigations of seizure disorders. In addition, various techniques have emerged that allow experimenters to utilize fMRI not only to evaluate the BOLD signal, but also to measure other hemodynamic responses in the brain. Notably, CBV can be measured throughout the brain using

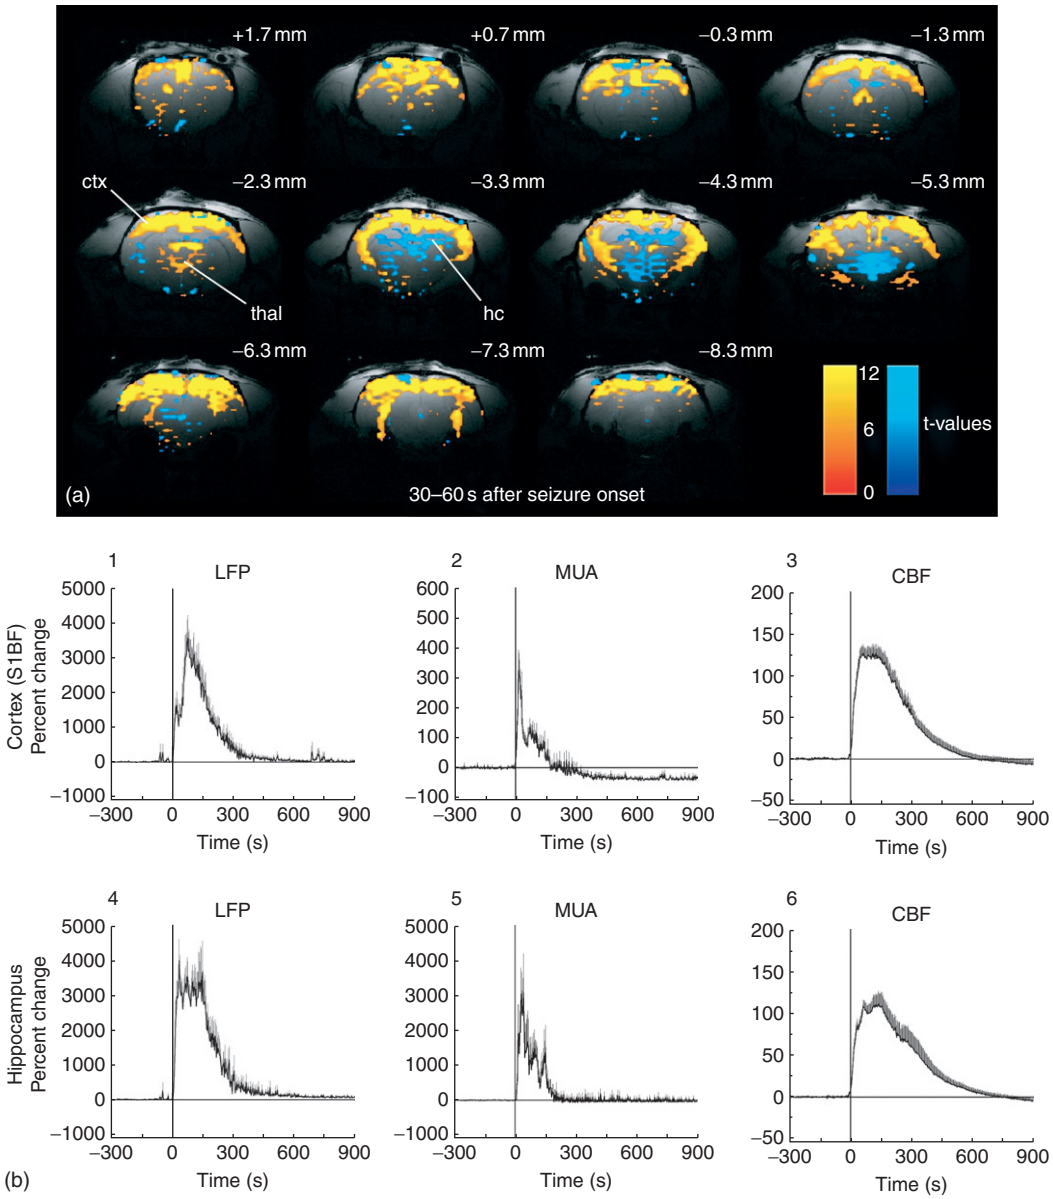

Figure 2 Changes in BOLD signal, CBF, and neuronal activity during bicuculline-induced generalized seizures. (a) Example of BOLD increases and decreases during bicuculline-induced generalized seizures. During the seizure, the BOLD signal showed not only a mixed pattern of widespread increases across the whole brain, including cortex (ctx) and thalamus (thal) but also prominent focal decreases, especially in hippocampus (hc). t-maps are shown for 30 s of data (10 consecutive fMRI images acquired every 3 s) during seizure compared with 30 s of baseline. Maps are superimposed on high-resolution anatomical images. Slices are shown from anterior to posterior, with approximate coordinates relative to bregma. Color bars indicate *t*-values for increases (warm colors) and decreases (cold colors). (b) Neuronal activity and CBF in both cortex (S1BF) and hippocampus show only increases during bicuculline-induced generalized seizures. Average time courses of percent signal change compared with 30 s of baseline data. Time courses are depicted as mean ± SEM (unidirectional only) and straight vertical line at time 0 marks seizure onset. Time courses on the top represent recordings for LFP power (1), MUA power (2), and CBF (3) in the barrel field cortex (S1BF), and on the bottom for LFP power (4), MUA power (5), and CBF (6) from hippocampus. Recording sites were matched to ROIs chosen in fMRI experiments. During seizures, LFP (1) and MUA (2) showed a marked increase in power in S1BF, accompanied by strong increases in CBF (3). Interestingly, hippocampal recordings also showed intense signal increases for LFP (4), MUA (5), and CBF (6) during seizures that were in marked contrast to the only slight changes or even decreases observed in the BOLD signal in the hippocampus. The signal changes in MUA power in the hippocampus during the first 150 s of seizures significantly exceeded those in the cortex ($P = 0.004$, 2-tailed unpaired *t*-test, $n = 43$). Note that *y*-axes in (2) and (5) are not drawn to the same scale. In both regions, the MUA also revealed a decrease in power after termination of the seizures, representing postictal depression commonly observed with this seizure type (postictal depression not visible in (5) due to scale). In (1–6) mean signals are based on the following number of experiments/animals: for cortex (S1BF) LFP (42/24), hippocampus LFP (38/22), cortex (S1BF) MUA (27/16), hippocampus MUA (16/10), cortex (S1BF) CBF (39/23), and hippocampus CBF (35/21). Adapted with permission from Schridde *et al*. (2008).

intravenous paramagnetic contrast during fMRI recordings, and CBF changes can be tracked by employing arterial spin labeling (ASL) and other techniques. Owing to this flexibility, investigators are now able to employ a multimodal approach to fMRI. Furthermore, by recording changes in the BOLD signal, CBV, and CBF during seizures, one can calculate high spatiotemporal resolution maps of the cerebral metabolic rate of oxygen consumption ($CMRO_2$) throughout the brain during these events using what is termed the 'calibrated BOLD' method. $CMRO_2$ is the most direct indication of neuronal activity short of simultaneous invasive electrophysiological recordings. Given that the BOLD signal is an indirect assessment of neuronal activity, the magnitude (or even sign) of BOLD signal changes might not accurately reflect true changes in neuronal activity throughout the brain. This problem was illustrated in the example described earlier of uncoupling between the BOLD signal and CBF in the hippocampus during generalized tonic–clonic seizures. Thus, the increased use of multimodal approaches to fMRI investigations will be an important advance in epilepsy neuroimaging, providing investigators with an opportunity to address the ambiguity inherent to BOLD signal interpretation.

In addition to the availability of multimodal neuroimaging techniques, the increased use of MRI-compatible recording electrodes has further improved interpretability of fMRI by allowing concurrent imaging and electrophysiology recordings within the same experiment. Performing simultaneous electrophysiology recordings with deep microelectrodes during fMRI studies was recently pioneered by Nikos Logothetis and colleagues in animal studies of nonepileptic states, although use of the technique in epilepsy studies has been limited. Our laboratory is now completing a study of partial seizures in rats during simultaneous fMRI, EEG, and hippocampal local field potential recordings. Although technically more challenging than unimodal fMRI studies, electrophysiological recordings provide the most direct assessment of neuronal activity and corroboration of BOLD signal changes.

Given the expanded availability and utility of current neuroimaging tools, there is currently an exciting potential for further fMRI studies of seizures. Although an understanding of its limitation and the use of corroboratory methods are essential, with proper utilization, fMRI will continue to offer a useful and versatile tool for studying epilepsy.

Optical Imaging in Epilepsy Research: Overview of Methods and Applications

Introduction

From DNA transcription within a single nucleus to cortical oscillations involving large networks of interacting neurons, different neurobiological activities have their natural temporal and spatial scales over which they are best characterized and studied. A variety of optical imaging methods are now available that are able to capture data from living brain tissue over a remarkable range of scales in time and space. For example, the location and timing of gene expression within individual cells can be measured using transgenic expression of fluorescent proteins, and patterns of neuronal firing activity over centimetres of intact cortex can be mapped using voltage-sensitive dyes. The applicability of an imaging method to a particular problem depends on whether the anatomical structures, molecules, or ions of interest can be selectively labeled with an optical reporter or dye, and whether the labeled target can be detected with an optical system.

All optical imaging techniques share some common features: a preparation is illuminated with light at one or several specific wavelengths, and photons that are reflected, absorbed, or fluoresced from the preparation are recorded by a detector (such as a camera or photodiode). Typically, the photons reflected or fluoresced from the specimen are first passed through a microscope or other optical lens system for focusing or magnifying the field of interest. When an optical dye is used to stain tissue or a cell, investigators use an illumination wavelength (the 'excitation wavelength') that excites the dye molecules to fluoresce and emit photons at a distinctly different wavelength (the 'emission wavelength'). In this way, the signal of interest at the emission wavelength is not contaminated by the photons used to excite the probe at the excitation wavelength. Some optical imaging methods rely on exciting endogenous light absorbing or fluorescing molecules, such as haemoglobin or NADH. Since these techniques depend upon chromophores or fluorescing molecules that are intrinsic to the cells or tissue, they are sometimes called 'intrinsic optical imaging' techniques.

Background and Methodological Issues

Common Imaging Detectors

Charge-coupled device (CCD) cameras

A CCD camera relies on a silicon wafer which has been manufactured to contain an array of individual light-sensitive cells called photosites. Each photosite contributes one element of the whole image that is formed, and is more commonly referred to as a picture element, or 'pixel.' Photosites generate and hold an electric charge that is proportional to the number of photons detected at that given site. The charge stored at each site is then digitized at some resolution (e.g., 16-bit cameras are capable of distinguishing between 2^{16} distinct levels of photon intensity), and software is used to convert the digitized representation of the CCD chip into an image. More expensive CCD cameras mount their detector chips on cooling-devices to reduce electrical noise. CCD cameras offer the special advantage of being able to provide high spatial resolution, but are relatively slow compared to other optical detection technologies. One strategy to improve image-acquisition speed is to include the hardware for digitization inside the camera electronics to directly digitize the data. Since these types of cameras provide a digital output rather than an analog signal, they are referred to as 'digital CCD cameras.' A typical spatial resolution of a CCD camera is 512×512, capable of measuring light at over 260 000 points on a specimen focused on the CCD chip.

Photodiode array

Photodiodes are optical detectors that are capable of converting light into voltage or current. Photodiode arrays used in optical imaging studies typically consist of a few hundred photodiodes, and hence offer much less spatial resolution than a CCD camera. However, this technology offers several significant advantages over the CCD camera, including extremely high data acquisition rates (sufficient to resolve individual action potentials), high dynamic range, and excellent linearity of output (current or voltage) as a function of incident light. This last attribute of linearity is critical for enabling quantitative analysis of optical measurements.

Confocal microscopy

When using classical wide field microscopy for optical imaging, the entire specimen is illuminated with light, and photons reflected or fluoresced by the specimen are passed through a lens system to some optical detector, such as a CCD camera or photodiode array. One disadvantage of this method is that light from areas of the specimen outside the focal plane contribute to the image. This results in a blurring of the image – a feature

that places a fundamental limit on what can be spatially resolved. Confocal microscopy overcomes this limitation by using point-illumination, in combination with a pinhole in an optically conjugate plane in front of the detector to eliminate out-of-focus information. A laser is used to scan the specimen to illuminate one point at a time, and the fluoresced light from each individual point is detected by a photomultiplier detector, the signal from which is digitized. Software is used to convert the digital data derived from the point-by-point scanned specimen into an image. In this way, it is possible to acquire higher resolution images of cells and their processes, in thicker tissue specimens, than would otherwise be possible. Since the image must be constructed by scanning the specimen one point at a time, confocal microscopy has limited temporal resolution.

Two-photon confocal microscopy takes a different approach to reducing out-of-focus information. This technique involves illuminating a sample with a wavelength that is twice the wavelength of the absorption peak of the fluorophore being used to label the tissue or the cell of interest. Little or no excitation of the fluorophore will occur at this doubled wavelength. However, if a laser generates sufficient photon density at the point of focus, special 'two-photon events' occur; two photons are simultaneously absorbed by the fluorophore, which is equivalent to the absorption of a single photon at the energy equal to the sum of the two that are absorbed. In this way, fluorophore excitation will only occur at the point of focus, eliminating excitation of out-of-focus fluorophores.

General Limitations of Optical Techniques

Associated with each type of optical imaging device and probe is a host of trade-offs that need to be balanced within the context of the goals of a particular experiment. For example, a specific voltage-sensitive dye might successfully be used to stain the tissue of a given preparation to yield a bright fluorescence – but it could also be prone to nonspecific staining which would diminish its signal-to-noise, or it may be unstable over the desired time course due to photobleaching. Photobleaching is the destruction of a fluorescing molecule through its excitation, and is a common property of most optical dyes and all currently available fluorescent proteins. Photobleaching places a limit on the total number of photons that a fluorescent molecule can emit.

As an example of trade-offs among optical detectors, a cooled CCD-camera has low intrinsic noise and can provide high spatial resolution, but it has poor dynamic range relative to a photodiode array and is much slower and a less desirable detector for imaging fast phenomena that undergo optical changes that are small in magnitude relative to their background. In contrast, although a photodiode has significantly poorer spatial resolution than a CCD camera, it is much faster and has a significantly greater dynamic range that makes it ideal for certain types of voltage-sensitive dye applications. Importantly, financial cost is another practical consideration: a two-photon confocal microscope with 'all the bells and whistles' might be out of range for most individual investigators, regardless of the extraordinary advantages of such a system over standard wide-field microscopy. Numerous books and review articles have been dedicated to elucidating the advantages and disadvantages of various optical dyes and technologies, and several useful references are provided in the Further Reading section.

Voltage-Sensitive and Calcium-Sensitive Imaging

Arguably, the use of calcium-sensitive dyes to measure changes in intracellular Ca^{2+} concentration has had the greatest impact of any dye imaging technique applied in neurobiological research; voltage-sensitive dyes are perhaps a distant second. Dyes are also available that are sensitive to a host of different ions, including Mg^{2+}, Zn^{2+}, Na^{+}, K^{+}, Cl^{-}, and pH.

Voltage-sensitive dyes and probes

Two categories of voltage-sensitive dyes are available for staining cells and tissue: (i) absorption dyes, which include RH479 and RH155 and (ii) fluorescence dyes, such as Di-8-ANEPPS, RH461, and JPW1114. Voltage-sensitive dyes are often labeled to denote the person by whom they were first synthesized; e.g., 'RH' dyes were first synthesized by Rina Hildesheim in collaboration with Amiram Grinvald at the Weizmann Institute. Absorption dyes require illuminating the stained tissue with light at the wavelength which is maximally absorbed by the dye; changes in light absorption correspond to alterations in membrane potential. Fluorescence dyes require loading a cell or staining tissue with a dye that is excited at one optical wavelength to fluoresce at a distinctly different wavelength. The changes in emission fluorescence correspond to membrane-potential.

Fluorescent voltage-sensitive dyes are further classified into 'fast-response' and 'slow-response' dyes. Fast-response dyes such as di-8-ANEPPS undergo electrical field-triggered changes of intramolecular charge distribution, and consequently change their fluorescent properties. Their rapid optical response enables measurements of transient potential changes on a millisecond timescale. However, their small fluorescence changes are difficult to detect. Slow-response dyes, which include the rhodamine, merocyanine, and oxonol probes, undergo voltage-dependent changes in their intramembrane distribution. For example, some slow-response dyes work by migrating across the cell membrane, from the outside to inside surface, in response to depolarization; this change is

accompanied by an increase in their fluorescence signal. This transmembrane movement of entire molecules is a significantly slower process than the intramolecular redistribution of electrons in immobile molecules of fast-response dyes.

Whether a specific voltage-sensitive dye is useful for a given preparation is a matter determined by empirical investigation. A website with a current list of voltage-sensitive dyes that have been successfully employed in various specific preparations is maintained by Larry Cohen at Yale, at http://www.med.yale.edu/cmphysiol/cohen/whichdye.html

There has been some recent progress in the development of genetically encoded fluorescent protein voltage sensitive probes (FP-voltage sensors), although further improvements are required for this technology to be widely useful. Three FP-voltage sensors, Flare, FlaSh, and SPARC, have recently been expressed and characterized in mammalian cells, but have yielded poor signal-to-noise because of low plasma membrane expression. Newer constructs (e.g., VSFP2.1) appear to yield improved signal-to-nose, and suggest great potential for future developments.

Calcium-sensitive probes

Calcium is by far the most widely studied ion because of its central role as a second messenger, linking membrane depolarization to important intracellular biochemical changes. Optical imaging of calcium is done for the purpose of studying its role both in signal transduction and as a marker of neuronal activity (since transient increases in intracellular calcium are elicited by action potential firing).

Most commonly used calcium-sensitive dyes fall into two categories: (i) ratiometric dyes such as Fura-2 and Indo-1, which undergo a spectral shift in the wavelength of light they emit in the presence of calcium and (ii) single-wavelength dyes such as Fluo-3 and Fura-red, which do not undergo a spectral shift, but rather increase or decrease their fluorescence at a single wavelength as a function of calcium concentration. The advantage of ratiometric imaging is that the calculation of the ratio of fluorescence at two different wavelengths compensates for differences in dye concentrations, allowing for the quantitative comparison of $[Ca]_i$ between different intracellular domains. This ratiometric approach is important, for example, when comparing changes in a brightly fluorescing cell soma (containing a large number of fluorescing molecules) to changes in a much smaller cell process, such as a dendrite, holding significantly fewer fluorescing molecules.

There have been a number of exciting recent developments in using fluorescent protein markers of calcium in transgenic mice to target specific cell types, with two approaches being most widely investigated to date. The first approach uses a green fluorescent protein (GFP) fluorophore as a sequence insert. The second approach uses 'chameleons' that involve connecting two spectrally different types of GFP by a calcium-sensitive linker. Changes in the degree of fluorescence resonance energy transfer (FRET) occur between the two GFP fluorophores. FRET is a fluorescence labeling technique whereby two different fluorophores are genetically fused to proteins. The emission and excitation spectra of the two fluorophores are matched in such a way that an excited donor fluorophore can transfer energy to another closely proximal acceptor fluorophore, with the net effect that the donor emits less light than it normally would, while the acceptor emits more light at its excitation frequency.

Recent Results

A More Detailed Example: Imaging of Intrinsic Optical Signals (IIOS)

IIOS is based on the principle that action potential firing changes the way neuronal tissue absorbs and scatters light at wavelengths throughout the visible and near-infrared spectrum. These activity-related optical changes are called 'intrinsic optical signals' because they do not require the use of optical dyes. The distinct advantage of IIOS is its simplicity: one need not deal with the issues involved in staining tissue with dyes, and the activity-evoked optical changes can be easily detected with standard CCD cameras using commercially available imaging acquisition and analysis software. Some major disadvantages of IIOS are that it is limited to detecting changes on the surface of tissues and it is not always obvious how the intrinsic optical signals are related – temporally and spatially – to action potential firing. IIOS imaging techniques involve illuminating the tissue with a continuous stable light source at the desired wavelength, and acquiring images with a camera mounted to a standard wide-field microscope (for tissue slices) or an operating or dissecting microscope (for in vivo imaging of the cortex). Our laboratory has been interested in IIOS imaging because of the ease with which it facilitates translational studies. We have used IIOS to study epileptic and normal activity in consenting human subjects in the operating room who are undergoing surgical treatment for epilepsy. These studies are complemented by subsequent animal studies that combine IIOS with more invasive techniques, such as microelectrode recordings and pharmacological treatments, to test hypotheses generated by our observations of the human disease.

The experiments involved in the specific example discussed here were aimed at better understanding the physiological mechanisms underlying the generation of the intrinsic optical signals. It has long been known that the in vivo optical signals are generated by the combination of

at least three components: (i) changes in blood oxygenation, (ii) changes in blood volume, and (iii) blood-independent light scattering changes, possibly due to glial cell-swelling and ion fluxes associated with increased action potential firing. However, the respective contributions of the specific vascular and tissue compartments at various optical wavelengths have not been clearly elucidated.

Rationale

Increases in neuronal activity are known to elicit localized changes in blood volume, and this activity-evoked redistribution of blood in the neocortex is controlled by the pial arterioles lying on the surface of the brain. The firing of action potentials by neocortical neurons results in the dilation of microscopic pial arterioles nearest the active neurons. Molecules such as adenosine and nitric oxide are generated by neuronal activity, and diffuse through the extracellular space to elicit dilation of nearby vessels. In this manner, small changes in neuronal activity are transduced into large changes in blood flow (since flow is related to the fourth power of vessel diameter). As a result of the large increases in blood flow that are elicited by increased neuronal activity, the transit-time of the blood within cortical tissue is greatly reduced, resulting in increases in the oxygen content of blood in the draining venous network. Other imaging modalities, such as BOLD–fMRI, rely upon detecting this increase in blood oxygenation in the veins receiving blood from active cortical tissue.

The light absorption spectra of oxy-hemoglobin (OxyHb) and deoxy-hemoglobin (Hb), show that at certain wavelengths (535 and 810 nm) known as isosbestic points, OxyHb and Hb are indistinguishable. In contrast, OxyHb and Hb are maximally distinguishable at other wavelengths such as 660 nm (**Figure 1**). Several predications follow from the previous discussion. First, intrinsic optical signals observed when illuminating the brain with 535-nm light should be generated by the dilating pial arterioles nearest to populations of neurons firing action potentials. The increase in light-absorbing haemoglobin molecules associated with the vessel dilation suggests that the tissue will absorb more light at this wavelength. Thus, the 535-nm optical signal should be a measurement of activity-evoked blood volume changes, and the tissue should appear to darken with increased activity. Second, optical signals measured at 660 nm should be localized to the veins near active neurons. Since OxyHb absorbs less

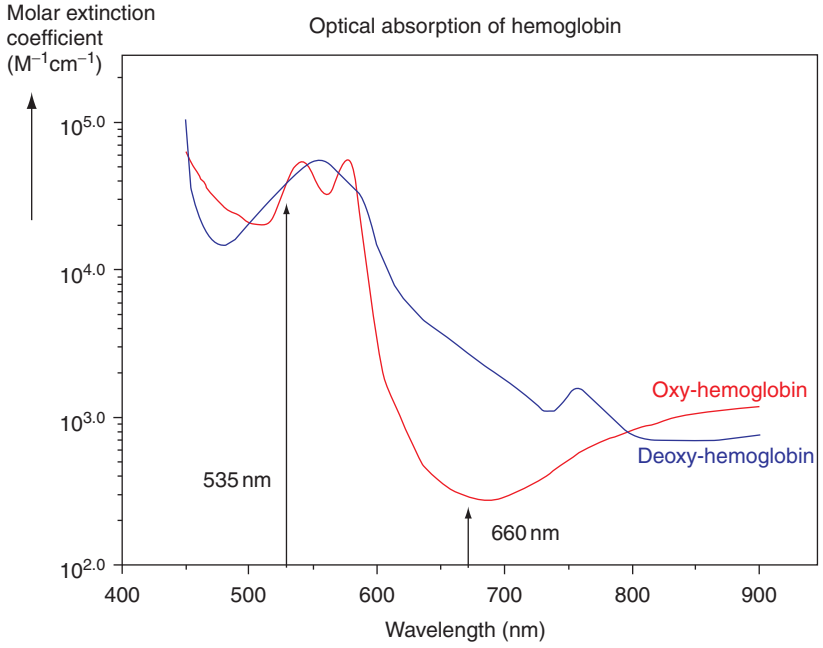

Figure 1 Optical absorption properties of hemoglobin. This plot compares the amount of light that is absorbed by oxy- and deoxy-hemoglobin at wavelengths from 400 through 900 nm. The graphs cross at some wavelengths, such as 535 nm, where oxy- and deoxy-hemoglobin absorb exactly the same amount of light, and hence imaging at these wavelengths is insensitive to differences in blood oxygenation. Optical imaging at such points where the absorption properties are equal (called isosbestic points) would be expected to be independent of changes in blood oxygenation, and hence primarily represent changes in blood volume. At other wavelengths, such as 660 nm, the optical absorption properties of oxy- and deoxy-hemoglobin are clearly distinguishable; changes in the optical signal at such points should represent changes in blood oxygenation. These graphs were generated from publicly available data on the web compiled by Dr. Scott Prahl, Oregon Medical Laser Center at http://omlc.ogi.edu/spectra/hemoglobin/summary.html, tabulated from data by Drs. W. B. Gratzer, Med. Res. Council Labs, Holly Hill, London and N. Kollias, Wellman Laboratories, Harvard Medical School, Boston.

light than Hb at 660 nm, the tissue should appear to become brighter with increasing neuronal activity. The following experiment was designed to test and validate these notions.

General methods

Macaque monkeys (*Macaca nemestrina*) are typically used in our laboratory's optical imaging studies. A 25-mm 'optical window' for acquiring optical and electrophysiological recordings is constructed over the hand motor cortex. This procedure involves a craniotomy and mounting a specially designed stainless steal chamber over the cortex. We typically choose hand motor cortex in optical imaging studies of epileptiform activity; in this way, electrophysiological activity from the cortex can be acquired simultaneously with observations of hand motor movements and EMG recordings from hand muscles. The cortex is stimulated with a bipolar stimulating electrode (5 mm inter-electrode distance) powered by an Ojemann Cortical Stimulator (Integra Life Science Corporation). In the studies shown here, the cortex was illuminated with either 535- or 660-nm light. Images are acquired with at 16-bit cooled digital CCD camera (Roper Scientific) mounted on an operating microscope.

A typical data acquisition trial involves acquiring a series of images at a rate of at least 5 Hz continuously for several minutes. Each trial consists of a 20-s control period prior to stimulation, followed by 4 s of electrical stimulation of the cortex, and ending with a 2–3 min recovery period. Percent-difference-images are generated by subtracting and then dividing the first control-image from all of the other images acquired during the same data-acquisition trial. The percent-difference-images are pseudocolored to facilitate the visualization of small optical changes.

Results

Figure 2 illustrates the results from an experiment aimed at determining the microvascular contribution to the intrinsic optical signal when the cortex is illuminated with 535 and 660 nm light. The top panel shows a low-magnification view of the optical changes evoked by 4 s of electrical stimulation (at 7 mA, which was found to be a stimulation current that was below the threshold for evoking epileptiform afterdischarge activity). As is typical, the largest optical changes at 535 nm occur around one of the poles of the stimulating-electrode, indicating an unequal distribution of current during the stimulation; no optical changes occur within the larger visible blood

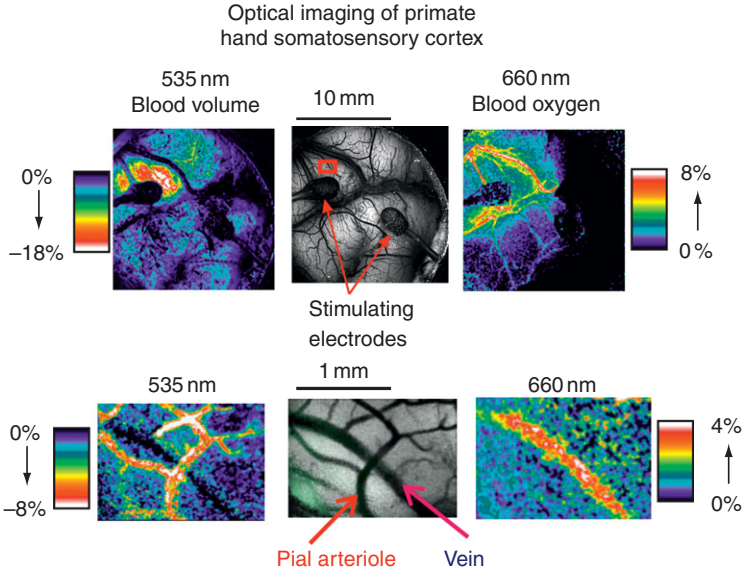

Figure 2 Localization of optical changes at 535 and 660 nm. The top panel shows low-magnification maps of optical changes during 7 mA stimulation, where no afterdischarge activity was elicited by the stimulation. These data are from an individual animal. The middle, top grey-scale figure shows the configuration of the stimulating electrodes, and the red square overlay show region the region whose optical map is plotted at a higher magnification in the bottom pane. Images on the left and right are pseudocolored to indicate their percent changes in the optical signal from baseline conditions. When the cortex is illuminated with 535-nm light (top, left), the largest optical changes are nearest to one of the stimulating electrodes, and distributed diffusely throughout the surrounding tissue. Under 660-nm light (top, right), the optical changes are greatest in the largest veins lying within the cortical sulci. The bottom panel shows optical changes acquired at high magnification, within the area indicated by the red square in the top middle figure. During stimulation, the pial arteriole was observed to undergo a 35% increase in its resting diameter. The 535-nm optical images (bottom, left) show that optical changes are restricted to the pial arteriole, and absent from the venule. The 660-nm images (bottom, right) show that changes are restricted to the nondilating venule. The pial arteriole shown here is approximately 20 μm in diameter at rest, and the venule is 35 μm in diameter. Modified from Haglund MM and Hochman DW (2007) Imaging of intrinsic optical signals in primate cortex during epileptiform activity. *Epilepsia* 48(supplement 4): 65–74, with permission from Wiley-Blackwell.

vessels (**Figure 2**, top left). At this wavelength, all optical changes occur in a negative-going direction (i.e., the tissue appears to become darker because it is absorbing more light). When imaging with 660-nm light, the largest optical changes are observed to occur within the larger veins lying within the sulci, near the site of electrical stimulation – and all optical changes occur in a positive-going direction (**Figure 2**, top right). High magnification optical imaging can be used to resolve the optical changes occurring within the microscopic blood vessels (**Figure 2**; bottom panel). With such magnification, the optical changes appear to be restricted to the dilating pial arterioles at 535 nm and to the venules at 660 nm.

The main conclusions from these data are: (i) optical imaging at 535 nm is selective for blood volume changes; the optical changes are generated by the increased blood volume associated with dilation of the microscopic pial arterioles; (ii) optical imaging at 660 nm is selective for changes in blood oxygenation since the activity-evoked signal is predominantly restricted to the veins that are draining blood from the stimulated cortex; and (iii) the blood volume wavelength at 535 nm appears to localize neuronal activity more accurately than the blood oxygenation wavelength at 660 nm.

In a second type of study, optical imaging at 535 nm (blood volume) was used to study spontaneously occurring epileptiform discharges in a primate seizure model. For these studies, a small epileptic focus was created by soaking a 0.5 mm Gelfoam pledget in bicuculline (100 μM) and placing it on the cortex for several minutes. Spontaneous ictal discharges typically occur for approximately 60 min after the bicuculline-soaked pledget is removed from the cortex. Blood volume imaging suggests that circular waves of propagating seizure activity spread from the site of the acute focus through surrounding nonepileptic cortex (**Figure 3**; top panel). By subtracting images in the reverse manner, opposite-going optical signals can also be observed (**Figure 3**; bottom panel). These results show that during the spread of ictal activity, blood is redistributed from regions in which intense epileptiform discharges have occurred into areas in which the ictal activity is beginning to spread.

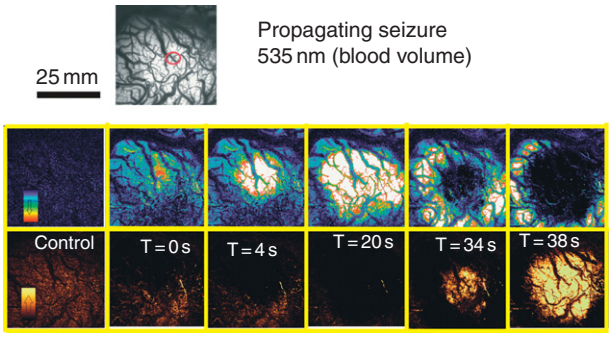

Figure 3 Positive and negative-going optical signals during ictal discharge at the blood volume (535 nm) wavelength. The images shown here were acquired during an ictal discharge spreading over the cortex. An acute seizure focus had been created by applying a 0.5-mm pledget soaked in bicuculline to the cortex for several minutes, in the center of the region shown in the image, within the colored-circular overlay shown in the top gray-scale image. A series of images were acquired during a spontaneous ictal discharge. The top line of rainbow pseudocolored images show positive going signals that are normally associated with increases in neuronal activity. The bottom series of gold pseudo-colored images show the negative going signals that may represent 'blood stealing,' or a redistribution of blood from areas of cortex undergoing a decrease in activity to surrounding areas undergoing an increase in activity. Modified from Haglund MM and Hochman DW (2007) Imaging of intrinsic optical signals in primate cortex during epileptiform activity. *Epilepsia* 48(4): 65–74, with permission from Wiley-Blackwell.

Future Directions

The increasing applicability of optical imaging techniques is the result of ongoing development of imaging hardware and optical reporters and dyes. Advances in imaging hardware are likely to include the development of photodiode arrays and low-noise charge-coupled device (CCD) cameras that are faster, more user-friendly, and have greater spatial resolution than current devices – and will continue to be more affordable as prices for solid state detector technologies fall. Developments in the area of optical dyes include ever-improving optical probes that allow for the measurement of membrane potential, pH, calcium, chloride, and sodium. Perhaps the most exciting recent developments in this area are methods for the transgenic expression of fluorescent proteins. By coupling nucleotide sequences encoding fluorescent proteins to cell-specific promoters, transgenes have been constructed that make specific cell types in a living organism fluoresce. Specific types of neurons, for example, can be made to express fluorescent proteins that allow for unprecedented resolution of morphology, or that have sensitivity to membrane potential, Ca^{2+}, Cl^{-}, and pH. These recent developments in the use of fluorescent proteins may represent the beginnings of a revolutionary leap in the power and applicability of optical imaging methodology.

Introduction

Nature is inherently colorful, but alas for those of us who want to watch neurons at work, the brain is not. This statement, however, may only have historical significance, for we are in the midst of a revolution that is touching all aspects of biological study, driven by our new found ability to add color. There are three facets to this technological leap: the development of a huge array of fluorescent dyes to explore both structure and function; the ability to introduce the dyes into preparations using molecular biological techniques, microinjection, or chemical tricks (e.g., esterifying the dyes to make them more permeable); and the development of microscopy techniques and equipment to optimize our ability to visualize these dyes. At its extreme, the results are stunning. For instance, it is possible to detect single molecules when bound to a marker fluorescent dye. And without doubt, this revolution will impact hugely on our efforts to understand epilepsy.

The desire to image network activity stems from a frustration with the limitations of electrophysiological recordings. Intracellularly recordings give a high temporal resolution view of that cell's firing pattern or the synaptic barrages that it experiences, but one then needs to put these recordings in the context of the other network activity. Recording electrodes are huge relative to the size of the cells, and so recordings tend to be done in relative isolation; at most, just a handful of such recordings can be made simultaneously.

Electrodes for extracellular recording are similarly bulky, but do provide a sensitive assay of changes in network activity. The signal though, is small and very complicated. It derives from the apparent electric field between two points (the electrodes), reflecting all the ionic fluxes within this field. Unfortunately, it cannot easily be 'reverse engineered' to derive these ionic fluxes. Thus, the entire network activity is integrated into a single signal with almost all spatial information lost. Multicellular recordings do better, but their spatial resolution remains poor; and again, the physical size of the electrodes can be an issue.

The power of functional imaging is that it allows us to collect detailed information from many separate locations simultaneously, often in places beyond the reach of other techniques (e.g., voltage and Ca^{2+} fluxes in dendritic spines), and with greatly increased spatial resolution. The relevance of these techniques to epilepsy research is obvious: seizures are among the most intense activity patterns within the brain, and our understanding will only

Introduction

Nature is inherently colorful, but alas for those of us who want to watch neurons at work, the brain is not. This statement, however, may only have historical significance, for we are in the midst of a revolution that is touching all aspects of biological study, driven by our new found ability to add color. There are three facets to this technological leap: the development of a huge array of fluorescent dyes to explore both structure and function; the ability to introduce the dyes into preparations using molecular biological techniques, microinjection, or chemical tricks (e.g., esterifying the dyes to make them more permeable); and the development of microscopy techniques and equipment to optimize our ability to visualize these dyes. At its extreme, the results are stunning. For instance, it is possible to detect single molecules when bound to a marker fluorescent dye. And without doubt, this revolution will impact hugely on our efforts to understand epilepsy.

The desire to image network activity stems from a frustration with the limitations of electrophysiological recordings. Intracellularly recordings give a high temporal resolution view of that cell's firing pattern or the synaptic barrages that it experiences, but one then needs to put these recordings in the context of the other network activity. Recording electrodes are huge relative to the size of the cells, and so recordings tend to be done in relative isolation; at most, just a handful of such recordings can be made simultaneously.

Electrodes for extracellular recording are similarly bulky, but do provide a sensitive assay of changes in network activity. The signal though, is small and very complicated. It derives from the apparent electric field between two points (the electrodes), reflecting all the ionic fluxes within this field. Unfortunately, it cannot easily be 'reverse engineered' to derive these ionic fluxes. Thus, the entire network activity is integrated into a single signal with almost all spatial information lost. Multicellular recordings do better, but their spatial resolution remains poor; and again, the physical size of the electrodes can be an issue.

The power of functional imaging is that it allows us to collect detailed information from many separate locations simultaneously, often in places beyond the reach of other techniques (e.g., voltage and Ca^{2+} fluxes in dendritic spines), and with greatly increased spatial resolution. The relevance of these techniques to epilepsy research is obvious: seizures are among the most intense activity patterns within the brain, and our understanding will only

come from an awareness of how the event plays out across the entire network. In short, we need to be able to record from many locations at once, and imaging gives us this capability. The usefulness of imaging, however, comes from an understanding of how activity has been made visible, and an appreciation of the limitations of the techniques, particularly with respect to the trade-offs between temporal and spatial resolution. In this article, we will discuss these issues with a particular focus on the main technique used in our own laboratories: Ca^{2+} imaging of network activity.

Background

There are two main techniques for imaging network activity, utilizing either changes in reflectance of the tissue, or changes in fluorescence. Imaging reflectance is generally referred to as intrinsic optical imaging (IOS), and utilizes subtle changes in the scatter of light caused by neural activitation. In vivo, these include vascular changes (vasodilation/constriction and changes in levels of blood oxygenation), but in vitro, the changes are thought to arise primarily from cell swelling. The signals are small and so generally require averaging or long image capturing over relatively large areas, both significant problems if events are variable and rapid. Furthermore, the underlying biological processes are only manifest over a time course of seconds, so this imaging is slow and of fairly low resolution (100s of microns). These various issues mean that IOS has not been used much in epilepsy research, although it has proved a popular tool to study spreading depression. In this respect, it is worth stating that it can be done very cheaply and almost completely noninvasively (e.g., through a thinned skull).

The remainder of this article will concentrate on imaging fluorescence changes. All fluorescent molecules work the same way. A photon within a particular range of wavelengths (the absorption spectra) is absorbed, raising the molecule to an 'activated state.' The molecule then releases a photon of lower energy (i.e., there is some energy lost in the process) to return to the 'ground state.' Because the released photon has lower energy, the emission spectrum is shifted to a higher wavelength. For chromofluors to be useful as functional markers, their spectral properties must be changed in some way by neural activity. This can happen if either the absorption spectrum is shifted or the absorption efficiency reduced or increased, or if photon emission is modified (again either by increasing or reducing the emission or shifting the spectrum). The fluorescence changes reflect structural changes in the fluorescent molecule, induced by binding or releasing other species such as Ca, or by changes in the electric field. This latter mechanism explains how voltage sensitive dyes (VSDs), embedded in the cell membrane, can indicate changes in the membrane potential.

The first Ca^{2+} dye to be developed was aequorin, but its usefulness was limited by its poor photon emission and the fact that it is consumed by Ca^{2+}. Thus, each molecule detects just a single event, and the signals need to be derived from populations of cells rather than individual cells. The field was really driven forward when Roger Tsien developed a means of modifying the two commonly used Ca^{2+} buffers – EGTA and BAPTA – such that the molecules fluoresced when they bound Ca^{2+}. A second inventive chemical modification then provided an easy means of loading the dye into cells: by adding an ester group on to the dye, Tsien found that the dyes crossed the cell membrane, whereupon they were cleaved by intracellular esterases, thus converting the nonfluorescent esterified molecule into a fluorescent de-esterified one, and fixing the dye within the cell into the bargain.

The usefulness of Ca^{2+} as an indicator of neural activity comes from its unique position as the principal transducer of electrical into chemical signals. All spiking neurons, when they fire action potentials, experience a sharp rise in intracellular Ca^{2+}. Consequently, by monitoring the somatic Ca^{2+} fluxes, one can derive an accurate picture of the cell's firing pattern. With the appropriate microscope and camera, one can thus record the activity, as indicated by their somatic Ca^{2+} fluxes, of 100s of neurons simultaneously, with single cell precision.

A further benefit of the rise of Ca^{2+} imaging is that it has thrust glial cells back into the center stage. Glia also experience large fluctuations in intracellular Ca^{2+}, albeit with the cytosolic Ca^{2+} coming from intracellular stores rather than from the extracellular space (as happens in neurons). This different source gives glial Ca^{2+} transients (GCTs) a distinctive appearance: they generally show far slower rise times than neuronal signals, and when viewed at high enough magnification and speed, the fluorescence signal appears as a wave travelling down glial processes, before smoothly progressing through the rest of the gap-junction coupled glial syncytium. By permitting such activity to be visualized, Ca^{2+} imaging has provided strong evidence for a prominent role for glia in all manner of neural activity, and a particularly important role in epileptogenesis.

Methods

Loading Issues

Different experimenters have used many subtly different loading protocols, the details of which can be found in their various publications. Generally speaking, sections are allowed to settle for 30–60 min following slicing, before

being transferred into a chamber (volume ~5 ml) warmed to 33–36°C. The dye is then added (to 3 ml of ACSF, add 10–30 µl of the following solution: 50 µg dye + 8–45 µl DMSO + 2 µl of 20% pluronic acid (mild detergent) in DMSO – the different amounts reflects experimenter and dye variability (some experimenters also add traces of Cremophor XL, another detergent available from Sigma)). We recommend drawing off some ACSF to mix with the dye solution prior to adding back to the incubation chamber, so that slices are not exposed to high concentrations of DMSO or detergents. The slices are incubated (aerating all the while with 95%/5% carbogen) for 20–40 min, and then washed with ACSF prior to transferring the slices to the microscope perfusion chamber.

All the published work to date on network Ca^{2+} imaging of in vitro preparations have used either neuronal cultures or slices from young animals, generally mice. The reason is simple: brain slices from young mice (<postnatal day 20 = P20) can be loaded with the dye far better than slices from older ones. There are also curious variations in how well different brain regions can be loaded. Thus, loading of neocortex is usually good up to P20, but hippocampal loading is generally poor beyond the first postnatal week, whilst with thalamic labelling, we have had very little success. While we do not fully understand the reasons for these limitations, the answer may relate to another feature of these dyes: the various Ca^{2+} dyes (Molecular Probes currently make more than 30 different dyes) show marked differences with respect to the relative loading of neurons and glia.

There seems to be a spectrum of relative neuronal-glial labelling patterns, with fluo-3 at one end (labelling primarily glia), and then progressing through Calcium Green, Fluo-4, Indo-1, Oregon Green Bapta 1, to Fura-2 (80–95% of Fura labelled cells appear to be neurons). The labelling can be assessed either by co-labelling with the astrocyte-specific marker, sulforhodamine 101, or by careful assessment of the nature of the Ca^{2+} signal (see later text). The difference between the dyes is likely to reflect two properties: the specificity of esterases in a given cell class for the esterified form of the dye, and the dynamic range of Ca^{2+} fluxes seen in that cell class relative to the K_D of the dye. To explain this last point a little further, the effective functional range of a dye, in terms of the Ca^{2+} concentration level, which shows a change in fluorescence, extends from about 0.1^*K_D to about 10^*K_D. If the Ca^{2+} fluxes that a given cell experiences is outside this range, then the dye is not going to show any measurable changes in fluorescence. Generally, dyes that give better glial signals tend to have higher K_Ds, reflecting either a higher baseline cytosolic Ca^{2+} concentration or larger Ca^{2+} fluxes in these cells. Given the clear differences between glia and neurons in these measures, it is perhaps also to be expected that different neuronal populations also show variability.

A related issue is that the act of slicing the brain appears to activate glial populations, and while we have not explicitly tested the hypothesis, it is our impression that the better the quality of the slice, the more the labelling is neuronal. Consistent with this view, organotypic cultures that are labelled days or weeks after preparation – when the glial activation has settled down – can give very good neuronal labelling. Of course, as we have indicated already, glia are increasingly seen as playing a key role in epileptogenesis, and the ease with which they can be loaded with certain Ca^{2+} dyes has been a fantastic stroke of luck for this field.

With respect to age differences, patch clampers have long known that slices from older animals scatter light much more, and consequently the DIC images become worse and worse as the animal gets older. The same will be true for Ca^{2+} imaging in older slices, a problem that working with 2-photon microscopes may conceivably avoid. Another factor, again untested, may be that older brains show increased glial activation following slicing, leading to relatively worse neuronal visualization.

Imaging Issues

In a loaded cell, the onset of neural activity is seen as a sharp deflection in the somatic fluorescence, subsequently relaxing back to baseline fluorescence levels with a time constant of about 0.5 s. Because of the very slow decay kinetics, it is possible to detect events using sampling rates down at 1 Hz. If one is trying to assess levels of participation in interictal events, a slow rate of image capture may be quite acceptable. Obviously, the key is to design the imaging protocol for the job in hand. And for capturing any of the dynamics of an epileptic seizure, it is of course desirable to image much faster than 1 Hz. So how fast can one do Ca^{2+} imaging? Performing a line scan on a part of a dendrite, using a 2-photon microscope with optimal optics (high power, high numerical aperture (NA)), one can easily detect event onsets while sampling at 1 kHz. To do network imaging, however, one needs a wider field of view while still sampling at sufficient spatial resolution to see individual somata. High NA 20× objectives seem optimal, but even then, the light collection is not as good as 2-photon imaging, and the best that has been achieved is imaging at about 60 Hz using a spinning disk confocal and a high speed, cooled CCD camera. On first consideration, this limitation is a real problem: electrophysiological studies of disinhibited slices have reported propagation speeds of 10–100 mm s^{-1}, and so if one is imaging an area of cortex about 400 µm wide (a typical field of view when using a 20× objective), then an event travelling at 40 mm s^{-1} will traverse this field of view in about 10 ms. If one is imaging at 60 Hz, the event will cross the entire field of view within the time course of

a single frame. Fortunately, epileptiform activity can propagate at speeds several orders of magnitude slower than reported for disinhibited slices. Furthermore, what appears to determine whether a seizure propagates rapidly or slowly is the network's own defence mechanism opposing epileptiform spread – in itself a fascinating and hugely important topic.

But before we describe this work, we want to make just a couple more points about methodology. Firstly, it is possible to image at much higher rates (~1 kHz) using VSDs. The signals are rapid, but very small, and thus require spatial averaging. Consequently, one cannot visualize single cells, and the signal is further complicated by the confusion of signals from all the different neural cellular compartments (somata, dendrites, axons). VSD imaging, however, by dint of its speed, does have the potential to address questions that cannot be examined readily using Ca^{2+} imaging, such as propagation in disinhibited slices, or the propagation of afterdischarges.

The second point regards the importance of making electrophysiological recordings synchronous with imaging. All imaging comes at a cost: illumination causes both photobleaching and phototoxicity, whether one uses an epifluorescence system (worst in these regards) or a 2-photon system (best). For these reasons, one must always strive to limit the imaging time. The best way of achieving such limits is to use the electrophysiological recordings to guide when one collects imaging data. Another argument for performing simultaneous imaging and electrophysiology is that all our information regarding epileptiform activity (going back to the first EEG recordings by Berger in 1929) has been electrophysiological in nature; electrophysiology is the frame of reference, and is the only means by which we can interpret our imaging data in terms of prior research. Finally, electrophysiological recordings provide a means of validating our results. As we mentioned earlier, currently we can only do imaging on a limited range of preparations. Our electrophysiological recordings have allowed us to confirm that what we see in a brain slice taken from an adolescent mouse also occurs in adult guinea pig brain slices and in adult cat in vivo – and there is a strong indication that it also reflects the pattern of activity in such phenomena as the Jacksonian march in humans.

Important Results to Date

Targeted Patching

Perhaps the simplest use of Ca^{2+} imaging, and still one of the most powerful, is to identify cells that are doing interesting things within the network. These cells can then be targeted for patch clamping, to allow a detailed electrophysiological and morphological characterization. Such experiments have identified (i) cells which sustain rhythmic (~1 Hz) firing independent of synaptic activity, suggesting themselves as pacemakers for cortical circuits, (ii) other cell classes showing distinctive activity patterns during early network events in hippocampus, and (iii) clusters of neurons participating in so-called 'UP-states.' UP-states are physiological network states that have now been recorded in a number of different preparations (mainly but not exclusively neocortical), both in vivo and in vitro. They are so called because all participating neurons experience a roughly synchronous depolarizing shift of about 10 mV, and the spiking rate switches accordingly from almost quiescent to spiking regularly. Note, however, that the term is generally used to refer to physiological activation when the firing rate is relatively restrained, and is thus different from the well-described epileptic phenomenon of the paroxysmal depolarizing shift (PDS) in which the depolarization drive is so intense that Na-channels fail to deinactivate and successive action potentials are much reduced in amplitude. UP-states may represent the network correlate of working memory.

An In Vitro Model of Surround Inhibition

In our epilepsy experiments, we sought to understand the interplay between inhibition and excitation in ictogenesis. To this end, we chose to use the 0 Mg^{2+} in vitro model, in which epileptiform activity occurs primarily as a result of relieving NMDA receptors of their voltage dependency. Thus, glutamate can open these receptors when the cell is at resting membrane potential, and this sensitivity enhances the excitatory drive. If the slice is kept for a sustained period in Mg^{2+}-free solution, then eventually inhibition also becomes impaired. For these reasons, the 0 Mg^{2+} model is a fascinating preparation in which to study epileptiform activity, because the earliest activity occurs with the inhibitory circuitry intact, but then the activity patterns evolve as the inhibition deteriorates. The model thus shows a wide range of epileptiform activity, and has allowed us to examine the role of inhibition in epileptic circuits.

In particular, we have been able to address a key hypothesis proposed over 40 years ago by Prince and Wilder – that there exists a surround inhibitory mechanism within the network which opposes the spread of ictal events. This proposal arose from in vivo studies, but the difficult nature of such studies has meant that our understanding of this mechanism has stood still for most of the intervening years. We discovered that the earliest epileptiform activity in the 0 Mg^{2+} in vitro model appears to recapitulate the in vivo state very well. With all the benefits that in vitro preparations ensue, including better control of the experimental milieu, access for electrophysiological recording and direct visualization of the

activity of most of the neurons in the circuit using calcium imaging, we have started to unveil the underlying network that provides this critical network protection.

When early 0 Mg^{2+} ictal events are imaged at low magnification (4× objective), the fluorescent signal from individual neurons cannot be discerned, but the progression of the event across the tissue can still be visualized (**Figure 1**). Simultaneous with all our imaging, we also collected patch clamp recordings from layer 5 pyramidal cells, since this cell class is thought to play a key role in ictogenesis. These synchronous recordings showed that there is a powerful inhibitory barrage ahead of the ictal wavefront that matched the timing of network bursts in the cortical territories that had already been recruited to the event. Other patch clamp experiments showed that this feedforward inhibition coincided with excitatory volleys emanating forward from the ictal wave. As a result, pyramidal cells experience rhythmic depolarizations at about 1 Hz ('slow waves' or δ-rhythms). Yet despite the significant depolarizations and the level of the excitatory drive, the cells fired very infrequently. The implication was clear-that the feedforward inhibition was vetoing the excitatory drive. And by doing so, the inhibition restrained the spread of the ictal event.

The crest of each slow depolarization represents a crisis for the network. This was apparent when we next imaged the epileptiform event at higher magnification (**Figure 2**). These experiments showed that the recruitment of new cells occurs only at specific times, coincident with the excitatory barrages. Thus, the ictal event appears to take episodic steps, about once a second, across the network. What determines whether a cell is recruited or not at these crisis points? The answer seems to be that it is the failure of the inhibitory restraint rather than the start of the excitatory barrages that governs the recruitment of pyramidal cells to the ictal event. This important conclusion comes because we know that the initial excitatory volleys, which ordinarily (in the absence of inhibition) would surpass the firing threshold many times over, start 10 s of seconds before the eventual recruitment. This is consistent with prior modelling studies which suggested that the arrangement of inhibitory and excitatory synapses across the pyramidal soma and dendrites – in particular the large inhibitory and absence of excitatory drive on to the soma – allow for a vetoing inhibition, however powerful the excitatory drive might be.

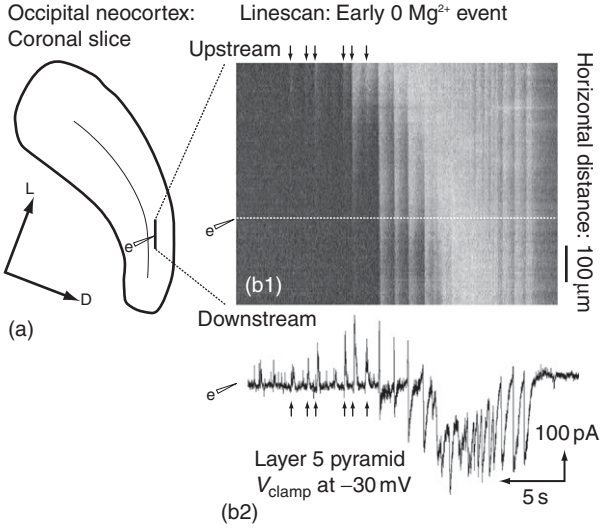

Figure 1 The slow stepwise propagation of zero Mg^{2+} epileptiform events reflects prominent feedforward inhibition. (a) Schematic of a coronal slice showing the recording electrode ('e') and the location of a 'line scan' through layer 5. Imaging was done at 30 Hz using a 10× objective. (b1) Line scan showing the neuropil Ca^{2+} fluorescence as an epileptiform event progresses from top to bottom – distance is plotted on the ordinate, and time on the abscissa. Each row of pixels represents the neuropil Ca^{2+} fluorescence from a bin 40 µm high by 4 µm wide (165 bins = 660 µm total length). The location of the recording electrode ('e') is shown. (b2) The V_{clamp} recording from the layer 5 pyramidal cell plotted below on the same time scale. The cell was held at −30 mV, approximately half way between the reversal potentials for GABA and glutamate, to distinguish inhibitory drives (upward deflections) and excitatory drives (downward deflections). Note the prominent inhibitory volleys (arrowed) corresponding with upstream activity in the line scan. Figure used with permission from Trevelyan *et al*. (2006).

The Role of Glia in Ictogenesis

Pathological clusters of glia, such as glial scars and gliomas, can induce seizures. Yet the etiology of these seizures remains obscure. Glia are known to regulate the extracellular space, for instance by taking up K^+ ions and neurotransmitters, and seizures had previously been presumed to arise from a failure in this function. The recent demonstrations that glia themselves can release neurotransmitters have provided a radically different hypothesis about epileptogenesis in this context – that glia may actively provoke seizures. Glutamate, and other neuroactive substances including nitric oxide, ATP, prostaglandin, have all been shown to be released from glial cells following a transient rises in intracellular Ca^{2+} (glial Ca^{2+} transient, or GCT), although the mechanism of glutamate release remains controversial. The released glutamate can activate local neuronal populations, even triggering epileptiform activity. Perhaps most remarkably, there is evidence that antiepileptic drugs can influence glial activity, seemingly independent of the neuronal effects of these drugs, raising the possibility that their antiepileptic action is mediated through glia and not neurons.

GCTs have also been linked to many other cellular processes, such as regulation of mitochondrial

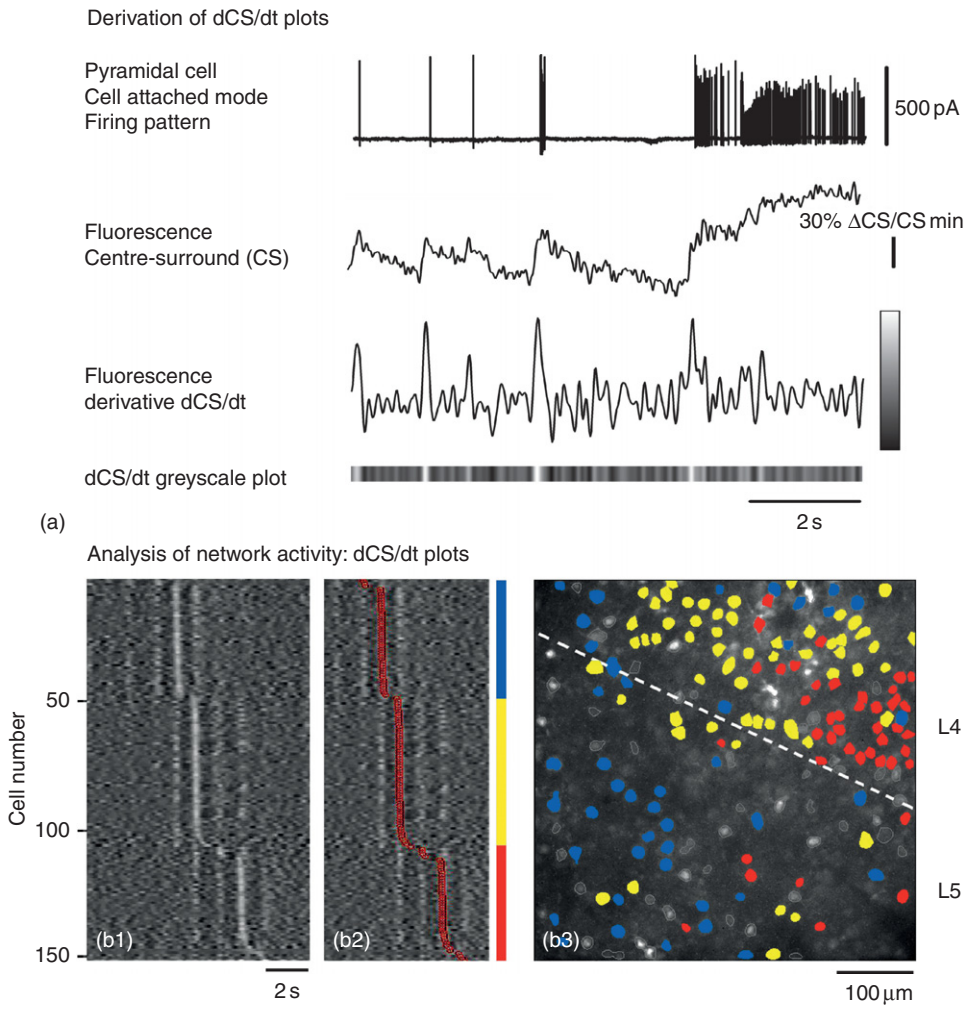

Figure 2 Somatic Ca^{2+} fluxes reveals episodic localized recruitment. (a) The derivation of the cellular Ca^{2+} signal. We recorded the firing pattern of a pyramidal cell (top trace) that had been bulk loaded with the Ca^{2+}-dye, Oregon Green Bapta 1. The second trace shows the somatic Ca^{2+} fluxes – note the sharp rises concomitant with each action potential. The derivative of the Ca^{2+} signal highlights the sudden increases in fluorescent signal, which reflect the sudden recruitment of neurons. The bottom panel shows how this derivative trace is transformed into the greyscale plots shown in **Figure (b)** which shows grayscale representations from 152 identified neurons. (b1) 'Grayscale plot' of the temporal derivatives (dCS/d*t*) of the centre-surround signals from 152 neurons ordered by the time of the maximum for each trace. Each row of pixels represents a dCS/d*t* trace: high rate of change of fluorescence is depicted as lighter grey. Each trace has several peaks. (b2) The same plot, with the single maximum rate of change for each cell marked (red). This ordering clearly shows three main clusters of cells. They are color-coded as shown, and their positions are indicated in the photomicrograph in (b3). Note the tight and largely non-overlapping spatial distributions of the yellow and red groups in layer 4. The lamina borders were determined from the location of the filled cells following post hoc staining for biocytin and matching this up to the electrode location in the field of view (the faint triangular shadow of one of the electrodes can just be seen at the bottom right corner of the field of view). Movie taken using a 20× objective. A movie illustrating this pattern of recruitment can be found in the supplementary information in Trevelyan *et al.* (2006) from which this figure was derived (with permission).

metabolism; morphological remodelling; cell division; control of gene expression; vasoconstriction and vasodilation; apoptosis. Extracellular Ca^{2+} influences gap junction and hemichannel opening. Clearly, GCTs are pivotal to glial behavior, yet there remain many unresolved issues. We know of some triggers (glutamate, ATP, prostaglandins, α-adrenoceptor and muscarinic stimulation), but there are likely to be others. As such, we have only a vague understanding of what determines the amplitude, kinetics and frequency of GCTs in the intact brain. What is clear, however, is that glia can no longer be viewed as passive players in the brain. Rather, they are active participants in neurophysiology and pathology. Our greatest ignorance perhaps concerns how GCTs influence network behavior, such as controlling brain states, rhythms, and pathologies such as migraine and seizures.

Challenges for the Future

Our specific goal is now to identify the interneurons that provide the protective restraint to seizure spread, since these cells represent an important potential target for pharmacotherapy. Our initial data suggest that interictal events may also reflect activation of the protective restraint, leading to an early suppression of a potential ictal event. This observation has suggested a means of identifying the critical interneurons providing the restraint, by targeted patching of those cells which show Ca^{2+} transients only during interictal events. Unfortunately this simple-sounding experiment is confounded by the sheer volume of data required. To capture enough interictal events and the start of a full ictal event involves imaging for 10–100s of seconds, and at 60 frames per second, that represents a large amount of processing that cannot be done within the lifetime of the slice. We are exploring other means of identifying these neurons.

We are also exploring the possibility that the intense feedforward inhibition is related to high frequency oscillations that various researchers have noted to be associated with the transition into a full ictal event. Previous workers have suggested that these oscillations may be culprits in the evolution of the seizure, but our alternative view is that these ripples of activity are actually representative of the tissue trying to stave off the impending ictal disaster.

More generally, there will inevitably be further technological improvements. Genetically engineered Ca^{2+} sensors continue to improve, and these new sensors permit life-long imaging. Also, the recent success in loading Ca^{2+} dyes into neocortex in adult cats in vivo is extremely promising, not only for adding these techniques to the in vivo armory, but also indicating how we might improve our in vitro labelling. Perhaps it will be possible to load the dye prior to sacrificing the animal, in which case the subsequent activation of glia may not be significant because the dye has already been removed from the extracellular space. Finally, a small plea to the community looking to express green fluorescent protein in every cell of interest in the body: The fluorescence spectrum for GFP overlies almost exactly that of the most commonly used Ca^{2+} dyes. For this reason, these dyes cannot be usefully used in tandem with GFP labelling; such is the intensity of the GFP fluorescence that the small fluctuations due to the Ca^{2+} dye are lost in the shot noise (which is proportional to the square root of the number of photons). We hope, therefore, that investigators will start to express a different member of the fluorescent protein family, with a longer wavelength excitation spectrum, to make these animals compatible with fluo-3, fluo-4, calcium green, Oregon green, etc. (Note: fura-2 and indo-1 are compatible already, but not always usable for other reasons).

To conclude, imaging techniques provide a brand new vista for exploring the brain. We have provided here only a small detail of what is being pursued, and what is (or soon will be) possible. Suffice it to say that the future for research in these fields looks colorful, even rosy!

SPECT in Epilepsy Research

M J Purcaro and H Blumenfeld, Yale University School of Medicine, New Haven, CT, USA

Introduction

Although about 75% of patients with epilepsy can control their disorder with medication, the remaining population must undergo surgery or live with their condition. A widely cited meta-analysis in the 1990s noted that over 50 000 patients a year in the United States are candidates for surgical intervention. Of the patients that do receive surgical intervention, many (over 70% for temporal lobe epilepsy patients, perhaps the most successful of all groups) will become seizure free. Surgical success is highly contingent upon localization of the epileptogenic zone during the presurgical evaluation.

Over the past 15 years, SPECT (single photon emission computed tomography) has become an important modality for noninvasively localizing or corroborating local epileptogenic foci for intracranial electrode placement or resective neurosurgery. SPECT has also demonstrated great utility for basic neurological research in anatomy, consciousness, neural network connectivity, and neuronal activation in epilepsy. On the basis of three-dimensional mapping of regional cerebral blood flow (rCBF), SPECT provides accurate localization of functional changes in the brain. While SPECT has relatively low spatial and temporal resolution compared to functional MRI (fMRI), it is the only feasible imaging modality available for capturing rCBF images during most seizure types. The SPECT scanner itself is a multiheaded camera that collects gamma particles emitted from nuclear decay of injected radiopharmaceuticals. For ictal SPECT studies, where patients move during seizures, the injection is given shortly after seizure onset, but images can be taken up to 1–2 h later. While many different areas of the brain will absorb the tracer because of natural blood circulation, areas in the seizure focus strongly correlate with areas of increased perfusion; hence, localization of seizure onset is ascertained by areas of ictal hyperperfusion. Ictal SPECT is usually compared to baseline interictal SPECT for each patient, obtained when seizures are not occurring.

Background

SPECT for Clinical Seizure Localization

For seizure focus determination, intracranial electroencephalography (EEG) is often necessary, especially when MRI lesions prove equivocal (i.e., discordant). Unfortunately, intracranial EEG poses some risk of complications (reported as high as 4% in several studies), as well as being quite costly. Moreover, sensitivity of intracranial EEG results is highly dependent upon electrode placement, and inadequate coverage of the brain could result in absent or misleading localization. From a practical standpoint, ictal SPECT is often capable of directly supplementing or replacing intracranial EEG. Indeed, some clinicians recommend omission of an intracranial EEG study if SPECT localizations exactly match the findings from MRI and other noninvasive study findings.

Ictal SPECT has a much greater sensitivity than interictal or postictal SPECT. In the late 1980s, investigators noted that ictal blood flow increases of 3–4 times baseline occur during seizure activity; these findings also indicated that areas of ictal hyperperfusion tend to be large compared with abnormalities noted during the baseline or postictal periods. A metaanalysis subsequently demonstrated that the sensitivity of ictal SPECT ranged from 97% to 100%, exceeding that of postictal SPECT (75–77%) and interictal (43–44%) SPECT.

SPECT vs. Other Imaging Modalities

Beyond the technical level, comparison of SPECT to MRI, fMRI, and PET is greatly complicated by the dissimilar measures (perfusion, structure, blood oxygen level dependent (BOLD) signal, CBF, and metabolism, respectively) provided by each. Naturally, these differences translate to varying application of each technique, as dictated by the specific needs of various epileptic patient populations.

MRI

Having the highest spatial resolution, magnetic resonance imaging (MRI) provides anatomical images that, when coregistered with images from other modalities, can allow for finer structural localization than provided by functional imaging alone. MRI has been found to often correlate with localizations found by other methods; for example, MRI has high sensitivity for detecting tumors and mesial temporal sclerosis, but the structural and functional abnormalities may not always localize in precisely the same area.

fMRI

Measuring BOLD changes, (fMRI can provide high spatial and temporal resolution in comparison with SPECT. fMRI is technically capable of providing information in ictal studies, but this application is rarely used for

practical reasons. EEG-triggered or EEG-monitored fMRI allows seizures to be captured soon after onset, but requires that patients have their seizures inside a scanner (that is either scanning or capable of scanning immediately upon seizure onset). Since most seizures do not occur frequently enough to be captured within reasonable time in the MRI scanner, and since most seizures are associated with significant movement (even minor movements markedly degrade fMRI signals), this approach is rarely used. SPECT alleviates many of these problems, since scans can be performed up to 1–2 h after a seizure. fMRI is useful for imaging interictal spikes, which do occur with reasonable frequency in many patients, and are not associated with movement artifact. The relationship between fMRI localization of interictal spikes and the region of seizure onset as determined by ictal SPECT (and other methods) is under active investigation.

PET

Positron emission tomography (PET) is most commonly used clinically to measure glucose metabolism. In FDG-PET, a glucose analog, 2-fluoro-2-deoxy-D-glucose (FDG), is tagged with the radioactive isotope ^{18}flourine (half-life of 110 min) to create ^{18}F-FDG. In the 40–60 min time-frame after injection, the tracer is taken up by cells with high glucose demands. However, until the fluorine isotope undergoes positron emission decay to form ^{18}O, the tagged sugar will not undergo glycolysis. The decay will eventually produce a pair of gamma particles traveling 180° opposite each other, which can then be detected and used to reconstruct images. Because of the long uptake time for ^{18}F-FDG, PET temporal resolution is much lower compared with SPECT, and PET studies within the ictal time-frame are generally not feasible. Several studies have shown that interictal PET sensitivity appears to be higher than that of interictal SPECT, possibly because of greater decrease in glucose metabolism in the seizure focus as compared with blood perfusion. However, ictal SPECT sensitivity appears to be roughly equal to interictal PET.

SPECT for Investigating Fundamental Epilepsy Anatomy

Temporal lobe epilepsy

Perhaps stemming from its common incidence and the high surgical success rate of resection, temporal lobe epilepsy (TLE) has been widely studied using all image modalities, including SPECT. The difference imaging and SPM-based SPECT analysis methods (see below) were first used and verified with TLE patients. In TLE, SPECT may show propagation from temporal to extra-temporal areas. Our laboratory has used SPECT studies of simple and complex partial seizures that occur with TLE to study network changes associated with loss of consciousness. For complex partial TLE seizures, bilateral hypoperfusion was noted in the bilateral frontal and parietal association cortex, along with hyperperfusion in the upper brainstem and medial diencephalon; for simple partial TLE seizures, no significant changes were found outside the temporal lobe. SPECT studies from other laboratories have also shown a large network to be involved during seizures in TLE.

Occipital lobe epilepsy

In occipital lobe epilepsy (OLE), seizure spread is often rapid, with propagation patterns from the occipital lobe to the temporal, parietal, and frontal lobes. The rapidity of this spread makes localization a challenge, often requiring multimodal studies for presurgical localization. Relatively few comparative SPECT studies have been performed on OLE patients.

A 1999 study of six postsurgical OLE patients found that ictal SPECT localized the epileptogenic region to the occipital lobe in five cases. The unilateral occipital hyperperfusion was often followed by hyperperfusion in the temporal lobe. In two of these patients, ictal SPECT was sufficiently useful to guide intracranial EEG studies, which in turn confirmed the SPECT diagnosis. MRI abnormalities were found in four cases, and three of these cases showed concordance with ictal SPECT. Interestingly, no interictal SPECT studies showed any localizing findings. In contrast, interictal PET findings were concordant, in three patients, with MRI findings, but provided no localization information in the remaining two patients in whom the epileptic foci were found by ictal SPECT. Overall, ictal SPECT demonstrated the greatest diagnostic value in this study, but the patient population was rather limited in size. Further, the ictal/interictal comparison was performed visually (in a blinded manner); more recent SPECT analysis techniques (such as SPM) would be useful in providing more quantitative and comparative SPECT information.

A 2005 follow-up study of 26 postsurgical OLE patients found ictal SPECT to be much less concordant with postsurgical findings than suggested by 1999 study. Difference analysis was utilized, but pixel thresholding was performed by finding areas where percent change in perfusion was greater than 20%. Of the 19 patients imaged with ictal SPECT, only seven had correct SPECT localizations. Intracranial EEG, MRI, PET, and scalp EEG all had greater success sensitivity, with best presurgical evaluation stemming from combined use of several modalities. While ictal SPECT injections were given as soon as possible after seizure onset, the rapidity of OLE seizure propagation may have also hindered clear interpretation of the results. Clearly, the localizing value of ictal SPECT in patients with secondary generalization requires further investigation.

Methods

Radiopharmaceuticals

Several different radiopharmecuticals have been used for SPECT perfusion imaging. Currently, clinical SPECT is performed with either of two ^{99m}Technetium-labeled ligands: ^{99m}Tc-d,l-hexamethyl-propylene amine oxime (^{99m}Tc-HMPAO or ^{99m}Tc-exametazime), or ^{99m}Tc-ethyl cysteinate dimer (^{99m}Tc-ECD or ^{99m}Tc-bicisate). The metastable nuclear isotope ^{99m}Tc has a half-life of 6 h and a gamma photopeak of 140 eV. It decays into the less radioactive isotope ^{99}Tc, and leaves the body within a few days. Whole body radiation exposure for a typical adult trace injection of 20–30 mCi is less than that of a standard head CT. Exposure is carefully limited in children, with reported pediatric dosages starting from 3 mCi. ^{99m}Tc-ECD is chemically stable in excess of the radiotracer half-life. Historically, ^{99m}Tc-HMPAO has been found to remain chemically stable for only 30 min in vitro. However, several methods have been found to better stabilize the compound (including use of methylene blue, ethanol, or $CoCl_2$), and stabilized ^{99m}Tc-HMPAO can be injected for at least 4 h after preparation.

Radiotracers reach the brain within 30 s of venous injection, and brain uptake of both tracers is rapid. Indeed, with both ^{99m}Tc-HMPAO and ^{99m}Tc-ECD, uptake is complete within 1–2 min. There may be differences in brain-to-background ratios between these tracers, but this has little impact on imaging results in clinical studies. Both tracers will cross the blood-brain barrier and become trapped: ^{99m}Tc-ECD is metabolized by enzymatic conversion to form a polar complex, and ^{99m}Tc-HMPAO is converted into a hydrophilic compound. While redistribution of tracer after initial fixation can occur, reverse transport or movement of the tracer is insignificant in practice. Interictal studies tend to be performed at least 24 h (four half-lives) after the ictal study; care must be taken to ensure that about 1 day of nonseizure (both clinical and subclinical) state has passed before initiating an interictal study, to avoid effects of recent seizures on the interictal study.

Timing of Injections

By far the most time-critical aspect of SPECT is the timing of injection after seizure onset. Studies have repeatedly shown that it is desirable to inject within 45–60 s of seizure onset to improve 'capture' of seizure localization. While injection times after this window are not without use (indeed, some information such as lateralization can be gleamed even from postictal injections), localization sensitivity begins to fade as the seizure spreads. Effectively, late injection may cause the seizure focus to appear as a hypoperfusion site, or make the contralateral propagation appear as hyperperfusion. Rapidly spreading seizures that propagate across hemispheres or become bilateral within 15–20 s of onset pose a practical limit for SPECT studies, since injections to assess this time-frame typically cannot be accomplished.

SPECT Study Procedure

Presurgical evaluation using SPECT is typically performed after scalp EEG recordings and fMRI imaging have been completed, but before intracranial implantation of electrodes. The study is usually an inpatient procedure that often takes several days because of the unpredictability of seizure events. Since imaging must be performed within 1–2 h after injection, radiotracer administration must also occur in coordination with scanner time availability.

After preparing the injection site by inserting an IV, nuclear medicine personnel watch for epileptic events, ideally in the same room as the patient. A syringe with correct radiotracer dosage must always be on hand for immediate use; due its short half-life, the dosage may have to be adjusted or replenished several times during a monitoring window.

An epileptic event is determined using both EEG monitoring and in-person evaluation of the behavioral state of the patient. Once seizure start has been determined, the radiotracer is injected immediately.

The SPECT scan itself takes 20–40 min. Motion artifact from patient movement is difficult to avoid because of this extended time period. Image reconstruction on the collected data is performed to obtain tomographic sections. Visual evaluation of the resulting images can often rapidly determine the usefulness of the images for further analysis. Motion, incomplete radiotracer perfusion (because of extravasation at the injection site), delayed injections, and other technical problems can render the study ineffective.

Recent Results

SPECT for Clinical Seizure Localization: Reading and Analysis

Visual assessment

Generally, the 'rating' of SPECT images for localization is first performed visually: an ictal-only study is visually examined (on a perregion basis) for any bilateral asymmetries. Obviously, the nature of this inspection precludes discovery of any diffuse or symmetric focal perfusion changes that occur bilaterally; thus, bilateral seizures may fail to be localized. Additionally, if a region shows hypoperfusion interictally, 'pseudonormalization' may occur during the seizure, so that a focal area of *relative* hyperperfusion could be missed without careful comparison to the interictal

scan. Visual side by side comparison of an ictal and interictal study from the same patient alleviates some of these issues. Complications arise, however, with this type of comparison: patient positioning will most likely be different, thus preventing one to one comparison of slices; likewise, tracer levels will differ because of different injection times, scan times, and blood flow and uptake characteristics that vary day-to-day.

Difference imaging

Researchers in the mid-1990s started to work around these limitations by digitally coregistering the ictal and interictal images, normalizing tracer levels across the brain, and subtracting the interictal from ictal images. Anatomical MRI images were also coregistered. Differences could then be quantified, and anatomy easily visualized. Techiques for performing this type of analysis have been called SPECT difference imaging analysis (DIA), or subtraction ictal SPECT coregistered to MRI (SISCOM). Several parameters must be carefully selected during digital subtraction analysis, including intensity thresholds and coregistration settings. To avoid artifacts and spurious results, it is crucial to visually inspect images, and not to use available algorithms as a 'black box' approach. When used correctly, difference imaging has been found to improve SPECT concordance (sometimes by a factor of two) with intracranial EEG or surgical findings as compared to traditional visual SPECT reading. Nevertheless, difference imaging has its pitfalls: many focal areas of activation are produced by the process, and results are thus still subject to substantial reader interpretation. While reader guidelines and some subjective evaluation will always be required, more sophisticated statistical analysis tools are helpful for more objective, repeatable interpretations.

SPM

Statistical parametric mapping (SPM) has been widely used to analyze many types of neuroimaging data. In this approach, statistical parametric maps of each study are made by applying univariate statistical tests to all voxels in the scans, and then combing the resulting voxel-by-voxel statistical parameters. The maps are, using the null hypothesis, distributed according to t or F probability density functions. The general linear model is used to define the experimental model (covariate, indicator, and confound variables). Problems associated with multiple comparisons are corrected by using Gaussian random fields to adjust voxel statistical significance. Ultimately, areas of clinical interest appear as differences between maps.

Commonly used with fMRI and PET, SPM is now increasingly being used for single-subject ictal–interictal SPECT analysis, using a method referred to as ictal–interictal SPECT analysis by SPM (ISAS, see http://spect.yale.edu/). Several studies have demonstrated the concordance of ISAS results to those using other subtraction techniques, and to surgical outcome. An example of ISAS analysis in a patient with TLE is shown in **Figure 1**. Our laboratory has defined some objective 'reading rules' for ISAS results, validated with a clinical epilepsy population. For a simple SPM ictal–interictal analysis against a predefined healthy control group, nonexperts can be quickly trained to run the software, and the subjective aspects of the program are limited to initial image reorientation and decisions of when to mask extracerebral artifacts. As with other computed analysis methods, however, visual examination of raw and difference images prior to preprocessing is desirable to appreciate potential complicating factors (scanner artifacts, reconstruction issues, etc.).

SPM also permits statistical comparisons of ictal-only studies to be made against healthy normal control groups. Although there are some financial savings if interictal scans are omitted, without within patient comparison of ictal and interictal scans, baseline areas of hypoperfusion may not be appreciated, and thus prevent detection of relative hyperperfusion areas in the ictal-only study. As we have already discussed, using a patient's interictal scan as an intra-subject control prevents this 'pseudo-normalization.'

SPECT for Investigating Fundamental Epilepsy Physiology

Ictal dystonia

Characterized by unilateral sustained muscle contractions, ictal dystonic posturing is a dependable indicator of lateralization of TLE, since dystonic posturing is usually contralateral to seizure onset. Ictal dystonia may be a result of seizure propagation to the striatum and globus pallidus. Understanding the specific networks involved with ictal dystonia in TLE has been the objective of several SPECT studies. One study of 22 patients (15 with ictal dystonia) demonstrated involvement of the caudate nucleus, putamen, and thalamus. These localizations were congruent with other studies on secondary dystonia resulting from infections, trauma, etc. Another SPECT study with a similar population size (13) found statistically significant hyperperfusion in the putamen and mesial temporal lobe associated with ictal dystonia.

Loss of consciousness

SPECT studies investigating loss of consciousness have been conducted in several different patient groups. SPECT studies of TLE by our group and several others suggest that impaired consciousness may be associated with abnormal activity in the upper brainstem/medial thalamus, along with depressed function (bilaterally) of the frontal and parietal cortex. Instead of focusing on one form of epilepsy, other studies have gauged consciousness across various seizure types; findings in one study indicate

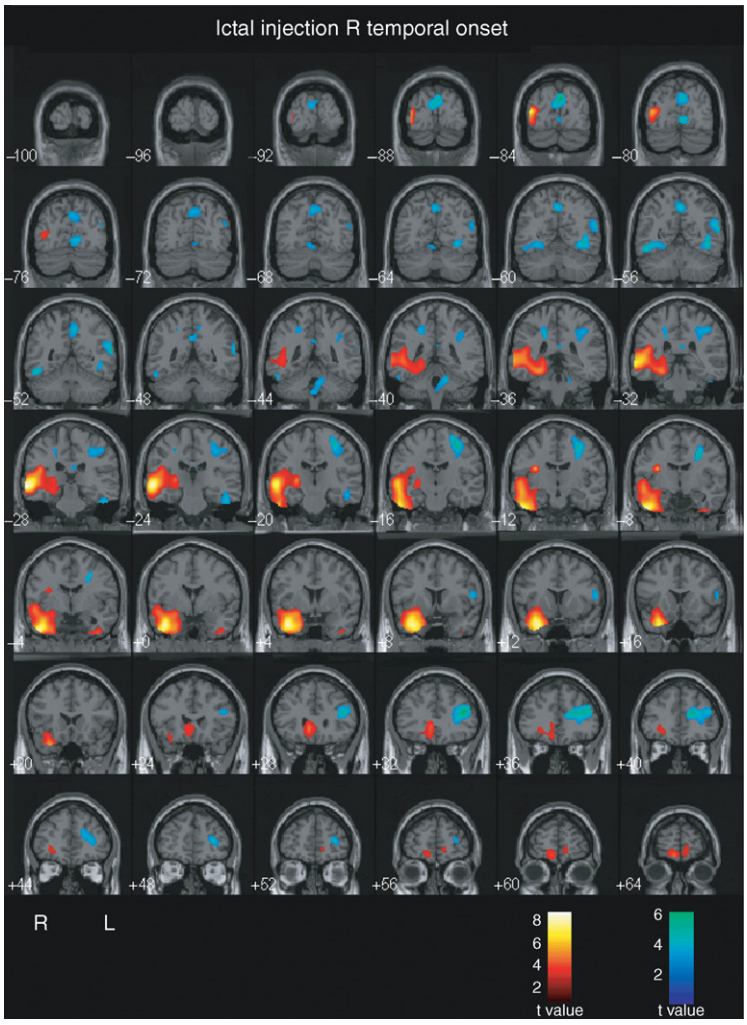

Figure 1 Ictal SPECT in mesial temporal lobe epilepsy (TLE) analyzed by SPM (ISAS). Ictal–interictal SPECT analysis is shown from a patient with right mesial temporal lobe onset, confirmed by surgical localization. Seizure duration was 153s and Tc99m-HMPAO was injected 69s before seizure end. The most significant hyperperfusion cluster was localized to the right temporal lobe (cluster-level significance $P < 0.0001$ corrected for multiple comparisons, Z-score of most significant voxel = 5.06, cluster size, $k = 10429$ voxels). The most significant region of hypoperfusion was localized to the L occipital lobe ($P = 0.035$, $Z = 4.04$, $k = 1625$). Hypoperfusion areas were not found to be helpful for localizing seizure onset. The ictal SPECT scan was background subtracted using the patient's corresponding interictal SPECT, and the difference was then compared to the database of normal SPECT pairs using ISAS (see http://spect.yale.edu). CBF increases are shown as red–white, and decreases are shown as blue–green; color bars indicate t values. Coronal views are shown superimposed on the SPM MRI template. Extent threshold, $k = 125$ voxels, voxel-level height threshold, $P = 0.01$. Reproduced with permission from McNally *et al.* (2005) *Epilepsia* 46(9): 1450–1464.

that impaired conscious is because of secondary hyperperfusion in the thalamus and upper brain stem. Our laboratory has also conducted studies using secondarily generalized seizures induced by electroconvulsive therapy (ECT) for depression. Although occurring under sedation, the induced seizure is similar to generalized epileptic seizures in both clinical and EEG aspects. SPM analysis demonstrated the largest hyperperfusion in the frontal and parietal association cortex, along with midbrain and thalamic involvement. Thus, the seizure's effect on the higher-order association cortex and upper brainstem/diencephalic activating systems may explain the root of impaired consciousness during generalized seizures. Ictal SPECT in epilepsy patients with secondarily generalized tonic–clonic seizures has also demonstrated SPECT changes in these same regions during seizures associated with ictal and postictal unconsciousness. We are currently investigating impaired consciousness in absence seizures, but using fMRI instead of SPECT; high temporal resolution is mandatory in these studies, since absence seizures usually last only 5–10 s, well below effective SPECT injection time.

Secondary generalization

We have recently collected SPECT data on 55 patients with secondarilygeneralized tonic–clonic seizures with pregeneralization, generalization, and postgeneralization radiotracer injections. Preliminary analysis of the results indicates focal, bilateral changes in rCBF during generalization. The data also suggest that epileptogenic lateralization, and in some cases localization to the correct lobe of seizure onset can be reliably determined based on SPECT in secondarily generalized seizures.

Hypothalamic hamartoma

Hypothalamic hamartoma is a rare, abnormal cellular growth (1–3 cm in size) on or near the hypothalamus. The mass does not appear on CT scans, and is isodense and nonenhancing on MRI. A typical symptom of hypothalamic hamartoma is gelastic epilepsy or ictal laughing, presenting with other seizure types (including complex partial). Gelastic seizures typically appear in infancy (3 months–1 year). The hypothalamic hamartoma mass may generate constant seizures, thus entraining surrounding networks. Clinical grading systems exist to denote the degree of attachment of hypothalamic hamartomas to other structures, and hypothalamic hamartomas with broad connectivity appear more often to induce seizures. The seizures (both gelastic and secondarily-associated) do not respond well to anticonvulsant treatment, and surgical resection outcomes are also mixed. EEG studies have demonstrated hypothalamic ictal discharges, and SPECT studies have confirmed that the hypothalamic hamartoma is the epileptogenic center during gelastic seizures, with ictal hyperperfusion. Use of ictal SPECT may allow for earlier detection and removal of hypothalamic hamartomas in some cases, although the diagnosis is usually made based on MRI and clinical features.

Infantile spasm

Infantile spasm (a component of West syndrome) is a rare form of infant epilepsy characterized by clustered spasms, hypsarrhythmia (interictal sharp and slow waves with high amplitude), and profound cerebral developmental abnormalities. Several SPECT studies have been performed to examine the origin and pathways associated with the spasms and hypsarrhythmia. SPECT studies and analyses must be read with regard to both the differences due to patient age (metabolism and perfusion are different for infants and young children, etc.), and to the severe structural abnormalities associated with infantile spasm. As perhaps expected, rCBF abnormalities are quite common: a 1996 study of 20 children for a 4 year period found over 85% had abnormal rCBF, with multifocal decreases in 40% of the children. Several studies have demonstrated that rCBF irregularities may appear in nonsymptomatic areas. Additionally, abnormal rCBF readings may present with normal MRI findings; a 1994 study of seven children all showed unilateral or bilateral hypoperfusion in the temporal lobe without accompanying abnormal MRI.

SPECT and PET studies have shown hyperperfusion or hypermetabolism of the basal ganglia and brainstem during spasms, with associated subcortical activations. Together with studies involving other modalities, the results suggest that a subset of infantile spasm patients have seizures that originate from focal cortical lesions, with additional involvement the basal ganglia and brainstem. Cortical resective surgery or drug therapy has been shown to lead to seizure freedom in some cases.

Conclusions and Directions for Future Research

SPECT is a useful technique; it has the unique capacity to image brain networks involved in human seizures while being unaffected by seizure movement. The ability to obtain ictal images, combined with digital analysis in comparison with interictal blood flow, has greatly enhanced the ability of SPECT to localize seizures for epilepsy surgery, and has shed new light on fundamental seizure networks and mechanisms.

There are many clinical avenues that have not been explored in depth, if at all, using SPECT. Future directions for SPECT research depend, in part, on increased use of the technique, which has been limited in part due to practical logistical issues involved in performing ictal injections. Automation of SPECT injections may help eliminate the time-consuming waiting process, and make studies more economical. While decreases in scanner time may not be technically feasible, advances in computational motion-correction promise to fix a major limitation of this technique. Modernizations being made in imaging software platforms (such as BioImage Suite, http://www.bioimagesuite.org/), in image coregistration, and in statistical analysis will further improve the results that can be obtained from SPECT studies.

Introduction

Epilepsy is a relatively diverse group of central nervous system disorders that may be acquired (infection, trauma, febrile seizures, etc.) or have genetic origins. Epilepsy is typically characterized by spontaneous and recurrent seizures. In electroencephalographic (EEG) recordings of brain activity, seizures appear as high frequency electrical discharges. These discharges may originate in, and be confined to a specific brain region with pathological features; for example, temporal lobe seizures (TLS) are often associated with mesial temporal-lobe sclerosis (MTS) – cell loss and gliosis in the hippocampus and related brain regions. However, in other cases, such as Rasmussen's disease, a focal abnormality may not be detected. The diverse etiology of these neurological disorders has prompted their development of numerous animal models to mimic the various manifestations of these disorders.

Electrophysiological and histological methods, applied in both the experimental laboratory and the clinic, have provided direction for treatments. However, these techniques have important limitations, including poor spatial resolution (EEG) and invasiveness (histology). In the last decade, non-invasive methods have gained momentum; they permit serial monitoring (days, weeks, months) and are now a standard tool for augmenting the armamentarium of the epileptologist and neurologist.

Of the various imaging modalities used for diagnosis and therapy monitoring, magnetic resonance imaging (MRI) is the most popular. It has several distinct advantages: it involves no ionizing radiation; multiple 'stains' or 'contrasts' are available from a single study; and both structural and chemical alterations can be probed. Most commonly, structural MRI (T1, T2, DWI) is performed to locate lesions that cause, or are a consequence of, the observed abnormal electrical activity. If lesions are not obvious in an initial 'standard' study, more advanced methods are available. For example, external contrast agents can be injected to detect areas where the blood-brain barrier has been compromised. In other cases, where ischemia is suspected, perfusion-weighted imaging (PWI) may be employed to assess the performance of the capillary bed. Similarly, subtle structural changes (for example, mossy fiber sprouting), may be probed using diffusion tensor imaging (DTI). Physiological information is also

Introduction

Epilepsy is a relatively diverse group of central nervous system disorders that may be acquired (infection, trauma, febrile seizures, etc.) or have genetic origins. Epilepsy is typically characterized by spontaneous and recurrent seizures. In electroencephalographic (EEG) recordings of brain activity, seizures appear as high frequency electrical discharges. These discharges may originate in, and be confined to a specific brain region with pathological features; for example, temporal lobe seizures (TLS) are often associated with mesial temporal-lobe sclerosis (MTS) – cell loss and gliosis in the hippocampus and related brain regions. However, in other cases, such as Rasmussen's disease, a focal abnormality may not be detected. The diverse etiology of these neurological disorders has prompted their development of numerous animal models to mimic the various manifestations of these disorders.

Electrophysiological and histological methods, applied in both the experimental laboratory and the clinic, have provided direction for treatments. However, these techniques have important limitations, including poor spatial resolution (EEG) and invasiveness (histology). In the last decade, non-invasive methods have gained momentum; they permit serial monitoring (days, weeks, months) and are now a standard tool for augmenting the armamentarium of the epileptologist and neurologist.

Of the various imaging modalities used for diagnosis and therapy monitoring, magnetic resonance imaging (MRI) is the most popular. It has several distinct advantages: it involves no ionizing radiation; multiple 'stains' or 'contrasts' are available from a single study; and both structural and chemical alterations can be probed. Most commonly, structural MRI (T1, T2, DWI) is performed to locate lesions that cause, or are a consequence of, the observed abnormal electrical activity. If lesions are not obvious in an initial 'standard' study, more advanced methods are available. For example, external contrast agents can be injected to detect areas where the blood-brain barrier has been compromised. In other cases, where ischemia is suspected, perfusion-weighted imaging (PWI) may be employed to assess the performance of the capillary bed. Similarly, subtle structural changes (for example, mossy fiber sprouting), may be probed using diffusion tensor imaging (DTI). Physiological information is also

available via volume selective spectroscopy (MRS) and functional MRI (fMRI). fMRI is particularly useful in identifying critical brain areas (speech, movement, etc.) that must be spared during surgical intervention (typically lobectomy). MRS offers metabolic information that is particularly useful in identifying neuronal loss and regions of necrosis. While magnetic resonance techniques are rapidly becoming the primary investigative imaging modalities, they are often augmented with information available from positron emission tomography (PET) or single photon emission computed tomography (SPECT) – techniques that probe cellular function. Finally, X-rays (computed tomography, CT) remain useful in identifying gross neuro-anatomical abnormalities, such as hemorrhage, necrotic tumors, and abscesses that may produce epileptic-like symptoms.

In the clinic, qualitative visual analysis of MRI data is often the primary method for diagnosis. Since this approach is highly dependent on physician expertise, analyst-independent quantitative approaches have gained popularity. Computational methods have been used to identify volumetric changes (i.e., hippocampal swelling), intrinsic tissue matrix alterations (neuronal loss, glial activation), and connectivity within the epileptic brain (e.g., contra-lateral injury). Typically these analysis techniques require additional data collection, in order to compute such tissue characteristics as diffusion coefficients (DWI, DTI), chemical changes (magnetic resonance spectroscopy, MRS), or tissue relaxation times (T1, T2). The added time required for these analyses limits their use in the clinic. However, they form the backbone within basic science research for determining epilepsy onset, progression, and efficacy of various therapies.

Background

Animal Models of Epilepsy

Rat models are widely used by experimental epileptologists. Partial seizures (arising from a restricted brain regions) can be induced by topical or regional application of amino acids antagonists (e.g., penicillin, bicuculline) or excitatory amino acid agonists (e.g., kainic acid); systemic injection of these agents (also including the cholinergic agonist pilocarpine) induces what appear to be partial seizures, arising from the hippocampus and related regions. Many of these excitatory agonists produce a period of *status epilepticus* (SE, sustained seizures, typically for greater than 10 min) followed by a latent period. After the inductive and latent phases, many animals go on to develop spontaneous recurrent seizures – i.e., become epileptic. Generalized seizures can also be modeled, using electrical stimulation paradigms as well as other chemical induction methods.

MRI of the Pilocarpine Model of Epilepsy

The rat pilocarpine model is characterized by a robust period (1–4 h) of *status epilepticus* that normally results in loss of neurons within various brain regions, including the hippocampus, piriform cortex, amygdala, retrosplenial cortex, and thalamus. Cell loss alters the chemical and physical properties of the brain matrix, and these changes permit tracking of injury progression and cell death using various MR contrasts. Diffusion-weighted imaging in the pilocarpine model has been particularly revealing. In DWI, the signal intensity (contrast) is based upon the relative mobility of the reporter molecule, water. Its motion in the tissue is measured as an Apparent Diffusion Coefficient (ADC) – 'apparent' because the three dimensional motion of water is observed in two dimensions only. ADC measurements suggest that water mobility is reduced within hours of seizure and SE onset, but that mobility gradually normalizes within 24 h. This transient reduction is interpreted as an indication of neuronal swelling, which decreases the relatively mobile extracellular water fraction. During the subsequent 48–72 h ADC values increase. This change indicates an enhanced extracellular water fraction that is temporally correlated with cell necrosis. In other words, as more cells die, water molecules encounter fewer reflective barriers (i.e., less restricted diffusion) and/or diffuse in a less viscous matrix. This reduction in tissue tortuosity (or viscosity) has become a key feature in characterizing ischemic-like injury associated with convulsive seizures (those involving muscle stiffening and contraction/extension of the limbs).

To measure a signal in MRI, it is first necessary to excite the reporter (in the case of DWI, the hydrogen nucleus of a water molecule) and then monitor the rate at which energy is released from the excited nucleus. There are two processes by which this occurs: cooling – where the energy is returned as heat to the environment, and dissipation – where the cohort of excited molecules lose coherence and internally cancel the measurable signal. These processes are characterized by distinct time coefficients, T1 and T2. The latter process is particularly useful in probing the nuclear environment because the loss of coherence is affected by various factors, including viscosity and the presence of paramagnetic compounds. As a guideline, compartments that are relatively viscous have shorter T2s than those containing pure water. In the rat pilocarpine model, T2-weighted image intensities increase (corresponding to increased T2 values) after cellular injury, an observation consistent with edema formation.

Changes in the relaxation or diffusion of the reporter molecule are reflected as intensity-contrasts in the image. A key advantage of these contrasts is the excellent anatomical localization of injury. High resolution imaging allows the investigator to compare imaging data directly with histological findings. This process has proven to be highly

complementary. That is, the MR studies provide unperturbed temporal evolution information, while the histology provides periodic cell based observations. Such analyses lead to an understanding of the evolution of injury following seizure activity, and have shown that each model (and each seizure type) has unique features. For example, in the pilocarpine rat model, changes seen on MRI (reflecting injury) are first apparent in the piriform cortex, and then in the retrosplenial cortex; involvement of the thalamus and hippocampus is apparent only after 72 h. In contrast, seizure-associated damage after injection of the neurotoxin soman (a cholinesterase inhibitor) first appears in retrosplenial cortex. These MRI-based temporal events have been confirmed on histological samples. Such experiments have shown that MRI can provide useful diagnostic and regional information about the onset, latent period, and cellular remodeling that occurs in the brain as a consequence of status epilepticus.

Methods

Pilocarpine injections (without lithium pretreatment) of adult rats were used to reliably invoke SE for 1–4 h. Less frequent convulsive activity often was observed in these animals for the next 4–8 h. Animals were scored for seizure severity using standard behavioral measures. To improve the health and recovery of these animals, moistened chow with fructose was provided. In our experience, mortality typically was about 30%. Animals were imaged at 1, 7, 14, 21, and 30 days following pilocarpine injections. While comprehensive behavioral observations were not conducted, many animals at 21 and 30 days regularly exhibited spontaneous seizures.

After SE induction, the animals were allowed to recover for 24 h prior to MRI. All MRI exams were conducted using a Bruker 4.7 Tesla (T) magnet, with the animals lightly anesthetized by isoflurane. To minimize motion during the MR acquisitions, animals were placed in a custom-built stereotactic head holder. A standard suite of MR sequences was used to acquire T2 and DWI data: T2WI acquisition was performed using a multi-echo spin echo acquisition protocol (6 echo, 20–120 ms), and the DWI data were obtained using two weighting factors ($b = 0\,s\,mm^{-2}$) and ($b = 434\,s\,mm^{-2}$). The T2 and DWI MR data sets were processed to compute T2 coefficient (transverse relaxation, ms) and ADC (water mobility, $mm^2\ s^{-1}$) maps using standard computational methods. Regions of interest (hippocampus, piriform cortex, etc.) were then overlaid on the initial T2 and DWI images, and the quantitative data extracted and summarized.

At the end of the experimental period, all animals were processed for standard histology and immunohistochemistry to evaluate tissue and cellular composition. Prior to histological sectioning, the *ex vivo* brains were re-imaged for high resolution MR microscopy in an 11.7T magnet, using sequences similar to those used for the 4.7T image acquisition.

Recent Results

Diffusion Weighted Imaging

Previously published data from our laboratory and from others have shown that during the initial 24 h after the onset of SE, there are temporally and regionally differential effects within the brain that are evident in the MR images (**Figure 1**). The ADC decreases within the retrosplenial cortex 12–18 h after pilocarpine induced SE, and then returns to control levels by 24 h (**Figure 2**). Perhaps more interesting is the concomitant increase in ADC within the hippocampus. Correlative histological observations indicate that the early ADC decrease reflects

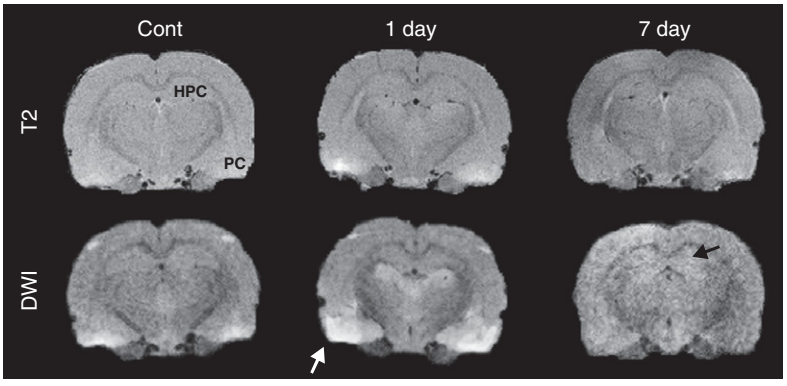

Figure 1 Serial imaging after epilepsy induction. Pilocarpine induced status epilepticus was initiated after control image data (T2, DWI) was obtained. In this example the same animal was repeatedly imaged to provide a temporal snapshot of cellular changes after seizure induction. At 1 day after pilocarpine injection, signal intensity in the weighted DWI within the piriform cortex (PC, white arrow) and midline structures increases. By 7 days there was increased signal within cortical structures, including the hippocampus (HPC, black arrow).

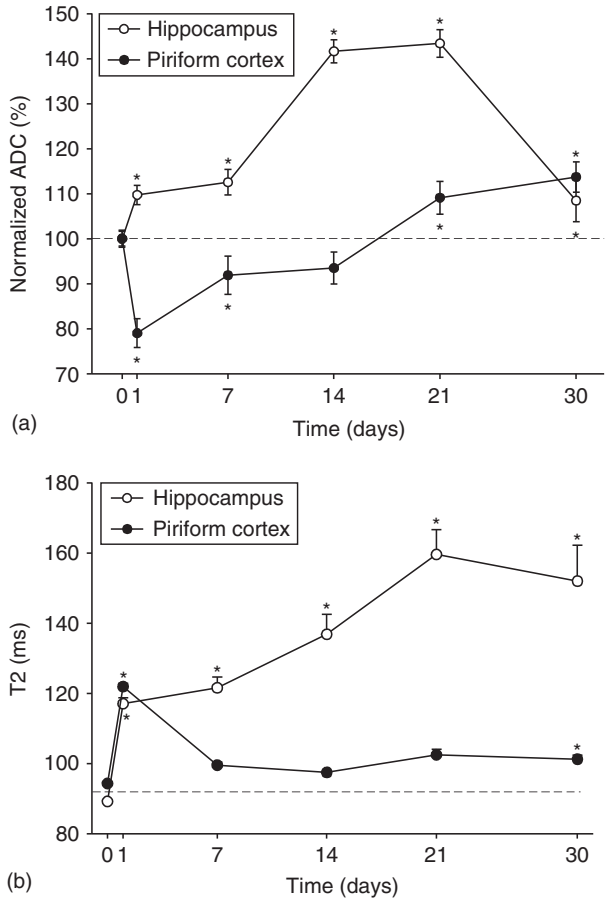

Figure 2 Temporal evolution of quantitative MRI changes. (a) Normalized ADC. The hippocampus and piriform cortex each have different ADC signatures during the first 30 days following seizure induction. Hippocampal ADCs increase during the first 21 days and then slowly return to control values (dotted line). In the piriform cortex there is a rapid decline in ADC, which then slowly increases over the next 30 days. These ADC changes are related to alterations in water diffusion in the tissue within each region. (b) T2 changes in the hippocampus and piriform cortex. T2 elevations in the hippocampus are progressive and become maximal at 21–30 days. This elevation of putative water content (edema) could be indicative of synaptic remodeling and neuronal loss within this region. Conversely, within the piriform cortex, rapid cell death and subsequent pan necrosis leads to an initial increase in T2 values at 1 day, which then quickly decreases back to control levels. Thus, edema formation in the piriform cortex is considerably less than that seen in the hippocampus.

neurodegeneration within the piriform cortex, while within the hippocampus there are few dying neurons.

One of the major advantages of MRI in epilepsy is the ability to monitor the same group of animals for long periods of time. For example, we extended our 7-day study to thirty days. In doing so, we found that ADC values in several regions, including the piriform cortex, gradually returned to control values by 14 days after SE. This normalization time-frame correlates, temporally, with reactive gliosis, reflecting tissue repair mechanisms characteristic of the inflammatory response. Glial cells, although substantially different in size and shape from neuronal cells, apparently produce a biophysically similar tissue matrix with diffusion properties similar to that of the original neuronal tissue. However, the post-SE remediation process is not complete at this 14-day timepoint; ADC values within the piriform cortex continued to increase in the ensuing days, so that at 21 and 30 days following SE, ADC values were significantly greater than controls. These experiments demonstrated that although substantial portions of the principal neuronal layers within the piriform cortex (Layers 2 and 3) are rapidly (24–48 h) lost after the initial seizure induction, the neurodegenerative processes are by no means complete. A growing area of cell loss was apparent in MR images, and was confirmed with periodic histological sampling. Based on the histological data, it appeared that MRI was equally effective in detecting cell loss owing to apoptotic and necrotic processes (**Figure 3**).

In the hippocampus, a different picture emerged. The ADC slowly increased over the first 21 days (to 145% of control) but then returned to near normal by 30 days. Again, these changes were consistent with the corresponding histological evidence; the relatively slow ADC changes in the hippocampus reflected gradual neurodegeneration. Also interesting is the fact that the apparent peak ADC changes within the hippocampus appeared at 14–21 days post-SE, a time period known for synaptic and cellular remodeling (i.e., mossy fiber sprouting (MFS)). In a similar cohort of animals also experiencing pilocarpine-induced SE, extensive MFS occurred within the dentate gyrus at this same time; other investigators have reported that the majority of this remodeling is complete by 30 days – when we see a trend toward normalization of the ADC (**Figure 3**).

More recently, using a variant of DWI – q-space imaging – we were able to further discriminate between what appeared to be neuronal and glial populations within the piriform cortex. In this case, discrimination is based on our ability to isolate different diffusing populations. In other words, water within neuronal cells diffuses, on average, at one characteristic rate, while that in glia diffuses, on average, at a different rate. While our q-space sampling paradigm contained limiting assumptions, it did establish a potential method to evaluate future therapeutic interventions based on cellular targets. More work is needed to validate this technique for its ability to discriminate various cellular populations important in epilepsy.

T2-Weighted Imaging

T2WI provides additional information on brain water content. The T2 coefficient provides an indirect or relative assessment of compartment viscosity. As with the ADC changes, T2 values increased soon after seizure induction (<1–6 h). In the piriform cortex, the average T2 coefficient

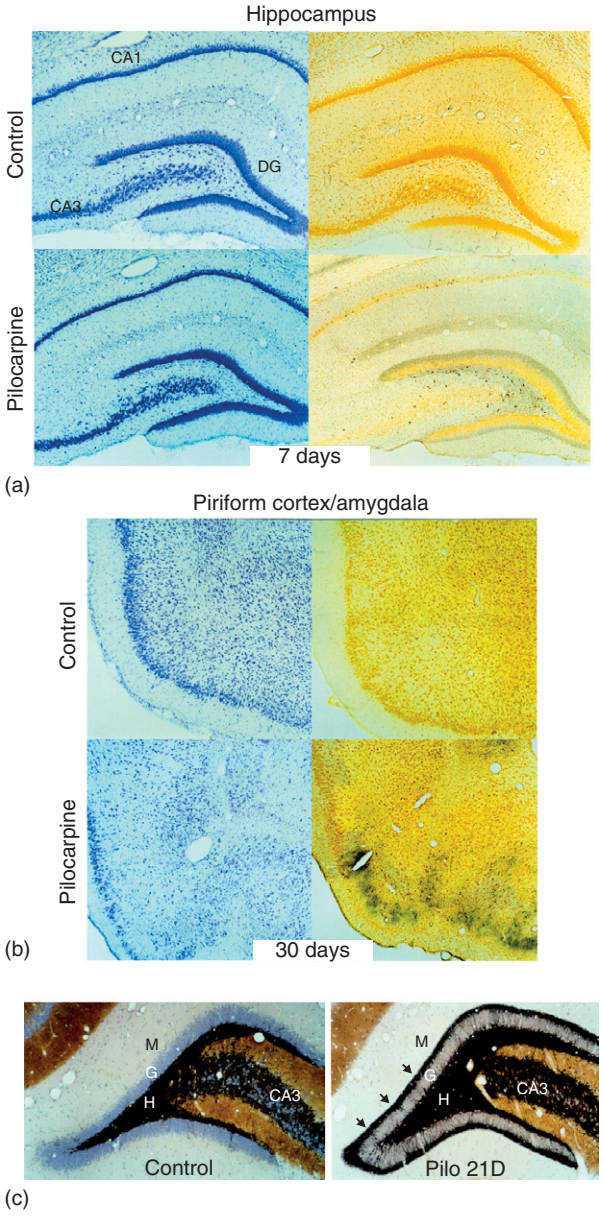

Figure 3 Cellular alterations within the hippocampus and piriform cortex after pilocarpine-induced seizures. (a) The hippocampus exhibits a slow but progressive increase in neuronal death predominantly within the dentate gyrus but also in the CA1 region (left panel, cresyl violet, right panel, silver degeneration stain). Within the hippocampus cell death is maximal at 7 days. (b) In previously published research we have shown that cell death within the piriform cortex is maximal within the first 24 h. The pan-necrotic lesion formed in the first several days is still present at 30 days with significant loss of the principal layers within the piriform cortex. (c) Mossy fiber sprouting (MFS) within the dentate gyrus is maximal within the dentate gyrus at 21 days in the pilocarpine treated animals. The formation of an additional layer of zinc positive (Timm's stain) staining on the molecular layer (M) side of the granule cell layer (G) (arrows) occurs at a time when ADC changes in the hippocampus are maximal. This would suggest that cellular alterations can be visualized with ADC derived MRI data.

value increased by 20% at 1 day post-SE, then returned to control values by 7 days. Of interest was the reappearance of a secondary slow increase in T2 within the piriform cortex at 21–30 days. It is tempting to speculate that this slow increase reflects the new tissue matrix formed during gliosis.

In the hippocampus, the T2 values gradually increased over 21 days post-SE, to 150% of controls, and this level persisted until the end of the observation period (30 days). This observation supports the hypothesis that there is a slow but steady formation of edema that peaks around 21 days. At this time point, the neuronal cell death process is virtually complete within the hippocampus, as is MFS-induced reorganization.

In summary, MR imaging – and in particular, diffusion and relaxation contrast imaging – is sufficiently sensitive to detect tissue changes that follow severe epileptic activity. In addition, the standard clinical sequences can be extended to provide quantitative insights – if increased acquisition and analysis times are not a limiting factor. There is emerging evidence that cell populations in the brain have distinct diffusion signatures, and that these characteristics may be accessible from detailed diffusion measurements. Chronic diseases such as epilepsy require serial measurements to determine the status of injury. MR technology provides an essential and versatile window for this type of measurement.

Future Directions

Conventional MR procedures provide excellent images with sub-millimeter resolution of brain structures. These imaging approaches have been applied in the laboratory setting to provide quantitative measures that characterize regions of interest. By correlating knowledge from complementary technologies (i.e., other imaging methods, histopathology), subtle features can be extracted that offer additional insights into the disease process.

MR spectroscopy has the ability to provide data on key cellular metabolites such as *N*-acetylaspartate acid (NAA – a neuronal marker), creatine/phosphocreatine (Cr – an energy metabolite) and choline (Cho – a membrane component). Lactate peaks often appear transiently on MRS images during injury, and thus provide sensitive information about the level of injury.

Diffusion tensor imaging (DTI) is a variant of diffusion-weighted imaging that can assess tissue microstructure in vivo. The microstructure of the white matter fibers preferentially limits the movement of water molecules diffusing perpendicular to the fiber direction; this privileged water diffusion is termed 'anisotropy.' Numerous quantitative parameters can be extracted from DTI data that

describe altered microstructure (primarily white matter) within the brain. Only recently have investigators begun to use DTI – experimentally and in the clinical setting – to study or diagnose epilepsy. This DWI variant has the potential of providing additional prognostic and diagnostic information about regional tissue status.

Functional MRI (fMRI) uses the hemodynamic response of the brain to various stimuli as a reporter of brain activity. fMRI is used extensively for brain mapping studies, including pre-surgical evaluation of epilepsy patients. With the appropriate cognitive, motor or sensory test, fMRI may define seizure-affected and normal brain regions. However, due to the extensive post-processing required, this technique is not likely to become part of routine clinical practice. fMRI evaluation in animal studies is difficult because some anesthesia is generally required to reduce motion artifacts of animal subjects, and inhalation anesthetics are known to reduce blood flow. Development of alternative methods to reduce movement, and or to compensate for movement during data processing, may increase the use of this technique in the laboratory.

Finally, many of the new advances in MRI are arising from computational methods that extract relevant MR parameters quickly and efficiently. Enhanced statistical techniques, wavelet analysis, histogram-based analysis and other data extraction methodologies will provide additional perspectives on the onset, evolution, and treatment of epilepsy.

Using Intrinsic Optical Signal Changes to Analyze Epileptic Activity and Seizures

H Meierkord, Johannes-Müller-Institut für Physiologie, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic activity and seizures represent highly dynamic phenomena potentially activating brain tissue in various regions of the brain. Analyzing such epileptiform activity, and the pathways through which it spreads, requires tools that provide both excellent temporal and spatial resolution. Optical imaging is capable of yielding information on this scale and is therefore well-suited to study the onset and spread of seizure activity. There are two main forms of optical imaging. 'Extrinsic' optical imaging relies on the use of indicators that change their optical

describe altered microstructure (primarily white matter) within the brain. Only recently have investigators begun to use DTI – experimentally and in the clinical setting – to study or diagnose epilepsy. This DWI variant has the potential of providing additional prognostic and diagnostic information about regional tissue status.

Functional MRI (fMRI) uses the hemodynamic response of the brain to various stimuli as a reporter of brain activity. fMRI is used extensively for brain mapping studies, including pre-surgical evaluation of epilepsy patients. With the appropriate cognitive, motor or sensory test, fMRI may define seizure-affected and normal brain regions. However, due to the extensive post-processing required, this technique is not likely to become part of routine clinical practice. fMRI evaluation in animal studies is difficult because some anesthesia is generally required to reduce motion artifacts of animal subjects, and inhalation anesthetics are known to reduce blood flow. Development of alternative methods to reduce movement, and or to compensate for movement during data processing, may increase the use of this technique in the laboratory.

Finally, many of the new advances in MRI are arising from computational methods that extract relevant MR parameters quickly and efficiently. Enhanced statistical techniques, wavelet analysis, histogram-based analysis and other data extraction methodologies will provide additional perspectives on the onset, evolution, and treatment of epilepsy.

Using Intrinsic Optical Signal Changes to Analyze Epileptic Activity and Seizures

H Meierkord, Johannes-Müller-Institut für Physiologie, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic activity and seizures represent highly dynamic phenomena potentially activating brain tissue in various regions of the brain. Analyzing such epileptiform activity, and the pathways through which it spreads, requires tools that provide both excellent temporal and spatial resolution. Optical imaging is capable of yielding information on this scale and is therefore well-suited to study the onset and spread of seizure activity. There are two main forms of optical imaging. 'Extrinsic' optical imaging relies on the use of indicators that change their optical

properties (e.g., fluorescence or absorbance) with variations in cellular activity (i.e., changes in neuronal membrane potential). With the use of voltage sensitive dyes, temporal resolution is excellent (within milliseconds), but as dyes are toxic, this approach is used in experimental studies only. In contrast, 'intrinsic' optical imaging is based on signal changes associated with tissue itself and is entirely noninvasive. This article deals with intrinsic optical imaging and its relevance to the study of different forms of epileptic activity, including their regions of onset and spread, with special consideration of experimental studies carried out in the brain slice preparation, in vitro.

Background

Basics of Intrinsic Optical Imaging

The processes which occur when light interacts with living cells (or tissues or organs), leads to loss of light intensity (attenuation), resulting from scattering, absorption, and fluorescence. Scattering indicates that photons undergo elastic collisions; that is, no energy is lost and the photon merely changes direction. Light reflectance and transmittance are affected in opposite ways. The more a medium scatters light, the more the light is reflected and the less is transmitted. Higher frequency (shorter wavelength) light at the blue end of the visible spectrum is scattered considerably more in cells and tissues than lower frequency (longer wavelength) light. For this reason, near-infrared radiation is more effective for noninvasive optical detection through bone and tissue, as less energy is lost through scattering. When light is absorbed by tissue, its energy is dissipated as either thermal energy or fluorescence.

Physiological processes

The physiological processes underlying changes in the intrinsic optical signal (IOS) are still elusive. The key data (and opinions) that have been published are summarized in the following paragraphs. In early studies, optical changes in the nerve trunk of the walking leg of the shore crap were found to correlate with nerve activation. The signal change consisted of an increase in light transmission in association with the period of electrical stimulation, followed by a prolonged decrease in transmission afterwards. Using optical and mechanoelectric movement detectors, investigators showed that rapid swelling in nerve fibers, related directly to the mechanisms underlying the action potential, is responsible for this IOS change. In experiments on single squid giant axons, combined electrophysiological and optical methods identified fast and slow scattering changes. The fast scattering changes were dependent on membrane voltage, whereas the slow scattering changes were caused by periaxonal volume changes.

A system of considerably higher complexity is represented by the mammalian brain slice preparation. This preparation permits investigators to study neuronal activation induced by electrical stimulation, and changes because of spontaneous neuronal activity under pathological conditions, across a fabric of cortical regions. In brain slice preparations, both transmitted and reflected light can be analyzed. In hippocampal slices, stimulation-induced IOSs are abolished in the presence of Ca^{2+}-free artificial CSF (ACSF) or by addition of kynurenic acid, suggesting that postsynaptic activation may be important for an IOS. Other studies clearly showed, however, that postsynaptic activation is not a prerequisite for an IOS; a reproducible IOS is associated with epileptiform discharges induced by low Ca^{2+} ACSF in which synaptic transmission is blocked. A widely held hypothesis suggests that cell swelling or shrinkage of the extracellular space (ECS) volume, associated with neuronal activation, may be the most important factor in generating the IOS; changes in plasma viscosity, cellular volume, and membrane potential have all been suggested to underlie the IOS change in slice preparations, and postsynaptic activation and shrinkage of the ECS are assumed to be important. However, the mechanisms and components underlying the signal generation are still elusive.

Methods

Combined Hippocampal–Entorhinal Cortex Slice Preparation

The experiments in our laboratory are performed on combined hippocampal–entorhinal cortex slices taken from Wistar rats. The animals are decapitated under deep ether anesthesia. The brains are rapidly removed and washed with cold ACSF containing (in mM): NaCl 124.0, KCl 3.0, $MgSO_2$ 2.0, $CaCl_2$ 2.0, NaH_2PO_4 1.25, $NaHCO_3$ 26.0, and glucose 10.0 (pH 7.4), oxygenated with 95% O_2, 5% CO_2. Brain slices (400 μm) are cut in a nearly horizontal plane using a vibratome. The slices contain the temporal cortex and the perirhinal cortex as parts of the neocortex, the entorhinal cortex, the subiculum, the dentate gyrus (DG), and the ventral hippocampus. Slices are stored in ACSF and are individually transferred to an interface recording chamber, placed on a transparent membrane illuminated from below, and continuously perfused with prewarmed (35 °C) and carbogenated ACSF. Epileptiform activity is induced either by omitting Mg^{2+} or Ca^{2+} from the ACSF, or by adding 4-aminopyridine (4-AP) to the ACSF.

Electrophysiological Recordings

The recordings are started after more than 1 h of equilibration of the slices in normal ACSF. Bipolar stimulation electrodes are placed into the perforant path and a recording electrode is placed into the granule cell layer of the DG. The viability of slices is tested by the single stimuli to the perforant path and observation of the extracellular field potential in the DG. After viability testing, the stimulation electrode is removed from the chamber. The recording electrode is moved from the DG to the medial entorhinal cortex, as amplitude and duration of seizure-like events are the largest in layers IV and V of this region. A second, ion-sensitive, microelectrode is used in some experiments, placed in the temporal cortex to monitor spontaneous epileptiform activity after omission of Mg^{2+} from the ACSF.

Optical Imaging

The slices are transilluminated from below using a halogen lamp supplied by a stabilized voltage-regulated power supply. Homogeneous illumination is achieved by a curved glass rod (Ø 8 mm) placed directly underneath the slice below the transparent floor of the interface chamber. The slices are viewed from above with an upright binocular microscope Video images using a CCD camera (8 bit, Sanyo, Osaka, Japan) are obtained via a monocular phototube. During the experiments, images are stored on videotape using an S-VHS video-recorder. The complete video signals are converted at a 12.5 MHz ratio into 240 lines by 640 320 pixel per line employing a frame-grabber board and in-house software. The 8 bit information of each converted pixel represents one of 256 grey levels. The first image used for the analysis is captured 5–10 s before the stimulus-induced onset of the seizure-like event, and the last image is obtained at least 45 s after the electrical offset. Our aim is to examine alterations of the IOS with time. Thus, the first image in a series serves as a control which is subtracted from each of the following images. These subtracted images disclosed areas in the slice where light transmission has changed (at the time the image is obtained) relative to control transmission levels. Pseudo-colored images are calculated also by subtracting the control image from subsequently acquired images and assigning a color lookup table to the relative pixel values.

The series of subtraction images typically contains between 200 and 800 images with a variable temporal resolution. During seizure-like events the intervals ranges from 50 ms to 2 s. In order to detect changes in light transmittance induced by the different manipulations, subtracted images are data-reduced by averaging four neighboring pixels, and covered with a grid of 81 regions of interest by employing in-house software. To graph data from specific slice areas, square regions of interest (10×10 pixels) are placed over subiculum, medial entorhinal cortex, lateral entorhinal cortex, perirhinal cortex, and temporal cortex and in the hippocampus proper in CA1 and CA3, and the DG. The average digital intensities are sampled and stored. The figures and plots illustrate relative differences in light transmittance (T). The magnitude of the intensity difference ($\triangle T$) is expressed as a percentage of the digital intensity of the control image in a series. Changes in light intensity ($\triangle T/T$) typically range from 0.4% to 5.12% during the discharges, whereas noise usually is below 0.1%. Therefore, the signal-to-noise ratio ranges from 4 to 51.

To analyze propagation of a single seizure-like event in time and space, subsequently captured images are compared. Corresponding pixels in consecutive images which exceed a previously chosen threshold of light intensity change (clearly above the optical noise) are marked. By this approach, a circumscribed area of IOS associated with epileptiform activity may be displayed. Changes in this area exhibit specific spread patterns from one image to another, providing information about region of onset, direction and extent of propagation, and the velocity of spread (the latter determined by analysis of the temporal interval between images).

Recent Results

Mechanisms

As indicated above, the mechanisms and components underlying the generation of IOSs are still elusive. In particular, whether IOSs are generated by neuronal or glial changes has been controversial, as has the manner in which subcellular compartments contribute to the signal change.

The notion of a predominant glial contribution to the IOS is on the basis of initial data indicating that IOSs are attributable to a furosemide-sensitive uptake of K^+ into glia cells and to a concomitant water influx causing cell swelling. However, subsequent experiments have modified this view, since a reduction in signal amplitude of only 11% was observed in the presence of furosemide. In addition, there is evidence that furosemide, in the concentrations used in these experiments, exerts nonspecific and pleomorphic effects – including reduced neuronal excitability, interference with glial volume regulation mechanisms, and pronounced changes in extracellular pH. Investigators have also argued for an important role for neurons as a source of the IOS change, primarily based on data generated in excitotoxicity experiments. Bath application of the glutamate agonists *N*-methyl-D-aspartate or kainate produced a large signal change reflecting cell swelling. This response was not prevented

or reduced by furosemide, a blocker of the $Na^+/K^+/2Cl^-$ transport system that is prevalent in glial cells. The changes were distinctly laminar compared with more widespread changes seen with glial swelling.

In recent experiments in our laboratory, we have tried to gain some insight into the contribution of glial changes to IOS generation. We have employed antidromic stimulation, and application of fluoroacetate (FAC) as a tool to selectively block glial cells. FAC significantly decreased the slope and the maximum amplitude of the IOS, without affecting most electrophysiological parameters. This result may indicate that under glial blockade with FAC, light scatter increases – perhaps due to changes in glia conformation.

On a subcellular level, changes in size of mitochondria also appear to contribute to the generation of the IOS change during neuronal activation. Using a dual-angle scatter ratio optical imaging system, investigators demonstrated that an increase in light scattering occurred in hippocampal slices following *N*-methyl-D-aspartate treatment and concomitant swelling of mitochondria. In our laboratory, we have chosen a different approach to gain information about the contribution of mitochondria in the generation of the IOS. Combining tissue activation and blockade of mitochondrial activity – via inhibition of complex I with rotenone – we analyzed the effects on signal amplitude. Under rotenone conditions, we saw significantly decreased amplitudes of the IOS.

In conclusion, our data show that the amplitude of the IOS change is on the basis of both glial and mitochondrial changes during tissue activation. This result indicates that the IOS changes not only reflect tissue activation, but also contain information regarding the underlying types of activation and participating cellular components.

Origin and Spread

Intrinsic optical imaging is advantageous for studying the spread of epileptiform activity since it allows for simultaneous monitoring of changes over an entire preparation. We have used this technique in vitro to investigate seizure-like events (SLEs) which are characterized by 'tonic' and 'clonic' features, resembling seizures in vivo. In the low Mg^{2+} model, we demonstrated, for example, that discharges originated in the entorhinal cortex and spread to the temporal neocortex. We have compared origin and spread patterns of discharges in both the low Mg^{2+} model and in the 4-AP model. Although SLEs induced by low Mg^{2+} solutions were initiated predominately in the entorhinal region, there was no consistent region of onset or spread in the 4-AP model. This difference was explained by the differing mechanisms in the two models; in the low Mg^{2+} model, epileptiform discharges result from unblocking the NMDA receptor – which is more richly expressed in entorhinal cortices, whilst 4-AP is an antagonist of various K^+ channels found ubiquitously.

Age Dependency

Tissue from juvenile rats

It is well known that infants and young children carry a higher risk of developing seizures and epilepsy than adults. Experimental studies have suggested that this sensitivity is because of discrete periods of altered seizure susceptibility and expression during development. Whether and/or how this increase in seizure susceptibility during development may be reflected in regions of seizure onset, spread patterns, and spread velocity are poorly understood. We have combined extracellular microelectrode (ionsensitive electrode) recordings with intrinsic optical imaging to study the spatiotemporal patterns of seizure onset and spread during development in low Mg^{2+}. We examined rats from three age groups: 4–6 days (age group I), 10–14 days (group II) and 20–23 days (group III). Seizure susceptibility was the highest in age groups II and III. In age group I, SLEs originated mainly in the hippocampus proper. SLEs in age group II originated mainly in the entorhinal cortex, and this tendency was even more pronounced in age group III. Seizure invasion of the hippocampal formation, via the perforant path–DG and via the subiculum, was seen in age group I and II. By contrast, in age group III, seizure invasion into the hippocampus was exclusively via the subicular pathway. The velocity of spread at which SLEs propagated within different regions of the slice increased with postnatal age. The characteristics of onset, spread patterns, and propagation velocities, as revealed by this study, provide insight into the evolving properties of the developing brain.

Tissue from old rats

The highest incidence of epileptic seizures has been reported to occur in the elderly. There is little doubt that the high incidence of cerebral structural lesions (i.e., vascular, infectious, neoplastic, neurodegenerative, traumatic), metabolic disturbances, and the potentially proconvulsive consequences of comedication play important roles. It is also well known that there are pronounced alterations in the plastic properties of the aging brain in the absence of structural lesions. However, the effects that those changes in brain plasticity may have on seizure susceptibility remain unclear. We, therefore, were also

interested in the effects of old age on seizure onset, spread patterns, and propagation velocities in the absence of structural lesions. To this end, we employed slices from 'senile' animals; in the case of Wistar rats, senescence is said to be at about 2 years of age. The main findings of this study were: seizure-like events in tissue from aged (compared to young adult) animals tend to arise in more than one onset region, they show a less extensive spread to adjacent areas, and are characterized by decreased propagation velocity in distinct anatomical regions. Furthermore, we saw less pronounced activity-induced reductions of the ECS-volume and a smaller increase of activity-induced extracellular K^+ concentration. These results suggest that the changes in plasticity that occur during the process of aging exert pronounced effects on spread patterns and propagation velocities. The restricted seizure spread and reduced propagation velocities may, in part, be explained by our findings of significantly reduced activity-dependent ECS-volume changes and the less pronounced K^+ increases in aged tissue compared to controls.

Future Goals

In future studies it would be of great interest to further elucidate the underlying mechanisms that contribute to the generation of the IOS change. Such experiments should include investigation not only of the role of neuronal elements, but also detailed studies into conformational changes of subcellular elements. A further area of great interest is the analysis of plasticity changes of the brain following insults such as status epilepticus. It is known that status epilepticus may cause pronounced plasticity changes, rendering the neuronal network more vulnerable to the development of seizure activity. However, there is a paucity of information about the exact time course of changes in the wake of status-like events, and information regarding the evolution of changes is lacking. A better insight into the sequence of plastic changes is the prerequisite if preventive therapeutic options are to be considered. In such experiments, it would be plausible to combine in vivo and in vitro experiments. Brain slices could be prepared from animals following experimental status epilepticus in vivo. The in vitro experiments using electrophysiological methods and intrinsic optical imaging could then be carried out at different time points after status epilepticus.

Introduction

A seizure is a paroxysmal event due to abnormal, excessive, hypersynchronous discharges from an aggregate of central nervous system (CNS) neurons. This abnormal electrical activity can be reflected in various clinical/behavioral manifestations, ranging from dramatic convulsive activity to experiential phenomena not readily discernible by an observer. Although a variety of factors influence the incidence of seizures, approximately 5–10% of the population will have at least one seizure during their lifetime, with the highest incidence occurring in early childhood and late adulthood. The term 'seizure' needs to be carefully distinguished from 'epilepsy.' Epilepsy refers to a condition in which a person has recurrent seizures due to a chronic or genetically predetermined underlying process. A subject with a single seizure does not necessarily have epilepsy, and an epileptic patient may rarely experience seizures. In fact, epileptic patients oscillate unpredictably between the 'ictal' state (seizures present) and the 'interictal' state (often no clinical symptoms). The distinctions between seizures and epilepsy, and between ictal and interictal activities, are clinically very well understood. However, sometimes confusion exists among nonclinicians in the research setting (including basic researchers) where interictal bursts or acutely induced seizures (in vitro or in vivo) may be falsely referred to as 'epilepsy.' This issue of accuracy becomes increasingly important when dealing with intravascular or cerebrovascular mechanisms of seizures or epilepsy, as we will attempt to elucidate in the following paragraphs.

Background

Seizures, Epilepsy, and the Blood–Brain Barrier

Seizures are a result of a shift in the normal balance of excitation and inhibition within the CNS. Given the numerous properties that control neuronal activity, it is not surprising that there are many different ways to perturb this normal balance, and therefore precipitate seizures. One of the main determinants of neuronal firing rate and synchronicity is the extracellular potassium level. Potassium controls glial and neuronal resting potential, repolarization, ion channel conductances, cerebral blood flow, and Na^+/K^+ pump activity. The complexity of CNS potassium homeostasis underscores its importance in the mammalian brain. The process involves different cell types (neurons, glia, and endothelium), several supercellular mechanisms (spatial buffering, cerebral blood flow), and a strictly controlled segregation of potassium concentrations between the blood (4.0–5.0 mM) and the brain parenchyma (2.5–3.0 mM). Other molecular elements that may either participate in seizure onset or decrease seizure threshold are brain levels of albumin, antibodies, or drugs.

The blood–brain barrier (BBB) serves as the main gate preventing the free communication of systemic cells and molecules with the brain parenchyma. The BBB is a specialized system of capillary endothelial cells that protects the brain from harmful substances in the blood stream, while supplying the brain with the nutrients required for proper function. Unlike peripheral capillaries, the BBB strictly limits transport into the brain through both physical (tight junctions) and metabolic (enzymes) barriers. Failure of the BBB may occur as a

consequence of intraparenchymal or systemic pathologies. These parenchymal pathologies include malformations of cortical development (MCD), brain tumors, seizures, and multiple sclerosis. Systemic pathologies causing BBB failure may be due to hypertension, stroke, blood hyperosmolarity, or systemically mediated inflammatory processes (due to the production of TNF-α, IL-1β, IL-6, histamine, arachidonic acid, or reactive oxygen species) (**Figure 1**). Investigators have hypothesized that disruption of the BBB will lead to seizures. This prediction is based on the following experimental findings:

1. Seizures are episodic and may have a cerebrovascular trigger. Patients with epilepsy have seizures intermittently and, depending on the underlying cause, many patients are completely seizure-free for months or even years. This sporadic appearance of seizures implies that there are precipitating factors that induce seizures in patients with epilepsy. Numerous groups, including ourselves, have described a number of vascular/blood-related factors that may be tipping the fragile epileptic brain toward seizures.
2. The normal brain is capable of seizing under appropriate circumstances if the BBB is transiently breached.
3. Opening of the BBB lowers the threshold for seizures. This effect implies that there are various underlying endogenous factors that influence seizure threshold. Whether these factors are the same in a chronically epileptic patient as those factors involved in the generation of acute seizures (e.g., in 'normal' brain) remains unknown.

A variety of conditions have a high likelihood of resulting in a chronic seizure disorder. For example, severe penetrating head trauma is associated with up to a 50% risk of subsequent epilepsy. The high propensity of severe trauma leading to epilepsy suggests that brain injury results in long-lasting, pathologic changes in the CNS that transform a presumably normal neural network into one that is hyperexcitable. This process is known as

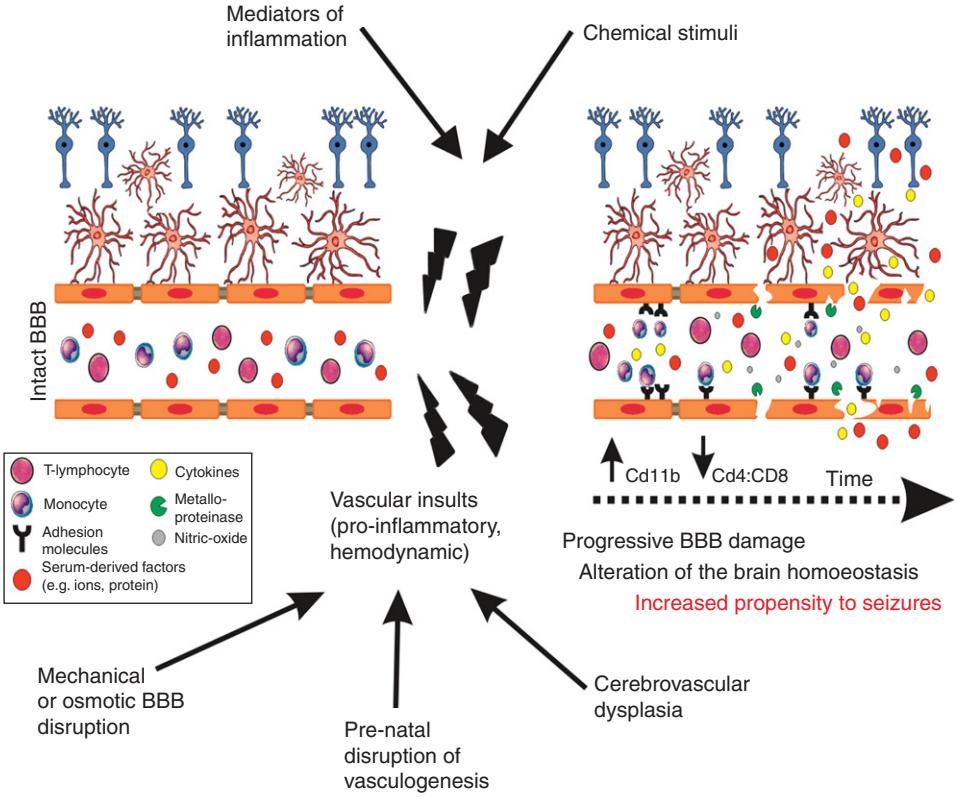

Figure 1 Acute seizures can be induced by a variety of manipulations of the neurovascular unit. Blood–brain barrier (BBB) damage occurs in response to pathological stimuli initiated intravascularly such as proinflammatory and hemodynamic changes. Activation of the circulating white blood cells and subsequent increase in vascular adhesion is responsible for breakdown of the BBB and cellular transmigration into the parenchymal side. Activation of specific enzymes such as metalloproteinases is associated with degradation of the vascular matrix and alteration of the BBB permeability. Constitutive cerebrovascular alterations as observed in malformations of cortical dysplasia are also associated with leaky BBB. We propose systemic intravascular pathological events leading to alteration of the BBB permeability to be a factor contributing to seizures.

epileptogenesis, and the specific changes that result in a lowered seizure threshold can be considered *epileptogenic factors*. Precipitating factors are responsible for causing a single seizure in someone without epilepsy. Precipitating factors may involve intrinsic physiologic processes, such as psychological or physical stress, sleep deprivation, or hormonal changes associated with the menstrual cycle.

Seizures and epilepsy are commonly observed in conjunction with stroke, traumatic brain injury, and central nervous system infections – all conditions known to compromise BBB function. It remains debatable whether the compromised integrity of the BBB is a factor involved in the etiology of epilepsy or secondary to such pathologies. In support of the etiological role the BBB plays in seizures is the fact that BBB disruption (BBBD) after acute head trauma is a well-known pathologic finding in both animal and human studies. BBB disruption may persist for weeks to years after the injury and may colocalize with abnormal EEG activity. The increased interest in osmotic opening of the BBB, as a viable mechanism of increasing drug delivery to the brain, provides an opportunity to explore the connection between BBBD and seizures in a controlled clinical environment. Osmotic opening of the BBB, by intravascular infusion of a hyperosmolar bolus of mannitol, is mediated by vasodilatation and shrinkage of capillary endothelial cells. Cell shrinkage results in widening of the interendothelial tight junctions to an estimated radius of 200 Å. The marked increase in BBB permeability to intravascular substances (10–100-fold for small molecules) following this osmotic disruption procedure is due to both increased diffusion and bulk fluid flow across the tight junctions. The permeability effect is largely reversed within minutes. In rodents, loss of BBB integrity by intraarterial hyperosmotic mannitol has been shown to rapidly lead to EEG changes consistent with epileptic seizures (spike/wave complexes interspersed with decreased EEG voltage that persisted for several hours after the BBB disruption event).

Given these findings, it is not surprising that seizures are the primary complication of osmotic BBBD. Indeed, seizures occur in a relatively large number of patients undergoing such procedure (13–55%). This high incidence was initially attributed to meglumine iothalamate, a known epileptogenic agent used as a contrast agent for CT. However, seizures associated with BBBD continued to occur (albeit with decreased frequency) when BBBD was monitored by radionuclide scanning rather than CT. To date, the correlation between level of BBBD and probability of seizure occurrence has not been carefully examined.

Recently, seizure onset was monitored in patients undergoing osmotic BBBD followed by intraarterial chemotherapy (IAC) to treat primary brain lymphomas. Procedures were performed under barbiturate anesthesia. Focal motor seizures occurred immediately after BBBD in 25% of procedures and originated contralateral to the hemisphere of BBBD. No seizures were observed when the BBB was not breached and only IAC was administered; the only predictors of seizures were positive indices of BBBD – namely, elevation of serum S100β levels and CT scans. The effect of osmotic BBBD was also evaluated in naïve pigs (**Figure 2(a)–2(c)**). Identical procedures generated an identical result; sudden behavioral and electrographic (EEG) seizures correlated with successful BBB disruption. The contribution of tumor or chemotherapy to acute seizures was in this case excluded. This study thus demonstrated a correlation between the extent of acute BBB opening and development of seizures in humans and in a large animal model.

Brain Development, Vasculogenesis, and Epilepsy

The evidence that epilepsy affects about 1% of the adult population and 4% of children supports the view that it is primarily a disorder of childhood. Various types of epilepsies diagnosed at a young age are included into three 'etiological categories': (1) epilepsies due to genetic abnormalities, (2) epilepsies resulting from disruption of normal developmental processes, and (3) epilepsies associated with a perinatal insult. One of the most common causes of neurological disabilities is malformations of cortical development (MCD). MCD result from abnormal neuronal positioning during corticogenesis, and are believed to be the morphological and perhaps physiological basis of several neurological diseases, including mental retardation and autism. MCD are commonly associated with epilepsy, and the clinical spectrum of epilepsies associated with MCD is broad.

In addition to neurogenesis, vasculogenesis also plays an important role in MCD and epilepsy. Some reports have emphasized that methylazoxymetanoic acid (MAM)-treated animals display an array of pathological features that include cerebrovascular changes. MAM-treated animals are obtained by prenatal exposure to the antimitotic agent MAM at gestational day E15. As adults, these MAM-exposed animals exhibit vascularization of the malformed cortex, with severe damage of the layered distribution of vascular trunks. Investigators have therefore hypothesized a decisive role of neuroblast migration and maturation in cortical angioarchitectural development. Thus, in addition to neuroblast toxicity, a parallel process targeting the vasculature may be responsible for MCD in MAM-treated animals.

Prenatal vasculogenesis is required to support normal neuronal migration and maturation. Altering this process leads to failure of normal cerebrovascular development and has a profound implication for CNS maturation. Previous data demonstrated that prenatal exposure of rats to the angiogenesis inhibitor, thalidomide, results in

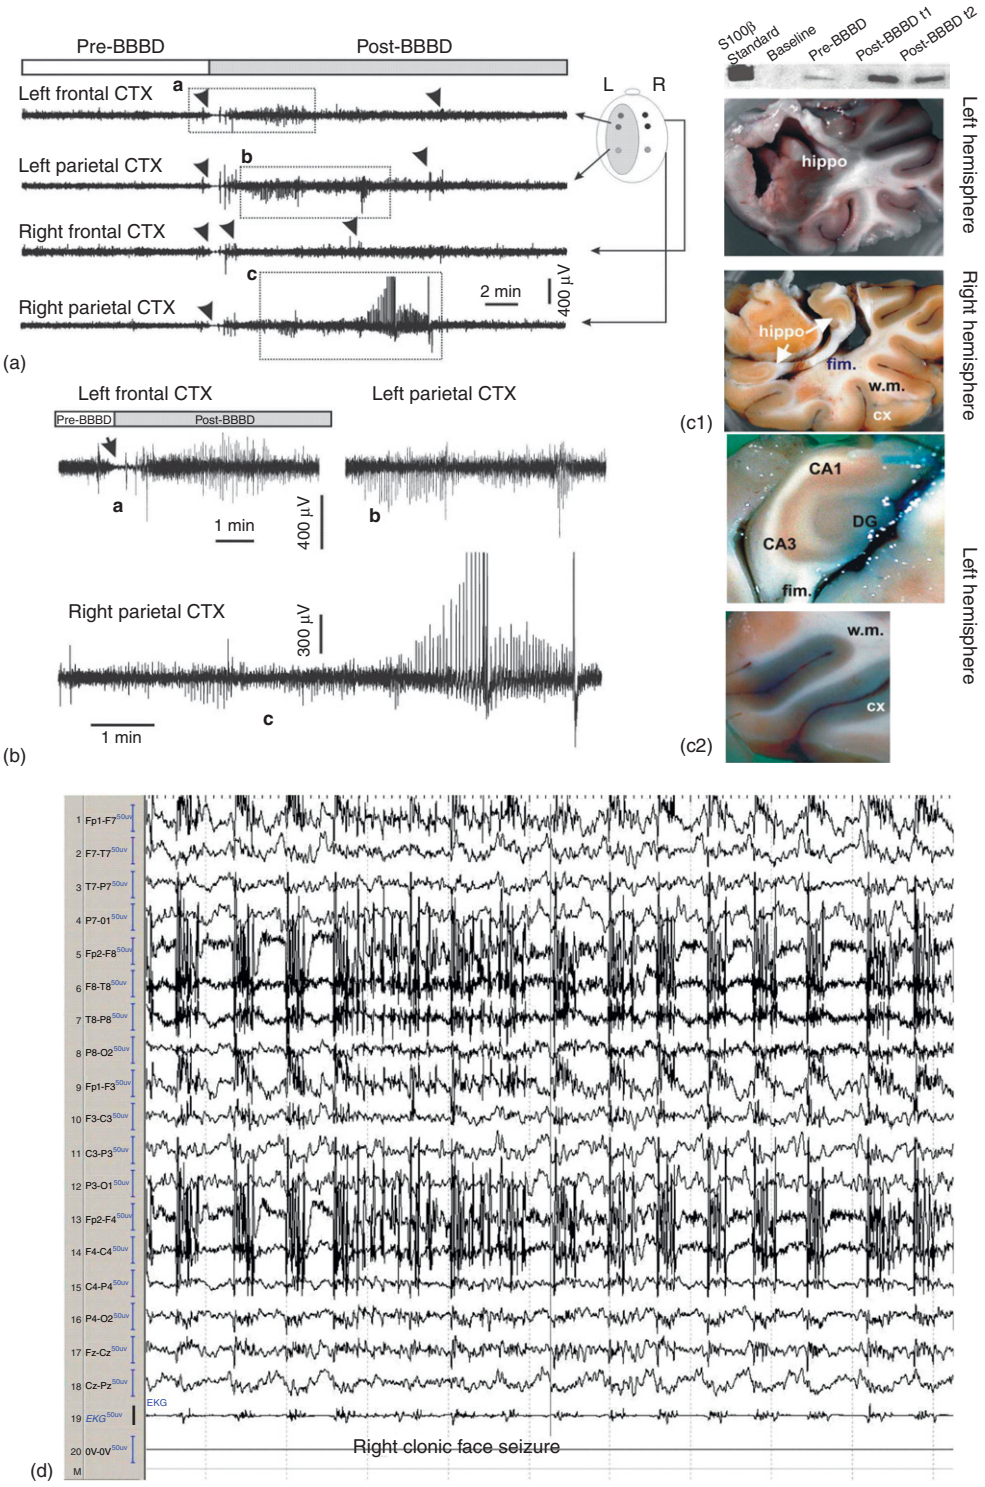

Figure 2 Examples of EEG recording to exemplify ictal patterns of seizures induced by some of the stimuli shown in **Figure 1**. EEG correlates of acute BBB disruption: a widespread increase in BBB permeability leads to seizures. (a) EEG recordings revealed a sharp increase in activity after BBBD in a naïve pig during BBB osmotic disruption. A hyperosmotic bolus of mannitol was injected in the carotid artery. The BBB disruption was performed on the left hemisphere. Subsequently, the EEG activity was predominant in this hemisphere. Motor seizures occurred controlaterally on the right side. The traces in (b) are magnified segments as indicated by the *dashed boxes* in (a). The *arrows* point to the EEG slowing that followed mannitol infusion (see also **Figure 4**). Filters used for viewing during collection were 0.08 and 300 Hz (low-pass and high-pass filters, respectively); sampling rate was 1000 Hz. (c1, c2) Serum S100β increase occurred immediately post-BBBD, as assessed by Western blot. Morphological demonstration of successful hemispheric BBB disruption by Evans blue staining. Note the ubiquitous leakage in the left hemisphere and the absence of extravasation in the right. w.m, white matter; DG, dentate gyrus, fim, fimbria. (d) EEG recording from a patient after BBB disruption.

significant morphological alterations in cortical and hippocampal regions. Abnormal neuronal development was associated with vascular malformation and a leaky BBB. Protein extravasation and uptake of fluorescent albumin by neurons was commonly associated with abnormal cortical development that usually results in neuronal hyperexcitability.

A recognized etiological link between cerebral vasculature and epilepsy is seen in the Sturge–Weber syndrome (SWS) (also called encephalotrigeminal angiomatosis), characterized by neurocutaneous angiomas that involve the leptomeninges and the skin of the face (the so-called port-wine stain). Leptomeningeal angiomas, as demonstrated by structural neuroimaging, may be unilateral or bilateral in the parietal and occipital regions. SWS is clinically characterized by seizures, which may be intractable, and transient focal 'stroke-like episodes' (such as hemiparesis and hemianopsia), headache, developmental disorders, and mental retardation. SWS may be caused by residual embryonic blood vessels and their secondary effects on surrounding brain tissue. A vascular plexus develops around the cephalic portion of the neural tube, under ectoderm destined to become facial skin. Normally, this vascular plexus forms at week 6 and regresses around the ninth week of gestation. Failure of this normal regression results in residual vascular tissue, which forms the angiomata of the leptomeninges, face, and ipsilateral eye. Neurologic dysfunction results from secondary effects on surrounding brain tissue, and blood flow abnormalities in the angiomas may cause increased capillary permeability, stasis, and anoxia. Venous occlusion might actually cause the initial neurologic event – either seizure, transient hemiparesis, or both. One of the most characteristic findings of SWS on MRI is gadolinium enhancement of angiomas that are undetectable on CT scan. BOLD-MR venography may also be sensitive in detecting early venous abnormalities in SWS, earlier than conventional MRI sequences.

BBB Dysfunction and Seizures: Which Comes First?

It was recently demonstrated that exposure of the cerebral cortex in vivo to bile salts resulted in BBB opening with subsequent extravasation of serum albumin into the brain extracellular space, and that this disruption caused the generation of epileptiform discharges within 4–7 days. Moreover, it was reported that interferon-γ induces seizures in patients with focal BBB disruption. Finally, investigators demonstrated that in rats, osmotic opening of the BBB determined encephalographic ictal activity and acute iatrogenic opening of the human and porcine BBB promotes seizures. Serum-derived factors that include normal constituents (e.g., glutamate, potassium, serum proteins, and white blood cells), disease-related products (e.g., IL-1β, TNF-α, IL-6, and antigens), xenobiotics, and heavy metals are normally excluded from the CNS by the BBB. To various degrees, all of these compounds may promote acute brain dysfunction and seizures. In particular, the involvement of cytokine production has been extensively studied in humans and in experimental models of epilepsy after the induction of *status epilepticus*. Recent reports have shown that IL-1β elevation in blood precedes status epilepticus while others have shown that interfering with the IL-1β system prevents onset of seizures. Taken together, these results strongly support a role for cytokines in the development of seizures.

How Do Systemic Inflammatory Events Affect the Brain?

Accumulating evidence supports the existence of an immune response in the brain during systemic inflammatory processes. In particular, components of Gram-negative bacteria such as lipopolysaccharide (LPS), when injected intraperitoneally or systemically, trigger an upregulation of MCP-1, IL-6, IL-6r, gp130, or TLR-4 in the circumventricular organs (CVOs), choroid plexus, leptomeninges, and endothelial cells along the cerebral blood vessel. Systemic injection of LPS, recombinant IL-1β, TNF-α, or IL-6 triggers proinflammatory signal transduction pathways within different populations of cells in the CNS, without being associated with substantial neurodegenerative processes. This interplay between the peripheral immune response and the CNS may play a role in the development of brain pathologies such as seizures and epilepsy. Interestingly, when LPS was administrated chronically in rats, an increased permeability of the BBB was observed as a consequence of the systemic inflammatory stimuli.

Methods

Osmotic Opening of BBB

An hyperosmotic bolus of mannitol is injected directly into the carotid artery, provoking a rapid opening of the BBB (within few seconds from the injection). This technique allows the study of the effect of acute BBB damage on physiological parameters such as brain electrical activity, as recorded by EEG. Two 35-kg Yorkshire pigs were placed under anesthesia using isofluorane (1–1.5%). Anesthesia was induced by intramuscular ketamine with the addition of xylazine (Rompun; 1–2 mg kg^{-1}) and atropine (0.02 mg kg^{-1}). In the supine position, the femoral artery was cannulated and under fluoroscopic guidance, the internal carotid artery was catheterized. Mannitol (1.4 M) was administered intraarterially via the catheter at a predetermined rate of 3–12 $cm^3 s^{-1}$ for 30 s. EEG data (13 channels, including ground, reference, EKG, and impedance electrodes) were collected using a Nihon

Kohden EEG System (Nihon Kohden, Tokyo, Japan). These tracings were collected on a Nihon Kohden JE910-A jack box, using sterile stainless steel subdermal needle electrodes (13×0.40 mm with 0.5×27 gauge) manufactured by Axon Systems, Hauppage, NY, USA. The system was electrically isolated from the pig and the equipment used in performing angiographic procedures.

EEG Recording and Video Monitoring

Stereotactic electrode implantation was performed under pentobarbital anesthesia (45 mg kg^{-1} i.p.), using the Kopf stereotactic frame and a stereotactic atlas of the rat brain. For intrahippocampal recordings, bipolar twisted stainless wire electrodes (0.1-mm diameter, 0.5-mm vertical tip separation, Medwire, New York, NY, USA) were placed bilaterally in the dorsal hippocampus (LH: left hippocampus, RH: right hippocampus, A: -3.9 mm, L: ± 3.0 mm, D: -2.5 mm from Bregma). EEG data were sampled at a rate of 100 Hz.

Animals and Tissue Sample Preparation

Status epilepticus was induced using the pilocarpine and the lithium–pilocarpine models of temporal lobe epilepsy. Rats (male Sprague-Dawley 200–250 g) were injected with LiCl (3 meq kg^{-1}) followed 20-h later by methylscopolamine (1 mg kg^{-1}, i.p., Sigma-Aldrich) and pilocarpine (30 mg kg^{-1}); methylscopolamine (1 mg kg^{-1}, i.p., Sigma-Aldrich) was injected 30 min before pilocarpine (320 mg kg^{-1} i.p.) to prevent peripheral cholinergic side effects. Animals were anesthetized (isoflurane) during recurrent motor seizures and at onset of status epilepticus (SE), as assessed by behavioral observation (stages 4 and 5 of Racine's scale) and EEG recordings. Blood was withdrawn from the right heart ventricle; brain areas (hippocampus and entorhinal cortex) were resected and frozen.

FACS and Cytokine ELISA

Fluorescence-activated cell sorting (FACS) allows the separations of subpopulations of white blood cells (WBCs) and the evaluation of the activation of such immune cells. In particular, we assessed the percentage of activated T lymphocytes (CD3+), monocytes, granulocytes, and macrophages cells (all positive for CD11b+) after pilocarpine or lithium chloride treatments. Blood samples were withdrawn before development of SE. For FACS analysis, 150 µl of whole blood (or brain homogenate) was incubated with a combination of specific antibodies recognizing different populations of WBCs. Specifically, mouse anti-rat CD8a-FITC, CD3-R-PE, and CD4-PE-Cy5 (BD-Pharmingen) were added (2, 5, and 5 µl, respectively) to blood samples. Mouse anti-rat CD11b-FITC and CD3-R-PE were added (2 and 5 µl, respectively) for the determination of neutrophils/monocytes. Blood samples were analyzed by the FACS-Core facility at LRI. IL-1β, TNF-α, and IL-6 ELISA test kits were purchased from Pierce Biotechnology Inc. and tests performed as described by the vendor.

FITC–Albumin Solution Composition

A microangiographic technique based on the injection of fluorescent probes enables confocal visualization of the entire brain micro- and macrovasculature. Simultaneous observation of functional changes in BBB permeability was also possible with utilization of appropriate microangiographic molecules. To this end, fluorescent albumin was used, since albumin does not extravasate abluminally if the BBB is intact. The fluorescent albumin solution was prepared by reconstituting 500 mg of bovine desiccate albumin-fluorescein isothiocyanate (FITC-albumin, MW 69 KDa; 12 mol mol^{-1} albumin; Sigma, St. Louis, MO) in 50 ml of phosphate buffered saline (0.1 M PBS) lacking magnesium and calcium ions. Presence of vascular leakage was evaluated by visual inspection and by confocal microscopy.

Recent Results

Lithium and Pilocarpine: Animal Models of Immunomediated Epilepsies?

Pilocarpine is a nonselective muscarinic agonist with a relatively high affinity for CNS muscarinic receptors. It is commonly used to induce an experimental model of temporal lobe epilepsy. In different animal species, intraperitoneal injection of pilocarpine leads to a convulsive status epilepticus (SE) that persists for several hours. The initial SE is thought to be triggered by a cholinergic activation of excitatory neurons in specific brain regions that include limbic cortices. Although there is a paucity of studies directly assessing pilocarpine penetration across the BBB, a recent report demonstrated that intracerebral pilocarpine does not exceed micromolar concentration ($\sim$200 µM) in rats sacrificed immediately before or at SE. Since this drug shows a relatively poor brain penetration, the CNS effect must be mediated by micromolar concentrations of pilocarpine.

Unfortunately, in spite of the extensive use of systemically injected pilocarpine to induce SE in vivo, very few studies have examined the proconvulasant effects of pilocarpine when applied directly to the brain. Interestingly, when pilocarpine was directly injected in a rat brain, the dose required to induce status epilepticus was three to four orders of magnitude higher than (1) what was predicted by the muscarinic receptor affinity constant or (2) the pilocarpine brain levels measured after intraperitoneal injection (350 mg kg^{-1}) at onset of SE. In in vitro

studies on hippocampal slices, direct application of micromolar (10 μM) concentrations of pilocarpine was reported to induce epileptiform activity. However, ictal epileptiform discharges were observed only when the potassium concentration was enhanced to 7.5 mM or after prolonged perfusion of pilocarpine. Similar conclusions were recently reported using brain slices and in an in vitro whole brain preparation.

In addition to the well-described histological alterations induced by pilocarpine SE, magnetic resonance studies in the rat in vivo show that pilocarpine treatment is associated with an enhancement of BBB permeability. Whether such changes are the consequence of the SE or are due to a peripheral effect of pilocarpine, independent from the epileptiform activity, is not known; however, data support a peripheral mechanism for BBB opening occurring prior to SE (**Figure 3**).

Recent results have demonstrated a remarkable inflammatory component in pilocarpine and lithium–pilocarpine acute seizures. **Figures 3** and **4** show examples in support of the systemic origin of triggers that may lead to pilocarpine– and lithium–pilocarpine-induced seizures. Activation of cholinergic neurons was originally recognized as the only factor triggering pilocarpine SE. However, a peripheral muscarinic effect of systemically injected pilocarpine cannot be excluded. After pilocarpine i.p. injection in vivo,

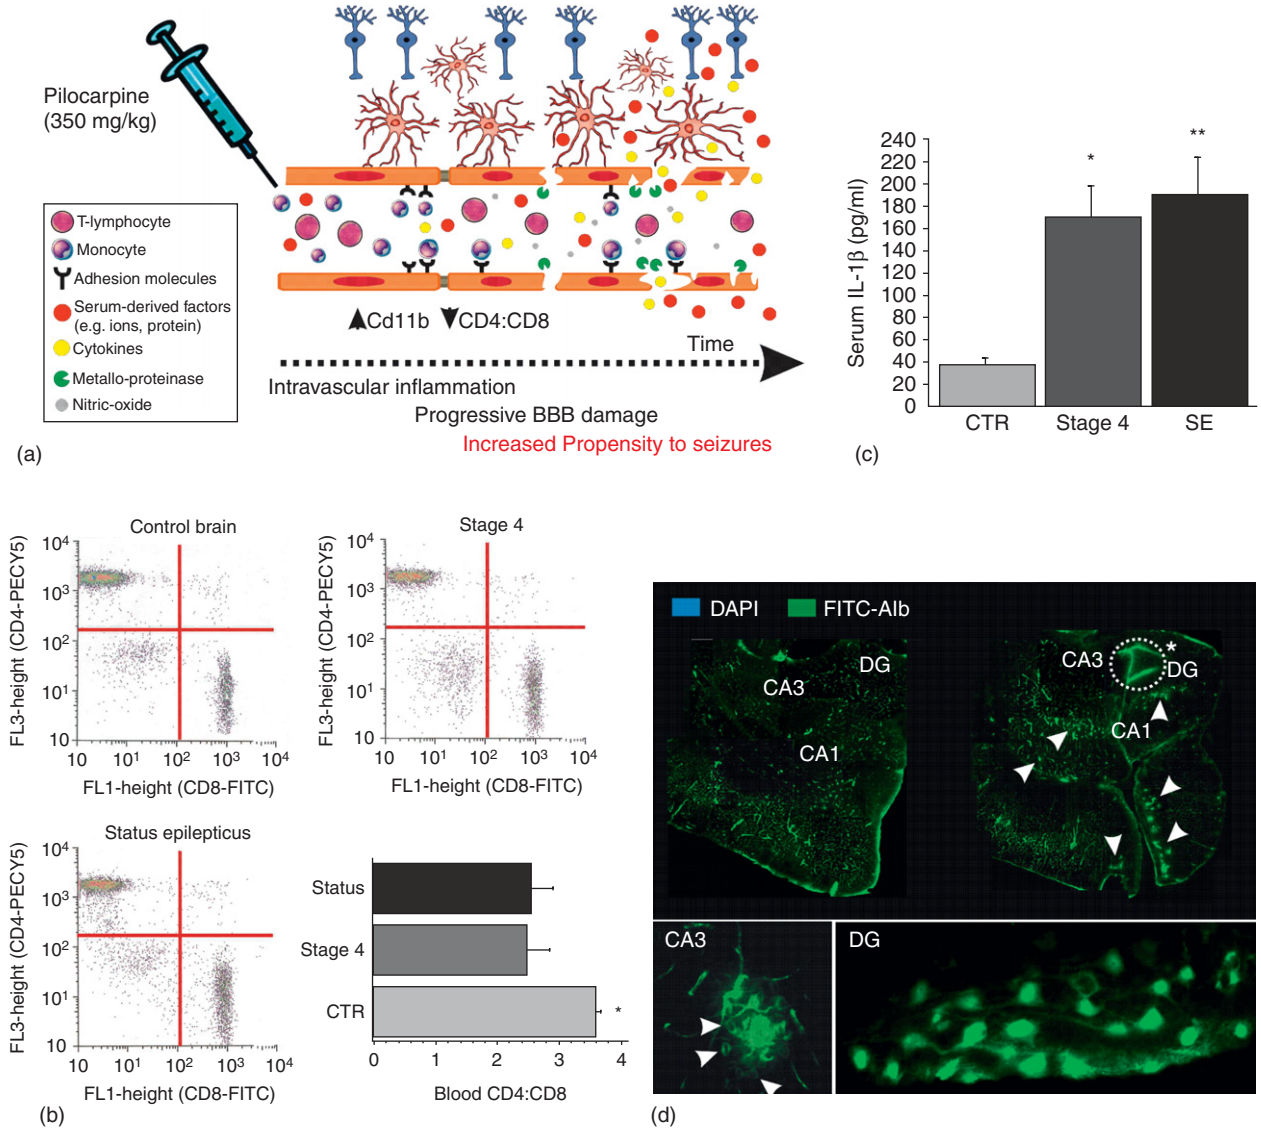

Figure 3 Pilocarpine-induced systemic proinflammatory changes in rats. A common experimental model of status epilepticus (SE) utilizes intraperitoneal administration of the cholinergic agonist pilocarpine preceded by methyl scopolamine treatment. In vivo, after pilocarpine i.p. injection (350 mg kg^{-1}), increased serum IL-1β (c), decreased CD4:CD8 T-lymphocyte ratios (b) and focal BBB leakage, and neurons containing fluorescent albumin (d) were observed. Early systemic events increasing BBB permeability may promote entry of serum-derived cofactors into the brain leading to pilocarpine-induced SE. Disturbance of brain homeostasis represents an etiological factor contributing to pilocarpine seizures (a).

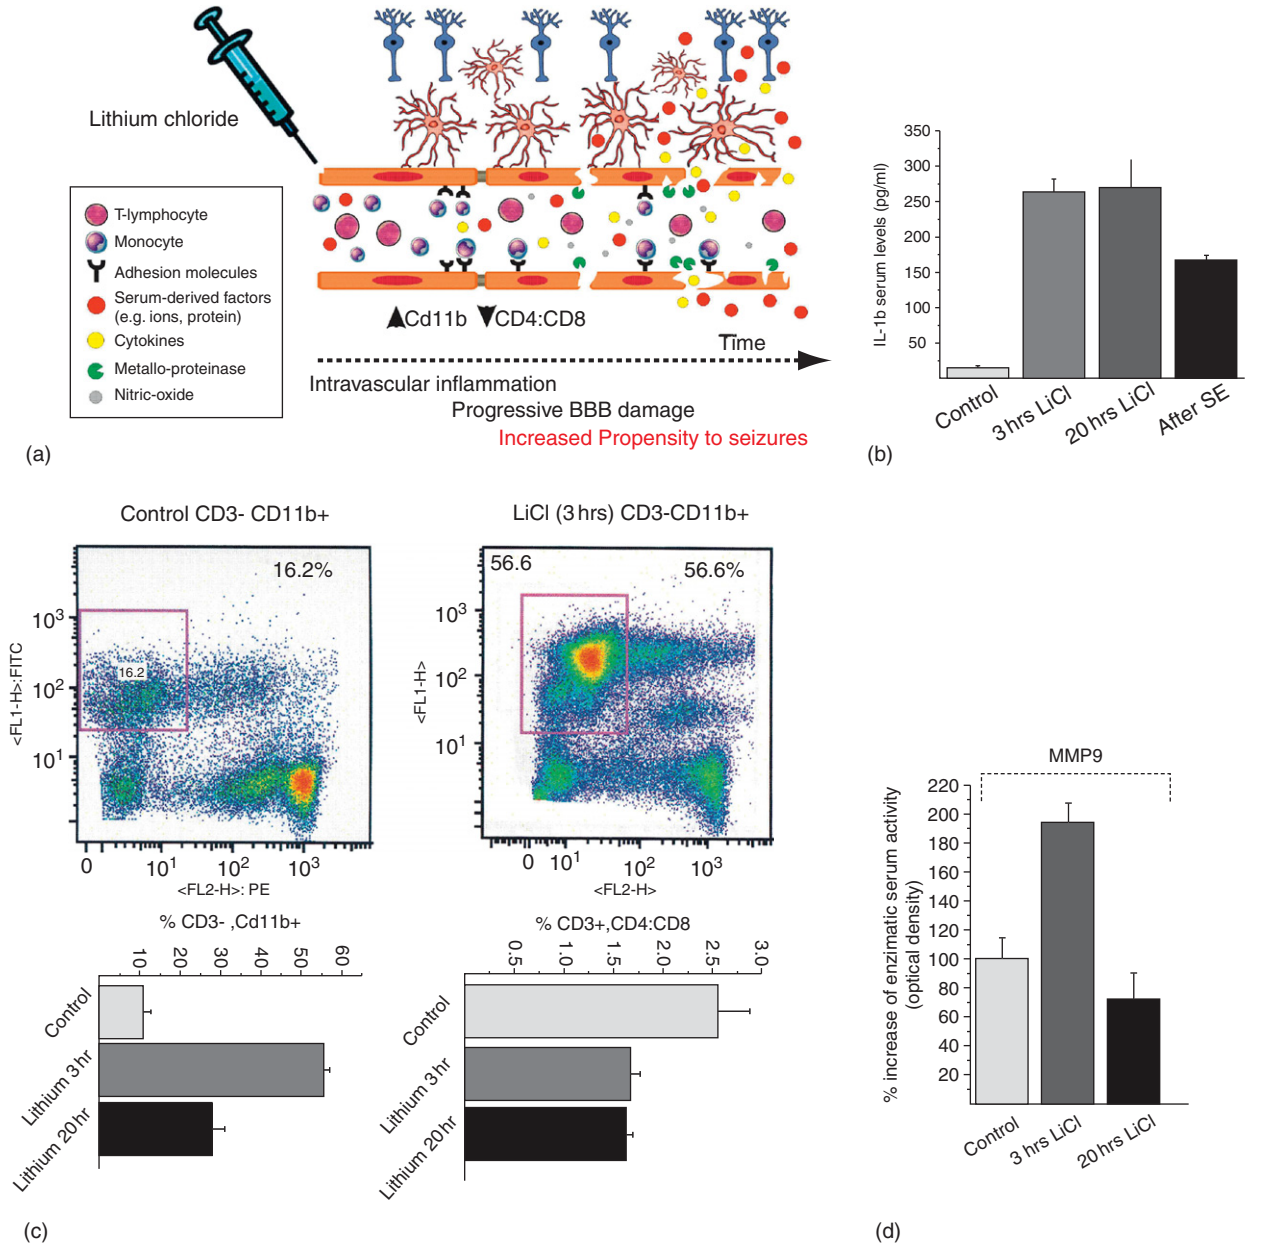

Figure 4 Lithium chloride-induced systemic proinflammatory changes in rats. Comparably to what was observed in the pilocarpine model of temporal lobe epilepsy, LiCl induces systemic proinflammatory changes and BBB damage. In particular, a profound activation of monocytes (CD11b+) was observed starting 3 h after LiCl administration. CD4:CD8 T-lymphocyte ratio was also decreased. The cytokine IL-1β was increased in blood and MMP-9 was activated. Of relevance is the fact that MMP-9 is the effector of vascular damage remodeling. These findings demonstrate the occurrence of proinflammatory changes before the injection of pilocarpine, preceding the onset of seizures, thus proposing a complementary mechanism contributing to seizure onset.

serum IL-1β rapidly increased, CD4:CD8 T-lymphocyte ratios decreased, and focal BBB leakage was observed (Figure 3). In vitro, pilocarpine failed to trigger significant synchronized epileptiform activity when applied at concentrations identical or higher to blood levels measured in vivo. Intense electrographic seizure-like events occurred in brain slices only in the copresence of levels of K^+ (6 mM) that mimic BBB leakage. These results suggested that early systemic events that increase BBB permeability may promote entry of cofactors (e.g., K^+) into the brain, subsequently leading to pilocarpine-induced SE. Focal pilocarpine accumulation into the brain, resulting from BBB leakage, could also contribute to seizure generation, as demonstrated in the isolated in vitro whole brain preparation. Therefore, disturbance of BBB was suggested to be an etiological factor contributing to pilocarpine seizures.

Another model of SE relies on the use of pilocarpine preceded by systemic treatment with lithium chloride.

Status epilepticus can be induced by the intraperitoneal administration of 30–35 mg kg^{-1} pilocarpine only if preceded by lithium chloride (3 meq kg^{-1}). Interestingly, the pharmacokinetic properties of lithium show a peak serum level at 30 min after administration and a rapid decay with complete clearance from the bloodstream after 22 h. Previous data demonstrated that the ideal interval between administration of lithium and pilocarpine, required to maximize seizures, is about 2 h, yet most studies used an interval of 20 h. Interestingly, lithium is a proinflammatory agent, in as much it can mimic white blood cell activation seen under conditions of acute inflammation. Additionally, lithium exposure may facilitate or promote seizures in the absence of cholinergic stimuli. We recently tested the hypothesis that exposure to lithium may replicate some of the inflammatory events observed after exposure to high concentrations of cholinergic agonists (e.g., pilocarpine 350 mg kg^{-1}). The results are shown in Figure 4. Rats responded to lithium (at 3 mEq kg^{-1} dosage), before exposure to pilocarpine, with EEG changes resembling those seen in patients undergoing lithium treatment for bipolar disorder. The hematologic changes in lithium-treated rats (before pilocarpine administration) consisted of systemic proinflammatory changes identical to those seen after exposure to convulsive levels of pilocarpine (Figures 3 and 4). Both pilocarpine (convulsive dose) and lithium alone caused extravasation of FITC-labeled albumin into the brain, consistent with BBB disruption.

Our current hypothesis is that lithium lowers threshold for seizures that occur after muscarinic action on neurons. This interaction would help explain the mechanism underlying the lithium–pilocarpine model, where lithium levels should have dissipated by the time the cholinergic drug is administered. Our data suggests that pilocarpine-induced seizures are not due solely to a direct action of

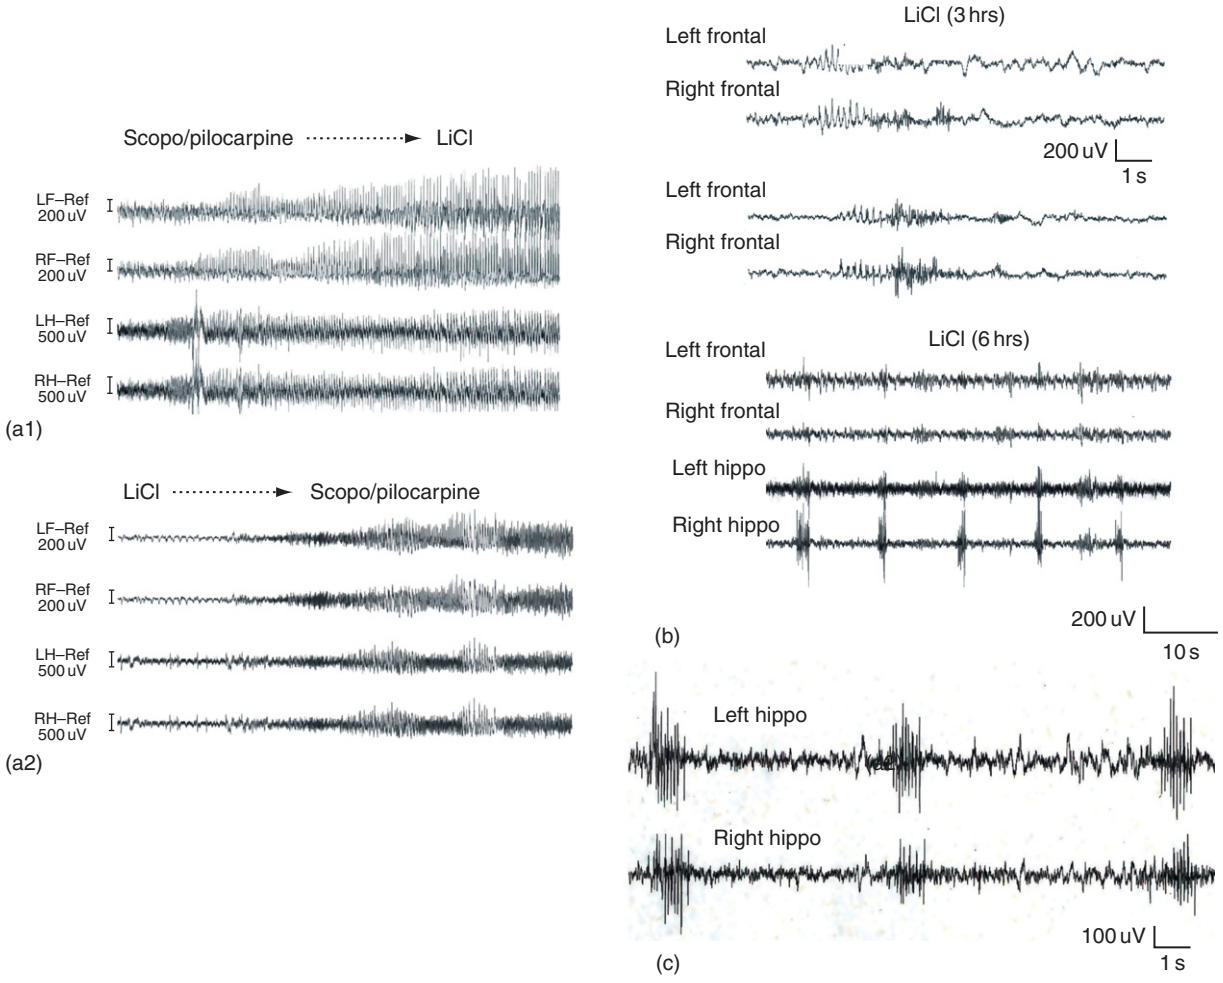

Figure 5 Systemic treatment with pilocarpine and lithium chloride induces EEG changes by a mechanism involving systemic inflammation and BBB damage. A change in the behavior (head nodding, stiffing of the dorsal muscles, and repetitive chewing) was observed in the majority of rats injected with LiCl. EEG analysis revealed an increase in the occurrence of low-frequency beta and theta waves starting 2–3 h after LiCl injection, at the time of ongoing intravascular inflammation and BBB damage (see Figures 3 and 4). Six hours later, a faster activity developed.

the drug on CNS neurons. If lithium and pilocarpine 'cooperate' to reduce seizure threshold – by inducing an inflammatory response – then the temporal sequence of exposure should not be crucial to the seizure-inducing process. This possibility was directly tested by comparing seizure induction by the 'traditional' paradigm of exposure (lithium then pilocarpine) to the opposite sequence (lithium *after* subconvulsive pilocarpine). **Figures 5** and **6** show that either approach produced SE, further unraveling the current belief that the seizure-inducing effect of lithium and pilocarpine is specific to their actions on neuronal targets.

Future Directions

In summary, there is growing evidence supporting the role of alterations in cerebrovascular function in determining seizure propensity. While seizures are a result of neuronal oversynchronization and excitability, the propensity for abnormal firing may be dependent on systemic events. Particularly within this context, the distinction between seizures and epilepsy is critical; specific treatments designed to target these two distinct pathologies may have considerable benefits. In particular, the detection and treatment of the 'first' seizure, as a secondary manifestation of an acute vascular event (e.g., stroke, hemodynamic, systemic inflammation) could prevent the initiation of processes leading to cognitive impairment or to epilepsy. In this scenario, seizures could be controlled by targeting the prodromic (vascular) events rather than the seizure itself. This approach would open the possibility of employing drugs other than classical antiepileptic medication. Of importance will be the discovery of mechanisms linking damage of the BBB to the alteration of neuronal excitability. While imbalance of the ionic brain content could represent one factor involved in such a cascade, other serum-derived factors (e.g., albumin as recently proposed) could play a role. Moreover, experimental evidence demonstrates the seizure-promoting effect of both acute and chronic opening of the BBB, in naïve or epileptic animals, suggesting the possibility of multiple vascular pathways of altering neuronal excitation.

Seizures elicited during iatrogenic vascular interventions (e.g., cardiopulmonary bypass, endarterectomy) have been associated with alteration of cerebral blood flow,

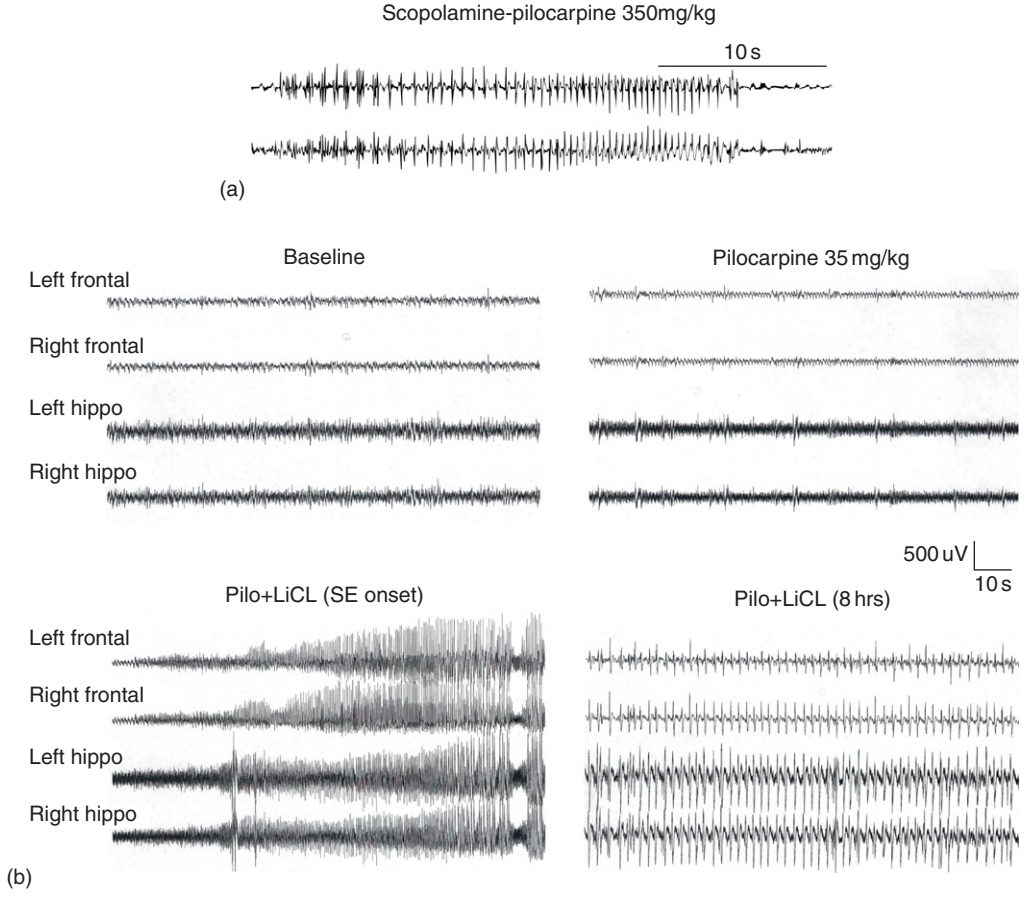

Figure 6 Status epilepticus was elicited by the combination of LiCl and pilocarpine independently from their sequence of administration. No significant EEG changes were induced by the low dosage of pilocarpine (35 mg kg^{-1}).

activation of circulating white blood cells, and increased permeability of the BBB. If systemic intravascular inflammation is involved in the occurrence of seizures, then prophylactic control of systemic vascular inflammatory processes and preservation of BBB integrity (e.g., using antiadhesion molecule or antiinflammatory drugs) may represent alternatives and/or complementary pharmacological approaches to prevent seizures and possible subsequent epileptogenesis.

Introduction

About 5% of patients with an infection of the central nervous system will experience a seizure. A seizure may be the presenting symptom, or only one manifestation of the infection. Common infections of the central nervous system that may present with seizures include: herpes simplex, cytomegalovirus, arbovirus, human immunodeficiency virus, neurocysticercosis, malaria, toxoplasmosis, bacterial meningitis, and brain abscess. The seizures may be due to direct invasion of brain tissue by the infecting organism, production of toxins by the organism, or production of inflammatory mediators by the brain. Infectious processes in the brain can lead to breakdown of the blood–brain barrier and brain edema. Severe systemic infections can also be associated with seizures, even if the infection is not present in the central nervous system. In this latter instance, the seizures are most likely due to hypoxia or some other severe metabolic change (such as hyponatremia) that is the result of the overwhelming infection. In all cases, treatment for the seizures associated with infection usually involves treatment of the underlying infection.

Bacterial infections in the central nervous system are less likely to cause seizures than do viral infections. However, generalized convulsions may occur with bacterial meningitis. Compared with other bacteria, infections with *Haemophilus influenzae* are more commonly associated with seizures. The mechanism of the seizure induction is not known. As with other signs of infectious processes, it has been postulated that the seizures are either a result

activation of circulating white blood cells, and increased permeability of the BBB. If systemic intravascular inflammation is involved in the occurrence of seizures, then prophylactic control of systemic vascular inflammatory processes and preservation of BBB integrity (e.g., using antiadhesion molecule or antiinflammatory drugs) may represent alternatives and/or complementary pharmacological approaches to prevent seizures and possible subsequent epileptogenesis.

Introduction

About 5% of patients with an infection of the central nervous system will experience a seizure. A seizure may be the presenting symptom, or only one manifestation of the infection. Common infections of the central nervous system that may present with seizures include: herpes simplex, cytomegalovirus, arbovirus, human immunodeficiency virus, neurocysticercosis, malaria, toxoplasmosis, bacterial meningitis, and brain abscess. The seizures may be due to direct invasion of brain tissue by the infecting organism, production of toxins by the organism, or production of inflammatory mediators by the brain. Infectious processes in the brain can lead to breakdown of the blood–brain barrier and brain edema. Severe systemic infections can also be associated with seizures, even if the infection is not present in the central nervous system. In this latter instance, the seizures are most likely due to hypoxia or some other severe metabolic change (such as hyponatremia) that is the result of the overwhelming infection. In all cases, treatment for the seizures associated with infection usually involves treatment of the underlying infection.

Bacterial infections in the central nervous system are less likely to cause seizures than do viral infections. However, generalized convulsions may occur with bacterial meningitis. Compared with other bacteria, infections with *Haemophilus influenzae* are more commonly associated with seizures. The mechanism of the seizure induction is not known. As with other signs of infectious processes, it has been postulated that the seizures are either a result

of the primary infection or due to the inflammatory response to the bacterial infection. To date, there are few data to support either possibility.

Encephalitis due to a viral infection of the brain can be associated with both focal and generalized seizures. Viral encephalitis is characterized by neuronal and glial degeneration, inflammatory infiltration, edema, and tissue necrosis. Herpes simplex virus is the most common pathogen associated with seizures in cases of viral encephalitis. Seizures occur in ~85% of children infected with Japanese encephalitis and up to 10% of adults with West Nile virus. Equine encephalitis, St. Louis encephalitis, cytomegalovirus, and rabies have also been reported to cause seizures. Finally, it has been estimated that 2–5% of HIV-infected patients have seizures because of the primary infection of the brain by the virus.

The issues surrounding the relationship between herpes virus infections of the central nervous system and seizures are quite complex. Infection with herpes virus, particularly herpes virus 6B (HHV-6B), is quite common. A number of researchers have suggested that there is a causal association between infection with HHV-6B and seizures in infants aged less than 1 month. Recently, however, this causal relationship has been questioned; it could be that the infection is causing the seizures, but it is also possible that infants susceptible to the infection are those most likely to have seizures. The evidence distinguishing these two possibilities is not clear. Herpes viruses can also result in a latent or persistent infection. This persistent infection has been implicated in febrile seizures and some forms of epilepsy – in the absence of symptomatic encephalitis. HHV-6B has been found in astrocytes within resected tissue from a substantial proportion of patients with temporal lobe epilepsy. The current hypothesis is that the presence of the virus is a result of an early infection and its continued presence somehow lowers the seizure threshold or increases the likelihood of developing epilepsy. This hypothesis is potentially appealing, given that herpes is easily reactivated, particularly by other viral infections. It is possible that reactivation of the virus results in a series of consequences that result in a lowering of the seizure threshold. For example, reactivation of HHV-6 may alter gene expression in astrocytes, which in turn alters glutamate pathways. Thus, the seizures could be due to a direct action of the reactivated virus, or to a secondary action initiated by the presence of the virus in the latent form. Again, the available data do not provide definitive support one way or the other.

Other infections that involve the central nervous system have been reported to cause seizures. Neurocysticercosis, infection of the central nervous system with the cyst form of tapeworms, is the most common parasitic infection of the brain. In developing countries, up to 50% of adult-onset epilepsy is due to neurocysticercosis. Malaria is estimated to spread into the central nervous system in approximately one-third of the cases, and cerebral malaria can present with seizures. The incidence of acute seizures in neurosyphilis is 14–60%. Infectious diseases in which seizures have been reported, but are not typically the presenting feature, include rubeola, schistosomiasis, trichinosis, paragonimiasis, echinococcosis, trypanosomiasis, typhus, and amebiasis.

In summary, infections of the central nervous system are clearly associated with seizures, either during the acute infection or as a delayed response. The mechanisms underlying these seizures are not understood and are, most likely, dependent on the infectious agent and time course of the infection. In addition, inflammatory processes in the brain have been implicated in a number of cases, and could be the underlying cause of seizures in some, if not all, infections.

Background

Studies of infectious causes of seizures have been limited by a number of significant issues. Seizures are most commonly studied in the laboratory in rodents – rats or mice. However, infectious processes are quite different in rodents than in humans; in particular, rodents are generally resistant to a number of organisms that commonly infect humans. Conversely, agents infectious to rodents may not be infectious in humans. When a common agent infects both species, the infection may follow a different course in each species, making comparisons difficult. Host responses to the infecting organism can also be different. Finally, work on infectious agents in the laboratory is carried out under significant constraints, and some pathogens are difficult to grow and maintain in the laboratory. Two infectious agents that have been studied in animal models are Herpes simplex type 1 (HSV-1) and neurocysticercosis.

HSV-1 is a neurotropic virus that can travel through the central nervous system by retrograde axonal transport and has been shown to have an affinity for the temporal region of the brain. In patients with encephalitis due by HSV-1, 38% will have seizures. The symptoms associated with HSV-1 infection are thought to be due to both viral and host factors. As a herpes virus, HSV-1 also has the ability to become latent. In order to study the mechanism of the seizures in HSV-1 infection, attempts have been made to produce an animal model of HSV-1 infection with adequate recapitulation of both the acute and chronic characteristics of the infection.

Mice, rats, and rabbits have since been used in generating models of HSV-1 infection. The virus must be grown in cultured monkey kidney or baby hamster kidney cells. Mice have been infected by corneal scarification, rats by intranasal inoculation, and rabbits by injection into the olfactory bulb. In most publications, animals are

reported to have symptoms of a systemic viral infection. The severity of the symptoms is relative to the dose and route of administration of the virus. There is a significant mortality rate in all of these approaches, and viral shedding has been measured in ocular and nasal secretions from the infected animals.

Seizures have been documented by observation and electrical recording in these models. Both generalized and partial seizures have been reported. The severity of the seizures seems to correspond to the severity of the viral infection, as determined by the systemic symptoms. Brain slices have also been obtained from infected animals, and recordings have demonstrated abnormal excitability with depolarized membrane potentials and a lower threshold for burst generation. In one study using rats, in animals with seizure activity, inflammatory infiltrates and hemorrhagic lesions were detected in the trigeminal ganglia, olfactory bulb, amygdala, hippocampus, piriform cortex, entorhinal cortex, and the spinal trigeminal ganglia. Astrocytic hypertrophy has also been demonstrated. These rodent models have successfully modeled human infection with herpes, in that they exhibit inflammation and neuronal death, hyperexcitability, and seizures. However, these models have considerable mortality and have not yet yielded answers to the questions about the mechanisms underlying the seizures.

Hippocampal slice cultures have also been infected with HSV-1 by adding the virus directly to the culture medium. Acute infection can induce epileptiform activity and neuron loss, suggesting that this model could be used to examine the mechanisms by which the virus causes cell loss and hyperexcitability. Whether any mechanism determined in this model would relate to the human infection remains to be determined.

Another type of infection that has been studied in animals is neurocysticercosis, an infection of the human central nervous system by the helminth *Taenia solium*. Since pigs serve as the intermediate host, humans become infected with the tapeworm form (taeniasis) by eating undercooked pork that is infected with the egg form. The larvae hatch and cross the intestinal mucosa to enter the bloodstream. They exit the bloodstream and migrate into tissues, including the brain, where they mature into cysts called cysticerci. These cysticerci are viable parasites, which modulate and inhibit the host immune response. The presence of cysticerci in the brain does not normally produce symptoms. Individuals who have died of other causes have been found to have viable cysticerci in the brain. Those patients who do have seizures invariably have a prominent inflammatory infiltrate around the cysts (**Figure 1**), including the presence of proinflammatory cytokines and an altered blood–brain barrier. Since the viable cysticerci can suppress the host immune response, it has been suggested that the seizures are not a result of the parasitic infection per se, but rather result from the host response initiated by dying cysts. It is not known what causes the seizures, but it has been postulated that one or more epileptogenic substances are released by the dying parasite or produced by the surrounding inflammatory cells. There is no animal model for neurocysticercosis, but a model has been developed to examine the seizures produced by the dying parasites.

Methods

Taenia solium, the human tapeworm, is not infectious in rodents, but a closely related helminth – *Taenia crassiceps* – can produce cysticercosis in mice. However, it will not produce infection of the brain. Inoculation of mice with *T. crassiceps* leads to infestation of the peritoneal cavity with a large number of cysts. In the peritoneal cavity, the parasites eventually begin to die and granulomas form around the cysts. These granulomas mature through a series of defined stages (1–4), depending on the amount of intact organism remaining. By stage 4, only host cells and debris remain, without clearly identifiable parasite elements.

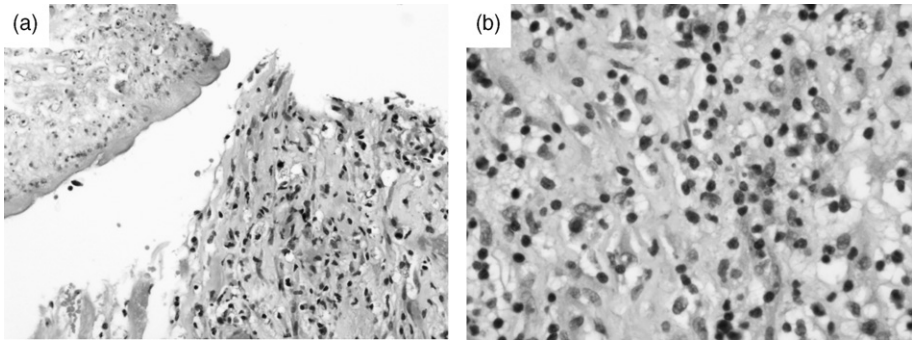

Figure 1 Histopathology of human infection with neurocysticercosis. Two images from the right frontal lobe of a 27-year-old man with new onset seizures are presented. In (a) (40×), both the degenerating parasite (upper left) and the surrounding brain with inflammation (lower right) can be seen. The cuticular surface of the worm is well preserved in this section. The higher power (400×) photomicrograph in (b) shows the brain parenchyma filled with lymphocytes, plasma cells and an occasional eosinophil. Hematoxylin and eosin stain. Photomicrographs courtesy of Dr. J. Clay Goodman, MD.

To test whether the seizures are a result of the host response to the dying cyst, granulomas were harvested from mice infected with *T. crassiceps*. A portion of the granuloma was saved for histological analysis and the remainder was homogenized in phosphate-buffered saline. The extract prepared from the granulomas was then injected into the brain of an adult rat to mimic the presence of these substances in neurocysticercosis. Preliminary data showed that injection of the extract into either the hippocampus or the amygdala could produce electrographic seizures. With the animals under low levels of anesthesia, no behavioral seizures were observed after injection of extract. The hippocampus and amygdala were chosen because of their relatively low seizure threshold. A single injection of 10 μl extract (containing 25 μg total protein), or control substance, was administered and the animals were monitored continuously for at least 1 h. Control experiments with known convulsants determined that the recorded electrical activity had to reach at least twice the amplitude of the baseline activity to be defined as epileptiform, and that the onset of the epileptiform activity should occur within 3 min to be considered a direct effect of the injected material. After termination of each experiment, the brain was examined to confirm accuracy of the injection and recording sites.

Recent Results

Initial experiments determined that injection of 10 μl of phosphate-buffered saline had no effect on the recorded electrical activity. Each extract prepared from an individual granuloma was tested in at least two animals. Extracts from stage 1 and 2 granulomas consistently produced an epileptiform discharge in the hippocampus that started within 1 min of injection and lasted a mean of 44 s (range of 25–76 s). Extracts from granulomas in stage 3 or 4 did not reliably produce seizures. Once the epileptiform activity had stopped, it did not recur. Injections of extracts from nonstimulated host cells prepared from spleen of uninfected mice and from homogenized viable parasites did not produce epileptiform activity. This study provided direct evidence that a substance produced in early stage granulomas, but not a substance released by the degenerating parasite, can initiate seizure activity. This suggests that the inflammatory reaction by the brain may be the sole source of the epileptogenic activity.

Future Goals

To really understand the relationship between seizures and infections of the central nervous system, there is need for better animal models. This will require a thorough understanding of the pathophysiology of the infectious process in both humans and whatever experimental animal is chosen. For the case of neurocysticercosis, we would like to know how the cyst suppresses the immune response. What leads to death of the organism, to the formation of the granuloma, and to stimulation of the host immune response? What is the role of the inflammatory response in the genesis of the seizures? For herpes infections, we would like to explain the direct effect of an acute infection on neuronal and glial function. Are there changes in cellular function when the virus is latent? How is the virus reactivated in the brain, and is the effect of a reactivated virus different from that of a new infection? There is still much that needs to be learned about infections in the brain and how they lead to seizures.

In addition, the infecting organism needs to be clearly defined, and means to grow it reproducibly in the laboratory developed. While some questions can be answered in in vitro systems, such as slice cultures or acute cultures of dissociated cells, it is clear that many issues must be addressed in vivo – e.g., where there are questions about the role of the blood–brain barrier or inflammatory processes.

The seizures in patients with neurocysticercosis are thought to be provoked by active inflammation. The seizures often resolve as the inflammation subsides, suggesting that one of the mediators of the inflammation is the cause of the seizures. This idea that the inflammation is a major contributor to the seizures has been voiced in studies of many different infectious processes. Inflammation is a host response to injury. Local and sustained inflammatory responses have benefits in infectious disease, generally limiting bacterial replication and spread. However, sustained and/or inappropriate inflammation is the cause of a number of human diseases. Until recently, the brain was considered to be resistant to inflammation or immune activation. While we now know that the brain is not 'resistant,' the immune responses in the brain are somewhat different than those seen peripherally. The brain exhibits a number of key features of inflammation, including glial activation, edema, an acute phase response, and synthesis of cytokines, free radicals, adhesion molecules, and other markers of the inflammatory response. Finally, immune cells do invade brain tissue. Most inflammatory mediators are expressed at very low (or undetectable) levels in the normal brain, but can be rapidly induced. For example, infection will stimulate microglia to transform into macrophages, which will move to the site of infection. Activated microglia produce cytokines and trophic factors that can either damage or protect surrounding cells.

A number of cytokines have been investigated for a possible link to seizures. Interleukin 1 (IL-1) is a proinflammatory cytokine that is released following damage; it can, in turn, induce growth factors and nitric oxide synthase, and affect a number of neurotransmitter systems. There is evidence for both a proconvulsive and anticonvulsive action of the β form of IL-1. Tumor necrosis factor-α (TNF-α) is also an inflammatory mediator in

the brain. It can have opposing actions (pro- or anticonvulsant), depending on which receptor it binds to and the duration of the inflammatory process. TNF-α and IL-1 also control expression of other cytokines, which can in turn modulate neuronal excitability by a direct action on ion channels or by inducing gene transcription. The role of these cytokines in those seizures that are associated with infections of the brain is not known. Both IL-1 and TNF-α, as well as a number of other bioactive substances, have been shown to be present in the inflammatory granulomas found in neurocysticercosis. The contribution of these substances to the seizures seen in this disease is an area of active investigation.

Another goal of research into the link between seizures and infection is to develop better treatment strategies for these seizures. Clearly, the primary treatment is aggressive management of the underlying infection, especially for bacterial infections. However, consider the case with neurocysticercosis. The helminth does not appear to cause seizures while alive. So, should an asymptomatic patient be treated with antihelminthic drugs, which will cause death of the parasite? Should this antihelminthic treatment be combined with a potent antiinflammatory drug? In a patient with seizures, should an antiinflammatory agent be used alone or with an anticonvulsant? These issues continue to be debated. In viral infections of the central nervous system, will aggressive antiviral therapy reduce the incidence of later seizures? Should there be an attempt to treat a latent infection? Can reactivation of herpes be detected before seizures begin? Finally, can understanding how infectious processes lead to seizures improve the treatment of idiopathic seizures?

Introduction

Recent experimental and clinical evidence has highlighted the activation of inflammatory processes in the epileptogenic brain, involving cell components of the innate and adaptive immune systems, thus fostering more in-depth investigations on the mechanisms underlying this activation and the functional consequences of changes in brain levels of inflammatory molecules. There is a growing evidence for the involvement of

inflammatory reactions in a large variety of maladaptative changes occurring in epileptic tissue, including neuronal hyperexcitability and cell damage, glial cell activation and proliferation, and alteration in the blood-brain barrier (BBB) permeability. These observations suggest that inflammatory reactions in the brain may be implicated in the pathogenesis of seizures, thus opening new perspectives to their pharmacological treatment using non-conventional anti-inflammatory approaches.

Background – Expression Studies

Inflammatory Molecules in Experimental Models of Seizures

Seizure induced in rats or mice by electrical stimulation or intracerebral application of chemoconvulsants increases the production of prototypical inflammatory cytokines, such as interleukin(IL)-1β, IL-6, and TNF-α prominently in glia, and in some instances also in neurons. Using experimental models of status epilepticus in which epileptogenesis eventually gives rise to spontaneous seizures, researchers found that the levels of expression of cytokine mRNAs and their related proteins, levels which are barely detectable in normal healthy brain, are rapidly ($\leq$30 min) increased after seizure induction. This induction is transient and decays within a few days, except for IL-1β, which remains upregulated during epileptogenesis and in chronically epileptic tissue. Evidence for increased production of cytokines and other downstream inflammatory mediators in brain has been also reported in genetic models of audiogenic seizures and in kindling. Cytokine expression is induced in brain areas specifically involved in seizure generation and propagation. Glial cells, including both astrocytes and microglia, represent the main sources of proinflammatory cytokines in the brain; cytokine receptors, however, are expressed both by glia and neurons, suggesting that inflammatory molecules may be soluble mediators that can establish functional interactions between glia and neurons. Recently, it has been shown that IL-1β and its signal-transducing receptor (IL-1R1) are highly expressed during epileptogenesis in the astrocytic endfeet impinging on brain microvasculature and in endothelial cells of the BBB. Interestingly, the brain areas where these phenomena were observed coincided with areas of alterations in BBB permeability, resulting in serum albumin parenchymal extravasation and in neuronal damage.

The induction of proinflammatory cytokines is responsible for the NFkB-dependent transcription of various inflammatory genes and the synthesis of the related proteins such as cyclooxygenase-2, chemokines, major histocompatibily complex class I and II, and Toll-like receptor family members. The cascade of inflammatory mediators can, in turn, activate adaptive immunity mechanisms leading to infiltration into the brain parenchyma of T and B cells, and dendritic or NK cells. However, adaptive immunity does not appear to contribute to brain inflammation in models of temporal lobe epilepsy (TLE) or in human epileptogenic tissue from TLE patients, in contrast to what has been reported for Rasmussen's encephalities.

Inflammatory Molecules in Human Epileptogenic Tissue

An increased level of proinflammatory molecules has been demonstrated in brain tissues surgically removed from patients with drug-resistant epilepsies using immunohistochemistry, western blot, and mRNA analysis. In particular, IL-1β and its signaling receptor IL-1R1, as well as NFkB activation were found in reactive glia and surviving neurons in TLE hippocampal specimens (as compared with postmortem hippocampal tissue from neurologically unaffected subjects or surgically removed tissue from epileptic patients with an extrahippocampal tumor). In TLE patients, increased BBB permeability was detected in the same areas showing activation of the IL-1 system. Finally, scattered T and B lymphocytes and NK cells were found mainly associated with microvessels but not in brain parenchyma. These changes observed in human TLE tissue overlap with those observed in experimental models.

Brain tissue analysis also shows evidence of inflammation in tuberous sclerosis, focal cortical dysplasia (FCD), and glioneuronal tumors (GNT) – all conditions associated with epilepsy. In particular, expression of NFkB and TNF-α has been reported in dysplastic neurons and giant cells in tubers. Strong induction of the IL-1β system has been found in the neuronal dysmorphic neurons, balloon cells, and glial components of FCD and GNT specimens. Interestingly, the density of IL-1β- and IL-1R1-positive cells in FCD and GNT specimens is positively correlated with the frequency of seizures evaluated before tissue resection. The presence of perivascular lymphocytes, scattered microglia nodules and a dramatic increase in the expression of several cytokine genes have been described in brain specimens from patients with Rasmussen's encephalitis and active seizures.

Among the various cytokines measured in plasma and cerebral spinal fluid, IL-6 is the one consistently and significantly upregulated in patients with recent tonic-clonic seizures. Increased serum levels of proinflammatory cytokines have been described in West syndrome and in children with febrile seizures. The observation that brain inflammation occurs also in epileptic disorders that do not features an inflammatory pathophysiology raises the possibility that this phenomenon may be a common substrate contributing to the pathogenesis of seizures in various form of epilepsy with different etiologies.

Methods

Adult male Sprague-Dawley rats, and various strains of adult wild-type and transgenic mice, were used for inducing seizures and to investigate the expression and role of inflammatory mediators. Seizures were induced in freely moving rodents by intraperitoneal or intracerebral injection of chemoconvulsant drugs, such as kainic acid, bicuculline and pentylentetrazole. Hyperthermia-induced seizures were induced in immature rodents to mimic febrile convulsions. Seizures were monitored by electroencephalographic (EEG) and behavioral analysis. Systemic or intracerebral application of pro- or anti-inflammatory compounds to rodent models of seizures was carried out to investigate the role of inflammation in seizure onset and recurrence.

Recent Results

Functional Studies: Modulatory Effects of Cytokines on Seizures

To understand the functional consequences of inflammatory mediators in the epileptic brain, three main experimental approaches have been used:

1. Proinflammatory molecules were injected into the rodent brain before the convulsive stimulus, to mimic a preexisting inflammatory state and to exacerbate the production of these molecules during seizure;
2. A chronic inflammatory state in brain was induced by administering lipopolysaccharide (LPS), a bacterial toxin, to rodents or by using transgenic mice that overexpress specific cytokines, and seizure susceptibility was then assessed;
3. Pharmacological agents interfering with the cytokine systems were injected in rodents, and their effect on seizure susceptibility was assessed.

Role of IL-1β. The application of IL-1β in the rodent hippocampus shortly before the convulsive stimulus prolonged the duration of seizure activity. In contrast, intracerebral injection of IL-1 receptor antagonist (IL-1ra), the naturally occurring competitive antagonist of IL-1R1, mediated powerful anticonvulsant effects *via* blockade of IL-1 signaling. Accordingly, mice overexpressing the human soluble form of IL-1ra in astrocytes showed a reduced susceptibility to seizures. Intracerebral injection of IL-1β or systemic administration of LPS, which induces high levels of IL-1β and other cytokines in brain, decreased the threshold for seizure induction in an experimental model of febrile seizures in immature rodents; in contrast, seizure threshold was raised in mice with a genetic deletion of IL-1ra gene and after intracerebral application of IL-1ra. These findings suggest that an increase in IL-1β levels, as it occurs during seizures, infection or various brain damaging events has proconvulsant effects since an experimentally-induced increase in IL-1β levels prolongs seizure duration and lowers the threshold for seizure induction. These data are reinforced by the evidence that inhibition of IL-1β synthesis in rodents, using selective inhibitors of interleukin-converting-enzyme (ICE or Caspase-1) significantly reduced the frequency and the duration of seizures. Thus, these data support a crucial role of IL-1β in the mechanisms of ictogenesis.

Role of TNF-α. Pharmacological studies have shown that the injection of TNF-α into the mouse hippocampus significantly reduced seizures via interaction with TNF-α type II receptors (p75). Transgenic mice with low to moderate overexpression of TNF-α in astrocytes show decreased susceptibility to seizure, while mice with high overexpression of TNF-α develop signs of neurological dysfunction, including seizures. These findings highlight the importance of the tissue microenvironment (i.e., cytokine concentration, receptor subtype predominantly involved) in determining the final outcome of an increase in this cytokine on brain tissue excitability.

Role of IL-6. Transgenic mice overexpressing IL-6 in astrocytes show an increased susceptibility to seizures induced by glutamatergic agonists, as well as a loss of GABA- and parvalbumin-positive neurons in the hippocampus which may be implicated in their propensity to develop seizures. High overexpression of brain IL-6 is associated with the occurrence of age-dependent neurodegenerative changes and sporadic spontaneous seizures. Recent evidence, however, shows that IL-6 attenuates hyperthermia-induced seizures in developing rats, thus highlighting a possible dual role of this cytokine on neuronal excitability.

Role of other cytokines. Limited information exists about the effects of other inflammatory cytokines on seizures. For example, IL-2 facilitated sound- and chemoconvulsant-induced seizures in mice, and relatively high doses of this cytokine can cause recurrent seizures, although transiently. Intraventricular injection of IL-3 increased spike-and-wave discharges, and epileptic-like activity was observed after in vitro application of interferon to neuronal cultures or hippocampal slices. Finally, it has been shown that administration of LPS to rodents can facilitate spike-and-wave discharge activity in genetically seizure prone rats, and decreases the threshold to pentylentetrazole-induced seizures in mice, suggesting that a proinflammatory state in the brain can increase neuronal excitability and the propensity to develop seizures.

Mechanisms Underlying Cytokine Modulation of Neuronal Excitability (Fig. 1)

Initial studies, mainly focusing on IL-1β and TNF-alpha, attempted to explain the mechanisms by which cytokines

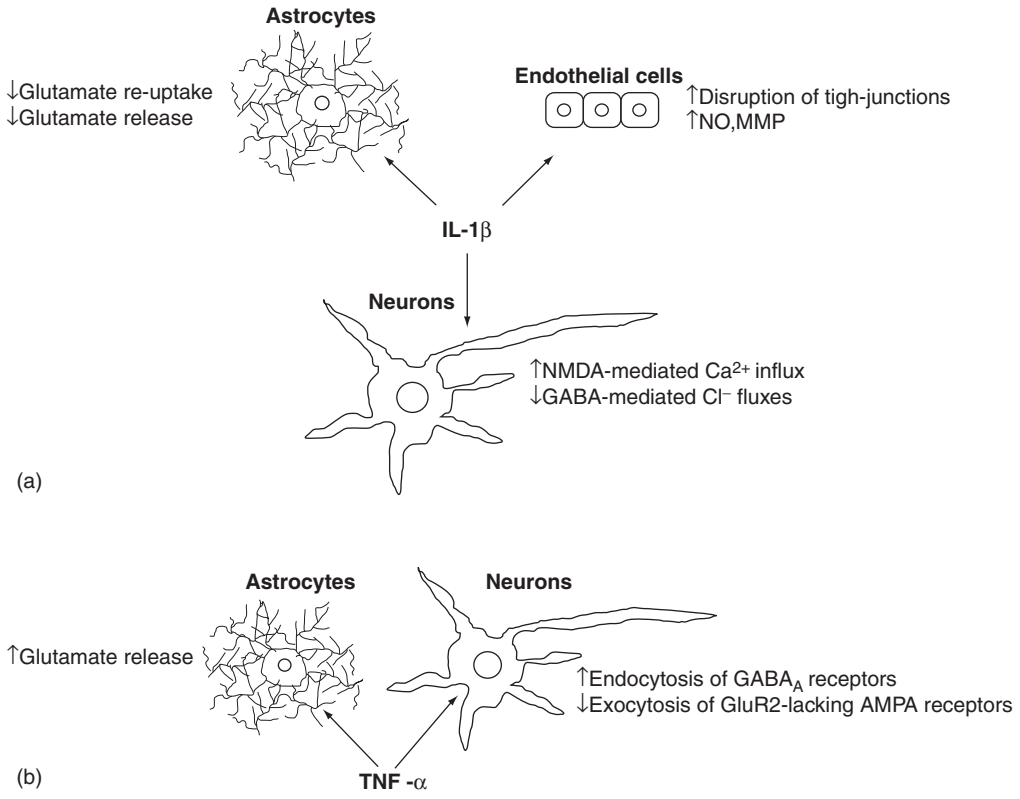

Figure 1 This schema depicts some of the mechanisms so far explored possibly underlying the increase in neuronal excitability mediated by inflammatory cytokines. Experimental data suggest that functional interactions between cytokines, glutamate, and GABA may result in increased excitatory strength. Changes in BBB permeability induced by cytokines may also contribute to enhancement of neuronal excitability (see text for details). NO, nitric oxide; MMP, matrix methalloproteinase.

may deleteriously affect neuronal excitability. The main approach was to investigate whether cytokines alter the function of classical neurotransmitters that are known to play a pivotal role in neuronal network excitability, such as glutamate and GABA. IL-1β has been reported to affect glutametergic neurotransmission by at least three routes: (1) by increasing extracellular glutamate concentration via inhibition of astroglial reuptake; (2) by increasing astrocytic or neuronal release of glutamate; and (3) potentiating *N*-methyl-D-aspartate (NMDA) receptor function via enhanced tyrosine phosphorylation of the NR2B subunit, resulting in increased neuronal Ca^{2+} influx. The dendritic colocalization of IL-R1 with NMDA receptors in hippocampal neurons supports their functional interaction mediated by IL-1β induced post-translational NMDA receptor changes. In addition to its interactions with glutamatergic transmission, IL-1β also reduces GABA-mediated Cl^- fluxes in hippocampal slice preparations.

The effects of IL-1β on endothelial cells of the BBB may also play a role in altering neuronal excitability in surrounding brain tissue. IL-1β can increase BBB permeability to serum albumin *via* disruption of tight junctions possibly mediated by the cytokine-mediated production of nitric oxide in endothelial cells as well the activation of methalloproteinases. The impairment in BBB permeability may lead to chronic neuronal hyperxcitability via parenchymal extravasation of serum proteins; moreover, a recent study reported a positive correlation between the extent of BBB leakage and the frequency of spontaneous seizures in rats.

A functional interaction between TNF-alpha and AMPA receptors was recently shown. This cytokine, by interacting with its type I receptor (p55) which contains an intracellular 'death domain' involved in cell damage, increased the surface expression of Ca^{2+}-permeable AMPA receptors at the neuronal plasma membrane, thus amplifying glutamate responses. TNF-alpha also promoted the endocytosis of $GABA_A$ receptors, thus decreasing inhibitory synaptic strength. This cytokine has also the ability to increase the release of glutamate from astrocytes.

These effects of IL-1β and TNF-alpha can also underlie their detrimental effects on neuronal survival to an excitotoxic insult since these cytokines can exacerbate necrotic and apoptotic neuronal cell loss, depending on their concentration, the time the brain tissue is exposed to the cytokine vis-à-vis with the injurious event and the type of cytokine receptors involved.

Conclusions and Future Goals

The activation of inflammatory pathways in brain areas involved in seizure inititiation and propagation has been well documented in experimental models as well as in chronic epileptogenic tissue from drug-refractory epileptic patients. Moreover, specific inflammatory processes triggered in the brain by seizures persist during epileptogenesis until the occurrence of spontaneous convulsions. The availability of clinically relevant experimental models of epilepsy is instrumental to study the chronological sequelae of inflammatory events following different kinds of brain injuries associated with a high risk of developing spontaneous seizures, and the role of brain inflammation in the epileptogenic process. Several studies are still required to further investigate the functional interactions between inflammation and epilepsy:

- analysis of the profile of inflammatory markers in blood and/or CSF, evaluated at the first seizure and during follow-up, to determine whether some inflammatory molecules can be predictive for the occurrence of epilepsy, particularly in those symptomatic cases with a high risk of developing epilepsy;
- characterization of inflammatory markers in those patients in which anti-inflammatory drugs appear to modify seizures;
- characterization of the detailed molecular signaling processes activated by inflammation to highlight new potential therapeutic targets;
- definition of the genetic backgrounds regulating the expression of the inflammatory response in epileptic patients, to determine whether there is a genetic predisposition to develop brain inflammation following brain damaging events.

If a link between brain inflammation, epileptogenesis and ictogenesis is established, this finding will provide strong support for the development of novel pharmacological strategies for inhibiting seizures using anti-inflammatory treatments directed against specific inflammatory pathways, and possibly for arresting epileptogenesis. The expression of inflammatory molecules is constitutively very low in the brain, suggesting a limited role of these molecules in normal brain physiology, thus targeting specific inflammatory mediators for controlling seizures may also reduce the chances of neurological side-effects.

Introduction

After many decades of animated debate in the scientific community about putative mechanisms, including neurodegenerative pathways, involved in epileptogenesis in the most common animal models of limbic epilepsy (e.g., those based on kainic acid or pilocarpine administration), we are still far from a commonly accepted explanation. In our opinion, one of the major theoretical limitations is represented by the fragmented approach to this problem. Biological mechanisms involved in epileptogenesis and in the brain response to an ictogenic insult have been rarely studied from a holistic point of view. Electrophysiology, neuropathology, neuroimmunology, and other biomedical approaches have focused independently on particular aspects of the complex pattern of brain alterations associated with the epileptic condition. Our goal has been to adopt an integrated and multidisciplinary approach that can take into account different factors – in in vivo studies of alterations of the 'whole brain' – in epilepsy. We attempt, therefore, to combine electrophysiological, neuropathological, and neuroimmunological data, considering the multiple players involved in vivo in this dangerous game.

Background

A wealth of data, obtained both in human and animal studies, indicate that perturbations in neurovascular integrity and breakdown of the blood–brain barrier (BBB) may lead to neuronal hypersynchronization and epileptiform activity. However, the mechanisms underlying these processes are still unclear. Furthermore, inflammatory processes related to the activation of brain vessel endothelia and/or BBB leakage have been reported, but no explanations have yet been provided for the relevant mechanisms of action.

Seizures bring about, by definition, electrical alterations of the electroencephalogram (EEG). For this reason, experimental neurobiological studies of the etiopathogenesis of epilepsy are historically based on electrophysiology and, in particular, on the study of neuronal discharges. This focus has led to a relative neglect of two other potentially key (and probably crucial) factors – vascular and inflammatory processes (and their combined role).

In our investigations, we recently showed that pilocarpine-induced status epilepticus (SE) produces marked vascular effects in a neocortical (somatosensory) and an allocortical (cingulate) brain region of Wistar rats (**Figure 1**). We reported that vascular alterations, characterized by hyperemia and neurons degenerating by apoptotis, are evident in the supragranular layers of the somatosensory cortex and in superficial (II/III) layers of the cingulate cortex 12 h after SE (which lasted 4 h) (**Figure 2**). Deeper layers (V, VI) exhibited early edema and necrotic cell death. These results suggest that cortical injury caused by pilocarpine-induced SE may involve different mechanisms in different cortical layers, probably due to laminar differences in blood vessel organization and regulation.

Blood–Brain Barrier

The BBB is a selective barrier formed by tight junctions between endothelial cells, acting primarily to limiting the penetration of different substances from the blood into the brain. The BBB presents a 'physical barrier,' which forces most molecular traffic to take a transcellular route across the BBB, rather than moving paracellularly through the junctions. The high density of the tight junctions that compose the BBB restricts the passage of substances from the bloodstream much more than endothelial cells in capillaries elsewhere in the body. Astrocyte cell processes, called 'end-feet,' surround the endothelial cells of the BBB (forming the so-called *glia limitans*), providing biochemical support to the endothelial cells. BBB disruption is associated with various neurological disorders. During the past years, there has been increasing interest in BBB alterations in epilepsy, both in humans and in animal studies.

BBB Alterations in Epilepsy

Technical advances in neuroimaging procedures in humans and in animal models have contributed knowledge about cerebrovascular alterations consequent to seizures, demonstrating that the BBB can be reversibly disrupted by pathologic processes, leading to – and caused by – epileptic activity. Vascular alterations have been correlated with neuronal and glial cell degeneration in different animal models of chemically induced acute or

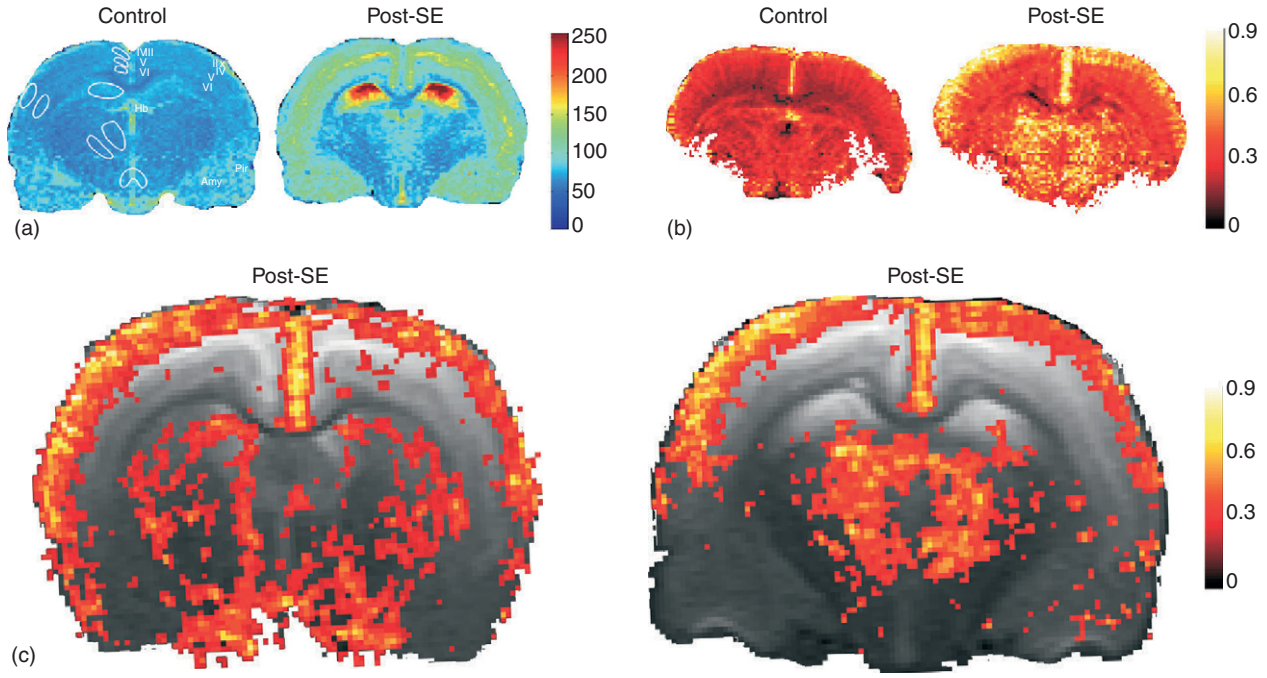

Figure 1 (a) T2 parametric maps of control brain and in postacute phase of status epilepticus (SE). (b) Regional cerebral blood volume (rCBV) maps in control and post-SE animals. Pseudocolor images refer to one rostrocaudal levels (–2.5 mm from bregma). (c) Maps generated to show the highest values of rCBV increase (cut off at 0.40 arbitrary units) at two different levels (a: 0.26 mm from bregma, b: –2.5 mm from bregma) superimposed to T2-weighted images (T2W) in the same post-SE animal. In the cerebral cortex the simultaneous detection of the two signals shows clearly that rCBV peaks in the superficial layers, overlying the T2W hyperintensity. An increase of rCBV is also evident in the dorsolateral striatum and medial basal forebrain, as well as in the medial thalamus. Modified from Fabene PF, Marzola P, Sbarbati A, and Bentivoglio M (2003) Magnetic resonance imaging of changes elicited by status epilepticus in the rat brain: diffusion-weighted and T2-weighted images, regional blood volume maps, and direct correlation with tissue and cell damage. *Neuroimage* 18: 375–389.

chronic seizures. Recently, BBB permeability disruption in limbic regions of the rat brain, shortly after SE as well as in the latent and chronic seizure phases, has been reported. BBB leakage likely contributes to the progression of epilepsy. In epileptic rats, artificial opening of the BBB induces a persistent increase in the number of seizures, and BBB permeability disruption is positively correlated with chronic seizure frequency. Acute vascular failure seems to be sufficient to cause seizures in the absence of other central nervous system (CNS) pathology, not only in animal models but also in humans.

Bridging the Gap Between BBB Alteration and Neuronal Hyperexcitability

We now need to bridge the gap between BBB leakage, documented in both human and rat epileptic brain tissue, and neuronal hyperexcitability. By definition, a seizure is a paroxysmal hypersynchronous discharge generated by CNS neurons. Since seizures are electrical alterations, it is important to address the question of what mechanisms link vascular alterations to the electrical activity of a given neuron. Are such mechanisms passive or active? Are they sufficient to explain the pathology, or do we need a wider theoretical framework?

The role of albumin in epileptogenesis has been recently studied in detail. Focal BBB opening by direct cortical application of albumin-containing solution can lead to the generation of an epileptic focus in rats. In particular, extravasated albumin accumulates in astrocytes and neurons in the hippocampus of temporal lobe epilepsy (TLE) patients, as well as in microglia, astrocytes, and neurons of the rat epileptic brain. Interestingly, blood volume is consistently highest in regions with highest concentration of degenerating neurons and glia. Furthermore, adult rats undergoing focal BBB disruption exhibit over time a reduction in cortical volume compared with control rats, associated with reduced number of neurons and increased number of astrocytes, as well as increased threshold for spreading depression and increased propagation velocity of evoked epileptic potentials.

Similarly, by means of long-lasting focal neocortical BBB disruption or direct exposure to serum albumin in in vivo studies in rats, as well as albumin exposure in brain slices in vitro, it is possible to induce hypersynchronous propagating epileptiform field potentials. In these experiments, direct brain exposure to serum albumin was

Scale bars: (b, c, e) = 35 μm, (d) = 50 μm. Modified from Fabene PF, Marzola P, Sbarbati A, and Bentivoglio M (2003) Magnetic resonance imaging of changes elicited by status epilepticus in the rat brain: diffusion-weighted and T2-weighted images, regional blood volume maps, and direct correlation with tissue and cell damage. *Neuroimage* 18: 375–389.

associated with albumin uptake into astrocytes, followed by downregulation of inward-rectifying potassium (Kir 4.1) channels, resulting in reduced buffering of extracellular potassium in astrocytes. This process, in turn, led to an activity-dependent increased accumulation of extracellular potassium, resulting in facilitated *N*-methyl-D-aspartate-receptor-mediated neuronal hyperexcitability.

Mechanisms of BBB Permeability and Leukocyte Recruitment

Recent studies have shown that BBB opening leads, by itself, to neuronal hypersynchronization and epileptiform activity, which is mediated by exposure of neuronal cells to blood albumin or potassium ions. Moreover, as indicated earlier, chronic BBB leakage during epilepsy contributes to its progression. Changes in BBB integrity may be caused by increased local blood pressure that occurs during seizures, free radical formation, and inflammatory responses such as leukocyte recruitment, cytokine and chemokine production, and/or loss of tight junction molecules.

Leukocyte migration through the endothelium represents a critical event in the pathogenesis of inflammatory responses and involves complex, sequential events. Leukocyte tethering and rolling represent the first step of leukocyte recruitment in blood vessels. Leukocyte migration from bloodstream to tissue requires rapid coordinated regulation of integrin-dependent adhesion and deadhesion. The immunoglobulin superfamily is in part composed by two adhesion molecules: intercellular adhesion molecule type 1 (ICAM-1) on the superficial part of vascular endothelial cells, and vascular cells adhesion molecules type 1 (VCAM-1). The tie between leukocyte function-associated antigen (LFA)-1 and ICAM-1 is the adhesion mechanism stabilizing the contact between the cytolytic cell and the endothelial cell.

Cytokines and Chemokines

Cytokines are small (8–10 kDa) signaling proteins, which play a key role in cellular communication and are produced by a variety of hematopoietic and nonhematopoietic

cell types. Chemotactic cytokines, characterized by the ability to induce directed chemotaxis in nearby responsive cells, are called 'chemokines.' Cytokines and chemokines are involved in both innate and adaptive immune responses. They are usually secreted by immune cells after pathogen detection, in order to activate and recruit more immune cells and to increase the system's response to the pathogen, but they can also be secreted by glial cells. Besides their role in the functioning of the immune system and in a variety of inflammatory diseases, cytokines and chemokines are involved in neuroplasticity and glia–neuron communication. Numerous cytokines can have both proinflammatory and anti-inflammatory roles, depending on target cells and their state of responsiveness to the cytokine. Chemokines can be induced during an immune response to promote immune cell recruitment to a site of infection; their release is often stimulated by proinflammatory cytokines such as interleukin (IL)-1. Inflammatory chemokines function mainly as chemoattractants for leukocytes, recruiting monocytes and neutrophils from the bloodstream to sites of infection or tissue damage. Others chemokines ('homeostatic chemokines') are involved in controlling physiological cell migration. Chemokines can also be involved in angiogenesis.

Methodological Approaches

In our laboratory, seizures are usually induced in Wistar rats and C57BL6/J mice by systemic administration of pilocarpine. Limbic seizures provoked in rodents by systemic administration of this muscarinic cholinergic agent provide a widely used model of human epilepsy, in which brain injury consequent to SE leads to spontaneous recurrent seizures after a latent phase.

Seizure severity and duration and occurrence are assessed by an EEG acquisition system, using telemetric technology (Dataquest® A.R.T. Data Acquisition 3.0 for telemetry systems, Data Sciences International, Arden Hills, MN, USA). With this system, EEG, body temperature, blood pressure, and movements can be recorded in each animal for 24 h day^{-1}, for up to 9–12 consecutive months in rats and 4–5 months in mice.

Magnetic resonance imaging (MRI) data are acquired using a 4.7-T Biospec Tomograph (Bruker, Karlsruhe, Germany) equipped with an Oxford 33-cm bore. Structural, functional, and perfusion data are obtained to analyze neurodegenerative and inflammatory processes in the epileptic brain, and to assess, quantitatively and qualitatively, the effects of pharmacological treatments. Relative alterations in the cerebral blood volume and flow (rCBV and rCBF) in given brain areas, relative to other brain regions, are assessed by acquiring T2*-weighted images during the first passage of a superparamagnetic contrast agent (USPIO) and at the equilibrium distribution.

Histochemistry is routinely used to evaluate cell density or morphology (Nissl staining) and neurodegeneration (Flouro Jade B and/or Dark Neuron stains), and immunohistochemical procedures are used to identify cell types and analyze the cellular expression of different proteins. Sections are studied on a Zeiss LSM 510 confocal microscope (Zeiss, Oberkochen, Germany), equipped with argon (488 nm) and helium/neon (543 nm) excitation beams. Sections treated as earlier, but in the absence of the primary or secondary antibody, are always used as control. For ultrastructural analysis, dissected tissue blocks are fixed, and 1-μm-thick semithin sections are stained with toluidine blue. Ultrathin sections are cut at 70-nm thickness on an Ultracut-E ultramicrotome (Reichert-Jung), stained with lead citrate and uranyl acetate, and observed on a Zeiss EM 10 electron microscope.

To make vascular cast preparations, animals are anesthetized with sodium pentobarbital and then thoracotomized. A catheter is introduced into the arch of the aorta through the left ventricle, and the right atrium is opened. The circulatory system is rinsed with phosphate-buffered saline, and a freshly prepared solution of a low-viscosity resin, Mercox CL-2B (Dainippon Ink & Chemicals, Tokyo, Japan), is injected along the same route. Maceration of the brain tissue is performed using a 10% solution of potassium hydroxide until only the resin casts of blood vessels remain. These specimens are rinsed by several passages in distilled water, and then frozen. The casts are freeze-dried (Modulyo, Edwards-Kniese, Marburg, Germany), fixed to stubs with colloidal silver, sputter-coated with gold (MED 010, Balzers), and examined under a scanning electron microscope (DSM 690, Zeiss).

For microarray analysis, mRNA is isolated from different brain areas. mRNA is used as template for generating a cDNA library. cRNA labeled with dUDP-biotin (Enzo Roche Molecular Biochemicals, Mannhein, Germany) is retrotranscribed. dUDP-biotin-cRNA is purified and hybridized on different OligoGEArrays containing probes specific for genes implicated in signal transduction pathways, apoptosis, DNA-damage response, chemokines, cytokines, or adhesion molecules. The hybridization pattern is revealed by CDP-Star® substrate fluorescence using Chemiluminescent Detection Kit and recorded on an X-ray film. Data from arrays are analyzed using GEArray Analyzer software (Superarray Bioscience Corporation).

Recent Results

As stated earlier, we recently showed SE-induced vascular alteration in cortical areas of Wistar rats (**Figures 1** and **2**), demonstrating that degenerating neurons are related to brain sites characterized by hyperemia. We decided to

better elucidate such pathological modifications of brain perfusion by assessing changes in the vascular structure, gene expression, and time course of neuronal degeneration in the cerebral cortex during the postacute phase of pilocarpine-induced SE. We showed that after 2 h, the infragranular layers of the somatosensory cortex exhibit reduced vascular perfusion indicative of ischemia, whereas the immediately adjacent supragranular layers exhibit increased perfusion (**Figure 3**). Infragranular layers exhibit necrotic pathology, whereas the supragranular layers are characterized by a delayed (24 h after SE) degeneration, apparently via programmed cell death. These results indicate that pilocarpine-induced SE elicits both excitotoxic and ischemic injury, and that vascular alterations play a major role in epileptogenesis.

One of the consequences of vascular alterations and consequent increased BBB permeability is the accumulation of serum proteins that enter the brain, which may contribute to increased excitability. It has been shown recently that epileptiform activity can be induced in rats by direct cortical application of an albumin-containing solution, suggesting that serum proteins play a role in

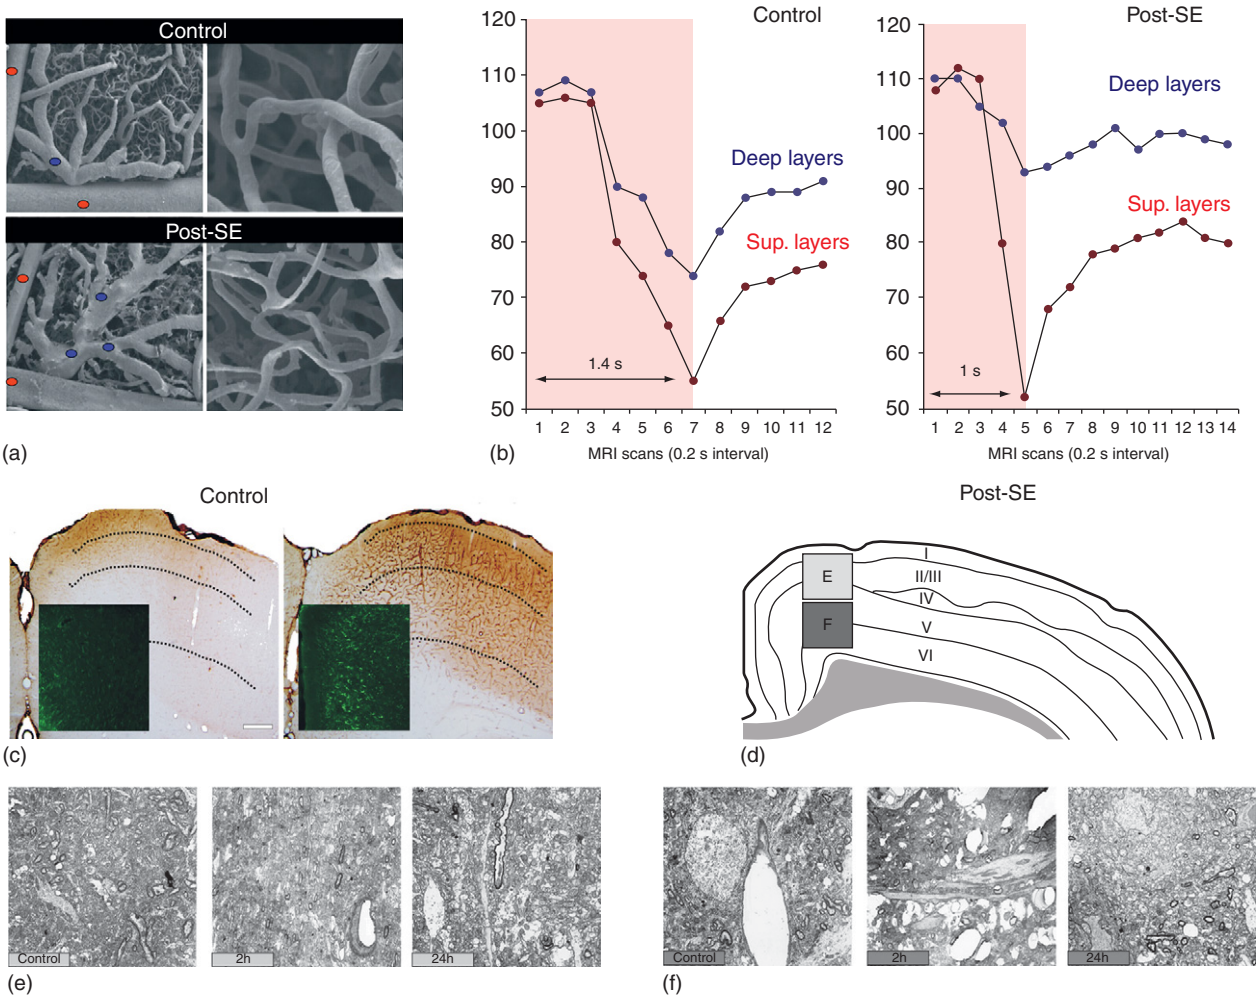

Figure 3 (a) Vascular casts reveal structural alterations in brain vessels 2 h after the onset of status epilepticus (SE). In the superficial, hyperperfused zone, veins are increased in diameter (right column) whereas in the hypoperfused, edematous subgranular region, veins appear collapsed (left column). (b) Peak enhancement in control and pilocarpine-treated animals. Compared with controls, in rats during SE infragranular layers show a decreased contrast medium peak concentration, indicating a relative ischemic core, whereas supragranular layers are characterized by hyperemia (red dots). (c) Agrin expression in control and pilocarpine-treated animals. Increased agrin expression in the endothelial cells is evident in both superficial and deep layers 2 h after SE onset. This increase is more evident in the supragranular than in the infragranular layers. Localization of glial fibrillary acidic protein (GFAP)-like immunoreactivity reveals selective increase in astrocytic GFAP expression in the less acutely damaged superficial layers (square). (d) Schematic drawing of the two different brain areas analyzed by electron microscopy (EM): (e) EM images in control animals, and 2 and 24 h after SE in both supragranular (e) and infragranular layers (f). Infragranular layers are characterized by severe tissue damage 2 h after SE whereas supragranular layers at this time point appear unaffected except for the perivascular edema. Twenty-four hour after SE, damage is evident in both regions. Modified from Fabene PF, Navarro Mora GN, Martinello M, *et al*. (2008) A role for leukocyte – endothelial adhesion mechanisms in epilepsy. *Natural Medicines* 14(12): 1377–1383.

the pathogenesis of focal epilepsies. Interestingly, albumin is found specifically in regions with more EEG spiking activity in human epileptic brain, and albumin can induce calcium waves in rat cortical astrocytes. A positive correlation between vascular alteration, BBB permeability to serum proteins such as albumin, and the occurrence of spontaneous seizures in epileptic rats has thus been demonstrated.

Recently, the involvement of cytokines in the pathogenesis of epilepsy has been suggested by a wealth of evidence. Limbic seizures increase mRNA of inflammatory cytokines in rodent forebrain. Proinflammatory cytokines (IL-1beta, tumor-necrosis factor-alpha, and IL-6) are rapidly upregulated by seizures in a reversible manner; IL-1beta is upregulated in rodent brain up to 60 days after SE during the occurrence of spontaneous and recurrent seizures. Microglia and astrocytes appear to be the first and main source of cytokine production in brain. Importantly, brain inflammation following seizures contributes to epileptic activity and to the associated neuronal cell loss.

In summary, the aforementioned data indicate that (i) pilocarpine-induced SE involves vascular alterations; (ii) these alterations can take the form of hyper- or hypoperfusion at different brain sites, even sites very close to each other; (iii) delayed neurodegeneration following SE is related to hyperemia and vascular lumen dilatation; (iv) during acute epileptic insults resulting in a vascular alteration, there is a considerable active and passive escape of plasma proteins from the bloodstream to the brain parenchyma; and (v) proinflammatory cytokines and chemokines are involved in the epileptogenic process.

We hypothesized that the inflammatory response involves three major sequential events: dilatation of capillaries to increase blood flow, microvascular structural changes and escape of plasma proteins from the bloodstream, and leukocyte transmigration through the endothelium and accumulation at the site of injury. The first two steps have been extensively investigated, whereas leukocyte recruitment and transmigration have not received significant attention. We, therefore, decided to examine whether SE can induce leukocyte recruitment. We are currently analyzing whether, by interfering with leukocyte recruitment, we can prevent the BBB breakdown and related cascade of inflammatory processes that appear to be responsible for, or at least contribute to, epileptogenesis.

Our data show a direct correlation between endothelial activation, leukocyte adhesion, BBB opening, and seizure generation. These mechanisms could be involved in inflammatory processes causing seizures and epilepsy by different causes. Our results suggest that leukocyte–vascular interactions can contribute to seizure generation, amplifying existing signals and reducing the threshold for seizures by acting synergistically with other pathogenetic events. Leukocyte adhesion to the BBB endothelium, BBB leakage, and neuronal hyperactivity may 'synergize' with each other, amplifying the vascular and neuronal changes that ultimately initiate a full-blown seizure. Thus, endothelial activation that allows leukocyte adhesion and BBB damage may represent a key event, not only in seizure induction but also in the progression toward chronic seizure generation.

We thus hypothesize that a cycle of seizure-induced inflammation and inflammation-mediated stimulation may amplify initial effects, leading to recurrent seizure activity (**Figure 4**). BBB activation, with upregulation of adhesion molecules, is provoked by a convulsant agent (pilocarpine in our experiments) or can be provoked by inflammatory pathology, such as CNS infections or head trauma. Moreover, seizure activity, generated in experimental models of

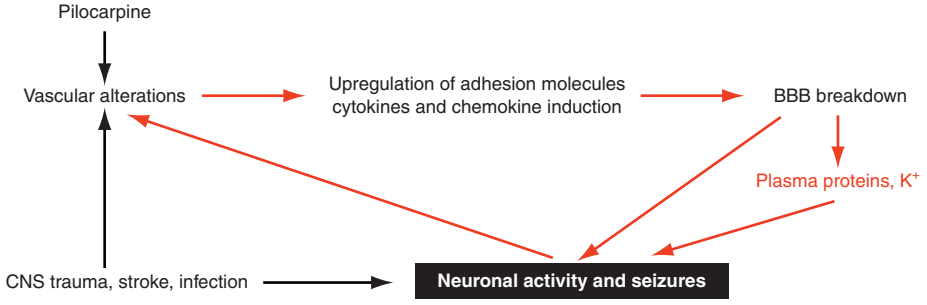

Figure 4 Proposed model for the contribution of vascular inflammation to seizure pathogenesis. CNS vascular activation with upregulation of adhesion molecules, cytokines, and chemokines can be provoked by the convulsant agent (pilocarpine) or by inflammatory pathologies such as CNS infection or injury following head trauma. Activation of brain endothelium can alter endothelial barrier function resulting in leakage of plasma constituents into the brain parenchyma. Exposure of neuronal cells to plasma proteins such as albumin and K^+ accumulation contribute to neuronal electrical hyperactivity, lowering the threshold for seizures. Seizure activity, whether induced by inflammatory processes or by primary neuronal or developmental defects (such as heterotopic gray matter), exacerbates and may itself induce vascular activation. The 'triggering' event(s) in the model could thus be primarily neuronal, vascular, or inflammatory. Neuroinflammation, BBB leakage, and neuronal hyperactivity may synergize with each other, amplifying the vascular and neuronal changes that ultimately lead to seizures. Ongoing positive feedback between adhesion molecule upregulation, altered vascular function, and CNS electrical hyperactivity may contribute to chronic pathology and recurrent seizures (red arrows).

epilepsy or in humans suffering from developmental abnormalities such as cortical heterotopias, can lead to upregulation of adhesion molecules in brain endothelium. Activation of brain endothelium leads, in turn, to leukocyte adhesion, which contributes to BBB leakage; this sequence further compromises barrier function, resulting in lowered threshold to seizures. Exposure of neuronal cells to plasma proteins such as albumin and K^+ accumulation contribute to neuronal electrical hyperactivity.

Leukocytes may contribute to seizure pathogenesis acutely through effects on the BBB, and chronically through several mechanisms, including occlusion of microvasculature, generation of oxygen free radicals, release of cytotoxic enzymes, vascular alterations, and increase in the release of cytokine and chemoattractant molecules. Importantly, even leukocyte adhesion to the vessel wall alone – triggered rapidly after an in vivo stimulus and occurring normally at low stimulation frequency – induces signaling events in the endothelium. These events include calcium signaling, and modifications of small GTPases involved in cytoskeletal organization and c-Jun-N-terminal kinase. Moreover, neutrophil adhesion is known to induce alterations in vascular permeability. BBB leakage in the cortex supports the occurrence of leukocyte–endothelium interactions and upregulation of adhesion molecules in cortical vessels.

Consistent with this scenario, pilocarpine-induced vascular adhesion molecule expression is reduced if seizures are prevented pharmacologically with diazepam, suggesting that electrical activity amplifies the vascular response. Moreover, electrical activity is reduced if leukocytes are depleted or vascular interactions are inhibited. It has also been shown that BBB leakage per se may result in the development of seizures, while drugs able to reduce vascular damage reduce seizure activity.

In conclusion, the earlier discussed data show that vascular alterations and BBB leakage induced by protracted seizures are not merely epiphenomena detected in animal models of chemically induced epilepsy, but they may represent crucial steps of a cascade of events responsible for epileptogenic mechanisms. Furthermore, we suggest that such events can be followed by leukocyte recruitment and by cytokine and chemokine release.

Identify the Challenges for the Future

Future challenges concern the identification of the adhesion molecules involved in leukocyte recruitment in the brain after experimental seizures. Characterizing the effect of adhesion molecule blockade on the clinical course of disease is another major challenge. By means of blocking monoclonal antibodies, we hope to identify the adhesion molecules involved in the process of sticking leukocytes to inflamed brain endothelium at various time points in experimental rodents after protracted seizures. Investigation of the effects of anti-integrins and anti-immunoglobulins blocking antibodies, and the consequences of gene deficiency of integrins and immunoglobulins on the induction and clinical course of experimental limbic epilepsy, are likely to open interesting new perspectives.

Neurodegeneration, Neuroprotection and Inflammation in the Brain

S J Czuczwar, Medical University of Lublin, Lublin, Poland; Institute of Agricultural Medicine, Lublin, Poland

Introduction

Brain insults, such as infection, febrile seizures, inflammation, may result in a sequence of pathological events, leading eventually to the occurrence of seizures. This long-lasting process of epileptogenesis can take years, and may be associated with progressive cell loss initiated by the insult.

Neural Degeneration

There is no doubt that even a single seizure can be a reason for neuronal cell loss in vulnerable brain areas. Status epilepticus (SE), a neurological condition that may last for hours, often produces diffuse brain lesions, as is evident from diverse animal models. The more quickly SE is stopped, the fewer neurons die. Excitotoxic damage to neurons occurring during seizure activity is mainly due to the excessive release of glutamate, which acts on ionotropic glutamate receptors – for *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA), and kainate (KA). The neurotoxic potential of glutamate analogs in vitro and in vivo has been broadly documented. The same effect was later reproduced by prolonged electrical stimulation of the glutamatergic perforant path, resulting in damage to hippocampal neurons. These results suggest the possibility that glutamate antagonists, or antiepileptic drugs (AEDs) with anti-glutamatergic potential, may limit seizure-related brain damage – and thus be 'antiepileptogenic.'

Neuronal death is caused by two separate processes – necrosis and apoptosis. The former is a direct result of the excitotoxic activity of glutamate and the latter is dependent on the activation of apoptotic enzymes – caspases. Excessive glutamate release (caused by seizure activity) acts on AMPA receptors to cause massive sodium ion and subsequent water influx into neurons, which leads to the first phase of neurodegeneration – neuronal swelling. Initial depolarization mediated by AMPA receptors alleviates the magnesium block of NMDA receptors, and the neurodegenerative process enters its second phase, involving neuronal calcium ion influx. Calcium influx in turn activates proteases (e.g., calpain I and cathepsin D) and phospholipases, eventually destroying the cytoskeleton and damaging microtubular functions. Also, nitric oxide synthase is activated, which eventually generates free radicals (peroxynitrite), causing damage to DNA. Damaged DNA stimulates the repair enzyme, poly (ADP-ribose)polymerase-1, a process responsible for profound reductions in neuronal ATP and nicotinamide adenine dinucleotide, causing total energy failure. Intraneuronal increase in calcium ion concentration seems to be the main factor of necrosis. In this regard, it is noteworthy that hippocampal granulae neurons are relatively resistant to glutamate excitoxicity, probably because of their high content of the calcium binding protein, calbindin.

Mitochondria are assumed to play an important role in both necrosis and apoptosis. In trying to maintain neuronal calcium homeostatsis, mitochondria become loaded with calcium ions upon glutamate-induced excitation. This excessive mitochondrial calcium load is associated with increased mitochondrial permeability through mitochondrial permeability transition pore or enhanced permeability of the outer mitochondrial membrane. Activation of the transition pore by excess of calcium causes mitochondrial swelling, followed by impaired ATP production and increased synthesis of free radicals. This sequence of events leads to further opening of pore, and eventually causes necrosis. In contrast, increased mitochondrial permeability also triggers apoptosis via release of pro-apoptotic proteins – apoptosis-inducing factor and cytochrome c – leading to activation of caspases.

Inflammation

Experimental convulsions as well as clinical epilepsy generate pro- and anti-inflammatory cytokines in the central nervous system. Data from experimental models indicate that inflammation in the brain may elevate the neuronal excitability, promote neuronal death, and decrease the integrity of the blood-brain barrier.

Background

Neural Degeneration

Pilocarpine-induced SE in rats results in diffuse brain damage, including the substantia nigra, amygdala, hippocampus, septum, thalamus, olfactory and temporal cortex. Also, in epileptic patients who have died within a couple

of days after SE, massive neurodegeneration was evident in the cerebellum, hippocampus, and neocortex. Studies of seizure-related brain damage have developed, therefore, aimed at finding effective neuroprotective agents. AEDs, used as seizure-preventing drugs, have been widely tested for their potential neuroprotective properties.

The benzodiazepine, diazepam (which enhances GABAergic inhibitory function via the $GABA_A$ receptor complex), has been shown to provide essential protection against pilocarpine-induced brain damage in adult rats. However, benzodiazepines (diazepam, clonazepam) themselves produced diffuse apoptosis in infant rat brains. Similarly to benzodizepines, administration of phenobarbital to young rats resulted in neurodegenration which was apoptotic in nature. The barbiturate, phenobarbital (also mainly a GABA enhancer), proved effective against KA-induced neurodegeneration in the dentate gyrus but not in other hippocampal regions. Carbamazepine (a voltage-gated sodium channel blocker) was also only partially effective against SE-induced hippocampal lesions, in that it protected only CA_1 neurons but was ineffective in the remaining hippocampal regions. In a perinatal rat model of NMDA-induced neurodegeneration, carbamazepine conferred a partial (less than 40%) protection. However, no neuroprotection was offered by carbamazepine against 4-aminopyridine-induced hippocampal neuronal death. Phenytoin (another sodium channel blocker) was shown to afford some protective effects in rat cortical or hippocampal cultures exposed to glutamate, although it was without effect in cortical cultures exposed to NMDA. When added to neonatal mouse cerebellar cultures, phenytoin was clearly neurotoxic, this effect being concentration-dependent. In contrast, mature cerebellar cultures were resistant to phenytoin neurotoxicity. Phenytoin was also shown to be an apoptosis-inducer in vivo. Valproate (a sodium channel inhibitor, GABA enhancer, and probably T-type calcium channel blocker) protected cultured cerebellar neurons against neurotoxic effects of glutamate but was ineffective against 4-aminopyridine-induced hippocampal damage in vivo. However, valproate afforded potent neuroprotection to the hippocampus in a rat model of SE, induced by electrical stimulation of amygdala. Similarly to benzodiazepines, phenobarbital, and phenytoin, valproate was an apoptotic agent in young rats in vivo.

Inflammatory Reactions and Epileptogenesis

There is now considerable interest in the question of whether inflammatory reactions are in some way related to epileptogenesis and the progressive nature of epilepsy. The answer is probably 'yes,' as chronic inflammation in the brain contributes to neuronal death, seizure activity, and increased permeability of the blood-brain barrier – which in turn affect both, neuronal plasticity and neurogenesis.

Methods

Experimental seizures may be induced by means of physical stimuli (for example, electroconvulsions) or chemical stimuli (for example, bicuculline, KA, NMDA, pentylenetetrazol, pilocarpine, or picrotoxin – given systemically or intracerebrally). Electroshocks may be delivered via auricular electrodes or via electrodes implanted into the brain (amygdala, hippocampus). With brain electrodes, it is possible to induce SE by prolonged suprathreshold stimulations or kindled seizures, by subthreshold stimulations every 24–48 h. SE may be also produced by chemical convulsants – most frequently by KA and pilocarpine. It is noteworthy that SE results in massive neurodegeneration which may be modified by, for instance, AEDs; in this way, neuroprotection by various treatments may be evaluated. Following SE, after a latent period, spontaneous seizures may develop, enabling the investigators to study epileptogenesis.

Inflammation in the brain can be triggered by administration of bacterial lipopolysaccharide in order to mimic infection. The lipopolysaccharide is recognized by so-called TLR receptors, the activation of which stimulates antigen-presenting cells. This process eventually leads to the proliferation of microglia, lymphocytes, monocytes and neutrophils. Experimental brain inflammation can also be induced by viral infections (for example, measles virus- or mouse-hepatitis-virus-induced encephalitis).

Recent Results

Neuroprotection Provided by Newer AEDs

Some of the newer AEDs have now been studied for their neuroprotective potential. Gabapentin (binds to the $alpha_2\delta$ subunit of calcium channels) afforded a significant protection to hippocampal neurons in rats with KA-induced SE. Interestingly, the drug was injected 24 h *after* induction of SE and administered for one month. Lamotrigine (a sodium and calcium channel blocker) also protected hippocampal neurons in rats with KA-induced SE. Levetiracetam, which has a unique mechanism of action (binds to the vesicle synaptic protein, SV2A, and blocks N calcium currents), has been shown to provide neuroprotection in a model of SE (self-sustaining SE) in rats; in contrast, it has been found ineffective against pilocarpine-induced hippocampal damage. Pregabalin, (similarly to gabapentin, blocks the $alpha_2\delta$ subunit of voltage-dependent calcium channels), potently protects against lithium/pilocarpine-induced neurodegeneration. Interestingly, this neuroprotective effect was associated with the subsequent inhibition of spontaneous seizure activity. Tiagabine (an inhibitor of neuronal and

glial GABA uptake), in a model of rat SE induced by stimulation of perforant path, considerably reduced hippocampal cell loss, as well as impairment of spatial memory. In an in vitro study, tiagabine, however, was toxic to developing hippocampal neurons. Topiramate (an AED with multiple mechanisms of action – blockade of AMPA receptors, enhancement of GABA-mediated inhibition, blockade of sodium and L-calcium channels, enhancement of potassium currents) significantly and dose-dependently reduced the extent of hippocampal damage caused by SE in rats, evoked by unilateral hippocampal electrical stimulation. The drug was given to animals seizing for 140 min; at 40 and 80 mg/kg, the neuroprotective effect was evident for the whole hippocampus, while at 20 mg/kg, only neurons in the CA_3 region and hilus were protected. In a pilocarpine (380 mg/kg) model of SE (lasting for 40 min) in rats, topiramate was given at 20, 40, and 100 mg/kg and SE was stopped after 3 hrs with diazepam (4 mg/kg); topiramate was protective in a dose-dependent manner. At 100 mg/kg the protection was full in the whole hippocampus, and spontaneous seizure activity was reduced (suggesting an antiepileptogenic effect of topiramate). However, in another study using the lithium/pilocarpine model of SE in rats, while diazepam-topiramate treatment produced clear-cut neuroprotection in the hippocampus and ventral entorhinal cortex, the occurrence of spontaneous seizure activity was not modified. Vigabatrin (elevating GABA concentration in the synaptic cleft by irreversible inhibition of GABA transaminase) has been found neuroprotective in the perforant path stimulation model and pilocarpine model of SE, but not in the electro-stimulation of hippocampus. A summary of the neuroprotective and apoptotic potential of AEDs is shown in **Table 1**.

Table 1 Neuroprotective effects of conventional and newer AEDs and induction of apoptosis (studied in young animlas) by AEDs in vivo

AEDs	*Neuroprotection*	*Induction of apoptosis*
Benzodiazepines	+	+
Carbamazepine	+/−	NT
Phenobarbital	+/−	+
Phenytoin	−	+
Valproate	+/−	+
Gabapentin	+	NT
Lamotrigine	+	NT
Levetiracetam	+/−	NT
Pregabalin	+	NT
Tiagabine	+	NT
Topiramate	+	+[a]
Vigabatrin	+/−	+

[a]Effect observed at supramaximal doses.
+, neuroprotective effect; +/−, inconsistent data or partial protection; NT – not tested in vivo.

Inflammation, Seizure Activity, and AEDs

Recent experimental studies clearly indicate that seizure activity may induce inflammation in the brain, that seizure-accompanying neurodegeneration promotes inflammatory reactions, and that anti-inflammatory drugs may provide protection against seizure activity (as has also been shown in clinical studies of epilepsy). Increased concentration of pro-inflammatory markers has been found in the serum of children suffering from the West syndrome; since these markers are seen in both cryptogenic and symptomatic forms, it appears that elevated inetrleukin-2 is related to the epilepsy per se. Interestingly, anti-inflammatory drugs (e.g., ACTH and steroids) are therapeutically effective in this syndrome, and their positive effect lasts beyond their discontinuation. This effect speaks not only to their acute anticonvulsant effects, but also to the likelihood that they 'reset' some disturbed central mechanisms – possibly associated with inflammation. Interestingly, among conventional AEDs, carbamazepine and valproate share some anti-inflammatory properties; they reduce lipopolysaccharide-induced activation of nuclear factor κB and inhibit lipopolysaccharide-stimulated production of prostaglandins and nitric oxide. However, it is not clear to what extent these effects contribute to the anticonvulsant action of these AEDs.

Future Goals

Taking into consideration that even a single seizure episode may result in significant neuronal loss, the neuroprotective activity of AEDs (as seen in models of SE) offer clinically relevant potential. A substantial body of evidence indicates that several conventional and newer AEDs provide significant neuroprotection in models of SE in which diffuse brain damage is generally encountered (i.e., without any neuroprotective treatment). Interestingly, in mice with intracerebroventricular KA-induced lesions of the hippocampus, the protective action of benzodiazepines and barbiturates against electroconvulsions, when evaluated five days after the lesion, is markedly reduced. In this context, it would be of interest to find out whether the anticonvulsant activity of newer AEDs is reduced – using this experimental approach. Moreover, it would be crucial to find out if lesions to other than hippocampal brain areas may result in the impairment of the anticonvulsant action of some AEDs.

Since epileptogenesis may be associated with neurodegeneration, neuroprotective strategies may stop or retard the conversion of normal brain into epileptic brain. However, some experimental data do not support this assumption. For instance, dizocilpine (MK-801; un

uncompetitve NMDA receptor antagonist) was found to exert a potent neuroprotective effect in the hippocampus in rats surviving SE induced by KA, and yet the spontaneous seizures were not inhibited. This relationship between neuroprotection and epileptogenesis needs further study. Indeed, there are also studies indicating that neuroprotection may be associated with *increased* epileptogenesis, although cognitive functions may be improved. Generally, individual AEDs have been examined for their neuroprotective effects, as well as their effects on subsequent spontaneous seizures and cognitive performance. Considering that many diverse combinations of AEDs have been evaluated for their anticonvulsant activities, and that some of them exert potent synergistic effects with other drugs, it is possible that such combinations may provide qualitatively better neuroprotection, not only resulting in more beneficial cognitive functions but also in impaired epileptogenesis.

A possible use of AEDs as neuroprotective agents in other conditions than epilepsy (Alzheimer's disease, Parkinson's disease, Huntington's chorea) also needs experimental and clinical evaluation. Further, the search for neuroprotective agents should expand beyond AEDs, and focus on agents that are known to inhibit the processes involved in neurodegeneration – for example, immunophilins (affecting transition pores of mitochondria and stabilizing ion channels), antioxidants, and caspase inhibitors. Initial results of such studies are encouraging, and further research on this issue may provide valuable neuroprotective agents. Studying the association between inflammatory processes and epileptogenesis may also open new therapeutic approaches to delay the progression of epilepsy.

Genetic background is also an important factor in regulating the neuronal susceptibility to neurodegenerative insults. For instance, KA has been shown to produce similar seizure activity in two different strains of mice, although clear-cut neurodegeneration was evident in one strain only. With recently emerging molecular techniques, it will be possible to conduct detailed studies on the relationship between the genetic background and neuroprotection or epileptogenesis.

Finally, a considerable number of AEDs (benzodiazepines, phenobarbital, phenytoin, valproate, and vigabatrin) may induce massive apoptosis in immature rodent brain upon administration at pharmacologically relevant doses (anticonvulsant levels used in young or adult animals). Topiramate has been documented to produce a comparable effect, but at supramaximal doses, several folds higher than its respective anticonvulsant ED_{50} in infant rodents. It is thus necessary to evaluate other newer AEDs in immature animals, and to find out whether there is clinical relevance of this hazardous action for treatment in pediatric patients.

Introduction

The most widely accepted dogma explaining hyperexcitability of cortical networks in epilepsy is the imbalance of glutamatergic excitation and GABAergic inhibition. This view is supported by well known observations on the proconvulsant effects of glutamate receptor agonists and $GABA_A$ receptor antagonists, and the anticonvulsant effects of glutamate receptor antagonists and $GABA_A$ receptor agonists. However, the precise mechanisms and sequences of events that ultimately result in reorganized cortical networks generating spontaneous recurrent seizures are still debated. The search for elucidation of these mechanisms leads to numerous questions for future research: Is the key (and initiating) change an enhanced excitation or a decreased inhibition, or do they both change together? Are these changes interrelated? – that is, does the potentiated excitation result from a loss of inhibitory control of glutamatergic synaptic plasticity, or is the loss of inhibition caused by potentiated excitatory input and excitotoxic death of interneurons? – Are these changes and causal relations constant throughout the various stages of epileptogenesis – that is, during the initiating trauma, the latent phase, and the chronic recurrent seizure phase – or do the changes differ profoundly across stages? If the inhibitory and/or excitatory networks are permanently reorganized, why are seizures sporadic, and separated by normal activity patterns? Do interictal events develop into full-blown seizures as a result of an impaired homeostasis of GABAergic and/or glutamatergic transmission, which will only surface when challenged?

Answers to at least some of these questions can be approached, if we better understand the organizational principles of local cortical microcircuits, particularly their inhibitory components. GABAergic inhibition in cortical networks is supplied by a wide range of interneuron types that subserve different functions, and possess specific

Introduction

The most widely accepted dogma explaining hyperexcitability of cortical networks in epilepsy is the imbalance of glutamatergic excitation and GABAergic inhibition. This view is supported by well known observations on the proconvulsant effects of glutamate receptor agonists and $GABA_A$ receptor antagonists, and the anticonvulsant effects of glutamate receptor antagonists and $GABA_A$ receptor agonists. However, the precise mechanisms and sequences of events that ultimately result in reorganized cortical networks generating spontaneous recurrent seizures are still debated. The search for elucidation of these mechanisms leads to numerous questions for future research: Is the key (and initiating) change an enhanced excitation or a decreased inhibition, or do they both change together? Are these changes interrelated? – that is, does the potentiated excitation result from a loss of inhibitory control of glutamatergic synaptic plasticity, or is the loss of inhibition caused by potentiated excitatory input and excitotoxic death of interneurons? – Are these changes and causal relations constant throughout the various stages of epileptogenesis – that is, during the initiating trauma, the latent phase, and the chronic recurrent seizure phase – or do the changes differ profoundly across stages? If the inhibitory and/or excitatory networks are permanently reorganized, why are seizures sporadic, and separated by normal activity patterns? Do interictal events develop into full-blown seizures as a result of an impaired homeostasis of GABAergic and/or glutamatergic transmission, which will only surface when challenged?

Answers to at least some of these questions can be approached, if we better understand the organizational principles of local cortical microcircuits, particularly their inhibitory components. GABAergic inhibition in cortical networks is supplied by a wide range of interneuron types that subserve different functions, and possess specific

connectivity features – morphological, electrophysiological, and neurochemical characteristics that enable them to fulfil these diverse roles. The major transmitter of these interneurons is invariably GABA, but several types may contain and corelease neuropeptides as well. In addition, interneurons considerably differ in their vulnerability to damage in epilepsy (also in ischemia), and therefore differentially contribute to epilepsy-related synaptic reorganization of cortical networks. Since vulnerability correlates with cell type and function, certain well-defined inhibitory operations are expected to be impared, others unchanged, and yet another aspect of inhibitory control may even be enhanced during epileptogenesis. In the following article, a functional classification scheme of interneuron types will be described together with the sensitivity/plasticity profile of these cell populations. In addition, the potential contribution of these different interneuron populations to epileptogenesis and seizure activity will be examined. However, it should be emphasized that none of the pathophysiological events associated with epileptogenesis can be explained by changes in inhibition alone. Abnormalities in glutamatergic transmission is crucially involved at every stage of the process, and these changes are described in other articles in this encyclopedia.

Background – Inhibitory Cell Types of the Hippocampus

Detailed reviews have been published by the author and several other investigators on this subject (see Further Reading), and therefore only an updated brief account is given here. The present classification scheme is based mostly on rodent data, but the correspondence to major interneuron types in humans is rather close, although there are variations particularly in the neurochemical characteristics. The majority of in vivo and in vitro electrophysiological features also derive from rodents, their correspondence to the behavior of human interneurons can only be estimated based on indirect lines of evidence.

For a functional classification of interneurons, the most important features are their input–output properties – i.e., identification of afferents driving the particular cell type, and the targets at which these cells exert their inhibitory effects. Postsynaptic targets of cortical interneurons in most cases are principal cells (pyramidal or dentate granule cells), and in a few special cases, other interneurons. This difference in targets represents the first dichotomy in the classification scheme, as there are subsets of interneurons containing the calcium binding protein calretinin (CR) or the neuropeptide vasoactive intestinal polypeptide (VIP), that were shown to form synapses mostly on other GABAergic cells (particularly those inhibitory neurons that innervate pyramidal cell dendrites); these interneurons were therefore termed interneuron-selective interneurons (or IS cells). These IS cells occur in all subfields and layers of the hippocampus, often form dendrodendritic contacts with each other, and are ideally suited to synchronize inhibition (arriving to pyramidal cell dendrites) throughout the hippocampus. IS cells represent only a small proportion of interneurons, as the vast majority selectively innervates different compartments of principal cells.

Selection of the principal cell compartment results in the next major branching in the classification scheme. Inhibitory input to pyramidal cell dendrites is functionally distinct from that to the perisomatic region; the latter domain is responsible for the summation of postsynaptic potentials arriving from all dendritic branches, and determines whether cell depolarization will reach threshold for action potential generation. The perisomatic region of pyramidal cells, in particular the axon initial segment which has the highest concentration of voltage-gated sodium channels, plays a crucial role in the generation of the cell's output. Thus, interneurons (the perisomatic inhibitory cells) innervating somata, proximal dendrites or axon initial segments are specialized to control output from large principal cell populations. Their likely function is to synchronize principal cell activity rhythmically at theta (4–8 Hz) and gamma (30–100 Hz) frequencies. In contrast, the dendritic tree is the site of termination of most (if not all) excitatory (largely glutamatergic) afferents onto principal cells, as well as the site of short- or long-term plastic changes in synaptic efficacy resulting from various dendritic active conductances, calcium spikes and backpropagating action potentials. Thus, interneurons (the dendritic inhibitory cells) innervating principal cell dendrites are designed to control the efficacy, and most notably the plasticity, of excitatory inputs to principal cells. Finally, there are a number of GABAergic cell types in the hippocampus that, in addition to their local axon collaterals, send major projections outside their own subfield, or even outside the hippocampus (e.g., to the medial septum), and are therefore termed long-range interneurons.

Perisomatic Inhibitory Cells

The precise site of their termination, as well as their specific input characteristics, makes it possible to dissect this cell group into three major types. The axo-axonic, or chandelier cells innervate exclusively the axon initial segments of principal cells. Each axo-axonic cell forms radially running rows of boutons that climb along the axon initial segments of 1000–1500 pyramidal cells. Due to the strategic location of their axon terminals, axo-axonic cells were previously thought to simultaneously inhibit output from large principal cell populations. However, recent evidence suggests that, via a depolarizing GABA effect,

these interneurons may be able to discharge the entire pyramidal cell population they innervate, thus synchronizing the pyramidal cell output and/or resetting conductances in their dendritic trees. Axo-axonic cell bodies are located within or near the pyramidal cell layer, and have radially running dendritic trees that span all layers (although a few exceptions have dendrites confined to stratum oriens). They can be recruited by both feed-forward and feed-back inputs, and fire characteristic bursts at the initiation of hippocampal sharp wave-associated ripple oscillations (synchronous discharges of CA3 pyramidal cells). Their activity is phase-coupled to the positive peak of the theta waves recorded extracellularly in stratum pyramidale.

The remaining two types of perisomatic inhibitory cells are basket cells that form multiple synaptic contacts on the somata and proximal dendrites of principal cells, each basket cell targeting 1500–2000 principal cells. The two types can be distinguished most easily on the basis of their neuropeptide/calcium binding protein content. This neurochemical difference is coupled to functionally meaningful unique features related to synaptic inputs and receptor expression patterns. The parvalbumin (PV)-containing basket cell bodies are located within or near stratum pyramidale, and have radially running dendrites that span all layers. They are driven mostly, and very efficiently, by local principal cells in a feed-forward manner, and form synapses on pyramidal cells via α1 subunit-containing $GABA_A$ receptors. The cholecystokinin (CCK)-containing basket cell bodies can be located in all layers, but typically in stratum radiatum, and have radially running dendritic trees spanning all layers. In addition to CCK, one subset of these interneurons may also contain VIP, and another subset the vesicular glutamate transporter vGluT3. CCK basket cells generally receive far fewer local glutamatergic inputs than PV cells, but express $5HT_3$ receptors and are selectively innervated by serotonergic afferents from the median raphe nucleus. They also express nicotinic α7 and α4 receptor subunits, as well as presynaptic cannabinoid (CB_1), $GABA_B$ and estrogen1 receptors, and form synapses on pyramidal cell bodies and dendrites largely via α2 subunit-containing $GABA_A$ receptors. In contrast to PV basket cells, feed-forward input alone can hardly activate them. However, due to their large membrane time constants, they are uniquely capable of summating feed-forward and feed-back drives over long time windows. Thus, they appear to come into play, when external excitatory inputs are strong enough to discharge local principal cells, leading to a summation of local and external excitation on CCK basket cells. During theta activity, both basket cell types fire at the positive peak of extracellularly recorded field EEG waves (out of phase with pyramidal cells, which fire at the trough), with PV cell firing shifted slightly towards the descending, and CCK cell firing towards the ascending phase. While PV cells strongly increase their firing during sharp waves, CCK cell discharges remain unchanged. This difference is consistent with the fact that ripples in CA1 are driven by CA3 in a feed-forward manner, which is insufficient to recruit CCK cells, as they can be activated only by a combination of feed-back and feed-forward drives. Recent data indicate that CCK massively enhances the firing of PV basket cells, and reduces IPSCs derived from CCK basket terminals via triggering the release of endocannabinoids as retrograde signaling molecules from postsynaptic pyramidal cells. Thus, CCK – via acting on different CCK receptors expressed by PV basket and pyramidal cells – can change the relative weight of inhibition derived from the two basket cell types.

Although both basket cell types are primarily responsible for rhythmic synchronization of the activity of large principal cell populations at theta and gamma frequencies, there is a considerable division of labour between them associated with their differential behaviour during sharp waves, and with different excitatory drives. A synthesis of the above features led to our proposal that the electrically- and synaptically-coupled, and mostly locally driven, ensembles of PV-containing basket cells are indispensable components of the oscillating cortical hardware; they represent a precision clockwork without which no cortical operations are possible. The activity of a similar syncytium of CCK-containing basket cells is superimposed on the PV basket cell-entrained network, conveying emotional and motivational effects carried by serotonergic and cholinergic pathways. In addition, actions of the CCK cell ensemble are highly modifiable by local neuromodulators and retrograde signaling molecules, which may allow further fine tuning of principal cell cooperation. Impairment of this tuning system is likely to result in mood disorders such as anxiety. Interestingly, most if not all of the inputs and receptor expression patterns that distinguish CCK cells from PV cells are strongly implicated in anxiety. For more details about this hypothesis, see Further Reading.

Dendritic Inhibitory Cells

This group of interneurons is the most diverse, both morphologically and functionally. The functionally relevant classification – based on afferent and efferent connectivity – is easy to determine in the hippocampus, where afferent pathways and cellular compartments are confined to different laminae. Distinct types of dendritic interneurons have evolved to control glutamatergic inputs to principal cells from different sources. The so called oriens–lacunosum-moleculare (O-LM) interneurons selectively terminate in stratum lacunosum-moleculare in conjunction with exitatory input coming from the entorhinal cortex. They have a cell body with

horizontally oriented dendritic tree confined to the stratum oriens in the CA1 subfield; in the CA3 subfield, the dendritic tree reaches all layers but stratum lacunosum-moleculare. In the dentate gyrus, these cells have been named HIPP (hilar perforant path associated) cells, as their somata and dendrites are confined to the hilus, and the axon extensively arborizes in the outer two-thirds of the molecular layer, in perfect overlap with the entorhinal input to granule cells. These HIPP cells are driven exclusively in a feed-back manner by recurrent collaterals of local principal cells. Their distinctive neurochemical marker is somatostatin (SOM), but some of them also contain neuropeptide Y (NPY) or low concentrations of PV only in the cell body. Their axon arbour is rather focused in the transverse plane but elongated in the longitudinal direction, covering an area of about 400 by 800 μm. During theta activity, O-LM cells fire together with the pyramidal cells at the trough of extracellularly recorded field EEG waves, and are silenced during sharp wave-associated ripples. Their function is likely to be the blockade of synaptic plasticity of entorhinal inputs in time windows, when the largest number of local pyramidal cells discharge – i.e., during the trough of extracellularly recorded theta – as it is in this phase when local pyramidal cell activity is sufficient to provide feed-back activation of O-LM cells. However, in time windows, when only some pyramidal cells fire in phase precession mode (i.e., ahead of the population – which happens when they are conveying specific signals such as place field-dependent activity), their chance of activating O-LM cells is much lower; thus, they will escape feed-back inhibition and their entorhinal input synapses can be potentiated.

The other major excitatory pathway innervating hippocampal principal cells derives from pyramidal cells of the CA3 subfield, which give rise to Schaffer collaterals that terminate in strata radiatum and oriens. The interneurons that specialize to control this input are called Bistratified cells. This cell type has an axon that arborizes in perfect overlap with Schaffer collaterals – i.e., in strata radiatum and oriens, skipping stratum pyramidale – and form synaptic contacts with second or third order thin dendrites of pyramidal cells, in the vicinity of spines that receive the excitatory input. The axon of a subtype of Bistratified cells is confined to stratum radiatum only, and there seems to be a continuum between this subtype and the classical Bistratified arbors, with a varying degree of a stratum oriens component. The Bistratified cell bodies can be found in all layers, and possess radially oriented dendritic trees. The molecular characteristics of this cell type typically include expression of calbindin (CB), and occasionally CCK, PV and SOM.

There is also a CCK-containing interneuron subset that has considerable axon collateralization entering str. lacunosum-moleculare, and is therefore not considered as a classical Bistratified cell. It is probably closer to the type of CCK-containing cells that selectively innervates str. lacunosum-moleculare, and is called LM-perforant path associated (LM-PP) cell. The dendritic tree of both Bistratified and LM-PP interneurons arborizes most extensively in str. radiatum or lacunosum-moleculare, which explains their predominantly feed-forward drive.

Bistratified cells fire in phase with O-LM and pyramidal cells during theta activity (i.e., at the trough of the extracellularly recorded EEG waves), whereas they are strongly excited during sharp wave-associated ripples, consistent with a strong feed-forward input from Schaffer collaterals. Their likely roles include feed-forward gain control of the efficacy of Schaffer collateral synapses, as well as the regulation of synaptic plasticity via inhibiting active conductances, calcium spikes and backpropagating action potentials in the dendrites.

The recently discovered Ivy cells also belong to the group of dendritic inhibitory interneurons. They were named after their dense and fine axonal meshwork that targets predominantly the basal and apical tufts of the pyramidal cell dendritic tree. Cells of this type are suggested to be more numerous than the parvalbumin-expressing neurons, and are characterized by the expression of nitric oxide synthase together with neuropeptide Y. They fire rather slowly, but phase-locked to network patterns such as theta or gamma oscillations. The slow rise and decay of the IPSCs they produce in their target pyramidal cells and the similarity to the neocortical neurogliaform cells suggest that their IPSCs may be mediated, at least in part, by $GABA_B$ receptors.

Individual dendritic inhibitory cells of any type provide 2–20 synapses onto a single target pyramidal cell, which are scattered all over the dendritic tree. Thus, the contribution of a single dendritic inhibitory cell to the control of dendritic functions of principal cells is likely to be negligible. They must fire in synchrony. The interneuron-selective interneurons (the IS cells described above) are designed to synchronize the dendritic inhibitory cells, thereby enabling them to exert a powerful effect on dendritic electrogenesis and associated synaptic plasticity.

Long-Range Interneurons

Commissurally projecting GAD/GABA-positive neurons have been described in the hilus and stratum granulosum of the dentate gyrus, as well as in the rat somatosensory cortex decades ago. With the advent of more sensitive tracing techniques several GABAergic projections have been revealed in the hippocampal formation, neocortex and between the two regions, challenging the traditional view of cortical inhibition in which all trans-areal inhibition was thought to be disynaptic. A reciprocal long-range GABAergic projection has been described between the medial septum and the hippocampus. The hippocampal

sources of this projection are the so called hippocampo-septal (HS) cells, which are the best characterized of all long-range GABAergic neurons. They express SOM and CB, and have a cell body in stratum oriens of CA1–3, in str. lucidum and radiatum of CA3, and in the hilus of the dentate gyrus. HS cells have horizontal dendrites that remain in str. oriens in CA1, and are restricted to the dentate hilus, which is consistent with a predominantly feed-back drive. The dendrites are extremely long, suggesting that the neuron is sampling input from a large population of local principal cells, apparently monitoring the level of global population synchrony. This information is then fed back to the medial septum, where their targets are the GABAergic pacemaker cells that project back to the hippocampus to selectively innervate all interneuron types. The local axon collaterals of HS cells span very large distances; they can cross the entire hippocampus from the rostral to the temporal pole, and one subset appears to innervate predominantly other interneurons (including other HS cells). Thus, these HS cells are ideally suited to synchronize inhibition, and thereby the entire principal cell population, along the hippocampo-septo–hippocampal loop that is crucial for the generation of theta activity. There are HS cells that innervate mostly principal cell dendrites, and rarely interneurons; thus, they are functionally different from the interneuron-selective HS cells. There are reports of so-called 'back-projection' interneurons, which innervate all hippocampal subfields, form synapses primarily with principal cells, and are very similar to the HS cells. They may in fact also be HS cells, but with their septally projecting axon not labelled (due to technical accident). Connectivity features of the trilaminar cells are also remarkably similar to HS (or backprojection) cells with no (or limited) preference for interneuron targets; however, trilaminar cells are without extrahippocampal or distant projections. Thus, they too may reflect incompletely filled HS cells. Another variation of HS cells may include a population that, besides participating in the septal pathway, also projects to the subiculum and other cortical areas.

Methods

Temporal lobe samples, surgically removed from epileptic patients, have been examined by light and electron microscopy following immunostaining for several different antigens. Patients with intractable temporal lobe epilepsy were operated on in the National Institute of Neurosurgery, Budapest, within the framework of the Hungarian Epilepsy Surgery Program. The anterior third of the temporal lobe was removed together with the temporomedial structures. Control autopsy brain samples were obtained from six individuals (3 women, 3 men; ages, 37, 47, 48, 51, 53, and 56) who died from nonepilepsy related causes; none of the control subjects had a record of any neurological disorders. Brains were removed 2–4 h after death. Autopsies were performed in the Department of Forensic Medicine of the Semmelweis University Medical School, Budapest; harvesting of tissues was approved by the local ethics committee, and informed consent was obtained from the next of kin.

After surgical removal, the epileptic tissue was immediately dissected into 3–4 mm thick blocks, and immersed into a fixative containing 4% paraformaldehyde, 0.05% glutaraldehyde and 0.2% picric acid in 0.1 g mol^{-1} phosphate buffer (PB, pH = 7,4). Two of the control brains were removed from the skull 2 h after death, both internal carotid and vertebral arteries were cannulated, and the brains were perfused first with physiological saline (2 l in 30 min) followed by a fixative solution containing 4% paraformaldehyde and 0.2% picric acid in 0.1 g mol^{-1} PB (6 l in 1.5 h). The hippocampus was removed after perfusion and cut into 3–4 mm thick blocks, which were postfixed in the same fixative solution overnight.

Vibratome sections (60 μm thick) were cut from the blocks, and processed for immunostaining as follows: They were transferred to TRIS buffered saline (TBS, pH 7.4), then endogenous peroxidase activity was blocked by 1% H_2O_2 in TBS for 10 min. TBS was used for all the washes (3 × 10 min between each antiserum) and for dilution of the antisera. Nonspecific immunostaining was blocked by 5% milk powder and 2% bovine serum albumin. The sections were incubated in the primary antisera, usually for two days, at 4 °C. For the visualization of immunopositive elements, biotinylated anti-rabbit IgG (1:300, Vector) was applied as secondary serum followed by avidin-biotinylated horseradish peroxidase complex (ABC, 1:300, Vector). The immunoperoxidase reaction was developed by 3,3′-diaminobenzidine tetrahydrochloride (DAB, Sigma) as a chromogen dissolved in TRIS buffer (TB, pH = 7.6). Sections were then treated with 1% OsO_4 in PB for 40 min, dehydrated in ethanol (1% uranyl acetate was added at the 70% ethanol stage for 40 min.) and mounted in Durcupan (ACM, Fluka). Pre-embedding immunogold reaction was carried out in the same way, but after 48 h incubation in the primary antiserum, sections were washed extensively and blocked in 0.8% BSA, 0.1% IGGS gelatin (Amersham Life Science) and 5% normal goat serum in TBS for 30 min. This step was followed by incubation with 1 nm gold-labeled goat anti-rabbit IgG (Amersham Life Science) diluted 1:50 in 0.8% BSA, 0.1% IGGS gelatin and 1% normal goat serum in TBS for 6 h. After incubation, sections were washed and postfixed with 1% glutaraldehyde in TBS for 10 min. The 1 nm gold particles were silver-enhanced by IntenSE™ M (Amersham Life Science) for 5–10 min.

After light microscopic examination, areas of interest were reembedded and sectioned for electron microscopy. Ultrathin serial sections were collected on Formvar-coated

single slot grids, stained with lead citrate, and examined with a Hitachi 7100 electron microscope.

In a previous study, we examined 12 control brains – with different post mortem delays, different ages, of both genders – for several antigens. The progression of age influences the quality and quantity of immunostaining; i.e., most of the antisera showed weaker staining and lower number of cells in aged subjects. Therefore, subjects older than 60 years have been excluded from the detailed analysis in our current studies. For electron microscopic studies, subjects were chosen with a post mortem delay of less than 4 h, because longer post mortem delays (6–24 h) resulted in poor ultrastructural preservation, and a decrease in immunoreactivity. The electron microscopic analysis of these tissues revealed acceptable ultrastructural preservation even in the immersion-fixed controls, although preservation was inferior to the perfused tissue.

Mice and rats (control animals or epileptic animals at various times after status epilepticus or spontaneous seizures, induced by kainate or pilocarpine) have been perfused with the same fixatives as the human samples, and the brains were processed in the same way for light and electron microscopic immunohistochemistry. For details see Further Reading.

Results – Differential Vulnerability of Interneurons

The efficacy of GABAergic inhibition in cortical networks can be modified in various ways. Proconvulsive changes may affect GABA receptor numbers or their subunit composition. Alternatively, changes in GABAergic inhibition can be associated with changes in intrinsic features of interneurons which influence their firing properties, release probability, presynaptic control machineries, the direction of chloride gradient through the $GABA_A$-chloride channel, etc. The focus of this article is on the most widely investigated proconvulsive alteration in cortical networks: the damage of interneuron types (described above) and plastic changes in their afferent or efferent connectivity. Numerous studies reported a decrease in spontaneous or evoked inhibitory events, and/or a decline in the underlying molecular and anatomical substrate, associated with seizure activity. The latter changes include a decrease in the number of neurons and/or axon terminals labelled with markers of GABAergic transmission (e.g., GABA itself, or its synthesizing enzyme, glutamic acid decarboxylase (GAD), GABA transporters, coexpressed neuropeptides, calcium binding proteins), and/or a change in the level of $GABA_A$ receptor binding, immunoreactivity, or subunit composition. All these changes have been seen in identified epileptic foci, both in animal models and human patients. However, other reports – using different experimental models, markers, or paradigms – have not found any preferential loss of GABAergic neurons, and some human studies support their preservation in both the sclerotic and nonsclerotic hippocampus. Indeed, some studies even report hypertrophy or sprouting of certain interneuron types, which may be induced by excessive release of neurotrophins by principal cells following seizures. Moreover, evidence has emerged that supports the view that the hypersynchrony required for the propagation of seizure activity depends on highly efficient GABAergic inhibition. Many of these controversial findings can only be resolved by a differential investigation of the funcionally distinct interneuron types in epileptic brains. A synthesis of data from such studies will be presented in the following sections. Most of the studies reviewed here rely on immunocytochemical localization of neurochemical markers selectively expressed by different cell types; in this way the entire population is simultaneously visualized. In contrast, single cell labeling data are difficult to obtain (especially in human epileptic tissue), and it is hardly possible to generalize such data to the entire population due to the generally very small sample size. However, the immunostaining approach also has its major disadvantages. For example, it is difficult to establish whether a loss of immunostaining is due to the actual loss of the particular cell type that used to express this marker, or simply the expression of this marker has diminished below detection threshold (while the cell is still functioning normally). Wherever animal data are available, the changes in interneuron types will be described separately for the three phases of epileptogenesis: the acute initiation phase, the latent period, and the chronic phase with spontaneous recurrent seizures. In human surgical samples, all available data obviously reflect the chronic stage – and only of medically intractable cases, as the other cases don't proceed to surgery. Nevertheless, even in this limited sample of human epileptic tissue, we can distinguish between the non-sclerotic and sclerotic cases.

Perisomatic Inhibition

The most widely used marker for this cell group is PV expressed by both axo-axonic and basket cells, as well as CCK that is present in another subset of basket cells. Most of the reports, in both human tissue and animal models, are consistent with the survival of perisomatic interneurons, and the preservation of IPSCs arriving at the somata of principal cells in all hippocampal subfields. Only a transient downregulation of perisomatic IPSCs occurs during the latent phase, which recovers by the chronic stage, as perisomatic interneurons were shown to increase their exitability and firing. This plasticity may partly be explained by the reported increase in excitatory inputs to PV-containing dendrites in the dentate gyrus, mostly

as a result of mossy fiber sprouting. A decrease in PV-immunoreactive cell numbers has been repeatedly reported in humans and in all phases of epilepsy in animal models, but it is likely to be due to a loss of PV from surviving interneurons, as suggested by the electron microscopic demonstration of the normal synaptic coverage of the soma membrane and significant increase in the synaptic coverage of axon initial segments of dentate granule cells in human samples. These data suggest that chandelier cell axons may even sprout (in spite of loosing their PV content).

Basket and chandelier cells remain intact also in the CA1 region whenever/wherever their target pyramidal cells survive. In the human nonsclerotic hippocampus, there is no change in the numbers of these interneurons, but in the sclerotic CA1 there is a profound decrease both in cell and terminal numbers – in parallel with the disappearance of pyramidal cells. There is evidence for the formation of highly complex chandelier cartridges around the axon initial segments, and unusually dense basket-like arrays of boutons around the somata of neurons at the border of extensively damaged areas. In the pilocarpine model, there seems to be a small reduction in axon initial segment synapses on CA1 pyramidal cells in the chronic phase of epileptogenesis.

The question arises whether the frequent enhancement of perisomatic inhibition in the chronic phase – due to hyperactivity of basket cells and/or sprouting of axon initial segment synapses – is: (a) a compensatory change with a neuroprotective role, or (b) has a proconvulsant effect by generating abnormal degrees of population synchrony. The former interpretation is supported by recent data on the voltage-gated sodium channel, $Na_v1.1$, in the cortex; a loss-of-function mutation of the gene for this channel is known to lead to a disorder called severe myoclonic epilepsy in infancy (SMEI). This channel is clustered predominantly on the axon initial segments of PV-containing cells. A mouse knock-in model with non-functional $Na_v1.1$ shows an epileptic phenotype, and action potential amplitudes of fast-firing PV cells exhibit a strong decrement in bursts. Thus, impaired firing of PV-positive interneurons seems to be causally linked to a form of epilepsy, suggesting that enhancement of perisomatic inhibition found in animal models or in human TLE is likely to be a compensatory neuroprotective change, rather than a primary cause of hyperactivity or hypersynchrony.

CCK-containing interneurons are also resistant in epileptic tissue, with only a transient downregulation of CCK observed in some interneurons during the initiation phase of epileptogenesis in animal models. A seizure-induced loss of CCK cells has been observed in the piriform cortex. However, CCK cells are functionally heterogenous in cortex (e.g., only 60% express CB1 receptors, and even fewer can be considered basket cells), and the identity of the sensitive cortical CCK cell type has not yet been determined. In hippocampus, CCK cells were found to be damaged only in models with extensive, nonselective cell loss due to intense seizure load (e.g., following over 90 seizures in a kindling model). CCK-positive axons may even sprout, as suggested by the increased density of the CCK-immunoreactive fiber meshwork in the dentate inner molecular layer, as well as in the pyramidal cell layer of rodents. However, as there is no significant enhancement in perisomatic synapse density either in human or in rodent hippocampi, this observation is unlikely to be a reflection of real sprouting, but is rather an increase of CCK content above detection threshold in a larger number of boutons.

Dendritic Inhibition

The least debated observation both in anatomical and physiologcal studies is that dendritic inhibition is impaired in epileptogenesis, from the initiation phase through to the chronic phase. In animal models, SOM and/or NPY-containing neurons were found to be damaged 6 h after initiation (e.g., by status epilepticus); the damage persisted throughout the latent period, and was maintained at an even more decreased level during the phase with spontanous recurrent seizures. The loss of SOM cells accounted for over 80% of GABAergic cell loss in the hilus, and for about half of that in stratum oriens of CA1–3. The number of SOM cells is profoundly decreased also in the human epileptic dentate hilus, both in nonsclerotic and sclerotic cases, the latter being more severe and accompanied by a nearly complete damage of all hilar cell types. Similar to the case of PV-containing cells, it is important to ask whether the SOM cells indeed die or only lose their SOM content. As the damaged SOM cells are positive for the TUNEL stain (visualizing fragmented DNA), for active caspase-3 (the apoptotic enzyme), as well as for the degeneration marker Fluoro-Jade B at 6 h after the insult, and as a marked decrease in total cell number is seen in the hilus of the dentate gyrus, we can conclude that the majority of cells of this type indeed disappear from the hilus. A similar conclusion can be drawn about SOM cells in stratum oriens of CA1–3, although on a smaller scale. There is some evidence for a possible SOM and/or NPY axon sprouting, which may be just an enhanced peptide expression or staining intensitiy of the axons of remaining SOM/NPY cells. Even if there is real sprouting, these fibers are unlikely to be able to compensate for the loss of the majority of cells of this type. GABAergic synapses are decreased by about one third in the termination zones of SOM cells (i.e., in stratum lacunosum-moleculare of CA1 and in the outer two thirds of the dentate molecular layer), which again confirms the loss of considerable

numbers of this type of dendritic inhibitory cells, and the lack of compensation by sprouting.

Electrophysiological experiments in rodent models lead to the same conclusions: Recordings of spontaneous and miniature IPSCs from pyramidal cell dendrites in CA1 stratum radiatum revealed that there was a significant reduction in the frequency of distal dendritic IPSCs, and demonstrated that the likely explanation was a loss of the presynaptic interneurons. A similar conclusion has been drawn from whole-cell recordings from dentate granule cells, in which the typical dendritic IPSCs with slow rise times were selectively reduced one day after status epilepticus. These acute changes are maintained throughout the latent period, and the frequency of spontaneous dendritic IPSCs tends to decrease even further during the chronic phase.

The reason for this exceptional vulnerability of SOM cells is still unclear. The uniquely homogenous excitatory input could be one reason. These cells are exclusively driven in a feed-back manner – i.e., they receive glutamatergic synapses only from recurrent collaterals of local principal cells. In the dentate hilus, this pattern means extensive input from zinc-containing mossy fibers largely onto kainate receptors which the SOM cells share with all other hilar cell types. And indeed, all other hilar cell types, whether glutamatergic (mossy cells) or GABAergic, are highly vulnerable both in epilepsy and ischemia. An alternative explanation may be the presence of a unique molecular machinery in SOM cells. In particular, they express large amounts of a potent negative regulator of the neuroprotective ERK/MAPK pathway (the striatal enriched protein tyrosine phosphatase, STEP). The inhibition of STEP is able to rescue hilar SOM cells from excitotoxic death.

The transcription factor Dlx1 is required for the development and adult viability of SOM- and calretinin-containing interneurons; hence, these cells undergo apoptotic death from early adulthood in the Dlx1 knockouts. Importantly, behavioral and electrographic seizures begin only 3–4 weeks after the loss of these interneurons, providing evidence that the loss of SOM cells is the cause, and not the consequence, of epileptic activity. In epilepsy models, dendritic interneuron damage happens only a few hours after the induction insult, and persists throughout the latent period without resulting in recurrent spontaneous seizures. This period can range from a few weeks (as in animal models involving status epilepticus, or in Dlx1 KOs), to a couple of years (as in epilepsies in humans following head trauma or transient ischemia). The only abnormality observed during this latent phase is the occurrence of interictal spikes at various frequencies, as observed in the pilocarpine model. Thus, the loss of dendritic inhibition alone does not cause spontaneous seizures, but – in conjunction with the interictal spikes – provides the necessary conditions for abnormal degrees of plastic changes in the excitatory network. Impaired feed-back inhibition in the distal dendrites facilitates dendritic electrogenesis and backpropagating spikes, and enhances the NMDA component of EPSCs. The most consistent loss of inhibition is from the termination zones of the entorhinal cortex, where the role of this inhibitory input is normally to regulate the efficacy and plasticity of these glutamatergic afferents. Therefore, the most likely gradual change of the hippocampal network that takes place during the latent period is the abnormal potentiation of entorhinal inputs either to the dentate gyrus, or directly to the CA1 subfield through the temporo-ammonic pathway, as convincingly demonstrated in animal models. In the dentate gyrus, this process is accompanied by sprouting of granule cell axons, providing excessive recurrent excitation, which further distorts the excitation/inhibition balance.

Much less is known about the functional consequences of changes in calbindin-containing cells, which represent, at least in rodents, another type of dendritic interneurons – those that innervate apical and basal dendrites of pyramidal cells in conjunction with the Schaffer collateral input (Bistratified, or stratum radiatum interneurons). CB-positive cells appear to be highly resistant in the epileptic human hippocampus, at least in regions where most of their targets survive (i.e., in the CA1–3 subfields of nonsclerotic cases), and in the dentate gyrus of both sclerotic and nonsclerotic cases. In many cases, these cells not only survive but even become hypertrophic, with a considerably enhanced soma size (suggesting the maintenance of a more extensive axon arbor), elongated dendrites, and the appearance of spines on their somata and dendrites. This alteration is more typical of the dentate CB cells, but it can be observed also in the sclerotic CA1. In Ammon's horn, their postsynaptic target selection also changes; they tend to innervate significantly more interneurons, including other CB cells, than in controls. Since these changes can be found both in sclerotic and nonsclerotic cases (more pronounced in the former), they likely precede pyramidal cell loss. CB cells are also largely preserved in animal models. Interneurons in stratum oriens that colocalize SOM and CB are known to correspond to the hippocampo-septal (HS) cells. They were found to be resistant, in contrast to cells in the same layer containing SOM alone (O-LM cells). However, a specific subset of HS cells, the spiny CR-containing neurons found exclusively in areas where mossy fibers arborize, are particularly vulnerable (see below).

Recordings from feed-forward driven interneurons in stratum radiatum, which likely correspond to CB-positive Bistratified or stratum radiatum interneurons, showed cell firing frequency to increase twofold. This increase may be due to potentiation or sprouting of their excitatory

inputs, or an impairment of their inhibitory input (e.g., from calretinin-positive cells). Evidence for the latter will be described in the following section.

Interneuron-Selective Interneurons

The routinely used marker of these cells is calretinin (CR), although in the human hippocampus CR-containing cells are heterogenous with regard to target selectivity. In addition to the types characteristic of rodents, there are also others that innervate predominantly pyramidal cell dendrites. In rodents, a subset of CR cells also contains VIP. However, as VIP is present also in some of the CCK-containing basket cells, this peptide is rarely used for the visualization of IS cells. IS cells have recently begun to gain more attention in physiology and pathophysiology due to their unique function in normal network activity patterns and their selective vulnerability in epilepsy and ischemia (**Figure 1**). They were found to show the first signs of exitotoxic damage a few hours after the initial insult, either status epilepticus or transient ischemia. CR-containing IS-like cells decrease in number in the epileptic human dentate gyrus, both in sclerotic and nonsclerotic cases, whereas the small, CR-positive Cajal–Retzius cells near the hippocampal fissure survive. A specific subset of CR-containing neurons – located in stratum lucidum of CA3 and the dentate hilus where mossy fibers arborize – colocalize SOM, and are particularly vulnerable both in ischemia and epilepsy. They receive extremely sparse GABAergic input, but are densely covered by long hair-like spines, each of which receives several synapses from mossy fiber filopodia. This profound imbalance in favour of excitatory input may be related to their exceptional vulnerablity. In addition to SOM cells, CR-containing neurons are also lost in epileptic Dlx1 knockout animals. The lost neurons may include the spiny CR/SOM cells in the hilus and CA3 stratum lucidum, which are unlikely to belong to the IS type. However, several CR cells in CA1, which do not colocalize SOM and are definitely of the IS type, also degenerate, which confirms the conclusion that damage to IS interneurons contributes to epileptogenesis.

One study reported an increase in CR cell numbers in the epileptic human hippocampus, but in this study the control tissue was from a long-delayed postmorten sample in which most of the CR cells remained unstained or were disintegrated. However, lobectomy tissue is always fixed immediately after surgical removal, so that CR immunoreactivity is preserved much better. This observation highlights the importance of using adequate control tissue that is not only age-matched, but also fixed in the same way at a similar postmortem delay.

As mentioned above, the major function of IS cells is likely to be the synchronization of dendritic inhibitory cells, which are individually unable to exert significant effects on dendritic electrogenesis or other influences on glutamatergic input plasticity of principal cells. However, when acting in concert, they have been shown to block, for example, dendritic calcium spikes efficiently. Taken together, one may speculate that in the epileptic hippocampus, where dendritic inhibitory cells are reduced in number, dendritic inhibition is further impaired by the loss of a synchronizing element, the CR-positive IS cells. Thus, even if axonal sprouting of surviving SOM and NPY cells compensates for the loss of GABAergic synapses terminating on pricipal cell dendrites, the efficacy of dendritic inhibition is unlikely to recover if the synchronizing mechanism is impaired.

Directions for Future Research

The most vulnerable GABAergic cell types in the hippocampus are those that inhibit principal cell dendries, and thereby control the potentiation of their glutamatergic inputs. The IS interneurons, likely responsible (at least in rodents) for the synchronization of dendritic inhibitory cells, are also damaged, which further impairs the control of glutamatergic synaptic plasticity. Damage of these interneuron types precedes, and is causally related to, the development of the chronic phase of epileptogenesis (with spontaneous recurrent seizures). The loss of these interneuron types alone manifests as interictal spiking, which cooperates with reduced dendritic inhibition to produce a reorganized circuit capable of generating ictal activity. This 'maturation' or latent phase can last from weeks to years, depending on the species and the type or severity of the induction insult. In contrast, perisomatic inhibitory cells are resistant to damage, and their occasional sprouting serves to compensate for the loss of dendritic inhibition. However, due to their specific termination zone and afferent inputs, they are often unable to succeed with this compensatory task, and may even contribute to hypersynchrony of principal cells that characterize interictal and ictal bursts.

A major challenge for future research is to further elucidate the correspondence of interneuron types and functions between the rodent and the human hippocampus, and to directly demonstrate a causal link between early interneuron loss and the abnormal potentiation of excitatory inputs in the latent phase of epileptogenesis. Insight into this relationship could provide the basis for the development of neuroprotective strategies for rescuing vulnerable interneurons in the human hippocampal formation, based on their unique molecular architecture and receptor expression pattern. It is important to emphasize that any future pharmacotherapy should take into account the functional and neurochemical heterogeneity, as well as the differential vulnerability, of GABAergic interneuron types. Such considerations could help achieve a site-specific alteration of inhibitory operations in microcircuits of the epileptic temporal lobe.

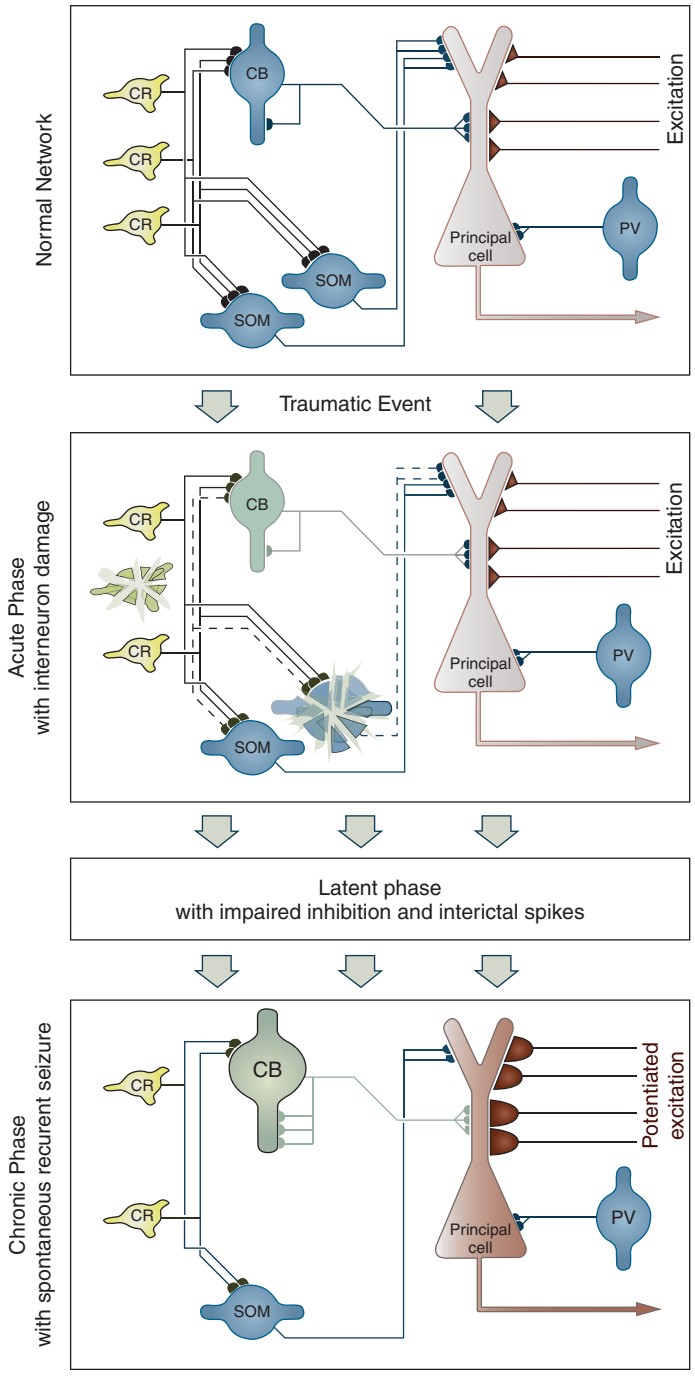

Figure 1 Schematic representation of changes in hippocampal interneuronal circuits in different phases of epileptogenesis. The top panel illustrates the Normal network. Principal cells, representing pyramidal cells of CA1–3 as well as dentate granule cells, receive excitatory input on their dendritic trees (distally from the entorhinal cortex, and more proximally from CA3 pyramids in the Ammons horn and from hilar mossy cells in the dentate gyrus). Their inhibitory input derives from two major sources, basket cells innervate the perisomatic region (only PV cells are represented here), and dendritic inhibitory cells terminate on different dendritic segments, the SOM cells in conjunction with the entorhinal input, and the CB cells in register with the Schaffer collateral input in CA1–3. The CR-containing interneuron-selective interneurons (IS cells) predominantly innervate dendritic inhibitory cells. A Traumatic event – which can range from a status epilepticus or perinatal ischemia to a tumor or acute head trauma – leads to the Acute phase in which, besides possible changes in other transmitter systems such as glutamate, GABAergic interneurons belonging to the SOM- and CR-containing populations are permanently damaged. These events are followed by the Latent phase, which can last from weeks to years. There are no spontaneous recurrent seizures in this phase, but impaired inhibition is accompanied by interictal spikes to generate the necessary conditions for an abnormal potentiation of glutamatergic excitatory circuits. This leads to the final stage of epileptogenesis, the Chronic phase with spontaneous recurrent seizures.

Introduction

Temporal lobe epilepsy is the most common type of epilepsy in adults. It usually involves a preceding brain injury. Complex partial seizures that initiate in the mesial temporal lobe may secondarily generalize, and frequently cannot be controlled adequately by medication. Developing better treatments and preventative strategies depends critically on understanding pathophysiological mechanisms. In patients with temporal lobe epilepsy, neuron loss and tissue shrinkage has been reported for several forebrain regions – including amygdala, thalamus, neocortex, and entorhinal cortex – but the hippocampus is affected most consistently and severely. Tissue shrinkage is associated with neuron loss, and the most vulnerable neurons are in the hippocampal CA1 region and hilus of the dentate gyrus. Hilar neuron loss is the most consistent neuropathological abnormality in patients with temporal lobe epilepsy. Many patients also display preferential loss of layer III neurons in the medial entorhinal cortex. Similar patterns of neuron loss occur in laboratory animal models of temporal lobe epilepsy (**Figure 1**). How might these neuropathological changes contribute to seizure activity?

EEG recordings in patients and models of temporal lobe epilepsy reveal that seizures frequently appear to

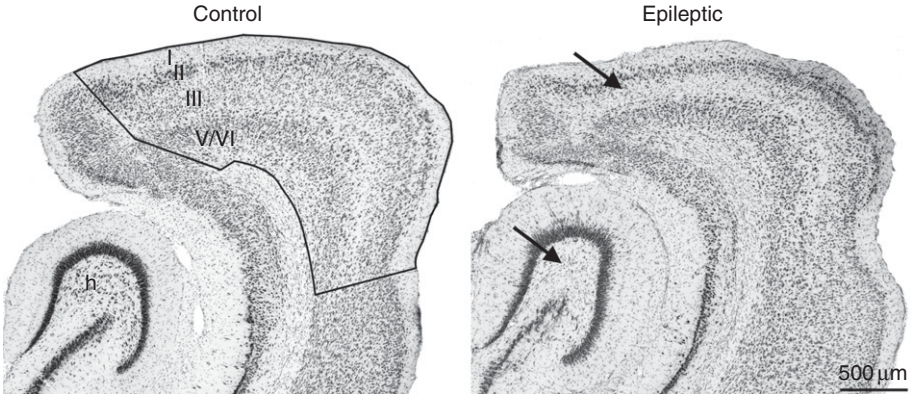

Figure 1 Neuron loss in the hilus and layer III medial entorhinal cortex in an epileptic rat. Nissl-stained 40-μm-thick horizontal sections from 103–112-day old, male Sprague-Dawley rats. The epileptic rat was treated systemically with pilocarpine to induce status epilepticus, observed to have spontaneous recurrent seizures in subsequent weeks, and perfused 79 days after pilocarpine treatment. The control rat was not treated with pilocarpine. The hilus (h) and entorhinal cortex (outlined) are indicated in the section from the control rat, and layers are labeled in the medial entorhinal cortex (I, II, III, and V/VI). Arrows indicate loss of neurons in the hilus and layer III of the medial entorhinal cortex in the epileptic rat.

begin focally or simultaneously in amygdala, hippocampus, dentate gyrus, and entorhinal cortex. Within this group of structures, the dentate gyrus and entorhinal cortex are particularly important. Normally, sensory cortical information enters and exits the hippocampal formation through the entorhinal cortex. The major excitatory synaptic input to the dentate gyrus comes via the perforant path from principal cells in layer II of the entorhinal cortex. Layer II cells of the medial and lateral entorhinal cortex project to the middle and outer thirds of the dentate molecular layer, respectively, where their axon terminals account for at least 85% of the excitatory synapses formed with granule cell dendritic spines. Output of layer II cells, therefore, profoundly affects activity of dentate granule cells.

Work from several laboratories (e.g., Jones, Heinemann, Lothman, and others) suggests the dentate gyrus normally functions like a 'gate' that restricts seizure activity in the entorhinal cortex from entering the hippocampus and then spreading to other brain structures. However, in epileptic tissue, granule cells and layer II cells are hyperexcitable. Single-cell recordings show that granule cells discharge excessively in response to synaptic activation in tissue from patients and models of temporal lobe epilepsy. Several laboratories (e.g., Lothman, Scharfman, Lopes da Silva, and others) have reported that in models of temporal lobe epilepsy, layer II cells in medial entorhinal cortex display prolonged excitatory responses to synaptic activation. We have found that layer II cells, in turn, generate excessive, spontaneous, hypersynchronous input to dentate granule cells. In TLE patients, stimulation of entorhinal cortex evokes responses in hippocampus that resemble interictal spikes. What causes this hyperexcitability of layer II EC cells and dentate granule cells? Intrinsic electrophysiological properties of granule cells and layer II EC cells in epileptic tissue appear relatively normal. Changes in excitatory synaptic input are likely to contribute to hyperexcitability of granule cells (mossy fiber sprouting), but not layer II ECs cells. Whether changes in inhibitory synaptic input contribute to hyperexcitability of granule cells and layer II cells is the focus of this article.

Background

Dentate Gyrus

Different approaches have been used to measure inhibition in the dentate gyrus of patients and models of temporal lobe epilepsy, and results have been mixed. Some studies, including our own, reported normal or enhanced granule cell inhibition. Other studies, including our own, found significant reductions. The mixed results are attributable, in part, to different methods used to evaluate inhibition. Field potential responses to orthodromic stimulation provide an index of activity of a relatively large population of granule cells, can be obtained readily in slices in vivo, and are used commonly. They can be obtained readily in slices and in vivo and are used commonly. However, the stimulation technique is of questionable physiological relevance. It is unlikely that perforant path fibers are ever normally activated so synchronously and intensely. Furthermore, if baseline inhibition is reduced, similar levels of stimulation are likely to activate more granule cells, which might recruit more feed-back inhibition, thereby masking underlying reductions in inhibition (i.e., polysynaptic amplification of inhibition). Intracellular current-clamp recording with sharp electrodes has been used to obtain recordings of evoked inhibitory postsynaptic potentials (IPSPs) that have fast and slow components that represent $GABA_A$- and $GABA_B$-receptor activation, respectively, permitting analysis of these different inhibitory mechanisms. Glutamate

receptor antagonists can isolate monosynaptic IPSPs and avoid confounding effects of excitatory PSPs and polysynaptic amplification. Again, however, the stimulation technique is not very physiological. Whole-cell voltage-clamp recording with patch electrodes offers the best signal-to-noise ratio for measuring spontaneous inhibitory postsynaptic currents (IPSCs), events that most accurately reflect normal functioning of $GABA_A$ synapses. A miniature IPSC, recorded in the presence of glutamate-receptor antagonists and tetrodotoxin, represents release of GABA at a single synapse, independent of action potential discharge. Frequency of miniature IPSCs serves as a functional measure of the number of inhibitory synapses impinging on a recorded cell and the probability of synaptic release. In normal bathing medium, the recorded spontaneous IPSCs reflect a combination of both miniature IPSCs and IPSCs that occur when presynaptic interneurons discharge action potentials. The whole-cell voltage-clamp approach is powerful; however, it too has disadvantages. The recording electrode has a large diameter tip, and the recorded cell is dialyzed, producing wash-out effects. Spontaneous $GABA_B$-receptor-mediated events are not evaluated, because they do not normally occur. And, three-quarters of the GABAergic synapses on granule cells are located on the dendrites, at distances where it is impossible to achieve complete voltage control with somatic voltage-clamp. Because of this space-clamp limitation, synaptic events generated in dendrites will be filtered and attenuated, and their apparent amplitudes and time-courses distorted. Each recording technique, therefore, has advantages and limitations for measuring functional inhibition of granule cells and other neurons, including layer II cells in entorhinal cortex.

Like the electrophysiological data, anatomical findings are mixed with respect to interneuron loss in the dentate gyrus of patients and models of temporal lobe epilepsy. Some studies report little, if any, loss of GABAergic interneurons, despite clear loss of excitatory cells in the hilus of the dentate gyrus. However, de Lanerolle's laboratory has found substantial loss of somatostatin-immunoreactive hilar neurons in patients with temporal lobe epilepsy. Somatostatin is expressed by a large fraction of GABAergic (but not glutamatergic) neurons in the dentate gyrus. Subsequent studies with human tissue by several laboratories (e.g., Mathern, Sloviter, Freund, and others) report significant loss of somatostatin-positive interneurons and other interneuron subtypes, including NPY-, parvalbumin-, substance P receptor-, and calretinin-expressing cells in the dentate gyrus. However, it is not always clear whether these interneurons have actually died or simply have become immunocytochemically undetectable. Surprisingly, despite apparent significant losses of specific interneuron subtypes (based on the above immunocytochemical results), numbers of neurons immunoreactive for glutamic acid decarboxylase (GAD), an enzyme that synthesizes GABA and is expressed by all GABAergic interneurons, have been reported to be similar to controls in human studies. The apparent discrepancy across studies may be attributable to limited sensitivity of GAD-immunocytochemistry and seizure-related changes in GAD expression. Houser's laboratory used in situ hybridization for GAD mRNA, a more sensitive method for detecting interneurons, and found significant loss of hilar GABAergic neurons in a model of temporal lobe epilepsy. Subsequent studies have confirmed loss of GAD-positive dentate cells in models of temporal lobe epilepsy. Some surviving interneurons in human epileptic tissue display changes in somatic, dendritic, and axonal morphology and, therefore, are likely to function abnormally.

Entorhinal Cortex

Compared to granule cells, inhibition of layer II cells of the medial entorhinal cortex in epileptic tissue has received less attention. There is little slice electrophysiological information about layer II cells in entorhinal cortex obtained from patients with temporal lobe epilepsy. The limited data from layer II cells in models of temporal lobe epilepsy include evidence for hyperexcitability but normal monosynaptic IPSPs. Previous anatomical studies of entorhinal cortex, including one of our own, reported no epilepsy-related reductions in interneuron profile density, despite clear reductions in layer III Nissl-stained profiles. However, methodological issues affect detectability of interneuron loss. Interneuron labeling methods vary in their degrees of sensitivity and specificity. Seizure activity affects expression of some interneuron markers, causing increased labeling in some cases (e.g., GAD and somatostatin) and transient marker drop-out in others (e.g., parvalbumin). Furthermore, studies vary in tissue sampling and cell counting schemes. Most studies measure neuron profile densities, and do not employ modern design-based stereological analyses, which can be more sensitive.

In sum, uncertainty about whether the neuropathology of temporal lobe epilepsy involves loss of GABAergic interneurons and reduced inhibition of dentate granule cells and layer II cells of medial entorhinal cortex motivated our experiments to evaluate interneurons and inhibition in those regions.

Methods

Animals

We make rats epileptic by treating them systemically with kainic acid or pilocarpine. Subsequent development of spontaneous, recurrent seizures is verified by behavioral monitoring. Control groups consist of naïve rats and pilocarpine-treated rats that do not develop status epilepticus or spontaneous seizures. Both control groups appear similar to one another.

Anatomy

We use in situ hybridization for GAD mRNA to label all interneurons. Interneuron subtypes are identified by specific immunocytochemical markers (e.g., parvalbumin and somatostatin). Stereological methods (optical fractionator) are used to estimate numbers of interneurons. Briefly, an entire structure (dentate gyrus or entorhinal cortex) is sectioned and sampled such that any part within has an equal probability of being sampled. The cumulative volume of sampled sites and total volume of the entire region of interest are calculated and used to extrapolate the number of counted cells to an estimate of the total number of cells per structure. Statistical tests evaluate adequacy of sampling.

Electrophysiology

Horizontal slices are prepared and recordings obtained at ~32 °C. Most recordings are obtained from visualized cells in whole-cell patch-clamp mode; some use sharp intracellular electrodes. Events analyzed include current-clamp responses to orthodromic stimulation, evoked IPSP/Cs, spontaneous and miniature IPSCs. In some experiments laser scanning photo-uncaging of glutamate is used.

Recent Results

Dentate Gyrus

The rat dentate gyrus normally contains approximately 1 million granule cells and 36 000 GABAergic interneurons: 50% in the hilus, 25% in the granule cell layer, and 25% in the molecular layer. Somatostatin-immunoreactive interneurons account for 25% of all GABAergic interneurons in the dentate gyrus, and parvalbumin-positive neurons account for 8%. Proportions of somatostatin- and parvalbumin-positive interneurons are similar in primate dentate gyrus. Like many patients with temporal lobe epilepsy, epileptic kainate-treated rats display obvious loss of Nissl-stained hilar neurons, while granule cells qualitatively appear relatively spared (**Figure 1**). There is significant loss of GAD-positive neurons in epileptic rats, which on average have only 87% of the number of GAD-positive neurons in dentate gyrus as controls. Somatostatin-immunoreactive neurons are highly vulnerable (50–63% of controls); parvalbumin-positive neurons are less so (78% of controls). GABAergic neuron loss is most severe in the temporal pole, which is homologous to the anterior hippocampus in humans – the region that displays the most severe neuron loss and is most typically surgically resected to treat some medically intractable cases. Other laboratories report similar anatomical results in models of temporal lobe epilepsy. Synaptic activation of granule cells evokes prolonged depolarizations and more action potentials in tissue from patients and models of temporal lobe epilepsy than cells in control tissue. Pharmacologically isolated, evoked IPSPs have smaller conductances (<40% of controls), and spontaneous and miniature IPSC frequencies are reduced (<50% of controls). Other laboratories have evaluated models of temporal lobe epilepsy and report similar deficits in granule cell inhibition.

Entorhinal Cortex

The rat medial entorhinal cortex normally contains approximately 460 000 neurons, of which 38 500 are GABAergic. Like many patients with temporal lobe epilepsy, epileptic pilocarpine-treated rats display obvious loss of Nissl-stained neurons in layer III of medial entorhinal cortex (**Figure 1**). Nissl-stained neuron loss is significant but less severe in other layers of medial entorhinal cortex. There is significant loss of GAD-positive neurons (75% of controls) in the medial entorhinal cortex (all layers included) of epileptic rats. Use of sensitive labeling (GAD in situ hybridization) and analysis techniques (optical fractionator method) may account for our detection of interneuron loss in medial entorhinal cortex, in contrast to previous studies. As reported previously by other laboratories, we confirmed that in epileptic tissue, synaptic activation of layer II cells evokes prolonged depolarizations and excessive action potential discharge. In layer II cells of medial entorhinal cortex in epileptic rats, frequencies of spontaneous and miniature IPSCs are reduced to 60% of controls. However, frequency and amplitude of spontaneous EPSCs in layer III GABAergic interneurons are not reduced in epileptic rats, suggesting normal excitatory synaptic input to surviving interneurons. To evaluate recurrent inhibitory circuits in layer II, we focally photostimulated interneurons (by release of caged glutamate) while recording inhibitory synaptic responses in layer II principal cells. IPSCs were evoked five times more frequently in slices from control versus epileptic animals, suggesting loss of interneurons and reduced recurrent inhibition.

Together, these findings suggest that in models of temporal lobe epilepsy, inhibition is reduced in dentate granule cells and layer II cells of medial entorhinal cortex. Previously proposed mechanisms of reduced inhibition include zinc-induced suppression of $GABA_A$-receptor function in dentate gyrus and dormancy of interneurons in dentate gyrus and entorhinal cortex due to loss of excitatory synaptic input. Other possible mechanisms include changes in GABA-receptor subunit expression and GABA uptake. These mechanisms may contribute to hyperexcitability in dentate gyrus and medial entorhinal cortex, but reductions in numbers of interneurons and their inhibitory synaptic input to granule cells and layer II

cells is the most parsimonious explanation consistent with our anatomical and electrophysiological findings. Because layer II EC provides the predominant excitatory input to granule cells, reduced inhibition of the closely linked neurons could lead to synergistic hyperexcitable effects. Furthermore, interneuron loss and reduced inhibition in other nearby regions, including CA1, suggests the loss of inhibitory interneurons might be a widespread and important pathophysiological feature of temporal lobe epilepsy.

Future Goals

There are many different types of inhibition (e.g., presynaptic vs. postsynaptic, $GABA_A$-mediated vs. $GABA_B$-mediated vs. non-GABA-mediated, phasic vs. tonic, feed-forward vs. feed-back) generated by a variety of GABAergic interneuron subtypes. Interneuron subtypes are functionally specialized. For example, highly vulnerable hilar somatostatin interneurons target their axon collaterals to granule cell dendritic shafts and spines in the outer molecular layer, an ideal position for inhibiting excitatory input from entorhinal layer II cells that arrives in the same stratum. Defining deficits in inhibition and interneuron loss more precisely is an important step toward specifically reversing the pathology and testing its clinical relevance. Furthermore, there is much to learn about underlying mechanisms of selective vulnerability or resistance of specific interneuron subtypes. And, it is important to evaluate whether surviving interneurons, including those that display epilepsy-related morphological abnormalities, function differently in epileptic tissue.

If reduced inhibitory synaptic input to granule cells and layer II cells is important for temporal lobe epileptogenesis, then preventing or reversing deficiencies should be therapeutic. In fact, the nervous system appears to compensate, albeit incompletely, through a variety of mechanisms, after hyperexcitability develops. For example, our findings are consistent with reports by the Mody laboratory that in models of temporal lobe epilepsy, amplitudes of miniature IPSCs increase in granule cells because more $GABA_A$ receptors are expressed per synapse. Work by the laboratories of Babb, Mathern, Freund, and others on epileptic tissue from patients suggests surviving interneurons sprout axon collaterals and form new synapses with granule cells. Neurogenesis in the dentate gyrus, especially after epileptogenic injuries, offers the possibility of endogenous sources to replace GABAergic interneurons. Although evidence of GABAergic neurogenesis is limited, recent findings suggest transplantation may be an option. Future work will continue to evaluate and attempt to enhance regenerative and compensatory mechanisms. If we could 'restore' inhibition of dentate granule cells and layer II cells of medial entorhinal cortex, we would better understand the clinical significance of interneuron loss and therapeutic potential of interneuron replacement.

Plasticity and Reorganization of GABA Neurons in Epilepsy

Introduction

Identifying the changes that occur in GABA neurons in epilepsy, and determining their functional consequences, remain among the most important issues in the epilepsy field. GABA neurons have long been considered important in epilepsy because of their inhibitory actions in many brain regions and their role in controlling neuronal excitability. Thus, it is logical to consider that loss of GABA neurons could contribute to epilepsy. However, it is also clear that changes in the GABA system extend beyond the simple loss of some of these neurons, and encompass an array of changes in remaining GABA neurons. The goal of this chapter is to highlight several types of morphological and neurochemical changes that occur in GABA neurons in the hippocampal formation in temporal lobe epilepsy (TLE) models. These changes emphasize the considerable plasticity of GABA neurons and raise questions regarding the consequences of the changes for the development and control of epilepsy.

Background

Initial suggestions that loss of GABA neurons might be a critical feature in epilepsy were based on alterations in a model of cortical focal epilepsy, in which investigators found a loss of basket and axo-axonic neurons in the cerebral cortex. Interestingly, in recent studies of several genetically-modified mice with an epileptic phenotype, GABA neuron loss has also been demonstrated in the cerebral cortex. Thus in some epileptic animals, loss of GABA neurons certainly occurs and may contribute to seizure development in a relatively clear and predictable manner. However, changes in the hippocampus in models of TLE are more complex.

For many years, the question of whether hippocampal GABA neurons are lost in TLE was vigorously debated, with some groups emphasizing the preservation of GABA neurons and other groups emphasizing the vulnerability of GABA neurons to excitotoxic damage. It now appears that both views are correct, and it is critical to consider both types of changes as the GABA system is analyzed in epilepsy models. Although GABA neuron loss clearly occurs in several models following insults such as status epilepticus, many GABA neurons are preserved. Importantly, these remaining GABA neurons undergo substantial changes, and the altered GABA neurons could be important pieces of the epilepsy puzzle. Since these neurons remain in the hippocampus following the initial insult, their function is critical for maintaining seizure control and their malfunction could contribute to seizure generation. Thus it is important to determine the characteristics of the remaining GABA neurons.

Methods

For morphological studies of GABA neurons in epilepsy, one ideally would like to visualize the cell bodies of the entire population of GABA neurons as well as their axonal arborizations and terminals. Unfortunately, no single method provides this information, and thus multiple methods are often required for a complete picture. Indeed, one's view of GABA neuron changes in epilepsy is likely to depend on the methods that are chosen to visualize these neurons.

Immunohistochemical localization of the two isoforms of the GABA-synthesizing enzyme, glutamate decarboxylase (GAD65 and GAD67), is often used for identifying GABA neurons. While these methods are quite effective for labeling the majority of GABA neurons in some brain regions, such as the cerebral cortex, they do not provide consistent labeling of all GABA neuron cell bodies in the hippocampus with currently available antibodies. For such cell body labeling, in situ hybridization methods for localizing GAD mRNAs are particularly useful. The in situ hybridization methods provide a clear view of GABA neuron cell bodies without occlusion by axon terminals, and the numbers of GABA neurons in all regions and layers of the hippocampus are striking when compared with those identified with other methods (**Figure 1(a)**).

In contrast, immunohistochemical localization of GAD65, the isoform involved primarily in local control of GABA synthesis at synaptic sites, identifies most GABAergic axon terminals but often labels only a limited number of cell bodies. Localization of GAD67, the isoform responsible for maintaining baseline levels of GABA for both neurotransmitter and metabolic functions, reveals many – though not all – GABA neuron cell bodies and proximal dendrites. In addition, GAD67 effectively labels moderate numbers of GABAergic axon terminals, including perisomatic terminals in stratum pyramidale of CA1. Thus, each method has its advantages and provides

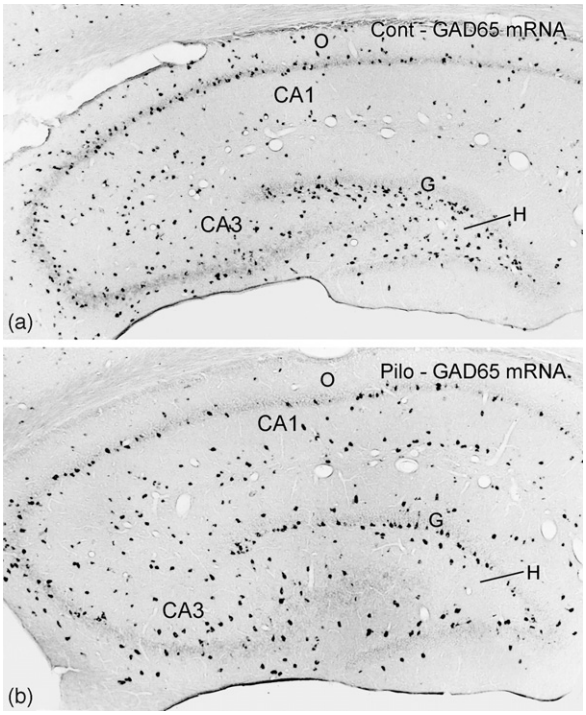

Figure 1 In situ hybridization of GAD65 mRNA in the hippocampus of a control (a) and pilocarpine-treated (b) rat. (a) In a control animal, numerous GAD65 mRNA-labeled cell bodies are evident throughout the hippocampal formation. (b) In a pilocarpine-treated animal during the chronic period, a distinct loss of GAD65 mRNA-labeled neurons is evident in the hilus (H) of the dentate gyrus and stratum oriens (O) of CA1. Many labeled neurons are present along the base of the granule-cell layer (G) despite loss of hilar neurons in the regions immediately below the layer. Numerous strongly-labeled GABA neurons remain in other regions of the hippocampus. Adapted from Houser CR (1999) Neuronal loss and synaptic reorganization in temporal lobe epilepsy. In Delgado-Escueta AV, Wilson WA, Olsen RW, and Porter RJ (eds.). *Jaspers's Basic Mechanisms of the Epilepsies: Advances in Neurology* 3rd ed., vol. 79, with permission from Lippincott Williams and Wilkins.

information about the broad population of GABA neurons in the hippocampal formation.

Subtypes of GABA neurons can be detected by labeling the neuropeptides or calcium-binding proteins that are present in many GABA neurons. These methods have been particularly useful for identifying vulnerable groups of GABA neurons in epilepsy, and have the advantage of focusing attention on specific groups of GABA neurons, although the more limited perspective must also be recognized.

One technically important and interesting aspect of GABA neuron localization in epilepsy is the potential for alterations in protein and peptide expression in many seizure models, either in response to an initial episode of status epilepticus or as a result of altered neuronal activity. Such functional changes contribute to the difficulties in evaluating GABA neuron loss and morphological reorganization with some markers. For example, an increase in GAD expression in either the cell bodies or axon terminals of remaining neurons could conceal GABA neuron loss by producing increased labeling of remaining neurons. Likewise, a decrease in protein expression could suggest loss of a subgroup of interneurons, even though that group remains viable (simply no longer expresses the marker of interest).

Despite some limitations, immunohistochemical and in situ hybridization methods for localizing GABA neurons have provided a wealth of information about these neurons and the changes that occur in epilepsy. It is now important to expand studies of remaining GABA neurons beyond the markers for these neurons, and identify potential changes in other proteins – including those of receptors and ion channels – that could be modified and thus alter the function of these neurons in epilepsy. Immunohistochemical and in situ hybridization studies are ideally suited for identifying interneuron-specific changes that might not be evident with other methods that involve analyses of entire brain regions.

Recent Results

Susceptibility and Resistance of GABA Neurons to Seizure-Induced Damage

Labeling cell bodies of the entire population of GABA neurons clearly demonstrates neuronal loss, and at the same time, emphasizes the large number of GABA neurons that remain in the hippocampal formation in lesion models of TLE (**Figure1(a)** and **1(b)**). GABA neurons in the hilus of the dentate gyrus are considered to be among the most vulnerable GABA neurons in the hippocampal formation (**Figure 1(b)**), and neurons in stratum oriens of CA1 are also frequently decreased in both pilocarpine and kainate models of TLE (**Figure 1(b)**). The loss of these neurons is in sharp contrast to the preservation of many GABA neurons along the base of the granule-cell layer (**Figure 1(b)**) and in the pyramidal-cell layer of CA1 (**Figure 1(b)**). Despite their close proximity, some GABA neurons are susceptible to damage while others appear resistant.

More selective views of GABA neuron loss in epilepsy have come from localization of neuropeptides and calcium-binding proteins that characterize subclasses of GABA neurons. Such labeling has demonstrated that somatostatin and neuropeptide Y (NPY) neurons in the dentate hilus are often severely depleted in human TLE and many animal models (**Figures 2(a)** and **2(b)**). The numbers of somatostatin neurons in stratum oriens of CA1 are also reduced, consistent with the findings from in situ hybridization studies of GAD mRNAs. In contrast, parvalbumin-expressing neurons in the dentate gyrus, many of which are basket cells, are relatively resistant to seizure-induced damage in humans and some animal models, and their labeling may even be enhanced during the chronic period (**Figure 2(c)** and **2(d)**). However, a decrease in

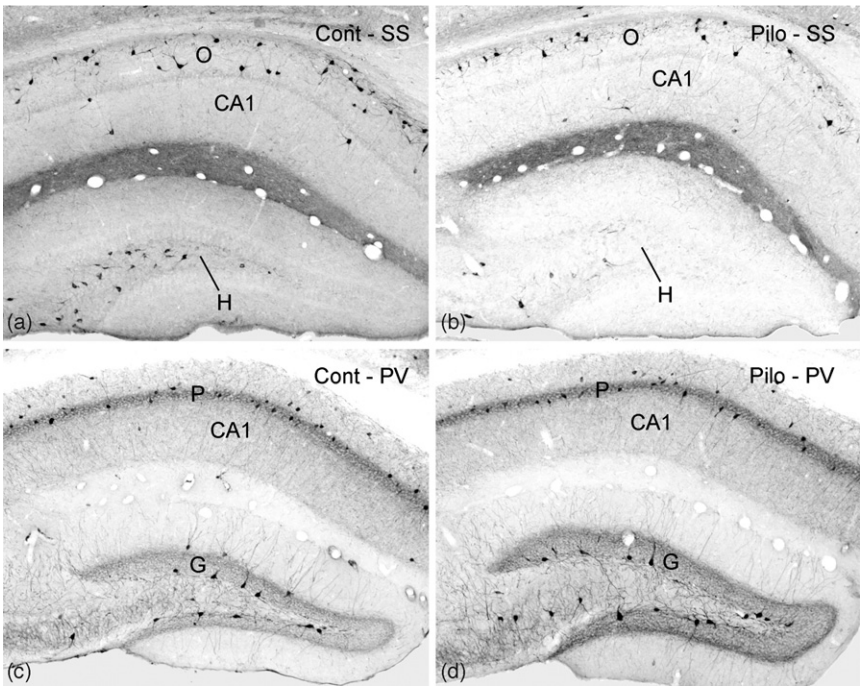

Figure 2 Immunohistochemical localization of somatostatin (SS) and parvalbumin (PV) in control (a,c) and pilocarpine-treated (b,d) mice at two months following status epilepticus. (a,b) In the pilocarpine-treated mouse, SS neurons are severely depleted in the hilus (H) of the dentate gyrus, where they are abundant in the control animal. A moderate loss of SS neurons is also evident in stratum oriens (O) of CA1. (c,d) In a pilocarpine-treated mouse, numerous PV-labeled neurons remain along the base of the granule-cell layer (G) of the dentate gyrus and throughout stratum pyramidale (P) of CA1. The labeling of parvalbumin terminals in the granule-cell and pyramidal-cell layers appears stronger than in the control animal, despite identical processing of the tissue.

parvalbumin-labeled interneurons in the hippocampal formation also has been reported in several models. Differences in the findings could reflect variations in the models, regional or species differences, or (in some instances) decreased parvalbumin immunoreactivity in remaining neurons.

From such findings, a broader perspective on GABA neuron loss in epilepsy is emerging. The data suggest that GABA neurons that innervate dendritic regions are most vulnerable to damage, whereas those that provide perisomatic innervation are often preserved. This view is consistent with loss of hilar somatostatin neurons that innervate the outer molecular layer of the dentate gyrus and preservation of many GABAergic basket cells at the base of the granule-cell layer that innervate the somata of granule cells. In CA1, electrophysiological studies demonstrate a reduction in dendritic but not somatic inhibition in a rat model of TLE, consistent with loss of interneurons that innervate primarily dendritic regions. These patterns have interesting functional implications, for they suggest that GABAergic modulation of the principal cells' response to excitatory input could be deficient while GABAergic control of the final output of the principal cells is preserved. This differential pattern has also led to the interesting suggestion that preservation of strong perisomatic innervation, and possible sprouting of these axon terminals, could promote synchronous firing of the principal cells, particularly when remaining GABA neurons are strongly activated. In this way, some remaining GABA neurons might contribute to seizure activity.

Alterations of Remaining GABA Neurons

Considering the severe loss of hilar somatostatin neurons, a depletion of GABAergic terminals in their target region (the molecular layer of the dentate gyrus) would be expected. However, such decreases are not evident during the chronic period in TLE animal models. Instead, GABAergic fibers and terminals are abundant throughout the molecular layer and have the highest density in the outer part of the layer (as in control animals) (**Figure 3(a)** and **3(b)**). Such findings suggest substantial plasticity of remaining GABA neurons. Changes in these remaining neurons include up-regulation of the GABA-synthesizing enzymes, potential morphological reorganization of GABAergic axons, and altered expression of receptors in remaining GABA neurons.

Up-regulation of GAD mRNAs and proteins

GABA neurons that remain in the hippocampal formation following an episode of status epilepticus show a remarkable up-regulation of the mRNAs for both GAD65 and

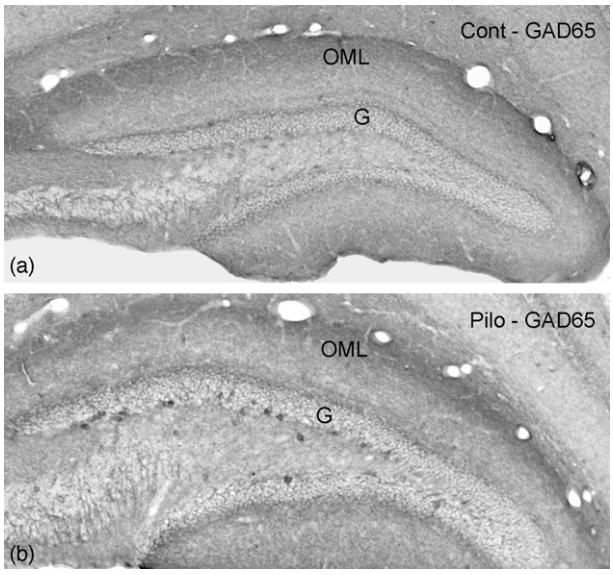

Figure 3 Immunohistochemical localization of GAD65 in the dentate gyrus of a control (a) and pilocarpine-treated (b) mouse during the chronic period. (a) In a control animal, GAD65-labeled axon terminals are most highly concentrated in the outer molecular layer (OML) and in a narrow band along the outer border of the granule-cell layer (G). A few lightly labeled cell bodies are evident at the base of the granule-cell layer. (b) In a pilocarpine-treated mouse, a dense field of GAD65-labeled terminals is present in the OML despite loss of hilar GABA neurons that normally innervate this region. Labeling in the inner and middle molecular layer appears to be increased slightly, and the laminar pattern of GAD65-labeled terminals in the molecular layer is less distinct than in the control mouse. Some GABA neurons along the base of the granule-cell layer (G) are more strongly labeled in the pilocarpine-treated mouse than in the control.

GAD67. This response extends beyond the region of severe GABA neuron loss and is evident in remaining GABA neurons throughout the dentate gyrus and hippocampus. The up-regulation of GAD mRNAs is generally viewed as a compensatory response to increased excitability in the region. The increased GAD mRNA expression presumably leads to increased GAD and GABA levels. These changes could influence GABAergic function as well as affect immunohistochemical labeling within the hippocampus. For example, increased GAD labeling in persisting axon terminals could conceivably mask the loss of GABAergic axons and terminals in regions such as the molecular layer (**Figure 3(b)**). In addition, increased GAD levels could lead to enhanced labeling of some GABAergic cell bodies, including those along the base of the granule-cell layer (**Figure 3(b)**).

Recently, increased labeling of the vesicular GABA transporter (vGAT) has also been demonstrated in GABAergic axon terminals in the hippocampus in a rat model of recurrent seizures, suggesting increased vGAT synthesis and possibly an associated increase in GABA release at some axon terminals.

The up-regulation of such GABA-related mRNAs and proteins suggests a very active GABA system that presumably could control neuronal activity for much of the time. However, with persistently elevated levels of activity, the system might have limited reserves to respond to any further increases in excitability, such as would occur during seizure onset. Another possibility is that the persistently increased activity of the GABA system could lead to additional adaptive changes within the system, including altered levels of GABA receptor subunits, that might then counteract the effects of enhanced presynaptic GABAergic function.

Potential reorganization of GABAergic axons

The preservation of many GABA neurons and an apparent increase in some GABAergic axon and terminal fields during the chronic stage have been described in humans with TLE and several epilepsy models. This has led to the suggestion that GABA neurons may exhibit axonal reorganization, similar to that of mossy fibers in epilepsy. Yet it remains uncertain whether the increased labeling of GABA fibers results from axonal sprouting of remaining GABA neurons or an increase of GAD and GABA in existing terminals. The classical sprouting of mossy fibers from granule cells in TLE has been relatively easy to document because of the aberrant location of the reorganized fibers as well as their high content of zinc, dynorphin, and other unique markers. In contrast, GABAergic axon terminals are normally found in varying densities in nearly all regions of the hippocampus, and sprouting within a local area is thus more difficult to detect.

Conclusive demonstrations of axonal sprouting of GABA neurons may require time course studies with markers for subgroups of GABA neurons that allow more selective analyses. Such studies of remaining somatostatin neurons in the mouse pilocarpine model are in progress. Preliminary findings suggest that axonal sprouting is initiated soon after the degeneration of hilar somatostatin neurons and continues to progress for several months. Such axonal reorganization could account for the difficulties in demonstrating a loss of GABAergic axon terminals in regions such as the outer molecular layer of the dentate gyrus, even when extensive loss of GABAergic innervation to this region has occurred as a result of hilar neuron loss.

If axonal reorganization occurs, the functional consequences will depend on the circuitry that is established. If GABA neurons of the same subtype as those that degenerate were to reinnervate the same regions, similar circuitry could be formed and considerable compensation might occur. Alternatively, the reorganized axon terminals could

originate from GABA neurons in other regions of the hippocampal formation or, possibly, extrahippocampal regions. In such cases, the neurons might not participate in the appropriate circuit and thus could be less effective than the original population of GABA neurons. Although GAD-containing fibers and terminals in the dentate molecular layer are abundant in the pilocarpine-treated animals during the chronic stage, their pattern appears less well-organized than in control animals (**Figure 3(a)** and **3(b)**). These changes are consistent with morphological reorganization of GABAergic innervation, possibly from different populations of interneurons than those that originally innervated the region.

Alterations in remaining GABA neurons that could impair their function

The response of remaining GABA neurons to their afferent input is another important consideration, and decreased responsiveness of these neurons could substantially impair GABAergic function. A decrease in excitatory drive to some GABA neurons, such as basket cells of the dentate gyrus, has been proposed as a mechanism for decreased inhibitory function in some epilepsy models. However, there is currently little direct evidence for a decrease in excitatory input to these GABA neurons. However, other changes in GABA neurons could alter their excitability.

Recently, an interesting change in expression of the δ subunit of the $GABA_A$ receptor was observed in GABA neurons in the mouse pilocarpine model during the chronic period. Expression of the δ subunit was markedly increased in interneurons throughout the dentate gyrus, despite decreased expression in dentate granule cells (**Figure 4(a)** and **4(b)**). This cell-type-specific regulation of the δ subunit in interneurons and principal cells was unexpected, and demonstrates unique plasticity of this $GABA_A$ receptor subunit.

δ Subunit-containing receptors mediate tonic or persistent inhibition that can be distinguished from phasic or synaptically-mediated inhibition, and appear to be quite important in controlling neuronal excitability. These receptors have a high affinity for GABA and are generally located either at the periphery of GABAergic synapses or at extrasynaptic locations where they can respond to ambient levels of GABA and spillover of synaptically-released GABA. Furthermore, activity of δ subunit-containing receptors can be modulated by physiological levels of neurosteroids and low levels of ethanol.

In epileptic mice, increased expression of the δ subunit was particularly evident in interneurons of the dentate

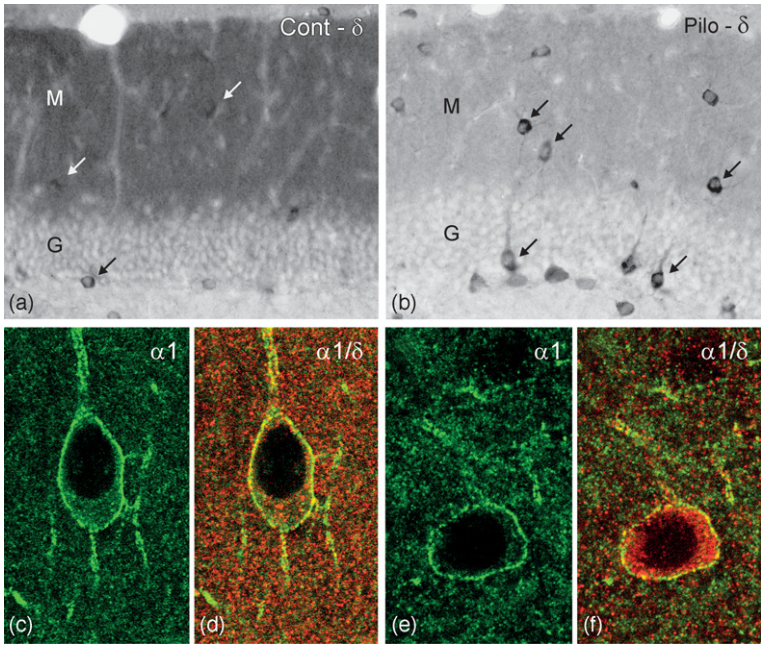

Figure 4 Immunohistochemical localization of the δ and α1 subunits of the $GABA_A$ receptor in the dentate gyrus of control and pilocarpine-treated mice. (a,b) In a pilocarpine-treated mouse during the chronic period, δ subunit labeling of interneurons (arrows) in the molecular (M) and granule-cell (G) layers is substantially increased. The increased labeling of interneurons contrasts with decreased labeling of granule-cell dendrites in the molecular layer and their cell bodies in the granule-cell layer in the pilocarpine-treated animal. (c–f) As revealed by confocal imaging, α1 subunit labeling (green) on the surface of interneurons in the molecular layer is similar in control (c) and pilocarpine-treated (e) mice. In contrast, δ subunit labeling (red) in the cytoplasm is increased in the pilocarpine-treated animal (f) compared with the control (d). Surface labeling of the subunits (yellow) remains prominent in the pilocarpine-treated animal (f).

molecular layer (**Figure 4(a)–4(f)**). Many of these neurons innervate granule-cell dendrites and, through feed-forward inhibition, help regulate the responsiveness of granule cells to excitatory input from the entorhinal cortex. When functioning optimally, input to these interneurons could stimulate their activity, and this activity could in turn help regulate granule-cell responses to entorhinal input. If tonic inhibition of these interneurons increased, as appears to be the implication of enhanced expression of the δ subunit, the interneurons could become less responsive to their normal excitatory input. Inhibition of the granule cells might then be compromised at precisely the times when it is most needed to control granule-cell excitability. Such functional effects remain to be demonstrated, but the possibility that increased inhibition of inhibitory interneurons could contribute to increased seizure susceptibility is intriguing.

Evidence that decreased excitability of GABA neurons can contribute to recurrent seizures has come from recent studies of a transgenic mouse with a loss-of-function mutation of the gene encoding the voltage-gated sodium channel $Na_v1.1$. Voltage-gated sodium (Na_v) channels play critical roles in the initiation and propagation of action potentials, and reduction in these channels was expected to lead to decreased neuronal excitability. Instead, heterozygous mice with decreased $Na_v1.1$ channels showed increased excitability and spontaneous seizures. It was then discovered that the $Na_v1.1$ channels were normally highly expressed on the soma of many hippocampal interneurons. Thus, the mutation produced alterations primarily in interneurons rather than principal cells, and resulted in substantially reduced action potential generation and inability of the interneurons to sustain firing. These findings provide strong support for the suggestion that impaired function of existing GABA neurons can contribute to increased excitability of the hippocampus and spontaneous seizures. Importantly, such alterations could occur in humans with severe myoclonic epilepsy in infancy (SMEI) as a result of the same mutation of the $Na_v1.1$ channel gene.

Additional changes that could alter the excitability of remaining GABA neurons are likely to be found. Such changes could be quite important, for many GABAergic interneurons have extensive axonal plexuses. Thus, changes in excitability of even small numbers of GABA neurons could have widespread influences. These remaining neurons could become targets of pharmacological treatment whereby relatively selective actions on GABA neurons could influence large populations of principal cells.

Future Challenges

Future studies will need to consider both loss and preservation of GABA neurons, and their influences within the reorganized circuitry of each brain region. Current studies have shown that each region of the hippocampal formation, including the dentate gyrus, CA3, CA1, subiculum, and entorhinal cortex, has unique changes in GABA neurons and their receptors. However, with time, common patterns may become evident. For example, GABA neuron loss could be found in virtually all regions, even if the types of vulnerable GABA neurons differ among regions. Following such loss, reorganization of remaining GABA neurons could occur, although the specific types of GABA neurons that undergo reorganization and their targets may differ. Finally, receptors and ion channels that regulate the responses of remaining GABA neurons could be altered in ways that reduce their activity and thus their effectiveness of controlling their target neurons. The functional effects of all of these changes are most likely to be evident when demands on the GABA system are increased. A critical question in all instances is how remaining GABA neurons function within their established circuits in the intact brain. Given the current emphasis on studying 'reduced' or 'simplified' models, it is important to remember that these in vivo functions could differ significantly from the responsiveness of these cells to specified, direct stimulation in vitro.

Identifying additional changes in interneurons that could alter their function is a particularly exciting challenge. Indeed, GABA neurons that remain following the initial insult could be as important as those that are lost, for these neurons maintain control of the system for the majority of time between seizure episodes. Also, it is the function of these neurons that may be deficient at the time of a spontaneous seizure. As alterations in remaining GABA neurons are identified, the challenge is to determine which changes are compensatory and might be enhanced for the prevention and treatment of epilepsy, and which are maladaptive and should be counteracted.

Introduction

Within the mammalian central nervous system, GABAergic synaptic inhibition is provided by a wide array of local circuit inhibitory interneuron types. Synaptic inhibition contributes to local processes (including information coding and synaptic plasticity) and global processes such as network synchrony and oscillations. Alterations in the intrinsic excitability or synaptic efficacy of inhibitory interneurons may impair their ability to regulate network synchronicity and overall excitability, often resulting in the production of electrographic seizure activity. Indeed, pharmacological agents that reduce inhibition are typically proconvulsant, while agents that selectively enhance inhibitory synaptic tone are widely used as antiepileptic drug therapies.

The excitability of GABAergic interneurons is defined by the unique set of ion conductances that each cell expresses. Potassium conductances are key determinants of cellular excitability, as they are largely responsible for determining the resting potential, input resistance, membrane time constant, and action potential repolarization rate. Therefore understanding the repertoire of potassium conductances expressed by interneurons, and how these conductances contribute to cellular function, will add to our understanding of the mechanisms by which interneurons preserve the optimal level of excitability.

An enormous diversity of potassium (K) channels exists. Over 100 distinct potassium channel subunits have been identified. These subunits can be classified into several groups based on their functional properties, including voltage-gated K channels, Ca^{2+} activated K^+ channels, inward rectifiers, K^+ 'leak' channels, and Na^+ activated K^+ channels. These groups can be further divided into families and subfamilies based upon their molecular similarity. A single neuron expresses many different K^+ channel subunits from each of the families and subfamilies; each of these channels contributes to the excitability of the neuron in a different way. For example, potassium 'leak' channels dominate the resting membrane properties, while voltage-gated channels are activated during synaptic transmission and action potentials.

Introduction

Within the mammalian central nervous system, GABAergic synaptic inhibition is provided by a wide array of local circuit inhibitory interneuron types. Synaptic inhibition contributes to local processes (including information coding and synaptic plasticity) and global processes such as network synchrony and oscillations. Alterations in the intrinsic excitability or synaptic efficacy of inhibitory interneurons may impair their ability to regulate network synchronicity and overall excitability, often resulting in the production of electrographic seizure activity. Indeed, pharmacological agents that reduce inhibition are typically proconvulsant, while agents that selectively enhance inhibitory synaptic tone are widely used as antiepileptic drug therapies.

The excitability of GABAergic interneurons is defined by the unique set of ion conductances that each cell expresses. Potassium conductances are key determinants of cellular excitability, as they are largely responsible for determining the resting potential, input resistance, membrane time constant, and action potential repolarization rate. Therefore understanding the repertoire of potassium conductances expressed by interneurons, and how these conductances contribute to cellular function, will add to our understanding of the mechanisms by which interneurons preserve the optimal level of excitability.

An enormous diversity of potassium (K) channels exists. Over 100 distinct potassium channel subunits have been identified. These subunits can be classified into several groups based on their functional properties, including voltage-gated K channels, Ca^{2+} activated K^+ channels, inward rectifiers, K^+ 'leak' channels, and Na^+ activated K^+ channels. These groups can be further divided into families and subfamilies based upon their molecular similarity. A single neuron expresses many different K^+ channel subunits from each of the families and subfamilies; each of these channels contributes to the excitability of the neuron in a different way. For example, potassium 'leak' channels dominate the resting membrane properties, while voltage-gated channels are activated during synaptic transmission and action potentials.

Because of the large diversity of K^+ channel subunits and functions, we have focused on how a single K^+ channel subfamily, the Kv3 subfamily, critically contributes to the excitability of interneurons.

Background

The Kv3 subfamily of voltage-gated potassium channels is composed of the subunits Kv3.1–3.4, which assemble as either homomers or heteromers to form tetrameric potassium channels. Of particular interest, in cortex and hippocampus expression of these Kv3 subfamily members is restricted to several inhibitory interneuron subpopulations. Knockout mice have been made of all four Kv3 genes. Of the single mutants, Kv3.2 has the highest propensity to develop spontaneous seizures. Furthermore, seizures are more easily evoked in Kv3.2-deficient mice using electrical stimulation of the thalamus, and Kv3.2-deficient mice injected with the convulsant picrotoxin (a $GABA_A$ receptor antagonist) develop more severe seizures with a shorter latency to onset than wild-type controls. The increased seizure susceptibility of Kv3.2-deficient mice suggests that Kv3.2-containing channels play a critical role in controlling network excitability.

To understand how channels formed from Kv3.2 subunits might regulate network excitability, we need to know which neurons express Kv3.2 and how Kv3.2 channels contribute to the function of these neurons. In the neocortex and hippocampus, Kv3.2 mRNA and protein are predominantly expressed in GABAergic interneurons. More specifically, Kv3.2 expression is limited to subclasses of GABAergic interneurons that are designed to fire at high frequencies. These 'fast-spiking' interneurons mainly consist of two anatomical classes: parvalbumin positive, soma-inhibiting (basket) cells, and somatostatin positive, dendrite-inhibiting cells (**Figure 1(a)**). Soma-inhibiting interneurons form multiple GABAergic synapses on the soma and proximal dendrites of excitatory (pyramidal) cells. Because their synapses are close to the site of action potential initiation, they are able to effectively exert control over action potential generation in pyramidal cells, leading to the hypothesis that they play a significant role in regulating excitation within the cortex. Dendrite-inhibiting neurons exert little control over Na^+-dependent action potential generation. Instead, they modulate Ca^{2+}-dependent spikes and postsynaptic potentials within the dendrites, influencing which signals propagate to the soma. Mice that lack dendrite-inhibiting interneurons have an increased susceptibility to seizures, suggesting that these interneurons have a significant role in determining network excitability. Thus, the two main types of interneurons that express Kv3.2 are involved in controlling pyramidal cell excitability.

As already stated, the ability to fire action potentials in rapid succession is a defining feature of Kv3.2-containing interneurons. Indeed, fast-spiking interneurons in Kv3.2 knockout mice have lower firing rates than fast-spiking interneurons in wild-type mice. The lower firing rates are correlated with broader action potentials and reduced after-hyperpolarizations. The lower firing rates suggest a

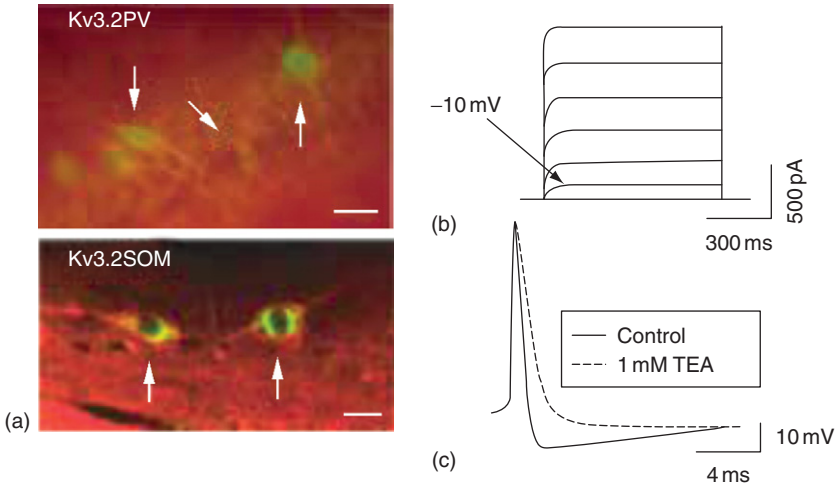

Figure 1 (a) Kv3.2 (red) is coexpressed with the calcium binding protein parvalbumin (green, top) and somatostatin (green, bottom) in hippocampus. While nearly all parvalbumin-positive interneurons express Kv3.2, only about 30% of somatostatin-expression interneurons express Kv3.2. (b) Kv3.2 currents in transfected Chinese hamster ovary cells. Kv3.2 currents are voltage-gated, sustained outward currents that are activated at potentials depolarized to −10 mV. (c) Low concentrations of TEA, sufficient to block Kv3 currents, broaden the action potential duration and decrease the afterhyperpolarization of cortical fast-spiking interneurons. Adapted from Rudy and McBain (2001).

decreased excitability of fast-spiking inhibitory interneurons, leading to reduced cortical inhibitory tone, which may account for the increased susceptibility to seizures observed in Kv3.2 knockout mice.

How do Kv3.2 channels contribute to the fast spiking phenotype of interneurons? Kv3.2-containing channels are optimized to ensure rapid repolarization of the membrane potential after an action potential, speeding Na^+ channel de-inactivation and enhancing the cell's ability to fire action potentials at a high frequency. In heterologous expression systems, Kv3.2 channels activate at −10 mV, well above action potential threshold, and rapidly deactivate upon repolarization of the membrane, suggesting that they are only active during action potentials (**Figure 1(b)**). Moreover, when Kv3.2-expressing HEK293 cells are voltage-clamped to an action potential waveform, current is not activated until the falling phase of the action potential and then quickly deactivates upon membrane repolarization. Thus, Kv3.2 channels do not alter the rising phase of the action potential but contribute a large outward current to the falling phase, a current which serves to more quickly repolarize the membrane potential. Fast repolarization quickly de-inactivates Na^+ channels, enabling them to participate in subsequent action potentials and thus facilitating high action potential firing rates.

The fast repolarization of the membrane potential mediated by Kv3.2-containing channels also occurs in native systems, and contributes to the high firing rate of Kv3-expressing neurons. While no specific Kv3.2 antagonists exists, Kv3 channels in general can be blocked with low concentrations of the nonspecific K^+ channel blockers TEA and 4-AP. Application of these drugs to acute brain slices increases the action potential duration, decreases the after-hyperpolarization, and reduces the firing rate of fast spiking interneurons (**Figure 1(c)**). Furthermore, after pharmacological blockade of Kv3 channels, reinsertion of a Kv3 conductance using a 'dynamic clamp' is sufficient to both reduce action potential duration and increase firing rate, rescuing the fast spiking phenotype. Finally, deep cortical layer parvalbumin positive interneurons in Kv3.2 knockout mice have broad action potentials with reduced after-hyperpolarizations and decreased firing rates, consistent with the view that Kv3 channels regulate inhibition in the cortex by controlling interneuron excitability.

Kv3 channel regulation of interneuron firing rate is almost certainly due to those Kv3 channels located in the soma and proximal axon, near the site of action potential generation. Indeed, Kv3.2, Kv3.3, and Kv3.1b (a splice variant of Kv3.1) are expressed at high levels in the perisomatic compartment. However, Kv3 channel expression is not limited to this compartment. Kv3.2 and Kv3.1b are also present in the axons and axon terminals of cortical interneurons. Furthermore, Kv3.1a is almost exclusively localized to axons and axon terminals. This localization places Kv3 channels in a position to directly influence the release of the neurotransmitter GABA from fast-spiking cells by regulating the shape of the presynaptic action potential within the axon terminal. The shape of the presynaptic action potential determines the time course of the voltage-dependent entry of Ca^{2+} into the presynaptic terminal, modulating the probability of neurotransmitter release. Typically, brief action potentials allow less Ca^{2+} to enter the presynaptic terminal than broad action potentials, reducing the probability of neurotransmitter release. Multiple lines of evidence suggest that Kv3 channels in the axon terminals shorten the duration of calcium entry, thereby reducing the probability of transmitter release. First, in the presence of Kv3 blockers, the size of the inhibitory postsynaptic current (IPSC) is increased and the paired pulse ratio decreased, suggesting an increase in release probability in the absence of Kv3 function. An increase in release probability is also found in Kv3.1/3.2 double knockout mice in comparison to controls. Second, calcium imaging of the presynaptic terminal reveals a larger and longer calcium transient in the presence of Kv3 channel blockers. Finally, TEA applied locally to the terminals affects release probability while somatic application has no effect. Thus, presynaptically localized Kv3 channels are involved in determining the probability of neurotransmitter release.

Kv3.2 plays two apparently antagonistic roles in regulating cortical inhibition. By shortening the time course of action potentials, Kv3.2 increases the frequency at which interneurons can fire action potentials, increasing the amount of inhibition. However, the shortened action potentials also reduce the presynaptic calcium influx, reducing neurotransmitter release probability, and reducing phasic inhibitory input to the postsynaptic cell. Thus, while Kv3.2 knockout mice have less frequent action potentials, they are broader, allowing for more Ca^{2+} influx, enhanced GABA release and increased IPSC amplitudes in the postsynaptic cells. One interpretation of this apparent dichotomy is that in Kv3.2-deficient mice, the reduced firing frequency of interneurons has a larger effect on the overall level of inhibition than the enhanced GABA release. However, this interpretation may be too simplistic and does not take into account the short-term dynamics of neurotransmitter release. When neurotransmitter release probability is increased, there is a concomitant change in the short-term plasticity of the synapse, reducing facilitation or enhancing depression of neurotransmitter release. The increased neurotransmitter release probability of GABAergic interneurons in Kv3.2-deficient mice is accompanied by increased paired pulse depression. The effects of release probability on a long train of stimuli in these mice are unknown; however, it may be that later in the train, the IPSCs are depressed

to the point that they can no longer effectively inhibit network activity. Thus, the effects of altered synaptic transmission may be greater during trains of stimuli than on a single stimulus.

Since Kv3.1 and Kv3.3 largely overlap with Kv3.2 in expression and function, it may be surprising that they do not compensate to maintain network stability in Kv3.2-deficient mice. However, Kv3.2 is unique among the Kv3 subunits in that it contains a protein kinase A (PKA) phosphorylation site on its C-terminus. PKA phosphorylation inhibits current through recombinant Kv3.2 channels. The ability to control channel conductance by phosphorylating or dephosphorylating the channel raises the interesting possibility that PKA phosphorylation of Kv3.2 channels is used to dynamically regulate interneuron, and thus network, excitability. Here we summarize work demonstrating that endogenous PKA inhibits a Kv3.2-like conductance, and that PKA-dependent phosphorylation of Kv3.2-containing channels is regulated by histamine H_2 receptor activation.

Method

To study how Kv3.2-containing channels dynamically-regulate excitability, Marco Atzori and Colleagues performed whole-cell voltage and current clamp recordings from acute hippocampal slices were performed. Since interneurons are located in cell sparse regions of the hippocampus, thin ($\sim$300 μm) sections that were transparent enough to enable the visualization of neurons, facilitating the targeting of inhibitory interneurons during recording. Kv3.2 channels are only expressed in subclasses of interneurons, and even with visualization, determining which cell-types are being recorded can be difficult. To bias recordings toward Kv3.2-containing cells, interneurons targeted for recording were located in the hilus of dentate gyrus, an area rich in both parvalbumin- and somatostatin-positive cells. Furthermore, the cells were filled with a tracer and post-hoc morphological analysis was used to verify that their morphology was consistent with Kv3.2-containing cells.

One of the challenges of this research is to specifically isolating Kv3.2 currents. Typically, a particular channel's currents can be isolated based upon its unique pharmacological and biophysical profile. However, there are no known Kv3.2 channel specific blockers. Two of the most commonly used blockers, 4-AP and TEA, block many classes of potassium channels. Specificity for Kv3 containing channels is increased by using low doses of these drugs (1–2 mM TEA; $<$100 μM 4-AP); however, even at these low doses, all Kv3-containing channels are blocked as well as a small number of other potassium channels. Furthermore, neither the kinetics nor voltage-dependence of Kv3.2 distinguishes it from other Kv3-containing channels. Finally, Kv3.1, 3.2, and 3.3 expressions are largely overlapping in hippocampal interneurons, so the variable expression pattern cannot be used to identify available currents. To overcome the challenges of specifically isolating Kv3.2 currents, the results of pharmacological experiments were verified in Kv3.2 knockout mice.

Recent Results

Similar to neocortical interneurons, in adult mice all hippocampal interneurons that express parvalbumin also express Kv3.2, and approximately one-third of somatostatin-expressing interneurons are Kv3.2 positive. Kv3.2 immunoreactivity is not detectable until P7; then it steadily increases until reaching adult levels by P14. The development of Kv3.2-expression coincides with the expression of parvalbumin and somatostatin and with the ability of these neurons to fire repetitively at high firing rates, providing further evidence that Kv3.2 channel expression contributes to the fast-spiking phenotype.

In the dentate gyrus, Kv3.2-expressing interneurons are located in the subgranular region and within the hilus. Whole-cell voltage clamp recordings of interneurons in this region reveal a TEA-sensitive outward current that is activated at approximately −10 mV. These currents activate rapidly and do not inactivate over the course of a 300-ms test pulse, consistent with Kv3-like current.

While all Kv3-containing channels can be modulated by PKC, only Kv3.2 has a PKA phosphorylation site. Currents through recombinant Kv3.2 are inhibited by PKA phosphorylation. In hilar interneurons, PKA activation also inhibits Kv3-like current. In the presence of the phosphodiesterase inhibitor IBMX, the PKA activators dibutyryl cAMP and 8-Br-cAMP reduce the sustained outward current. This reduction in outward current is occluded by pre-application of TEA, suggesting that the current inhibited by PKA is also TEA-sensitive, consistent with this being a Kv3.2 current. Further evidence that the PKA sensitive outward current is due to Kv3.2 comes from Kv3.2 knockout mice. PKA activation fails to alter the voltage-dependent outward current of hilar interneurons in Kv3.2-deficient mice, suggesting that PKA specifically inhibits Kv3.2 currents.

How is PKA-dependent inhibition of Kv3.2 currents regulated? PKA activity can be modulated by several G-protein coupled receptors, including β-adrenergic, dopamine, serotonin, and histamine H_2 receptors. H_2 receptors

are densely distributed within dentate gyrus, making them a good candidate for modulating Kv3.2 currents via PKA. Indeed, application of histamine or the histamine receptor agonist dimaprit reduced Kv3-like currents (Figure 2(a,b)), and pre-application of TEA or PKA-inhibitors blocks the action of histamine and dimaprit, indicating that activation of H_2 receptors leads to a reduction of Kv3-like currents via PKA phosphorylation. In Kv3.2-deficient neurons, dimaprit has no effect on outward currents, suggesting that H_2 receptor activation specifically inhibited Kv3.2 currents.

H_2 receptor activation can reduce Kv3.2 currents via PKA activation, but is this reduction in Kv3-like currents sufficient to alter the firing rate of interneurons? The maximum firing rates of interneurons were determined by delivering trains of brief, suprathreshold current pulses at various frequencies. The maximum frequency at which the interneuron spikes are able to follow current pulses without failing is reduced by approximately 25–30% in the presence of H_2 agonists or PKA activators (Figure 2(c)). Furthermore, in Kv3.2-deficient mice, H_2 agonists and PKA activators have no effect on the maximal firing frequency (Figure 2(d)). These results suggest that modulation of Kv3.2 currents alters the excitability of interneurons, reducing their ability of fire action potentials at high firing rates.

Kv3.2 modifies firing rate by efficiently and quickly repolarizing the membrane potential during the falling phase of an action potential, which facilitates the de-inactivation of voltage-dependent Na^+ channels, preparing them to participate in subsequent action potentials. Failure to repolarize the membrane potential and de-inactivate Na^+ channels decreases the action potential amplitude. H_2 agonists and PKA activators decreased the amplitude and increased the duration of action potentials, with greater effects occurring late in the train. The changes in action potential shape observed in H_2 agonists and PKA activators are consistent with impaired membrane repolarization and subsequent reduction in available Na^+ channels. The larger changes late in the train are likely due to the cumulative effects of Na^+ channel inactivation. As Na^+ channels fail to de-inactivate before the next depolarizing pulse, fewer Na^+ channels are available for the next action potential, further contributing to changes in action potential shape. PKA activators and H_2 agonists do not affect the shape of action potentials in Kv3.2-deficient neurons, indicating that their effects are specific for Kv3.2 currents.

Although these experiments clearly demonstrate that H_2/PKA dependent modulation of Kv3.2 currents affects the firing properties of individual neurons, these changes must be translated into altered network function for them to be involved in seizure activity. In hippocampal slices, pharmacological removal of excitatory synaptic transmission by bath application of glutamate receptor antagonists reveals spontaneously occurring high-frequency oscillations of the field potential in the principal cell layers. H_2 receptor agonists and PKA activators decrease the incidence of these population events in wild type mice but had no effect in Kv3.2-deficient mice, indicating that PKA-dependent inhibition of Kv3.2 currents is sufficient to reduce the excitability of a network of inhibitory interneurons.

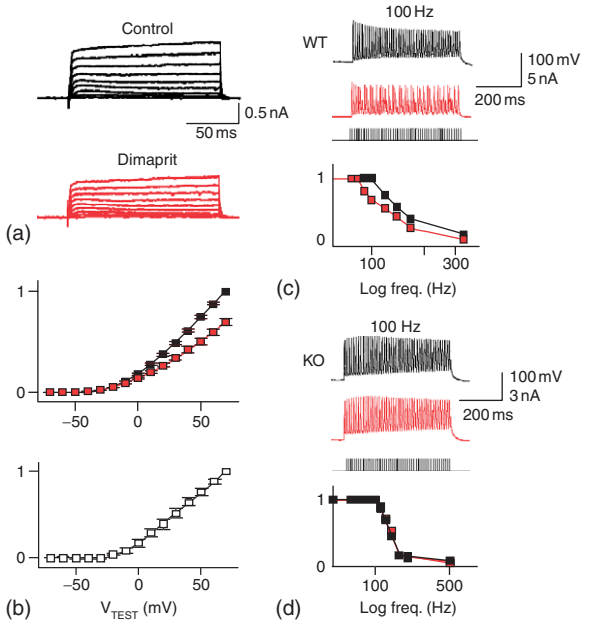

Figure 2 Kv3.2 current is modulated by H_2 receptor activation. (a) Whole cell sustained outward currents in hippocampal interneurons are decreased after application of the selective H_2 receptor agonist dimaprit. Outward currents were elicited by a 300 ms step to from a holding voltage of −70 mV to test voltages between −50 mV and +70 mV in 10 mV increments. (b) Top: Normalized current–voltage relationship measured in control (black) or in the presence of dimaprit (red). Outward current is reduced at positive voltages, consistent with an H_2 receptor dependent decrease in K^+ current. Bottom: The dimaprit sensitive current was isolated by subtraction of the current in dimaprit from control. The dimaprit-sensitive current is an outward current activated at −10 mV, consistent with it being a Kv3.2 current. (c) Dimaprit reduces the maximal firing frequency of wild-type interneurons. A train of stimuli delivered at 100 Hz can be followed for the entire 500 ms test period in control conditions (black); however, after application of dimaprit (red) the train of stimuli cannot be followed faithfully. Bottom: A plot of the action potential probability versus stimulus frequency demonstrates that dimaprit (red) reduces the ability of neuron to follow high frequency trains of stimuli. (d) In Kv3.2 knockout mice, application of dimaprit (red) has no effect on the ability of interneurons to fire high frequency trains of stimuli. Adapted from Atzori *et al*. (2000).

Future Goals

Kv3 channels have similar functional properties and largely overlapping distributions, yet Kv3.2-deficient mice have increased seizure susceptibility whereas other Kv3.x deficient mice do not. Understanding this difference will require dissecting the subtle differences between Kv3 channel function and expression.

One of the few features that distinguish Kv3 channels is their modulation by second messengers. Of the Kv3 channels, Kv3.2 is the only one phosphorylated by PKA activity, suggesting that the regulation of Kv3.2 current by PKA phosphorylation is key to network stability. In neurons, PKA activation can occur via numerous neuromodulatory pathways. Here we have described how the activation of H_2 receptors leads to PKA activation and a reduction in Kv3.2 current. However, PKA formation can be triggered by a variety of monoamine receptors, including adrenergic, serotonin, and dopamine receptors, all of which are present through the cortex and hippocampus. Thus, the PKA-dependent regulation of Kv3.2 receptors may be effected by several neuromodulators. Some of these receptors, such as D1 receptors and beta-adrenergic receptors, increase PKA activity; others, such as D2 receptors, decrease its formation. We hypothesize that activation of different receptor systems may be a mechanism of differentially modulating the system. Further study is necessary to determine which of these neuromodulatory systems act upon Kv3.2.

How can Kv3.2 modulation be important for maintaining network stability? Kv3 current decreases the duration of the action potential waveform, which allows for higher frequency firing, but also decreases the amount of Ca^{2+} influx, reducing the release probability. Modulation of Kv3.2 current by monoamine receptors may dynamically regulate the balance between high firing rates and high neurotransmitter release probability. To understand this action, the link between neuromodulators and neurotransmitter release must be more clearly defined. Importantly, we need to better understand how firing rate and neurotransmitter release probability contribute to overall network inhibition and whether there are situations that favor one over the other.

The study of Kv3.2 has largely focused on cortical structures, and there is some evidence that the lack of Kv3.2 in the cortex may influence the epileptic phenotype. During EEG recordings Kv3.2-deficient mice exhibit abnormal high amplitude sharp potentials that may reflect poor control of corticocortical inputs, indicating an inability of inhibitory interneurons to sufficiently suppress network function. However, Kv3.2 is also prominently expressed in many subcortical structures, particularly thalamic relay neurons, which also may be responsible for an epileptic phenotype. Elucidating the mechanisms underlying the enhanced seizure susceptibility of Kv3.2-deficient mice will require a deeper understanding of Kv3.2 function within individual cell types, and insight into how those cells contribute to network function.

Acquired Ion Channel Dysfunction in Epilepsy

Introduction

That ion channel dysfunction lies at the root of epilepsy has for decades seemed a self-evident truth. Ion channels, both voltage- and ligand-gated, mediate the excitable behavior of neurons, and since seizures result from neuronal hyperexcitability, surely altered biophysical properties or expression of ion channels must underlie this pathological hyperexcitability. Actual proof of this dogma, however, did not arrive until 1995, with the first publication of a genetic locus found in a human epilepsy syndrome, a mutation in nicotinic acetylcholine receptors underlying autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). Since 1995, a number of other idiopathic human epilepsy syndromes have been conclusively linked to single gene mutations (Table 1). Of note is the fact that all of these genes code for ion channel subunits or presumptive accessory subunits. The alterations of ion channel properties caused by these mutations are diverse, and include loss of expression or function (haploinsufficiency) as well as alterations that influence function of channels assembled from heteromeric subunits (a dominant negative action). The importance of these findings cannot be overstated: they prove that defects in individual ion channel subtypes can produce human epilepsy syndromes, complete with characteristic developmental courses and responses to antiepileptic drugs.

Table 1 Human genetic epilepsy syndromes resulting from ion channelopathy

Syndrome	*Affected genes*
Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)	*CHRNA4*, *CHRNB2*
Benign familial neonatal convulsions (BFNC)	*KCNQ2*, *KCNQ3*
Generalized epilepsy with febrile seizures plus (GEFS+)	*SCN1B*, *SCN1A*, *GABARG2*
Severe myoclonic epilepsy of infancy (SMEI)	*SCN1A*
Benign familial neonatal–infantile convulsions (BFNIC)	*SCN1A*
Idiopathic generalized epilepsy and episodic ataxia	*CACNB4*
Autosomal dominant partial epilepsy with auditory features (ADPEAF)	*LGI1*

Does ion channel dysfunction similarly underlie epilepsy arising from acquired causes, such as head injury, brain tumors, or cerebral hemorrhage as it does in genetic epilepsy? (Temporal lobe epilepsy (TLE), the most common cause of epilepsy in adults, is widely assumed to also be an 'acquired epilepsy.') It is reasonable to hypothesize that ion channel dysfunction forms the final common pathway resulting from a variety of acute insults to the CNS. However, unlike the case for some genetic human epilepsy syndromes, proof of this concept is still lacking. Reasons for our slow progress in testing this hypothesis include the relative inaccessibility of human brain tissue from patients with epilepsy – unless they come to epilepsy surgery – with which to study ion channel function (compared with the relative ease of finding pathology in a patient's genomic code). Also problematic is the lack of control data from unaffected patients. Thus, animal modeling is the principal means of studying the causes of acquired epilepsy.

Background

The animal models in wide use present a range of advantages and disadvantages in their similarity to human

epilepsies. Models that replicate typical CNS insults would seem the best candidates to study the biological processes underlying the induction of the epileptic state, or epileptogenesis. However, experiments thus far with rodent models of traumatic brain injury, cerebral hemorrhage, hypoxic–ischemic encephalopathy, and febrile seizures have produced animals with relatively mild epileptic phenotypes – with either subtle partial or subclinical seizures, an epilepsy course that may remit over time, or even no evidence of spontaneously recurring seizures. Thus, the most widely used models are the poststatus epilepticus (SE) models involving induction of SE by pilocarpine or kainate. These models produce a robust epileptic phenotype in rodents, with spontaneously recurring seizures that span (or exceed) the Racine scale (a behavioral measure of seizure type/severity), and which do not remit over time. Like human acquired epilepsy, there is a variable 'latent period' between the insult and the development of spontaneous seizures, although the duration of this period is dependent on model methodology and in some cases may be just a few days; also like human TLE, these post-SE models produce hippocampal pathology reminiscent of medial temporal sclerosis. A significant drawback to these models is their lack of a naturalistic insult: humans are rarely exposed to chemical convulsants, and it is unclear how status epilepticus is related to traumatic brain insult (or to TLE). It has been argued that post-SE models are relevant because some human cases of adult TLE are associated with a history of febrile SE as a child, but this finding is the exception rather than the rule.

An additional rationale for the use of post-SE models of epilepsy pertains to the doctrine of 'seizures beget seizures.' This idea, that the natural course of untreated epilepsy shows an accelerating seizure frequency, dates to observations of Gowers in the nineteenth century and suggests that successive seizures alter brain excitability in such a way as to make further seizures more likely. If true, one mechanism by which this progression might occur is through seizure-dependent modification of ion channel properties that results in increased neuronal excitability. Although 'seizures beget seizures' is an oft-quoted dictum, there is little clinical proof supporting it. While retrospective clinical observations do show that the interval between seizures tends to decrease for the first several seizures after the onset of epilepsy (but before treatment), a definitive prospective test of this hypothesis is impossible for ethical reasons. In animal models of acquired epilepsy, such as kindling, kainate, and fluid percussion injury, there is clear evidence that seizure frequency and intensity increase after the initial insult, eventually achieving a plateau level. Whether the accelerating seizure rate seen is seizure-dependent, or instead reflects an underlying progressive process of epileptogenesis set in motion by the initial insult, is unclear. This question can be experimentally tested by pharmacologically blocking seizures during the early period after the insult, when an accelerating seizure frequency would be expected. Then, after the antiepileptic treatment is discontinued, it can be determined whether seizures begin at their usual low, accelerating rate, or whether they immediately begin at their higher plateau frequency. An interesting example of this test comes from a study in the WAG/Rij rat model of generalized epilepsy in which blockade of seizures during the period when they make their spontaneous developmental appearance significantly decreases their age-dependent frequency after the antiepileptic drug is discontinued. This finding suggests that for one model of epilepsy with a genetic basis, spontaneous seizures appear with an accelerating time course that is independent of underlying developmental processes. Conclusive data for acquired epilepsy models on this question are thus far lacking.

Thus, there are multiple ways in which acquired alteration of ion channel function can contribute to epileptogenesis – either as a fundamental cause of hyperexcitability or as a mediator of the process in which spontaneous seizures progressively worsen the course of epilepsy. It is also possible that some ion channel alterations retard the development of epilepsy. When interpreting studies of ion channel property changes in epilepsy models, it is important to consider whether the changes seen reflect a seizure-dependent process occurring after the onset of epilepsy, or whether they are instead set into motion by the initial insult and precede the onset of seizures. A further question is whether the changes seen are likely proconvulsive versus homeostatic. That is, do these changes demonstrably increase the excitability of neurons, or do they diminish intrinsic excitability in an attempt at maintaining brain normality? With these thoughts in mind, we can consider recent evidence for acquired ion channel changes in various animal models of epilepsy.

Methods

The results described later derive from a survey of the literature published in the last 12 years using animal models of acquired epilepsy to study altered ion channel properties with electrophysiological, biochemical, and molecular biological techniques.

Results – Specific Ion Channel Changes in Epilepsy

Na^+ Channels

Na^+ channels represent an obvious target of seizure-induced plasticity. Gain of function mutations in the α subunit of Nav1.1 channels or the accessory β1 subunit

have been implicated in the inherited human epilepsy syndrome GEFS+; these mutations generally cause an increase in I_{Na}, the current mediated by Na^+ channels, either through slowed or incomplete voltage-dependent inactivation. In contrast, a significant loss of I_{Na} is seen in the progressive human epilepsy syndrome SMEI. This counterintuitive result may be explained by a selective loss of Na^+ channels in cortical interneurons, rather than in principal neurons, leading to diminished inhibition.

Acquired changes in I_{Na} in dentate granule cells (DGCs) have been seen after pilocarpine-induced SE, with voltage-clamp recordings showing a hyperpolarizing shift in I_{Na} activation coupled with a depolarizing shift in fast inactivation, producing a net increase in the 'window current,' or current activated at physiological potentials. Measurement of mRNA from microdissected dentate gyrus extracts, at dates postpilocarpine that were comparable to the physiological experiments, shows downregulation of Nav1.2 and 1.6 transcripts, along with the β1 accessory subunit. There does not appear to be any change in DGC I_{Na} current density corresponding to the decreased transcription of Nav subunits, but the loss of β1 transcription is possibly consistent with the depolarizing shift in I_{Na} inactivation.

An intriguing related question is whether ion channel plasticity in epilepsy affects the response to antiepileptic drugs (AEDs), most of which have been hypothesized to act through direct modulation of ion channels, especially Na^+ channels. Examination of tissue from both epileptic rats and humans undergoing temporal lobectomy has found that epilepsy diminished the inhibitory actions of carbamazepine (CBZ) on I_{Na}. Specifically, the reduction in rate of recovery from inactivation that CBZ induces under normal conditions is nearly absent in DGCs from epileptic tissue. The effect of CBZ in shifting I_{Na} voltage dependence in a hyperpolarizing direction, however, is maintained under epileptic conditions. These results suggest that changes to Na^+ channels in epilepsy render them less susceptible to AED actions, possibly contributing to medical intractability. However, it is unclear which of the actions of CBZ on I_{Na} are most important in reducing neuronal excitability. Another issue that limits interpretation of some in vitro studies is the relatively high concentrations of drug used to study biophysical actions, often an order of magnitude higher than clinically relevant concentrations seen in human cerebrospinal fluid. Nonetheless, studies of AED action in epileptic animals raise the important question of whether 'epileptic ion channels' might themselves be a different pharmacologic target than the native or heterologously expressed channels usually studied under normal conditions.

Ca^{2+} Channels

Upregulation of Ca^{2+} channel activity has been shown in experimental acquired epilepsy in a number of studies. This work began with the observation that during the chronic phase of epilepsy induced by pilocarpine, the proportion of 'bursting' (i.e., firing of multiple action potentials from a single short depolarizing current injection) CA1 hippocampal pyramidal neurons increased from <5% to nearly 50% of cells. Low-threshold T-type currents have been implicated on physiological and pharmacological grounds, with an increase in T-current density. When activated, this augmented T-current could mediate a depolarizing potential that promotes burst AP firing. In accord with prior work that had shown localization of low-threshold Ca^{2+} currents to the apical dendrites of pyramidal neurons, focal application of the T-channel blocker Ni^{2+} to the dendrites abolishes bursting, while application to the soma does not. It is interesting that this condition represents an acquired channelopathy confined to the apical dendrites, one of several examples to be discussed later. There has been no evidence thus far as to the mechanism underlying the upregulation of T current. Because the AED ethosuximide blocks T-channel activity, this work would suggest that ethosuximide, already used against absence epilepsy, might also be effective in temporal lobe epilepsy; however, there is no clinical evidence presently supporting this idea.

K^+ Channels

Bertil Hille commented in his classic textbook that K^+ channels were like the 'stops on an organ,' able to fine-tune neuronal excitability by their diverse biophysical properties. Somewhat surprisingly then, K^+ channel dysfunction has been underrepresented in genetic epilepsy, with only one syndrome (BFNC) clearly due to K^+ channel mutation. In experimental acquired epilepsy models, however, a number of changes in K^+ channel activity have been identified, some of which appear to be proconvulsive, while others appear to represent a homeostatic change.

An important milestone in the study of ion channel properties was the recognition that many ion channel species in pyramidal neurons are distributed in highly nonuniform somatodendritic patterns. The A-type (or transient) K^+ current was the first example, found to exist in pyramidal neuron dendrites in a density gradient pattern, with the apical dendrites containing a sevenfold higher density than the soma. The high dendritic density of rapidly activating Kv4.2 channels (the main channel type underlying the A-current in pyramidal neurons) reduces the amplitude of excitatory postsynaptic potentials, activity-evoked intracellular Ca^{2+} transients, and backpropagating dendritic action potentials. The dendritic location of Kv4.2 channels, while directly influencing integration of dendritic synaptic potentials, also hampers electrophysiological study. However, measurements of Kv4.2 channel expression in chronic epilepsy (i.e., tissue from

postpilocarpine rats) have shown that Kv4.2 channel number is diminished by about one-third, as quantified by both Western blotting and mRNA expression. The electrophysiological consequence of the loss of A-current is increased AP backpropagation in the dendrites, potentially allowing increased opening of other voltage-gated channels such as Ca^{2+} channels. An interesting additional finding is that the Kv4.2 channels that remain in this tissue are more phosphorylated at a site that is recognized by the extracellular stimulus-related kinase (ERK). Phosphorylation by ERK of Kv4.2 shifts the voltage-dependent activation of these channels to more depolarized levels, diminishing their activity. Thus, the Kv4.2 channel dysfunction seen in this model of chronic epilepsy is twofold: a loss of channel number, and downregulation of the channels that remained.

Whether or not changes in Kv4.2 function are a significant contributor to the epileptic phenotype remains to be seen. Despite its significant role in dendritic physiology, a knockout of Kv4.2 by itself does not appear to cause obvious seizures in the transgenic animals. One possible explanation for this observation is that there is upregulation of other Kv channels (i.e., non-Kv4.2) that can mediate transient A-type currents in Kv4.2 knockout mice; these currents, putatively mediated by the Kv1 family and localized to the cell soma or axon initial segment, may counteract the loss of dendritic Kv4.2 channels. Also, because Kv4.2 expression has been measured only in the chronic phase of epilepsy, it is unclear whether the loss of A-currents is a cause or a consequence of ongoing seizures. Indeed, one study has found that Kv4.2 mRNA expression was reduced by pentylenetetrazole-induced seizures alone, in the absence of established epilepsy.

Another K^+ channel modulated by seizures is the Kv2.1 channel that produces a delayed rectifier current. Unlike Kv4.2, Kv2.1 is localized to the soma and proximal apical and basal dendrites, and it appears to depress excitability during periods of repetitive action potential firing. Shortly following kainate-induced SE, several changes in the localization and biophysical properties of Kv2.1 channels occur. For example, their distribution on the somatic membrane transforms from clusters of ion channels to a more diffuse pattern, without a loss of overall density. Further, the voltage-dependent activation of I_K (the delayed rectifier current mediated in part by Kv2.1) shifts in a hyperpolarizing direction, potentially increasing I_K activation. These changes in Kv2.1 properties are mediated by glutamatergic stimulation followed by calcineurin-dependent dephosphorylation of a number of residues on Kv2.1 itself. These changes reflect a putative signaling pathway by which seizure activity can produce acute changes in ion channel properties. Unlike the changes seen in Kv4.2 with epilepsy, it would be predicted that upregulation of Kv2.1 activation would act in a homeostatic, anticonvulsant fashion. (It is not clear what the effect of declustered Kv2.1 channels would be on excitability.) Also, the changes in Kv2.1 were induced by SE, but were not assessed in animals after the development of epilepsy; thus, it was not determined if they persisted beyond the acute SE-related phase in the kainate model. Indeed, the declustering of channels is observed to gradually revert to near-control levels several hours following stimulation. However, these studies provided solid mechanistic evidence for the links between seizures and ion channel modifications, and lay the groundwork for investigation of these mechanisms in chronic epilepsy.

HCN Channels

Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels seem unlikely candidates for a pathogenic role in epilepsy. Originally, identified in the sinoatrial node as a key regulator of heart rate, they have since been found widely in brain, with the HCN1 subtype distributed primarily to neocortex and hippocampus, while the HCN2 subtype is found in subcortical regions such as thalamus. Recent evidence has implicated dysfunction of these channels in both genetic and acquired epilepsy. Genetic loss of function of HCN channels clearly causes epilepsy; knockout of the HCN2 channel produces a generalized epilepsy phenotype in rodents, while inbred rat strains with epilepsy demonstrate altered function of both HCN2 and HCN1 channels. It is unclear whether knockout of the HCN1 channel also produces an epileptic phenotype, although anecdotal evidence suggests that HCN1 knockout mice lack spontaneous seizures but show more severe seizures provoked by kindling or pilocarpine. To date, no human genetic epilepsy pedigrees have been associated with HCN channel mutation.

There is increasing evidence that acquired experimental epilepsy is associated with altered HCN channel function and expression. One of the first studies to make this association found an increase in I_h, the current mediated by HCN channels, in hippocampal pyramidal neuron somatic recordings after hyperthermia-provoked seizures. However, like Kv4.2 and T channels, HCN channels are predominantly localized to the apical dendrites of pyramidal neurons, so it was of particular interest that subsequent studies, measuring dendritic I_h, found that HCN channels show an acute loss of expression within the first week post-SE. This loss of expression is maintained in chronic epilepsy, and is associated with a hyperpolarizing shift in voltage-dependent gating that further downregulates I_h. (Since HCN channels are activated with hyperpolarization, a hyperpolarizing shift in activation reduces the amount of I_h present at resting potential.) Interestingly, when recurrent seizures post-SE are blocked with phenobarbital administration, the altered HCN channel gating reverts to normal, while the loss of HCN channel expression persists. This result

suggests that there are separate mechanisms of HCN channel downregulation in epilepsy, some clearly dependent on ongoing seizures, and not integral to epileptogenesis per se. Similar caveats may apply to other observed changes in ion channel function.

Changes in HCN channel function in epilepsy, at least for pyramidal neurons, represent another example of ion channelopathy confined to the dendrites, similar to that seen for A-type K^+ channels. The mechanisms underlying the loss of dendritic HCN and A-channel expression are unclear; although there is evidence that HCN1 channel transcription is chronically reduced following hyperthermia-provoked seizures, the rapid loss of dendritic HCN channels (with 24-h post-SE) suggests additional, probably posttranslational mechanisms. In pyramidal neurons, HCN channel downregulation produces neuronal hyperexcitability, although this is not as straightforward to demonstrate as it is for Na^+ and K^+ channels – given the sometimes conflicting influences of I_h on neuronal input resistance, time constant, and resting membrane potential.

$GABA_A$ Receptors

Blocking inhibition mediated by $GABA_A$ receptors ($GABA_A$Rs) reliably provokes seizures in in vitro and in vivo models of epilepsy. Thus, it would be expected that alterations of $GABA_A$Rs are well represented in genetic and acquired epilepsy. In fact, there are several reports of human pedigrees of generalized epilepsy associated with loss of function of various $GABA_A$R subunits. Good evidence also exists for acquired alteration of $GABA_A$Rs in experimental models. Because $GABA_A$Rs are composed of five subunits in varying combinations, numerous possibilities exist for altered $GABA_A$R function through differential up- or downregulation of its component subunits. A careful study of this phenomenon in the pilocarpine model has found that α1 and β1 subunit expression in dentate granule cells is decreased in the latent period prior to the onset of seizures, with increases in δ and ε subunits. These changes are maintained in the chronic phase of epilepsy and appear to contribute to increased Zn^{2+} sensitivity of $GABA_A$Rs. Because Zn^{2+} diminishes $GABA_A$R function, this change promotes hyperexcitability.

Contrasting findings with regard to the δ $GABA_A$R subunit have been seen using the pilocarpine model in mice. Immunohistochemistry in DGCs has found a diffuse loss of δ subunit labeling, beginning in the latent period postpilocarpine, and continuing into the chronic phase. Interestingly, δ subunit expression is increased in dentate gyrus interneurons. It is unclear how to explain the contrasting findings of these two studies; differing methods to measure $GABA_A$R subunit expression may contribute to these differences. However, the recent correlation of δ subunit-containing $GABA_A$Rs and extrasynaptic, tonic inhibitory currents suggests that these channels may mediate a component of GABAergic inhibition that is not subject to the phasic rundown shown by non-δ-containing receptors. Thus, the loss of δ subunits may constitute an additional mechanism by which selective changes in subunit expression could influence neuronal excitability through attenuation of a steady-state inhibitory current.

Downregulation of GABAergic function has also been seen in a model of perinatal hypoxia. While this model in itself does not produce epilepsy, it does produce persistent neuronal hyperexcitability, and this study is instructive for the mechanisms found to underlie altered inhibition. Acutely following a hypoxic episode in immature rats, evoked IPSCs in CA1 hippocampal pyramidal neurons are decreased. This effect is dependent both on Ca^{2+} influx through Ca^{2+}-permeable AMPA receptors, and activation of the serine-threonine phosphatase calcineurin. Correspondingly, calcineurin activity is increased postseizure and the phosphorylation of $GABA_A$R β2 and β3 subunits is also decreased (although it is not clear that these subunits are responsible for the decrease in IPSCs observed). This work points to signaling pathways, such as calcineurin, that might be acutely activated following status epilepticus. Identification of such mechanisms underlying the induction of ion channelopathy after a neural insult is a significant advance, for it opens the possibility of future therapeutic advances that might target these pathways. For example, phosphorylation signaling is an active area of clinical drug development, with numerous inhibitors of kinases and phosphatases either in preclinical testing, or in a few cases, already in clinical use (e.g., FK-506, an inhibitor of calcineurin used for immunosuppression in organ transplant). These agents are useful tools to test whether interruption of the signaling that underlies acquired channelopathy might prevent the ion channel alterations, and perhaps influence epileptogenesis as well.

Future Directions

The studies described here clearly demonstrate that experimental acquired epilepsy is associated with alterations in both voltage-gated and ligand-gated ion channel expression, including their biophysical properties. It is tempting to conclude that, as with genetic epilepsies, these changes in ion channel properties underlie the basis of neuronal hyperexcitability that produces seizures. But the situation with acquired epilepsy is not nearly so straightforward as with genetic epilepsy, and there are numerous challenges to be surmounted before we understand how *acquired* channelopathy contributes to epilepsy. While the genetic epilepsy literature shows that alteration of the properties of a single species of ion

channel is sufficient to cause a human epilepsy syndrome, the sheer number of ion channel changes observed in acquired epilepsy makes it unlikely that any one of them is causative on its own. The post-SE models used in experimental epilepsy induce a diffuse insult to the CNS that triggers widespread changes in neuronal function and viability. Associated with these changes in cell properties are multiple changes in ion channel function – some of which may contribute to epileptogenesis, some which may cause hyperexcitability but which may not influence epileptogenesis, and some of which may be homeostatic in nature, opposing the induced hyperexcitability.

To better understand how acquired channelopathy contributes to the induction and maintenance of the epileptic state, we will need to study ion channel changes at a more comprehensive level of detail than has often applied. One issue is that the course of epileptogenesis in the different experimental models is still to be detailed and 'validated'; thus, an assumption that a given ion channel change is occurring during the latent phase (and may be contributing to epileptogenesis) may be unwarranted. Measuring the onset of spontaneous seizures, using chronic video-EEG recordings, is a time-consuming but important step to determine the true extent of the latent period and to identify ion channel changes that are relevant.

Another question is whether ion channel changes observed in chronic epilepsy are independent of ongoing seizures. This point can be tested with periods of AED treatment after epilepsy is established. A change in ion channel properties that occurs before the onset of seizures and persists after seizure suppression is a possible contributor to epileptogenesis, while those that revert to normal after AED treatment are likely to be a result of the epileptic activity – although they may be involved in the maintenance of the epileptic state by promoting hyperexcitability. Another issue that often remains unproven in experimental epilepsy is whether alteration of a given ion channel actually causes hyperexcitability. While it might be assumed that a downregulation of K^+ channel activity or an upregulation of Na^+ activity is necessarily proconvulsive, counterintuitive examples abound – for example, the loss of I_{Na} in most cases of SMEI, and a recent description of a gain of function in a Ca^{2+}-activated K^+ channel in a genetic epilepsy pedigree.

Finally, evidence for a causative role of ion channelopathy in epileptogenesis will be strengthened by demonstration that reversing the channelopathy modifies the course of epileptogenesis. A recent exciting example of this approach was illustrated using gene therapy to increase expression of downregulated $GABA_AR$ subunits, delaying the onset of spontaneous seizures post-SE. Continuing advances in understanding the molecular mechanisms underlying acquired channelopathy offer the promise that similar benefits might result from pharmacological blockade of signaling intermediaries, such as calcineurin. Such clinical applicability, of course, remains the ultimate goal of understanding the process of epileptogenesis – the hope of intervening to prevent epilepsy after an acute insult to the CNS.

Channelopathies in Epilepsy

Introduction

Genetic factors are thought to account for approximately 70% of the risk of developing epilepsy. Although the genes responsible for the vast majority of this risk are not known, an increasing number of mutations in single genes have been identified in rare families. These families generally exhibit autosomal dominant transmission with high penetrance. Most of the genes identified in these families encode ion channels. This finding provides an unparalleled insight into possible mechanisms of sporadic epilepsy, which has – in many cases – very similar clinical features as monogenic epilepsy. The role of these 'channelopathy' genes furthermore suggests that inherited variation in ion channel genes may account for much of the heritability of common forms of epilepsy, although this possibility is yet to be proved.

This overview of the 'epileptic channelopathies' briefly considers how mutations can affect ion channel biogenesis and function, describes some of the syndromes that have been identified in association with such mutations (see Figure 1, Table 1), and then considers each of the main ion channels affected. We have, where possible, attempted to 'explain' the clinical phenotype on the basis of what is known of the normal function of the ion channels and of the mechanisms of the mutations.

Background

How do Ion Channel Mutations Affect Brain Function?

In principle, mutations can affect almost every step of gene expression – from transcription through ion channel function, including translation, assembly, trafficking from the endoplasmatic reticulum to the normal location in the neuronal membrane, gating, and permeation. However, mutations in promoter sequences have not yet been identified (although this fact could simply reflect our poor knowledge of promoter sequences). Mutations have been identified in introns and exons, and can consist of single nucleotide changes, or deletions or insertions. Many mutations lead to frameshifts or splice site alterations that generally result in aberrant sequences terminating in premature stop codons. Missense mutations in coding sequences can substantially alter channel properties if they are located in strategic positions (such as voltage-sensing or pore-forming parts of the channel, or regions necessary for correct folding of the peptide, or interaction with accessory subunits or other proteins).

Most attempts to understand the consequences of missense gene mutations have relied on heterologous expression in nonneuronal systems, although mouse knock-in models are providing invaluable insights. Intuitively, seizures might be expected to result from gain-of-function mutations of Na^+ and Ca^{2+} channels or loss-of-function mutations of Cl^- channels such as associated with $GABA_A$ receptors (which mostly mediate inhibitory neurotransmission), or some types of K^+ channels (which set the resting potential and terminate action potentials). Some channelopathies indeed conform to this assumption, but there are some notable exceptions, as are discussed below. Furthermore, this simple view of ion channels cannot account for the differences in phenotypes associated with distinct mutations affecting any one class of ion channels.

The link from ion channel mutation to clinical manifestation can be complicated for a variety of reasons.

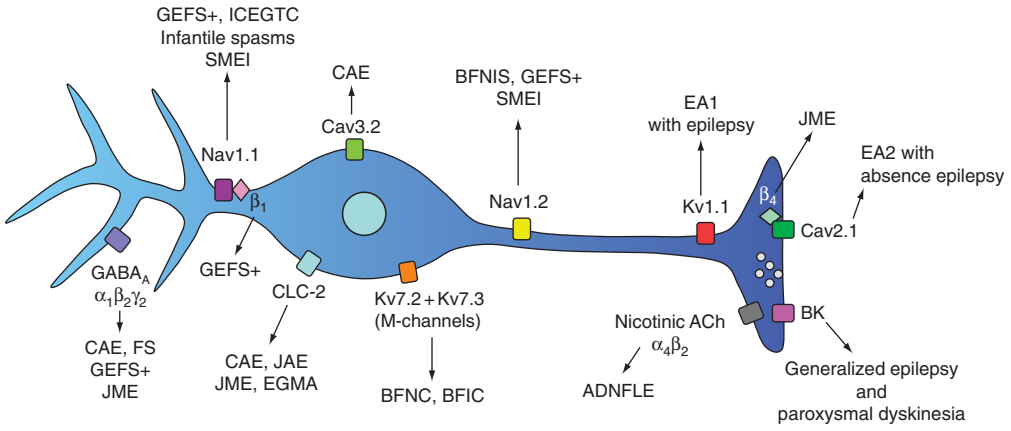

Figure 1 Summary of ion channels whose mutations cause epilepsy in some families.

Table 1 Overview of ion channels and modulating molecules whose mutations are associated with epilepsy

Channel type	*Gene*	*Protein*	*Clinical phenotype*
Voltage-gated			
Na^+ channels	SCN1A	α subunit of Nav1.1	• GEFS+ • ICEGTC • Infantile spasms • SMEI
	SCN2A	α subunit of Nav1.2	• BFNIS • GEFS+ • SMEI
	SCN1B	β_1 subunit	• GEFS+
K^+ channels	KCNQ2 KCNQ3	M-type K^+ channel subunits	• BFNC with or without myokymia • BFIC
	KCNA1	α Subunit of Kv1.1	• EA1 with epilepsy[a]
	KCNMA1	α Subunit BK channels	• Generalized epilepsy and paroxysmal dyskinesia[a]
Ca^{2+} channels	CACNA1A	α_{1A} Subunit of Cav2.1 (P/Q-type)	• EA2 with absence epilepsy[a]
	CACNB4	β_4 Subunit	• JME
Cl^- channels	CLCN2	CLC-2	• CAE • EGMA • JAE • JME
Ligand-gated			
Nicotinic ACh receptors	CHRNA2	α_2 Subunit	• ADNFLE
	CHRNA4	α_4 Subunit	
	CHRNB2	β_2 Subunit	
$GABA_A$ receptors	GABRA1	α_1 Subunit	• CAE • JME
	GABRG2	γ_2 Subunit	• CAE • FS • GEFS+
Molecules with influence			
on Ca^{2+} channels	EFHC1	EFHC1	• JME
on K^+ channels and/or AMPA receptors	LGI1	LGI1	• Autosomal dominant temporal lobe epilepsy with auditory features

[a]Mixed clinical phenotypes with epilepsies and nonepileptic paroxysmal neurological disorders.

Ion channels often display precise developmental and regional, cellular and subcellular expression patterns, and can undergo differential splicing and post-translational modifications. These factors crucially affect how mutations change the properties of neurons and neuronal networks. For instance, it has been argued that loss-of-function mutations of one Na^+ channel may cause epilepsy because it plays an especially important role in inhibitory interneurons. Among other factors that can distort the relationship between the molecular consequence of the mutation and its associated phenotype is that different splice variants of a given ion channel can alter its properties, and that the same channel can have different roles depending on the accessory subunits with which it assembles. Mutations can also have unexpected effects on the expression of other channels with similar or different properties.

Clinical Phenotypes in the Epileptic Channelopathies

Many of the epileptic channelopathies that have been identified exhibit clinical features indistinguishable from common sporadic idiopathic generalized epilepsies. The latter include childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME), and epilepsy with grand mal seizures on awakening (EGMA). Only a very small proportion of patients with these syndromic diagnoses have been shown to have mutations in the known epilepsy genes.

Among other syndromes that have been identified in patients with ion channel mutations are various types of benign neonatal or infantile seizures, which tend to resolve spontaneously. When there is demonstrated familial clustering, these syndromes have been named benign familial neonatal convulsions (BFNC), benign familial infantile seizures (BFIS), and the intermediate condition benign familial neonatal–infantile seizures (BFNIS). Again, making a diagnosis of benign neonatal or infantile convulsions does not predict that a mutation in one of the candidate ion channels associated with the familial disorders will be identified. Some channelopathies are associated with a very pleomorphic presentation, suggesting a strong influence of modifying genes or environmental factors. For example, patients with generalized

epilepsy with febrile seizures plus (GEFS+) carrying the same mutation exhibit highly variable forms of generalized epilepsy with respect to seizure type and severity, but with the common factor that they tend also to exhibit febrile seizures in childhood persisting beyond the age of 6 years. At the more severe end of this spectrum is severe myoclonic epilepsy of infancy (SMEI, Dravet syndrome), which is characterized by refractory and fever-sensitive generalized clonic, tonic–clonic or unilateral seizures that usually start in the first year of life, tend to worsen, and are frequently accompanied by cognitive deterioration. Clinically very similar, except for the absence of myoclonic seizures, is intractable childhood epilepsy with frequent generalized tonic–clonic seizures (ICEGTC). A diagnosis of SMEI carries a high probability that the affected child carries a mutation in the Na^+ channel gene SCN1A.

Finally, the rare syndrome of nocturnal frontal lobe epilepsy presents with focal motor seizures, often arising from sleep. If inherited in an autosomal dominant manner (ADNFLE), this disorder should prompt screening for a mutation in one of the nicotinic receptor subunit genes.

Methods

Gene Identification

Many genes underlying monogenic epilepsy have been identified by linkage mapping in large kindreds that exhibit Mendelian inheritance, followed by sequencing of genes in the interval thus defined. Among obstacles frequently encountered are difficulties in ascertainment, phenotypic variability, and the occurrence of sporadic epilepsy in the background population. Almost all epileptic channelopathies thus elucidated are transmitted in an autosomal dominant manner. It is not clear whether many recessively transmitted channelopathies remain to be discovered.

Although mutations in ion channel genes have, for a long time, been considered strong candidates to cause epilepsy, there are several hundred genes in this family, most of which have not been implicated in epilepsy. Nevertheless, the discovery of mutations in some ion channel genes has prompted sequencing of closely related genes in families or individuals with epilepsy, with some success.

Functional Expression

Some mutations are predicted to disrupt ion channel synthesis, for instance because they lead to premature truncation of the peptide. However, many other mutations alter one or a few amino acids, and in this situation heterologous expression combined with voltage clamp electrophysiology can shed light on the consequences of the sequence change for ion channel function. Briefly, this method consists of expressing the mutant ion channel gene, together with necessary auxiliary proteins, in cells grown in vitro. Among cells that have been used are oocytes of the Xenopus frog, cell lines such as human embryonal kidney (HEK) cells, and primary cultures of rodent neurons (although these tend to be more difficult to transfect). The ion channel kinetics can be studied by recording the current passing across the membrane in response to imposed voltage steps or agonist applications. Taken together, information about total current density and the behavior of individual channels provide a reasonably complete description of channel properties, which can be compared with properties of wild-type channels. Thus, it is generally possible to infer whether the channel mutation is likely to give rise to a loss or gain of function. Coexpression of the mutant channel with wild-type channels can also shed light on how mutations are likely to interact with the unaffected allele in heterozygous individuals.

Animal Models

Since ion channels may have very different roles in different neurons, and normally exhibit highly diverse patters of expression in the brain, it is not always possible to extrapolate from altered ion channel function to altered circuit function. Mouse models have been generated for several mutations, either by knocking out the orthologous ion channel gene (for nonsense or loss-of-function mutations) or by knocking in a missense mutation. Such animals can be studied with video and EEG for spontaneous seizure pattern, and with provocation methods (for instance with chemoconvulsant administration to look for altered seizure threshold). They can also be sacrificed for acute brain slice electrophysiology, which can shed light on changes in synaptic properties and neuronal excitability. Although these are very powerful methods, species differences can hinder a clear explanation for why some mutations predispose to seizure occurrence.

Results

Voltage-Gated Ion Channels

Sodium channels

Voltage-gated Na^+ (Nav) channels are composed of a pore-forming α-subunit, a large trans-membrane protein with four repeated domains, and accessory β-subunits (β_{1-4}), which influence the channel's cell surface expression and its biophysical properties. Five of the nine mammalian α-subunit genes are expressed in the brain (SCN1A-3A, SCN5A, SCN8A), with differential regional and subcellular expression patterns.

SCN1A mutations

A large number of inherited and de novo heterozygous mutations in SCN1A (chromosomal location 2q24) have been identified in GEFS+, SMEI, and ICEGTC.

Mutations associated with GEFS+ tend to be missense, whereas those associated with SMEI also include nonsense or frameshift mutations.

Functional expression studies of GEFS+ mutant channels have not yielded an unambiguous indication whether the disease results from gain- or loss-of-function. Some mutations appear to slow Na^+ channel inactivation, or alter its voltage dependence, resulting in an increase in Na^+ current. Other effects of GEFS+ mutations, such as depolarization of the activation threshold, slowed recovery from inactivation, and decreased current density, point instead to a reduction in Na^+ current. Although distinct mutations have different effects, some of the inconsistencies may also reflect the limitations of heterologous expression systems in which these channel properties are analyzed, which do not fully capture the behavior of channels in their native environment.

The fact that most mutations identified in association with SMEI result in disruption of one allele of SCN1A argues strongly for loss of Na^+ channel function in this disorder. Although several of the missense mutations also identified in this disorder have been shown to affect a broad range of biophysical properties, haploinsufficiency is the commonest finding in SMEI. This feature is perhaps unexpected, because loss of Na^+ currents would be expected to cause neuronal hypoexcitability. A possible resolution of this paradox, suggested by a recent analysis of a mouse SCN1A knock-out mutant, is that inhibitory interneurons, unlike principal cells, fail to tolerate a reduction in gene dosage. Thus, the product of the wild-type allele, and of genes coding for related Nav channels, is not sufficient to allow efficient spiking, resulting in a net increase in neuronal network excitability.

SCN2A mutations

Missense and nonsense mutations of SCN2A (chromosomal location 2q23-q24) have been associated with BFNIS, GEFS+, and a SMEI-like phenotype. Again, it has proved difficult to establish a consistent pattern of biophysical consequences for the different mutations identified.

SCN1B mutations

The β_1 subunit of Nav channels consists of a single membrane-spanning protein with a large N-terminal extracellular domain. β-Subunits increase the functional expression of α-subunits when coexpressed. They also accelerate the inactivation of sodium currents by interactions between their immunoglobulin-like fold and α-subunits. Only a few mutations in the SCN1B gene (chromosomal location 19q13) coding for β_1-subunits have been reported in GEFS+. Since β_1-subunits normally help to traffic Na^+ channels to the membrane, and also modulate inactivation kinetics, it is again difficult to establish with certainty whether epilepsy results from a net increase or decrease in Nav function.

Potassium channels

K^+ channels are a very large and heterogeneous group of ion channels, only a few of which have been implicated in monogenic epilepsy.

KCNA1 mutations

KCNA1 encodes the α-subunit of Kv1.1 channels. One α-subunit consists of 6 transmembrane segments with a voltage-sensor (S4) and the pore-loop between S5 and S6, and is homologous to each of the four repeated domains of Na^+ channels. Four α-subunits (which can be different members of the Kv1 family) assemble together with four β-subunits to constitute a complete channel, and the identities of the subunits determine its biophysical properties. Kv1.1-containing channels are mainly expressed in the axons of neurons throughout the nervous system, where they contribute to membrane potential stabilization and repolarization after action potentials. They are also thought to curtail the presynaptic depolarization that drives Ca^{2+} channel opening and neurotransmitter release.

Heterozygous missense KCNA1 mutations (chromosome location 12p13.32) cause autosomal dominant Episodic Ataxia type 1 (EA1), which can be accompanied by partial or generalized seizures. The mutations cause loss-of-function, although some have also been shown to interfere with inactivation. It remains unclear why only some of the mutations are associated with epilepsy.

KCNQ mutations

Voltage-dependent Kv7.1-Kv7.5 channel α-subunits are encoded by KCNQ1–5. Kv7.2 and Kv7.3 co-assemble to form channels that underlie the so-called 'M' current, which is modulated by muscarinic acetylcholine receptors, and which contributes to the neuronal input resistance at resting membrane potential. Heterozygous mutations in KCNQ2 or KCNQ3 (chromosomal locations 20q13.3 and 8q24) occur in BFNC, and generally decrease current density in heterologous expression. Since the affected individuals are heterozygous, only relatively small degrees of loss of function are sufficient to give rise to this syndrome. It remains unclear why BFNC usually remits spontaneously after a few weeks of age.

KCNMA1 mutations

KCNMA1 (chromosomal location 10q22) encodes the BK (or SLO1) channel. BK is a voltage- and Ca^{2+}-activated K^+ channel with a large ('big,' hence BK) conductance. Although BK shares features in common with other voltage-dependent channels, it has two special features:

each α-subunit consists of seven instead of six transmembrane segments, and the cytoplasmic-terminal contains a large Ca^{2+}-binding tail domain. BK channels are widely expressed in the brain and present on cell bodies, dendrites, and presynaptic terminals, where they contribute to the repolarizing phase of action potentials and the early part of the afterhyperpolarization.

A heterozygous missense mutation in KCNMA1 was found to cause generalized epilepsy and paroxysmal dyskinesia. Surprisingly, the mutation has a gain-of-function effect, increasing the Ca^{2+} sensitivity of the channels, which would be expected to decrease firing and neurotransmitter release. Among possible explanations for the neurological phenotype is that faster repolarization could minimize Na^+ channel inactivation, or facilitate the opening of I_h channels, which have a pacemaker function in some neurons. Either or both of these effects could theoretically allow neurons to fire at higher frequencies.

Calcium channels

Ca^{2+} channels have the same overall structure as Na^+ channels, with one pore-forming α_1-subunit containing four domains, each consisting of six transmembrane segments that resemble voltage-gated K^+ channel subunits. Ca^{2+} channels, however, tend to have slower kinetics, and the outer pore selectivity filter makes them permeable to Ca^{2+} ions. Accessory β-, $\alpha_2\delta$-, and (in some cases) γ-subunits influence their biophysical properties and surface expression. Nine different α_1-subunits occur, and are grouped into three classes (Cav1–3) with distinct biophysical and pharmacological properties, and different regional, cellular and subcellular expression patterns.

CACNA1A mutations

CACNA1A encodes the α_{1A}-subunit of Cav2.1 channels (also known as P/Q-type channels). Apart from the cerebellum (where they are abundantly expressed in the cell bodies and dendrites of Purkinje and granule cells), Cav2.1 channels are predominantly expressed on presynaptic terminals throughout the nervous system, where (together with Cav2.2 and, to a lesser extent, Cav2.3) they mediate the Ca^{2+} influx that triggers neurotransmitter release. Heterozygous mutations in CACNA1A (chromosomal location 19p13.2–p13.1) are associated with familial hemiplegic migraine, spino-cerebellar ataxia type 6, and episodic ataxia type 2 (EA2). Some patients with EA2 also suffer from absence seizures. Functional expression studies reveal loss-of-function effects of the mutations associated with EA2 and absence epilepsy.

CACNB4 mutation

To date, only one premature stop codon mutation in CACNB4 (chromosomal location 2q22–23, encoding the cytoplasmic β_4-subunit) has been identified in association with JME. This mutation, too, is expected to have a loss-of-function effect.

How does a reduction in Ca^{2+} current cause absence epilepsy? Interestingly, homozygous mutations in CACNA1A and CACNB4 have been identified in several inbred mouse strains, which have in common frequent spike-wave seizures and gait ataxia. Some indirect evidence obtained in these mice suggests that the balance of excitatory and inhibitory neurotransmission within the thalamocortical loop may be disturbed, leading to absence seizures. Compensatory changes in expression of Cav2.2 (N-type) and Cav3.x (T-type) channels may also contribute to seizure initiation. The involvement of Cav3.2 in absence epilepsy is, furthermore, supported by the finding that CACNA1H mutations occasionally occur in association with CAE. Some of these mutations have been shown to confer gain-of-function effects, in line with the prominent role of Cav3 channels in intrinsic oscillations of thalamic neurons. However, since the mutations do not cosegregate with CAE within families with affected individuals, CACNA1H may actually be a susceptibility locus that interacts with other genetic or environmental factors to determine the risk of developing this form of epilepsy.

Chloride channels

CLC channels are unrelated to other voltage-gated channels, and have a dimeric structure. Five of the nine members of the CLC family are expressed in the CNS. Although CLC-2 encoded by CLCN2 is widely present in the brain, the roles of this channel in neuronal function are poorly understood. The channels are modulated by membrane potential, internal Cl^- concentration, and pH, and mediate an inwardly rectifying current.

CLCN2 mutations

Three heterozygous CLCN2 (chromosomal location 3q26) mutations have been identified in association with different forms of idiopathic generalized epilepsy, including CAE, JAE, JME, and EGMA. Although two mutations resulted in nonfunctional channels, the third missense mutation has been reported to have a gain-of-function effect (although this report has been disputed). A possible explanation for epilepsy in association with loss of CLC-2 function is that the neuronal capacity to regulate internal chloride is impaired, thereby interfering with $GABA_A$ receptor-mediated inhibition.

Ligand-Gated Ion Channels

Ligand-gated ion channels (or ionotropic receptors) generally open when a specific neurotransmitter binds to an extracellular domain of the receptor/channel complex.

The channels implicated in epilepsy all belong to the nicotinic family, which are pentameric; each subunit has four transmembrane segments (termed M1-M4) with M2 contributing to the ion-conducting pore.

Nicotinic acetylcholine receptors

Neuronal nicotinic acetylcholine receptors (nAChRs) are either homo- or heteropentameric. The heteropentameric channels are composed of α_{2-6} and β_{2-4} subunits with an $(\alpha_x)_2(\beta_y)_3$ stoichiometry. A common subtype in the brain is $\alpha_4\beta_2$, with predominant expression in the thalamus and cortex. These channels have a high affinity for acetylcholine and nicotine, and are permeable to Na^+ and (to a lesser extent) Ca^{2+} ions. Because of predominant presynaptic expression, neuronal nAChRs are thought to modulate neurotransmitter release, but how they affect neuronal networks remains poorly understood.

CHRNA2, CHRNA4, and CHRNB2 mutations

Heterozygous mutations in the CHRNA2, CHRNA4, and CHRNB2 genes have been identified in about 10% of patients suffering from nocturnal frontal lobe epilepsy (NFLE), most commonly when this is transmitted in an autosomal dominant fashion (ADNFLE). Seven mostly missense mutations have been reported in CHRNA4 (chromosomal location 20q13) encoding the α_4-subunit and CHRNB2 (chromosomal location 1q21) coding for the β_2-subunit, whereas only one mutation has been reported so far for CHRNA2 (chromosomal location 8p12.3–8q12.3) which codes for the α_2-subunit. Overall, these mutations mostly affect the transmembrane segment M2 which contributes to the ion pore. However, the functional consequences of the different mutations are highly diverse, with different effects on Ca^{2+} dependence and Ca^{2+} permeability, and also opposite effects on the apparent acetylcholine affinity or desensitization kinetics. It is therefore difficult to identify a single common biophysical feature that could point to a net loss- or gain-of-function. The situation is further complicated by the various possible stoichiometries that can potentially exist if the affected subunit is substituted by wild type or other subunits. Mouse knock-in models have been generated for several ADNFLE mutations. Although homozygous mutant mice exhibit spontaneous and/or nicotine-evoked seizures and, in some cases, dystonic posturing, the neural circuits mediating these phenomena are not clear. Thus, a mechanistic explanation for epilepsy in association with nicotinic receptor mutations is still elusive. Why these nicotinic receptor-associated seizures selectively originate from the frontal lobe, and why they tend to occur during light sleep, remain to be explained.

$GABA_A$ receptors

$GABA_A$ receptors are heteropentameric and share many structural features with nicotinic receptors, although they are selectively permeable to Cl^- and, to a lesser extent, HCO_3^-. There are 16 different subunits (α_{1-6}, β_{1-3}, γ_{1-3}, δ, ε, π, and θ), with channels composed of $\alpha_1\beta_2\gamma_2$ being the most abundant in the brain. $GABA_A$ receptors open upon GABA-binding and permit chloride ions to flow across the cell membrane. This channel opening results in shunting of membrane currents as well as in a membrane potential change, the polarity of which depends on the intracellular Cl^- concentration; the intracellular Cl^- concentration generally decreases with development, making most GABAergic synapses hyperpolarizing in adult neurons. The receptor kinetics, as well as their sensitivity to drugs and endogenous modulators such as zinc and neurosteroids, depend on the subunit composition of the channel. $GABA_A$ receptors are widely expressed in the CNS, with predominant postsynaptic localization on cell bodies and dendrites where they mediate phasic inhibition. Extrasynaptic $GABA_A$ receptors have also been identified, which mediate tonic inhibition of neuronal activity.

GABRG2 and GABRA1 mutations

Heterozygous mutations in GABRG2 (chromosomal location 5q32–34) coding for the γ_2 subunit, have been shown to cause GEFS+, CAE, and febrile seizures. The missense mutations all lead to loss-of-function, although through different molecular mechanisms. Heterozygous mutations in GABRA1 (chromosomal location 5q34) encoding the α_1 subunit have also been found in association with autosomal dominant JME and a sporadic form of CAE. These also result in loss-of-function.

A reduction in functional $GABA_A$ receptors leads to impaired neuronal inhibition, favoring the occurrence of seizures. A recent experimental study has suggested that temperature-dependent impairment in membrane trafficking of the γ_2 subunit may explain, at least in part, why febrile seizures occur.

Molecules Modulating Ion Channels

Only two of the genes identified as causing relatively 'pure' epilepsy do not encode ion channels.

EFHC1

The EFHC1 gene encodes a protein also called EFHC1, which contains an EF-hand motif which is able to bind Ca^{2+} ions. Missense mutations in the EFHC1 gene have been identified in JME. Interestingly, EFHC1 is co-localized with Cav2.3 (R-type) Ca^{2+} channels, which contribute to the generation of neuronal afterdepolarization and bursting, and to Ca^{2+} influx in dendrites and presynaptic terminals. Furthermore, wild-type EFHC1 has been shown to increase Cav2.3 currents and to enhance apoptosis in vitro, while the mutations prevent these effects. A possible explanation linking EFHC1

mutations and epilepsy is that reduced apoptosis interferes with the normal elimination of neurons during development, thereby leading to hyperexcitable circuits. This proposal remains speculative.

LGI1

Leucine-rich glioma inactivated gene 1 (LGI1, chromosomal location 10q24) is a secreted non-ion channel protein that is mutated in autosomal dominant lateral temporal lobe epilepsy (ADLTLE, also know as autosomal dominant partial epilepsy with auditory features, ADPEAF). This unusual syndrome differs from other forms of temporal lobe epilepsy in that seizures can be precipitated by auditory stimuli or accompanied by auditory hallucinations. Two cellular mechanisms that could possibly relate mutant LGI1 to seizure generation have been proposed, both involving ion channel modulation. First, wild-type LGI-1 has been suggested to modulate the fast inactivation of K^+ channels composed of Kv1.1, Kv1.4, and Kvβ1 subunits. ADLTLE-associated mutant LGI-1, in contrast, appears to be incapable of slowing rapid inactivation, resulting in K^+ channels that inactivate more rapidly. This feature could, in turn, result in excessive presynaptic Ca^{2+} influx and neurotransmitter release, favoring seizure generation. This hypothesis is problematic because fast inactivation takes place on the cytoplasmic aspect of Kv channels, and yet LGI-1 is mainly extracellular. Second, wild-type LGI1 has been reported to increase the surface expression of excitatory AMPA-type glutamate receptors, via an interaction with the transmembrane adhesion protein ADAM22. As mutant LGI1 appears not to be able to bind ADAM22, this mutation could result in a decrease in excitatory AMPA currents. How this effect could result in epilepsy remains unclear, let alone why the seizures have auditory features.

Conclusion and Directions for Future Research

The list of ion channels mutated in epilepsy will, no doubt, continue to grow. Two main challenges for future research stand out. First, although 'explaining' epilepsy is reasonably straightforward in a few cases (for instance for the $GABA_A$ receptor mutations), it remains difficult to relate the molecular lesion to the syndrome for many other ion channels. Progress will require a detailed understanding of brain physiology, and benefit from mouse models of monogenic disease. Second, the monogenic epilepsies remain extremely rare, but idiopathic epilepsy is very common and shows strong heritability. The ion channel genes are obvious candidate susceptibility factors, and some progress has been made in identifying CACNA1H as one quantitative trait locus. To what extent subtle genetic variants in other ion channel genes, inherited in combination, account for the bulk of idiopathic epilepsy, remains to be determined.

Intrinsic Properties of Neocortical Neurons Relevant to Seizure Discharges: The Lesson of Epileptogenic Channelopathies

G Avanzini, Istituto Nazionale Neurologico C. Besta, Milan, Italy

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptic seizures are the result of excessive discharges arising in a population of neurons with altered excitable properties. These alterations are relevant to epileptic discharge when they involve a critical mass of hyperexcitable cells in highly synchronized activities. Most epileptic seizures are due to discharges generated in the cerebral cortex (neocortex) and hippocampal structures (also referred to as the paleocortex), although subcortical structures may also be involved. Here, the neocortical cell properties relevant to epileptic discharges are discussed.

Investigations in experimental animals have demonstrated that a number of changes in cell excitability can lead to the generation of epileptic discharges. An understanding of these changes, and in particular the pathways through which expression of gene mutations give rise to these changes, will help us understand the bases for many human epilepsies. Investigations in experimental preparations focusing on neurophysiological–biomolecular analysis of genetically determined structure–function alterations in ligand and voltage-gated channels have further advanced our understanding of the cell mechanisms responsible for excessive excitability.

Background

Excitable Properties of Nerve Cell Membrane

The lipid bilayer of the cytoplasmic membrane of nerve cells is largely impermeable to ions. Neuron excitability depends on Ion movements across the cell membrane through selective gates, schematically represented in **Figure 1(a)** The sodium (Na^+)–potassium(K^+) pump transports Na^+ from the intracellular to the extracellular compartment and K^+ in the opposite direction, in a ratio of 3:2. As Na^+ and K^+ are both monovalent, the result of Na^+–K^+ pump activity is membrane polarization, with the intracellular compartment becoming more negative. Under resting conditions, the difference between extra- and intracellular potentials (resting membrane potential) can be measured by means of a suitable electrode; its value is about −70 mV (**Figure 1(b)**, green lines). The energy required for transmembrane Na^+–K^+ ion transport is provided by adenosine triphosphate (ATP) molecules, hence the term Na^+–K^+ ATP pump.

Ion movements through the voltage-sensitive and the ligand-activated channels are simply due to electrostatic forces and the different ion concentrations between the extra- and intracellular compartments (electrochemical gradient), and therefore do not require an energy supply. Ionic movements through these gates (which are selectively permeable to specific ions) generate transient positive (depolarizing) or negative (hyperpolarizing) changes in membrane potential that determine cell excitability. When a channel opens, the type of ion to which it is selectively permeable moves passively on the basis of its electrochemical gradient until membrane potential attains the specific equilibrium potential for that ion. As the intracellular/extracellular Na^+ concentration gradient can be actively reconstituted by the Na^+–K^+ ATP pump, it can be said that ionic pumps create and maintain the resting membrane potential that is the prerequisite for excitation, whereas the ionic currents flowing through the channels are the main determinants of an excitable state.

The examples in **Figure 1(a)** refer to the Cl^- channel associated with the γ-aminobutyric acid (GABA) subtype A receptors (blue) and the voltage-activated Na^+ channel (red).

As a result of the extraordinary advances that have been made in molecular biology, we can now correlate the function and structure of ion channels, which are hetero-oligomeric membrane proteins typically consisting of 2–6 subunits, each subunit containing transmembrane segments that are assembled in a variable number of domains. The identification of the molecular structure of the various subunits and their corresponding coding genes has revealed a surprising multiplicity of distinct subunits whose assembly can lead to a great variety of channel subtypes with different properties. One experimental approach that has greatly contributed towards defining channel structure–function relationships is to express the channel constituents into elementary preparations – such as *Xenopus* oocytes, cell lines, or cultured neurons. This combined neurophysiological and biomolecular approach has made it possible to characterize the genetically determined alterations in intrinsic excitable properties that are responsible for human epilepsies.

Epileptogenic Alterations in Excitable Neuronal Properties

The role of ion channels in epileptogenesis has been recognized since the 1960s, when it was shown that

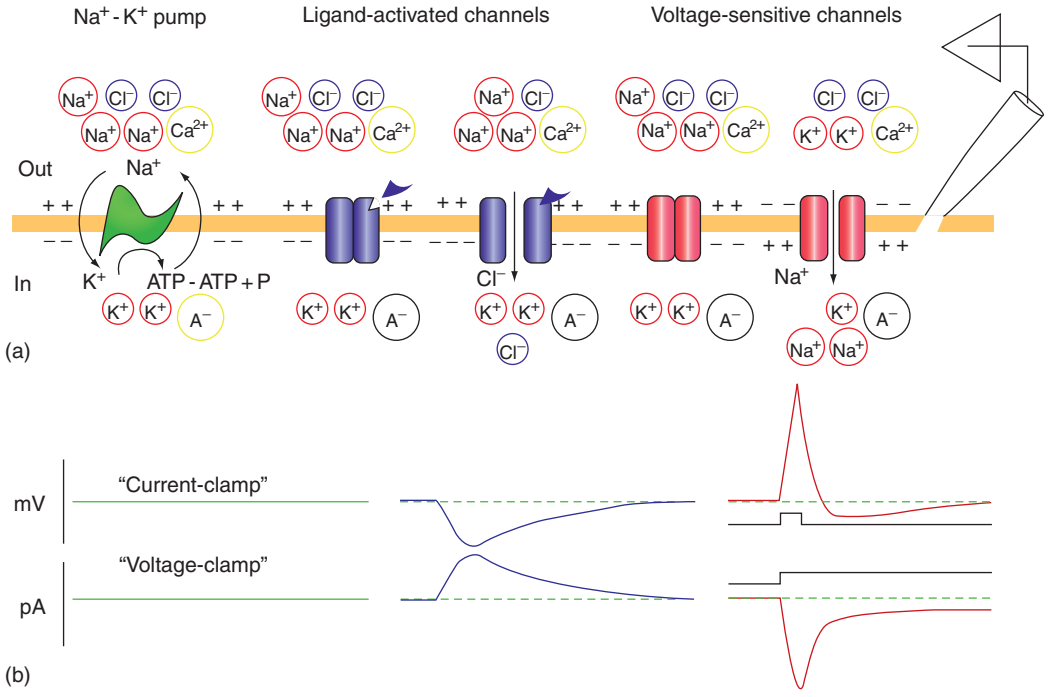

Figure 1 (a) Schematic representation of the cell membrane with Ionic pumps, ligand and voltage gated channels. The membrane is orange, and *out* and *in*, respectively, designate the extracellular and intracellular compartments. The main types of membrane gates are ion pumps (green), ligand-gated channels (blue) and voltage-gated channels (red). Ion movements across the membrane gates determine membrane potential and its changes relevant to neuron excitability. GABA receptors are key components of the inhibitory synapse between a presynaptic terminal of an inhibitory interneuron and a postsynaptic neuron. The inhibitory GABA neurotransmitter released from the presynaptic terminal binds postsynaptic receptors, which form a pore portion that is selectively permeable to either Cl^- (the $GABA_A$ subtype receptor) or K^+ (the $GABA_B$ subtype receptor). In the example shown in (a), the GABA-receptor interaction leads to a conformational change in the pore portion of the $GABA_A$ receptor that allows Cl^- to flow through it. At resting or positive-to-resting membrane potential, the Cl^- electrochemical gradient drives Cl^- from the extracellular to the intracellular compartment, thus leading to a negative-going change in membrane potential (b, upper blue trace) that represents the $GABA_A$ component of the inhibitory post-synaptic potential (IPSP). If the membrane potential is kept constant by means of voltage clamping, the time-course of the Cl^- current can be shown (b, lower blue trace). As Cl^- equilibrium potential is only slightly more negative than the resting potential, the ionic current has a limited amplitude. The Na+ permeable voltage-gated channel is shown in red. Depolarizing current pulses (b, black traces) open the channel and allow Na^+ to enter; as more Na^+ enters the intracellular compartment, the more the membrane depolarizes, thus putting a larger number of channels in the open conformation. This incremental depolarization (recorded by the microelectrode-b, upper red trace) creates the rising arm of the action potential. Once again, voltage clamping makes it possible to analyze the kinetics of the inward Na^+ current (b, lower red trace), which depends on its highly effective electrochemical driving force, its very positive equilibrium potential (around +60 mV), and the kinetics of Na^+ channel activation–inactivation. After opening, the large majority of Na^+ channels take on an inactivated conformation that does not allow any further ion flow. Reproduced from Avanzini G and Franceschetti S (2003) Cellular biology of epileptogenesis. *Lancet Neurology* 2: 33–42, with permission from Lancet Neurology.

neurons within experimentally induced epileptic foci have altered excitable properties that depend on transmembrane ion currents. Studies of various epilepsy models have shown that all of the neurons belonging to an epileptic aggregate consistently discharge in the form of protracted action potential bursts arising from a depolarized plateau (**Figure 2**). This 'paradigm' of an elementary epileptic discharge was initially observed in penicillin cortical foci and christened the paroxysmal depolarization shift (PDS) by Matsumoto and Ajmone Marsan; the PDS was later reported in different animal models and in human epileptogenic tissue, and therefore is considered reliable hallmark of an active epileptogenic process (see Further Reading section).

Similar discharges can be obtained using a number of experimental manipulations that enhance depolarizing ion currents (mainly carried by Na^+ and Ca^{2+} ions) or reduce hyperpolarizing ion currents (mainly carried by Cl^- and K^+ ions). However, it is only recently that we had direct evidence of the relevance of ion channel dysfunctions to naturally occurring epilepsies. One important step in this direction was made as a result of a series of experiments on the Drosophila Shaker mutant (carried out by the Jans and their colleagues), the results of which indicated that a mutation of a gene coding for a potassium channel caused the hyperexcitability that is responsible for the abnormal behavior of the Shaker mutant. The subsequent development of the analysis of genetically

determined channel alterations was greatly facilitated by the availability of techniques allowing gene mutations to be expressed in simple systems, which made it possible to characterize their functional consequences. The main types of experimental models used for such studies are summarized in **Figure 3**. Both in vitro and in vivo models are powerful means of assessing the functional consequences of the gene mutations that have been found to be associated with human epilepsies.

Methods

In vitro Models

Xenopus oocytes

The oocytes of the African clawed frog *Xenopus laevis* have been widely used as an expression system ever since it was first shown that messenger RNA (mRNA) injected into the cytoplasm can be translated into functional proteins and that receptors and channels could also be functionally expressed. Oocytes have a number of advantages: they can be easily removed without the need for animal sacrifice, they are large (a diameter of approximately 1–1.2 mm) and quite resistant to experimental manipulations, and they can be kept alive in vitro for a few weeks. They also have only a few endogenous currents, are easily impaled by microelectrodes, allow long and stable recordings, and make it possible to control the ratio of differently expressed subunits by injecting fixed amounts of RNA. Unfortunately, their large volume does not allow fast clamping of the membrane potential, a drawback that can be overcome by making patch–clamp recordings of macroscopic currents from a relatively large patch of oocyte membrane (macropatch), an approach that allows a good signal-to-noise ratio and fast voltage clamping. Alternatively, the cut-open oocyte voltage-clamp technique allows both fast voltage clamping and control of the composition of the intracellular medium. The most serious disadvantage of the oocyte system is its cell background; the expressed channels may interact with endogenous proteins and undergo posttranslational modifications that may be different from those occurring in mammalian cells. It is therefore not surprising that the ion channels expressed in *Xenopus* oocytes often have properties different from those studied in mammalian cell lines.

Mammalian cell lines

Heterologous expression in mammalian cell lines transfected with cDNA makes it possible to study the properties of the channel of interest while preserving a mammalian cell background. Two cell lines have become standard for ion channel studies: Chinese hamster ovary (CHO) cells and human embryonic kidney (HEK) cells, both of which have an epithelial-like morphology and very small endogenous currents, and are easy to maintain and transfect. They are also easy to use in electrophysiological experiments (typically, whole-cell patch–clamp recordings), thus allowing the relatively rapid screening of channel mutations, fast and accurate clamping of membrane voltage, and good control of the composition of the

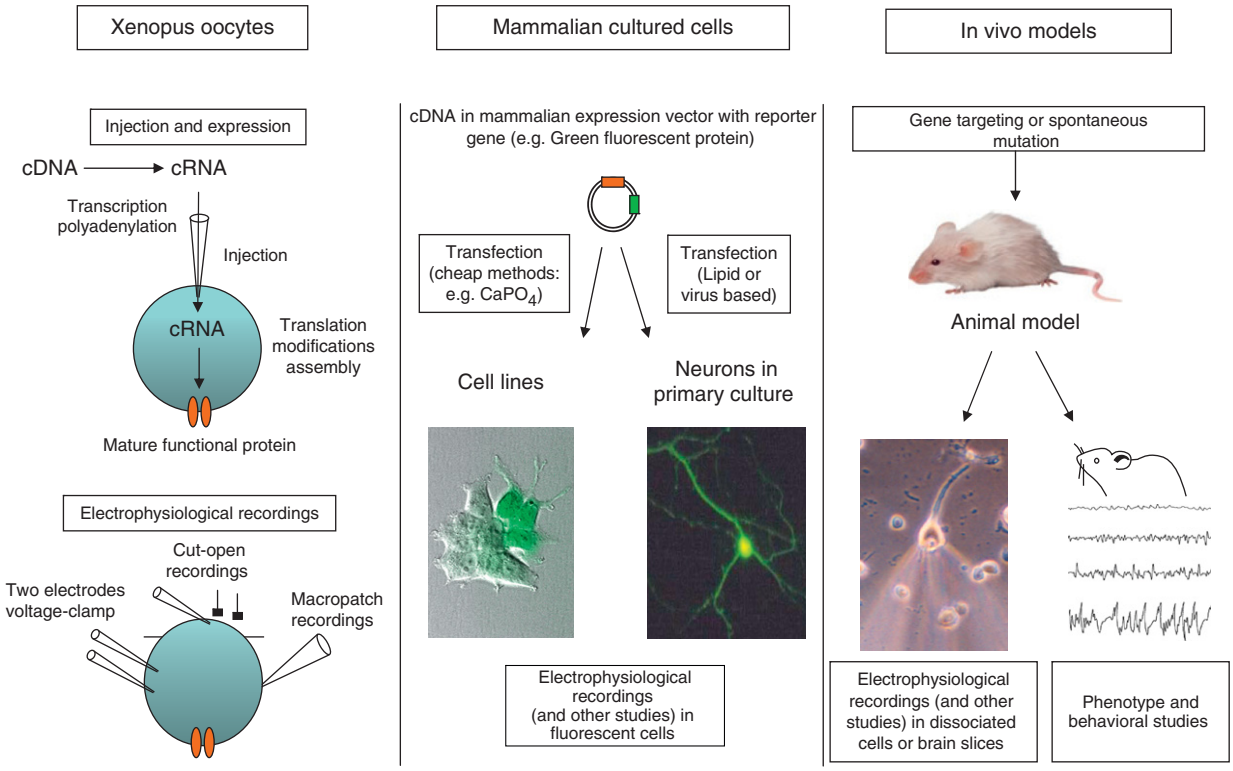

Figure 3 Experimental models for channelopathies. The most popular in vitro models are *Xenopus* oocytes and mammalian cultured cells. In vivo models include gene targeted animals and animal with spontaneous mutations. Detailed descriptions are to be found in the text. Reproduced from Avanzini G, Franceschetti S, and Mantegazza M (2007) Epileptogenic channelopathies: Experimental models of human pathologies. *Epilepsia* (supplement 2): 51–64, with permission from Blackwell publishing.

intracellular medium. In particular, HEK cells (especially the derived tsA-201 cell line) have been used because they have a human cell background (and express high density of the channel of interest when transfected). However, there are striking differences in channel properties when these channels are expressed in different mammalian cell lines (or even different subclones), possibly because the various cell lines express a variety of neuronal genes, including many accessory subunits of ion channels that may differently modulate exogenous channels and thus produce cell line-specific properties. Moreover, different cell lines can also have specific membrane lipid compositions, which may be surprisingly important when setting the functional properties of ion channels. Furthermore, cell lines do not completely reproduce the neuronal genetic background, cell variety, or subcellular specialization.

Primary cultured neurons

Transfected neurons in primary cultures provide an expression system that makes it possible to study exogenous channels while preserving neuronal properties, background, and variety. Neurons isolated from various brain areas can now be efficiently transfected and, in neocortical and hippocampal cultures, it is also easy to identify and make selective recordings of excitatory neurons (with typical pyramidal shapes) or inhibitory interneurons (bipolar, and positive for glutamic acid decarboxylase). Primary cultured neurons should therefore be the system of choice for reproducing differential neuronal cell backgrounds and studying the biophysical properties of wild-type and mutant subunits. However, these cells do have some disadvantages. First, neurons express a plethora of endogenous channels that need to be blocked in order to study exogenously transfected channels in isolation; therefore, the cultured neurons must be transfected with engineered exogenous channels that are resistant to specific blockers. Second, cultured central nervous system neurons develop long processes that make it difficult to space clamp membrane voltage; this problem can be overcome by making macropatch recordings as discussed earlier. Last, electrophysiological experiments with transfected cultured neurons are more difficult than those using cell lines.

In vivo Models

There are a large number of intact animal models in which to explore the consequences of genetic mutation on neuronal excitability. These models include animal strains presenting with spontaneous seizures, in which genetic studies have revealed specific ion channel

dysfunctions, and gene-targeted animals generated by means of genetic manipulation. The first group includes recessive mouse mutants in which Ca^{2+} mutations have been identified (e.g., tottering, lethargic, stargazer, and ducky mice). These animals exhibit spontaneous seizures similar to those of human epileptic syndromes with simple 'absence' seizures (both behavioral and EEG patterns); however, unlike human absence epilepsy (which often remits spontaneously and occurs in neurologically healthy subjects), the seizures in these animal models persist in adult and old rodents, and are associated with other neurological symptoms. Regarding the second set of 'targeted' models, there are currently relatively few that replicate human mutations. The phenotypes of some gene-targeted models are discussed below in comparison with the phenotypes of the corresponding human disorders.

Results

Functional Evaluations of Epileptogenic Channel Gene Mutations

Mutations of genes coding for nicotinic acetylcholine receptors (nAChRs)

Mutation of the nicotinic acetylcholine receptor was one of the first recognized epileptogenic channel mutations, associated with autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). The phenotype is characterized by clusters of motor seizures during light sleep, and complex behavioral symptoms including gasping, vocalizations, and thrashing hyperkinetic activity. In different families, ADNFLE is associated with mutations of the CHRNA4 and CHRNB2 genes, which respectively encode the α4 and β2 subunits of nAChRs, a heteropentameric ligand-gated ion channel that is permeable to cations with little selectivity. The α4 subunit is expressed in most brain areas and generally associated with the β2 subunit to form an α4–β2 pentameric complex. Studies of mutated channel subunits expressed in *Xenopus* oocytes and cultured cell lines, as a means of evaluating the functional consequences of the genetically determined receptor changes, have given rise to complex and sometimes contradictory data. Evidence for increased ACh affinity and an increased and/or delayed rate of channel desensitization, followed by a prolonged desensitization period, has been reported to account for epileptogenesis. Moreover, CHRNA4 mutations cause nAChR loss of function, whereas CHRNB2 mutations cause a gain of function; the final net effect depends on the pre- or postsynaptic location of the receptor. More work is needed to understand the pathophysiology of ADNFLE. Since the α4 and β2 subunits are expressed ubiquitously in the central nervous system, it remains unclear why the epileptic focus is in the frontal lobe.

K^+ channel mutations

The heterotetramer products of the KCNQ genes form M-channels that regulate the threshold of neuronal electrical excitability. M-currents activate at close-to-resting-membrane potentials, counteract membrane depolarizations, and are sensitive to muscarinic (M) acetylcholine receptor agonists. By expressing KCNQ2 and KCNQ3 genes in *Xenopus* oocytes, investigators demonstrated that M-currents require the coexpression of both subunits. Mutations in the KCNQ2 or KCNQ3 gene are associated with the human epileptic syndrome, benign familial neonatal convulsions (BFNCs). The clinical picture of BFNCs is characterized by clonic seizures (rarely tonic) that are lateralized and sometimes change side, and associated with apneic spells lasting 1–3 min. The most frequent age of onset is the third day of life, with frequent recurrences until the seventh day, and subsequent isolated occurrences. Spontaneous remission occurs in the ensuing weeks or months. Work in the in vitro system provided a logical explanation of BFNC's genetic basis, insofar as mutations in genes coding for either subunit lead to a similar loss of function, and consequently decreased the efficiency of the hyperpolarizing voltage-dependent currents carried by the K^+ ions flowing through the channels.

Na^+ channel mutations

Mutations involving the alpha (SCN1A) or beta (SCN1B) Na^+ channel subunits are associated with simple febrile seizures (FS), generalized epilepsy with febrile seizures plus ($GEFS^+$), and severe myoclonic epilepsy of infancy (SMEI). FS occur during infancy and childhood, and usually subside around the sixth year of age. The $GEFS^+$ phenotypes include febrile seizures ceasing by the age of six years or extending beyond it, afebrile tonic–clonic, myoclonic, absence or atonic seizures, and myoclonic–astatic epilepsy. The SMEI phenotype has a typical natural history starting with tonic, clonic, or tonic–clonic seizures that are often prolonged and associated with fever, followed by febrile myoclonic, tonic–clonic, absence, and simple and complex partial seizures later in life. There is early-onset photosensitivity. The prognosis is poor in terms of cognitive function and seizure control. Interestingly, the $GEFS^+$ phenotype was only recognized after an Na^+ mutation was identified in a large New Zealand family. Although clinically well characterized since the 1990s, SMEI was never considered a genetically determined epileptic encephalopathy until it was found to be associated with a de novo SCN1A mutation.

The functional consequences of SCN1B mutations in *Xenopus* oocytes consist of a longer-lasting Na^+ current flow, consistent with an enhanced cell excitability. SCN1A mutations enhance the fraction (2–5%) of non-inactivating Na^+ currents, which normally account for about 1% of the maximal Na^+ current peak amplitude; this enhancement reduces the depolarization threshold required for neuronal firing, again consistent with

neuronal hyperexcitability. Characterization of the functional consequences of the SCN1A mutations associated with SMEI has been more difficult, since these mutations lead to a truncated protein that would completely inactivate the channel (thus making it impossible to test dysfunction by expressing it in an in vitro system). However, a suitable alternative was provided by the in vivo NaV1.1 knockout mouse, obtained by deleting the last exon of SCN1A. This animal presents with severe seizures early in life and has a very high, early postnatal mortality rate. Recordings from dissociated hippocampal neurons taken from heterozygous SCN1A knockout mice clearly show that the mutated subunit is selectively expressed by inhibitory interneurons, thus leading to a disinhibition of the principal pyramidal neurons that could account for the epileptic symptoms.

Ca^{2+} channel mutations

It has been found that mutations in genes coding for high-voltage-activated (HVA) Ca^{2+} channels are associated with absence epilepsies in rodent models. These mutations lead to reduced P/Q current density in neurons and, in principle, imply reduced cell excitability because P/Q-type Ca^{2+} channels play a dominant role in synaptic transmission. On the basis of what is known concerning the physiology of the thalamocortical circuitry responsible for absence epilepsy with spike-wave (SW) discharges (Figure 4), it would be expected that the channels responsible for the low threshold T-type Ca^{2+} currents would be primarily involved in spike wave generation, as the integrity of the T-current in the thalamic nuclei (in the thalamic reticular nucleus) is a prerequisite for SW expression in rodents. Investigators have described an association between genetic variations in the T channel gene Cav3.2 and childhood absence epilepsy. However, attempts to create an absence model by targeting the genes coding for Ca^{2+} channels have so far been unsuccessful, so the role of Ca^{2+} in epileptogenesis has still to be clarified. In this regard, it is worth remembering the complexity of Ca^{2+} cell functions, which include signal transduction, cell differentiation/proliferation, and synaptogenesis, as this complexity greatly complicates the interpretation of the results.

Gene mutations affecting GABA receptors or Cl^- channels

Rare GEFS+ phenotypes can associate with mutations affecting the γ2 subunits of the GABA receptor (GABRG2, 5q31-33). Various mutations of GABA receptor subunits have been reported in families with absence seizure with or without febrile seizures (γ2 subunit and idiopathic myoclonic epilepsy (α1 subunit)). These mutations lead to various defects in channel function that are generally consistent with a decreased effect of exogenous GABA, including a decrease in the amplitude of GABA-induced currents, altered channel gating, and probably reduced surface expression of functional receptors. A mutation affecting the CLCN2 gene (3q27-28), coding a voltage-gated Cl^- channel that is possibly involved in physiological GABA-dependent inhibition, has also been reported in families with various types of idiopathic generalized epilepsies with absence and convulsive seizures. The mutated channels show complete loss of

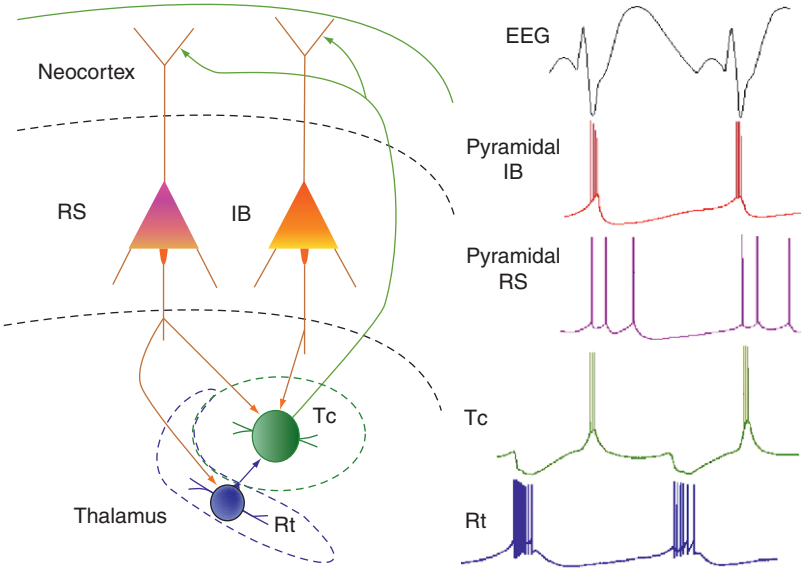

Figure 4 On the left the thalamocortical circuits responsible for absence seizures are schematically depicted. They include regular spiking (RS) and intrinsically bursting (IB) neurons of neocortex and thalamic reticular (Rt) and thalamocortical (Tc) neurons. In the right part of the figure spike-wave associated cell discharges are of the different neuronal populations are reported. function or altered voltage-dependent gating, possibly causing impaired Cl^- homeostasis or membrane depolarization, and favoring hyperexcitability.

Conclusions and Directions for Future Research

The combined neurophysiological and biomolecular approach to the analysis of genetically determined alterations in ligand- and voltage-gated channel has opened up a new and exciting scenario in the neurobiology of epilepsy. The findings, as reviewed earlier, provide direct evidence that channel dysfunctions due to single gene mutations may account for epileptogenesis. However, it must not be forgotten that alterations in individual excitable properties have to be considered within the context of the neural circuitry involved in epileptogenesis. Although altered neuronal excitability is a primary prerequisite of epileptogenesis, epileptic discharges do not come from the abnormal activities of individual neurons but require the synchronous activation of large populations of hyperexcitable cells. Moreover, during a seizure, discharges tend to propagate through normal or pathological fiber connections, and so the role of neuronal circuitry in the generation and spread of epileptic discharges should never be overlooked.

Despite this caveat, the demonstration that the structurally altered ligand- and voltage-gated channels found in some human epilepsies can lead to potentially epileptogenic changes in ionic currents is a major breakthrough for our understanding of epileptogenesis. The implications of genetically determined channel dysfunctions in other paroxysmal muscular and cardiac disorders have been increasingly acknowledged since the 1991 publication of the seminal paper by Ptaceck *et al.* on hyperkalemic periodic paralysis. The recognition that some epilepsies may fall within the category of 'channelopathies' has proved to be highly advantageous for epilepsy research, which can now benefit from the results obtained in other excitable tissues.

Many new pieces of information have been collected so far but even more are expected to be gained in the near future. We have learned that, depending on their subunit composition, a variety of channel subtypes can be identified whose functional properties are still to be carefully characterized. The first objective for the ongoing research is to systematically correlate the subunit composition of different subforms of ionic channels with their function. The second important objective is to map the distribution of the subtypes across the different brain areas, and their differential expression in different cell types. This information could lead to predict the effect of a given channel mutation in different neural systems and ultimately to link the epileptic phenotype with the respective genotype.

Most of what we know about epileptogenic channelopathies comes from investigations of relatively rare forms of monogenic epilepsies. The main challenge for the future is to understand the role of channel dysfunctions in the pathogenesis of more common types of idiopathic, probably polygenic, epilepsies and of symptomatic epilepsies – due to exogenously determined channel alterations ('acquired channelopathies').

From the practical point of view, a better understanding of the role of ligand- and voltage-gated channels in epileptogenesis can provide sound criteria for the ongoing revision of the classification of epilepsy, and for the molecular/pharmacological development of selective and targeted antiepileptic drugs.

Introduction – Neuronal Ion Channels: From Molecules to Complexity

Ion channels are macromolecular protein complexes mediating flux of physiological ions through cellular membranes. With hundreds of ion channel genes identified in the human genome, there is scope for enormous functional diversity. Splicing and heteromeric assembly contribute further to this diversity – a feature that presumably confers a selective advantage by optimizing signal processing in the various cell types throughout the body. Functional diversity of neurons is highly dependent on the repertoire of ion channels expressed, and a given neuron may express dozens of different ion channel genes. Further diversity is provided by the regulation of the subcellular distribution of these channels within the neuron. In these ways, the computational power of networks is amplified by the creation of specialized neurons with unique integration and firing properties. The three major cell types are the excitatory and inhibitory neurons and glia, with each cell type encompassing numerous subclasses.

Figure 1 summarizes expression and localization of ion channel classes in these cells. Underlying this elegance and complexity are highly concerted and intricate molecular regulation processes that govern ion channel spatial and temporal expression, assembly, trafficking, modification, and degradation.

Neuronal communication is effected by synapses, located primarily on the dendritic and somatic membranes of a neuron. At most chemical synapses, information flow is unidirectional and involves the conversion of an electrical signal to a chemical signal in the presynaptic neuron, and then to an electrical signal in the postsynaptic neuron. A neuron integrates signaling from dendritic and somatic inputs (up to 200 000) to create an all-or-none output in the form of an action potential in the axon. Action potentials generated by the coordinated gating of sodium and potassium channels enable a means of long-range communication within and between neurons. At the presynaptic terminal, Ca^{2+} channels are responsible for 'translating' action potentials into the release of transmitter, which then acts postsynaptically on a range of excitatory or inhibitory ion channels. Thus, ion channels play a central role not only in determining the functional properties of a single neuron, but also in the fundamentals of signaling between neurons.

Such signaling permits neurons to operate within 'networks,' separable functional units within the brain that serve its myriad of functions. Networks possess

Introduction – Neuronal Ion Channels: From Molecules to Complexity

Ion channels are macromolecular protein complexes mediating flux of physiological ions through cellular membranes. With hundreds of ion channel genes identified in the human genome, there is scope for enormous functional diversity. Splicing and heteromeric assembly contribute further to this diversity – a feature that presumably confers a selective advantage by optimizing signal processing in the various cell types throughout the body. Functional diversity of neurons is highly dependent on the repertoire of ion channels expressed, and a given neuron may express dozens of different ion channel genes. Further diversity is provided by the regulation of the subcellular distribution of these channels within the neuron. In these ways, the computational power of networks is amplified by the creation of specialized neurons with unique integration and firing properties. The three major cell types are the excitatory and inhibitory neurons and glia, with each cell type encompassing numerous subclasses.

Figure 1 summarizes expression and localization of ion channel classes in these cells. Underlying this elegance and complexity are highly concerted and intricate molecular regulation processes that govern ion channel spatial and temporal expression, assembly, trafficking, modification, and degradation.

Neuronal communication is effected by synapses, located primarily on the dendritic and somatic membranes of a neuron. At most chemical synapses, information flow is unidirectional and involves the conversion of an electrical signal to a chemical signal in the presynaptic neuron, and then to an electrical signal in the postsynaptic neuron. A neuron integrates signaling from dendritic and somatic inputs (up to 200 000) to create an all-or-none output in the form of an action potential in the axon. Action potentials generated by the coordinated gating of sodium and potassium channels enable a means of long-range communication within and between neurons. At the presynaptic terminal, Ca^{2+} channels are responsible for 'translating' action potentials into the release of transmitter, which then acts postsynaptically on a range of excitatory or inhibitory ion channels. Thus, ion channels play a central role not only in determining the functional properties of a single neuron, but also in the fundamentals of signaling between neurons.

Such signaling permits neurons to operate within 'networks,' separable functional units within the brain that serve its myriad of functions. Networks possess

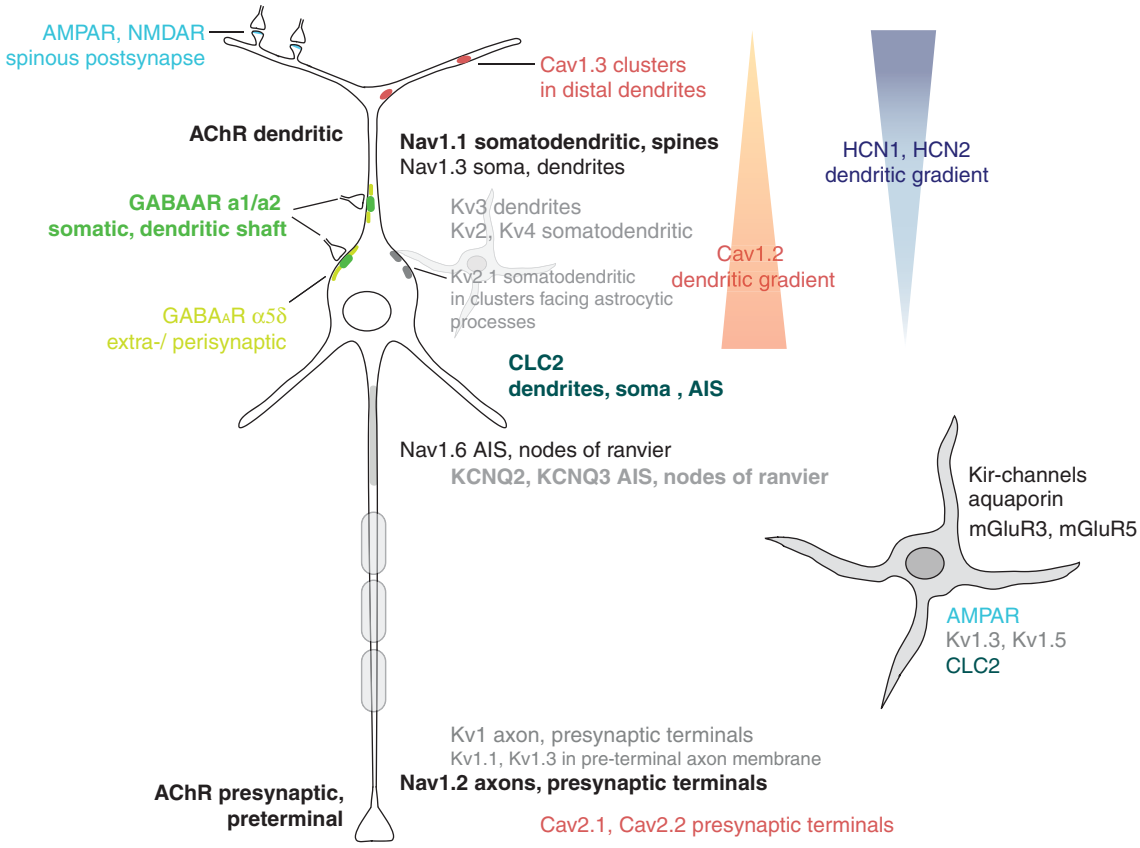

Figure 1 Schematic depiction of a typical excitatory neuron highlighting heterogeneous distribution of key ion channels. Channel types were selected because they are implicated in epilepsy (bold font); they are functionally critical for neurons and illustrate the complexity of ion channel distribution within a single neuron. The list of channels is by no means exhaustive (e.g., glycine receptors, 5-HT_3 receptors, kainate receptors, gap junctions, and others have been omitted).

Based on the mechanism of channel gating, ion channels can be classified: voltage gated, ligand gated, and others. Epilepsies associated with channel mutations are shown later in brackets.

Voltage-gated channels

Na^+ channels (Nav) are responsible for action potential generation and propagation and passive signal conductance involved in synaptic transmission [GEFS+, SMEI, BFNIC]. Four subtypes are found in the brain, three of which reside in the axon initial segment (AIS), nodes of Ranvier, and presynaptic terminals of the mature brain; Nav 1.1 and 1.3 also localize to soma and dendrites.

K^+ channels roughly divide into two functional subgroups: Dendritic **Kv**-channels regulate dendritic excitability, backpropagation of action potentials, and also the amplitude and waveform of excitatory postsynaptic responses. Axonal Kv subtypes limit action potential (AP) duration and membrane depolarization. Kv-subunits form heteromeric channels, which vary in gating, expression, and localization, and a simplified distribution is shown in **Figure 1**. Glial Kv1.3 and Kv1.5 function as delayed rectifying channels. KCNQ channels [EBN, BFNS] are slower delayed rectifying channels. They are found in AIS and nodes of Ranvier where they set subthreshold membrane potential, regulate excitability, and are themselves regulated by G protein-coupled pathways.

Ca^{2+} channels (CaV) mediate synaptic transmission in presynaptic terminals and are responsible for dendritic Ca^{2+} signaling [JME].

Hyperpolarization-activated channels (HCN) mediate a mixed cation current and regulate neuronal excitability and rhythmicity of AP firing. They show a gradient of distribution with a maximum at the distal dendrites declining toward the soma.

Voltage-gated Cl^- channels (CLC) are localized to spines, dendrites, soma, and AIS and are responsible for chloride homeostasis, thereby possibly modulating $GABA_A$R-mediated inhibition [JAE, EGMA].

Ligand-gated channels

Also known as ionotropic receptors, this group of channels open in response to specific ligand molecules binding to the extracellular domain of the receptor protein.

AMPA (α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) and *NMDA* (*N*-methyl-D-aspartic acid) receptors are gated by glutamate and mediate the bulk of excitatory neurotransmission in the brain. They mostly reside in postsynaptic densities in dendritic spines.

Nicotinic acetylcholine receptors (*nAChRs*) are cation-permeable and are found both pre and postsynaptically [ADNFLE]. In the CNS, ACh has a mostly neuromodulatory role.

Excitation is balanced by anion-permeable γ-aminobutyric acid-gated $GABA_A$ receptors (*$GABA_A$Rs*) [GEFS+]. $GABA_A$Rs are located in inhibitory synapses found at the soma and at proximal dendritic shafts. Synaptic $GABA_A$Rs are important for phasic inhibition, whereas extra and perisynaptic $GABA_A$Rs containing α5 or δ subunits mediate tonic inhibition.

G protein-coupled receptors (*mGluR3* and *mGluR5*) are the predominant metabotropic glutamate receptor subtypes expressed by glial cells. Activation of these receptors inhibits cAMP accumulation and leads to an increase in intracellular Ca^{2+}, respectively.

redundancy and plasticity, permitting dynamic and adaptive behaviors. Once again, ion channels are the molecular determinants of these emergent properties.

The delicate balance between the excitatory and inhibitory events within these networks is maintained by the exquisite control exerted by the function of ion channels. Although networks are inherently robust to variations in physiological input, subtle changes in the molecular constituents of networks may dramatically alter their properties and give rise to pathological instability – as seen in neurological disorders such as epilepsy.

Background – Familial Epilepsy: From Molecules to Malady

Subtle changes in ion channel function are a hallmark of familial epilepsy syndromes. These familial epilepsies are largely confined to the idiopathic syndromes that cover a spectrum of severity from relatively benign syndromes such as febrile seizures or childhood absence epilepsy to severe myoclonic epilepsy of infancy (SMEI, Dravet's syndrome). The genetic architecture also covers a spectrum, from 'complex monogenic' to polygenic inheritance. The majority of mutations studied to date fall into the former category, although several studies have identified risk factor mutations associated with polygenic diseases.

In sum, these studies are beginning to provide insight into the genetics of epilepsy – but they do not bridge the knowledge gap from molecular deficit to behavioral seizure. Establishing a chain of understanding from molecule to malady requires an understanding of the impact of a mutation at each of the levels of brain organization discussed earlier. Obtaining such insight requires analysis of the in vitro consequences of a mutation on ion channel kinetics, permeation, and pharmacology to give a 'molecular phenotype,' as well as elucidation of the in vivo regulation of channel expression, biogenesis, assembly, trafficking, and turnover, to establish a 'neuronal phenotype.' At the next level of neuronal organization, it is important to understand how affected neurons alter the function of networks in which they reside and, therefore, it is necessary to investigate synaptic properties and network behavior to establish the 'network phenotype.' Because epilepsy is often viewed as a disease of brain networks, fundamental knowledge of the epileptic process should emerge by the successful investigation and integration of these three levels of organization.

Rather than attempt to review all studies that have been done to date in pursuit of these goals, we focus below on selected examples that illustrate studies lending themselves to this stepwise integrative approach.

Methods

Molecular Biological Methods

Interactions at the level of individual molecules are frequently studied using biochemical assays like pull-down experiments, western blotting, or mass spectrometry. Expression patterns and expression levels can be assessed at the RNA level with quantitative polymerase chain reaction (qPCR) and in situ hybridization, or at the protein level using immunohistochemical approaches.

Heterologous Expression Systems

Heterologous expression experiments, that is, artificial expression of genes from a different species, have been used widely to study ion channel function in a well-defined, controllable environment. Amphibian oocytes, human embryonic kidney cells (HEK), and different immortalized cell lines, for the most part, do not natively express neuronal ion channels and can be transfected with cDNA encoding the ion channel genes under investigation. Therefore, they can be used to describe the function of specific combinations of ion channel subunits, regulatory proteins, or channel mutants in the absence of contaminating currents. Sharp electrode or patch clamp techniques are used to measure the currents produced by the expressed channels. Patch clamp allows measurement of not only whole cell currents but, in the cell-attached or excised-patch mode, enables the direct observation of single channel function in real time.

In addition to functional assessment, heterologous systems inform our understanding of the cell biological consequences of ion channel mutations. For example, the impact of mutations that alter interactions with intracellular matrix proteins can be visualized using fluorescent labeling and quantified using digital imaging methods such as confocal microscopy and fluorescence energy transfer (FRET).

Glial and neuronal *Kir-channels* are inwardly rectifying K^+ channels. They contribute to K^+ reuptake and spatial K^+ buffering in the extracellular space.

Neurons also express G protein-activated inwardly rectifying channels (*GIRKs*). These play a powerful inhibitory role downstream for the action of several neurotransmitters.

Others

Aquaporins function as 'water channels' in many cell types and tissues in which fluid transport is crucial. Both extracellular K^+ concentration and osmolarity have been shown to dramatically modulate neuronal excitability.

Neuronal in vitro Studies: Imaging and Electrophysiology

Neurons in cultures or brain slices are accessible to a multitude of different functional and morphological approaches. Patch clamp electrophysiology has been instrumental in understanding functional changes in single neurons – for example, using input–output curves, high-frequency stimulation, or pharmacological manipulation. Functional imaging techniques directly monitor the flux of specific ions, most commonly Na^+ and Ca^{2+}, in identified cells or small networks, and voltage-sensitive imaging can directly monitor membrane potential changes with subcellular resolution.

The advantage of fixed tissue is the good preservation of neuronal anatomy, and the high resolution preserved for microscopy. Such tissue can be used for immunohistochemistry and other morphological techniques (e.g., Golgi staining, TUNEL staining, etc.) as well as electron microscopy.

Genetically Modified Viruses

In the last few years, recombinant viruses have become popular tools in neuroscience. They are used for expression of tagged proteins and mutants, biosensors (e.g., Ca^{2+} indicators), enzymes (e.g., cre-recombinase), light-activated ion channels (channelrhodopsins), and other molecules that not only report function but can also perturb the system under investigation in a controlled manner. Advantages of viral expression systems are a quick turnaround time, and spatially (by virtue of where the virus is injected) and temporally targeted expression of the gene of interest, with the added potential of targeting different cell populations using cell type-specific promoters.

In vivo Approaches

Recently, several knock-in mice of human epilepsy mutations have been generated. These models specifically recapitulate the human genetic lesion and frequently share many of the core pathological features. They are, therefore, extremely useful in studying the systems level biology of epilepsy; for example, pharmacoresponses or pharmacodynamics (of antiepileptic drugs as well as proepileptic drugs), neuronal network function, and animal behavior. Similarly, epileptic rat strains, such as WAG/Rij or GAERS, provide insight into polygenic inheritance of epilepsy.

Other epilepsy models generate recurrent seizures in response to electrical stimulation (e.g., amygdala or corneal kindling) or pharmacological activation (e.g., kainic acid, PTZ).

Imaging techniques in rodent models include electrocorticographic (EEG, or ECoG) monitoring, MRI, voltage-sensitive dye imaging, and 2D and 3D in vivo multiphoton imaging. These approaches, together with single and multiunit recordings and in vivo patch recordings, allow for examination of neuronal network activity in an intact brain, in some cases even in freely behaving animals.

Behavioral tests are employed to study the impact of a particular ion channel mutation on seizures, cognition, and motor or psychosocial skills such as learning and memory, coordination, and anxiety.

Results

Molecular Phenotype

Mutations acutely altering ion channel function

Neuronal excitability is critically dependent on electrochemical gradients that drive the passage of ions across the membrane. Therefore, it seems very satisfying and logical to assume that epilepsy arises from malfunction of a mutated ion channel, leading to increased excitatory or decreased inhibitory currents.

It is, however, extremely difficult to infer network hyperexcitability from the mere presence of mutated receptors. For example, autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is associated with mutations in neuronal nicotinic acetylcholine receptors (nAChR). nAChRs are pentameric ligand-gated ion channels composed of different combinations of α and β subunits. In total, six mutations in the most abundant subtype, $\alpha4\beta2$, have been identified. Several pharmacological and biophysical properties of the receptors are influenced by the mutations; interestingly, changes in ACh sensitivity, ACh kinetics, and Ca^{2+}-dependency were common to all ADNFLE mutations, whereas use-dependent potentiation, peak ACh current response, or Ca^{2+} permeability were altered in some but not all mutations. Most investigators believe that these changes represent a gain of function in the mutant receptors, but the pathophysiological process that leads to seizures is unclear.

Mutations in modulatory subunits

The flow of ions through an ion channel can be modulated by several different factors. An example is the voltage-gated sodium channels, which comprise a pore-forming α subunit and a choice among four modulatory β subunits. These β subunits are not necessary for channel function and do not form functional channels on their own. However, in combination with the channel forming α subunit, they modulate a range of channel properties that include ion channel gating, intracellular localization of the ion channel complex, membrane expression, and protein–matrix adhesion and cell–cell adhesion.

Epilepsy-causing mutations occur in both the α and β subunits, demonstrating the critical role of the modulatory β subunit in normal and disease states. Given the functional scope for β subunit modulation, there is

enormous potential for mutations to influence channel and neuronal function in epilepsy. The C121W mutation in the sodium channel β1 subunit (SCN1β) is an excellent example to illustrate this point.

SCN1β comprises an intracellular C-terminus, one transmembrane helix, and a large extracellular N-terminal domain, the structure of which closely resembles an immunoglobulin (Ig) domain; Ig-like folds are common structural protein subdomains involved in cell–cell recognition and adhesion. The single C121W amino acid mutation disrupts a disulfide bond in this Ig-like region. The functional consequences of this mutation have been tested both in *Xenopus* oocytes and mammalian cell lines. The results differed remarkably between these model systems: after coexpression with sodium channel α subunits in oocytes, wild-type SCN1β increased sodium channel inactivation fivefold, but mutant SCN1β(C121W) had no effect on inactivation. In mammalian cell lines, in contrast, α subunit current inactivation was not faster than in oocytes; furthermore, the effects of SCN1β coexpression were less marked. In comparison to wild-type SCN1β, mutant SCN1β(C121W) caused a subtle positive shift in voltage dependency and a decreased use-dependence. Interestingly, a study in insect cells demonstrated that SCN1β(C121W) did not promote cell-to-cell adhesion – in contrast to wild-type SCN1β, suggesting a disruption of homophilic β subunit interactions in the mutant.

Clearly, the single point mutation SCN1b(C121W) influences many of the functions ascribed to accessory subunits, suggesting that combined effects of subtle changes in channel function that modify the cell's biology may cause an epileptic phenotype. In this context, it is interesting that the spectrum of clinical presentations associated with the SCN1B–C121W mutation is exceptionally broad, ranging from febrile seizures to SMEI and temporal lobe epilepsy (TLE). This diversity of phenotypes might reflect mutations in different domains of SCN1b, leading to perturbation of one or more of its multiple functions.

Mutations influencing ion channel biogenesis and trafficking

$GABA_A$ receptors are the main mediators of fast inhibition in the central nervous system. They are pentameric ligand-gated chloride channels consisting of two α- and two β-subunits in combination with either a γ-, δ-, θ-, ϕ-, or ε-subunit; the most common stoichiometry is α1β2γ2. Different $GABA_A$ receptor subtypes are located in postsynaptic compartments versus peri- or extrasynaptic membranes, where they mediate phasic and tonic inhibition, respectively.

Several $GABA_A$ receptor mutations associated with epilepsy have been discovered. One intensively studied mutation in the GABARγ2 subunit leads to an arginine to glutamine amino acid exchange at position 43 in the mature protein, and causes childhood absence epilepsy and febrile seizures in patients. The mutation is localized in the N-terminal extracellular domain of the γ2 subunit, most probably at the interface between γ2 and β subunits.

The functional effects of the R43Q mutation on GABA receptor kinetics are still a matter of some debate. There is, however, accumulating evidence suggesting a deficiency in channel assembly and cell surface expression or localization of the channels containing the mutated γ2 subunit. Experiments in several expression systems indicate a failure in subunit interaction between γ2 and α1/β2, leading to intracellular retention of mutant channel complexes. In neurons, α1β2 channels of unknown stoichiometry still reach the cell membrane and, it is speculated, induce an imbalance between phasic (synaptic) and tonic (extrasynaptic) inhibition.

In conclusion, inhibition of channel assembly and perturbed intracellular trafficking, in combination with changes in receptor kinetics, is likely to be responsible for the general cortical hyperexcitability and the epileptic phenotype observed in patients with this mutation.

Mutations influencing protein–protein interaction

Ion channels are embedded in a meshwork of proteins, which coordinate their intracellular localization, trafficking, and use-dependent recycling, mediate attachment to the cytoskeleton, and modulate their function. Several mutations in 'non-ion channel genes' have been identified in epileptic patients; for the purpose of this review, we will focus on *LGI1*, which was identified as the causative gene for ADLTE.

The LGI1 protein is characterized by leucine-rich repeats in its N-terminal half, indicating a function in protein–protein interaction. Recent publications have revealed that LGI1 is tightly associated with Kv1.1 potassium channel complexes. One effect of native LGI1 is to counteract Kvβ1 by selectively removing rapid inactivation from the A-type Kv channel. This function was completely abolished by the ADLTE mutation, probably resulting in frequency-dependent AP broadening.

Analysis in heterologous expression system reveals alterations in the molecular and biochemical properties caused by ion channel mutations, but such membrane-level analysis usually cannot fully explain the pathophysiological properties of cellular networks that express the channel. Therefore, unanswered questions remain. Which, if any, of the changes observed are important for epilepsy? Are there other changes in function that cannot be recapitulated or observed in the expression system? Why are seizures episodic? Does expression during brain development cause chronic changes that cannot be predicted from analysis of the acute deficit alone? Answers to these questions will require capturing the nature of the deficit in the natural environment of the channel – that is, the neuron – where a more complete repertoire of modulatory,

regulatory, and anatomical influences can exert their effects. Methodologically, this type of analysis can be achieved by transfer of the mutated gene to a neuronal cell culture, by creation of transgenic or gene-targeted mouse models, or by viral gene transfer.

Neuronal Phenotype

Ultimately, an epilepsy-causing mutation will alter the way in which a neuron functions, to result in abnormal electrical discharges characteristic of the disease. An appreciation of the consequences of a mutation on neuron behavior is critical to our understanding of disease genesis and progression. Furthermore, neurons are broadly divided into excitatory and inhibitory types, and the balance between inhibition and excitation is important for normal brain function. Any influence that disrupts this fine balance can lead to an epileptic state as a result of 'overexcitation' or 'underinhibition' (more commonly referred to as 'disinhibition'). Excitatory and inhibitory neurons may independently or collectively be affected by an ion channel mutation, and therefore different cell types may differentially participate in disease genesis.

One important property of neurons is that they fire action potentials in response to synaptic input. Each class of neuron has a unique transfer function that governs action potential output for a given input. That transfer function is generally determined by the morphology of the dendritic tree, the distribution of ligand-gated and voltage-gated conductances, properties of the axon initial segment, size of the soma, and (for certain neurons) the properties of dendritic specializations called spines. Passive properties, such as the membrane capacitance and leak conductances, also influence firing. Epilepsy-associated mutations that alter one or more of these parameters can alter neuronal input–output function to cause network instability and seizures.

Sodium channels and firing properties in epilepsy

Voltage-gated sodium channels are a well-studied and essential components responsible for action potential generation and propagation. Whole-cell voltage clamp studies in clonal cell lines (e.g., HEK293) of mutated sodium channels typically identify a range of changes in channel properties, including alterations in inactivation kinetics, channel availability, and voltage sensitivity of gating. It may be impossible to predict which of these changes result in an alteration of a neuron's firing pattern to cause epilepsy. Collectively, this problem is compounded because some changes cause increases in channel excitability while others cause decreases in channel excitability.

Numerical/computer modeling has been used to predict the consequences of such mutations on excitability, and for some mutations has encapsulated the range of biophysical changes associated with a mutation. For example, for a given input current, a model neuron containing the measured properties of mutated sodium channels would fire at a much higher rate than wild type. However, such modeling could not have predicted the mechanism of action of Dravet's syndrome-associated mutations in SCN1A. In a mouse model harboring a human disease-causing mutation (a truncation mutation), investigators showed a specific reduction in firing only in inhibitory interneurons; excitatory cell firing was rescued because of cell-type specific expression of Scn1a. This example highlights the potential strength of modeling, but also reveals a limitation that can only be overcome by a combination of genetic, cell biological, and electrophysiological analyses in a mouse model.

The axon initial segment (AIS) is a specialized region of the axon, adjacent to the soma, and is the site where action potentials are often initiated in response to somatic and dendritic input. Nav1.6 channels are enriched at the AIS, and epilepsy-causing mutations in Nav1.6 may result in an increased propensity for the AIS to trigger an action potential (i.e., for an input that would otherwise encode a lower chance of firing). In this case, it was important to understand not only the electrophysiological properties altered by a given mutation, but also the cellular localization of the mutant channel itself. It is possible that trafficking deficits caused by a mutation may not alter action potential initiation as assessed in a clonal cell (such as HEK293 cell) that lacks either the specialized trafficking mechanisms or the specialized geometry of a neuron; nonetheless, such a mutation could alter enrichment at the AIS and thereby impact firing.

Early ideas of the function of the dendritic tree emphasized the concept that the dendrite was a largely passive structure that relayed synaptic inputs to the soma and axon. More recent work showed that dendrites contain voltage-gated sodium, potassium, and Ca^{2+} channels, so that action potentials can either arise in, or 'backpropagate' into, the dendrite. The importance of this neuronal structure cannot be underestimated, and the role of dendritic function (or dysfunction) in epilepsy is likely to grow as our understanding of the basic biology increases. A number of sodium channels shown to be associated with epilepsy (SCN1A, SCN2A) localize to the dendritic tree, where they are likely to cause changes in synaptic integration and in action potential backpropagation. There is scant knowledge on the dendritic consequences of familial channel mutations.

Network Phenotype

The preceding sections have outlined the importance of understanding the molecular and neuronal consequence of familial ion channel mutations. However, neurons do not function in isolation; they participate in local and remote brain networks whose dysfunction is a hallmark of epilepsy.

Thus, understanding network behavior is a major challenge facing basic and clinical epilepsy research.

Networks and 'local' destabilization in idiopathic generalized epilepsy

Anatomically and functionally distinct regions of the brain express unique repertoires of ion channels and receptors; thus, genetic mutations may only directly impact particular brain regions. Nonetheless, these affected regions can participate in broad networks that include unaffected regions of the brain. The new network states created by the incorporation of affected regions could then create the unstable network behavior seen during epilepsy. An example of this scenario is provided by recent work in our Melbourne laboratory. We have shown that a mutation in the $GABA_A\gamma2$ gene appears to cause a specific synaptic deficit in the cortex, yet gives rise to absence-like seizures that involve thalamocortical networks. Patch clamp studies of neurons showed reduced amplitude of miniature inhibitory synaptic currents in mice heterozygous for the $GABA_A\gamma2$(Q43) allele when compared with wild-type controls. This abnormality could result in a reduction in inhibitory drive in local cortical microcircuits, which feed back to thalamic nuclei. In this example, it is possible that the thalamus – which itself would function normally if it were isolated or if it were connected to a normal cortex – would be driven into a pathological state because of the aberrant function of a component of the network in which it participates. In this way, local functional deficits can be amplified to create global pathological states through network mechanisms. In short, aberrant spike trains in a neuron may arise via a non-cell autonomous process.

Development and wiring

A potentially neglected aspect of the pathology of inherited epilepsies is the impact of ion channel mutations on brain development. Because ion channels play a central role in normal brain development, it is possible that familial mutations alter the developmental trajectory of the brain such that wiring of networks is subtly but importantly altered. One class of channels mutated in epilepsy, the $GABA_A$Rs, are particularly well positioned to impact development and network connections, since these receptors are critical in the regulation of neuronal proliferation, migration, and synaptic refinement. This regulation is due largely to $GABA_A$R-mediated depolarization, leading to Ca^{2+} influx, which occurs in the developing brain. Ligand-gated channels that themselves have significant Ca^{2+} fluxes, such as $\alpha7$ nicotinic, 5-HT3A, and NMDA receptors, are also likely to trigger signal transduction cascades with development consequences.

Other genetic mechanisms may impact network function. For example, dendritic arborization in the seizure-prone WAG/Rij rat is significantly different from that of nonepileptic controls, supporting the idea that morphological changes may underlie seizure susceptibility. Differences in dendritic branching may be developmentally altered by genetic variation unique to the WAG/Rij. In this context, it is becoming increasingly necessary to clarify whether a genetic ion channel mutation causes epilepsy because (a) it changes fundamental properties of migration, network wiring, or neuronal morphology in the developing brain; (b) it changes the acute, moment to moment function of ion channels; or (c) both developmental and acute effects combine to generate an epileptic phenotype. Separating these possibilities may be impossible in humans, but with recent advances in genetic and drug-inducible mouse models, answers to these questions should be within reach.

Future Challenges

Neural network level dysfunction is a predominant manifestation of seizures in both humans and animal models and it is not surprising that epilepsy is thought of as a 'neuronal network disease.' Genetic epilepsies have provided a wealth of information about the molecular and cellular changes that may underpin disease genesis but have not significantly impacted our understanding of pathogenic mechanism at the network level. This disconnect likely arises from the technical difficulty in translating single molecular or cellular changes to network dysfunction. Pathological changes at the level of a single neuron can be extremely subtle yet cause major effects on the networks in which they reside. Understanding the fundamentals of this 'amplification' of subtle molecular changes is crucial to our understanding of epileptogenesis. Long-term potentiation or depression may be mechanisms that are pathologically activated to amplify subtle molecular changes and impact network function, and thereby enhance seizure susceptibility. The challenge is to develop methods and approaches that can establish a chain of causality from the molecular defect to the network and behavioral consequence. Therefore, in vivo approaches, coupled with realistic computational modeling, will be necessary to bridge the various pathogenic mechanisms at work in familial epilepsies, and should provide an understanding of epileptogenesis from 'molecule to malady.'

Introduction

Temporal lobe epilepsy (TLE) may develop following a remote episode of status epilepticus (SE). There are several rodent epilepsy models that closely mimic TLE. The chemoconvulsants, kainate and pilocarpine models, have distinct mechanisms of action, but both agents induce SE within hours of injection followed by the development of chronic limbic motor epilepsy with hippocampal sclerosis. During the 'early phase' following drug injection, rats exhibit limbic motor seizures that can be observed both behaviorally and electrographically; the seizures then worsen and progress to SE. In most animal studies, an anticonvulsant medication, such as diazepam or pentobarbital, is used to decrease the duration of SE and to reduce the associated mortality. The 'late phase' (several months following SE) in these models is characterized by extensive loss of CA3 pyramidal cells, mossy fiber sprouting, and the development of spontaneous seizures involving limbic structures. These models are commonly used to evaluate the acute and late consequences of SE. During the acute phase, convulsant-induced seizures and SE are associated with multiple complex changes in the brain. Some of these changes include activation or repression of signal transduction pathways in the CNS. Such an effect on signaling pathways could influence numerous effector molecules throughout the nervous system that may have broad functional consequences. In the following sections, we focus on one candidate mechanism contributing to the alterations seen following convulsant-induced seizures and SE: aberrant regulation of Kv4.2 channels, mediated through the extracellular signal-regulated kinases 1 and 2 (ERK1/2) of the mitogen-activated protein kinase (MAPK) superfamily. We propose that through their coupling to ion channel regulation, kinase pathways have the potential to rapidly modulate neuronal excitability and contribute to seizures and SE.

Background

ERK1/2 Pathway Regulation of Excitability in Hippocampal Dendrites

The MAPK pathway consists of a superfamily of kinases that include ERK 1/2, c-Jun N-terminal kinases, p38 isoforms, and ERK5. MAPKs have been implicated in physiological processes involving the CNS. Specifically, the ERK pathway is involved in the regulation of neuronal excitability, learning, and memory. Cyclic AMP-dependent protein kinase A (PKA) and protein kinase C (PKC) are upstream regulators of the ERK pathway in neurons. Indeed, PKA and PKC activation leads to increased excitability in hippocampal CA1 pyramidal cell dendrites, through decreasing the amplitude of the rapidly-activating, A-type K^+ current (I_A) and increasing the amplitude of back-propagating action potentials (b-APs). ERK inhibition blocks this effect of PKA and PKC activation on I_A and the b-APs in dendrites. In addition, ERK inhibition shifts the voltage-dependence of activation of I_A toward more hyperpolarizing potentials. The implication of these findings is that ERK activation leads to a depolarizing shift in the voltage dependence of I_A, and

The 'late phase' (several months following SE) in these models is characterized by extensive loss of CA3 pyramidal cells, mossy fiber sprouting, and the development of spontaneous seizures involving limbic structures. These models are commonly used to evaluate the acute and late consequences of SE. During the acute phase, convulsant-induced seizures and SE are associated with multiple complex changes in the brain. Some of these changes include activation or repression of signal transduction pathways in the CNS. Such an effect on signaling pathways could influence numerous effector molecules throughout the nervous system that may have broad functional consequences. In the following sections, we focus on one candidate mechanism contributing to the alterations seen following convulsant-induced seizures and SE: aberrant regulation of Kv4.2 channels, mediated through the extracellular signal-regulated kinases 1 and 2 (ERK1/2) of the mitogen-activated protein kinase (MAPK) superfamily. We propose that through their coupling to ion channel regulation, kinase pathways have the potential to rapidly modulate neuronal excitability and contribute to seizures and SE.

Background

ERK1/2 Pathway Regulation of Excitability in Hippocampal Dendrites

The MAPK pathway consists of a superfamily of kinases that include ERK 1/2, c-Jun N-terminal kinases, p38 isoforms, and ERK5. MAPKs have been implicated in physiological processes involving the CNS. Specifically, the ERK pathway is involved in the regulation of neuronal excitability, learning, and memory. Cyclic AMP-dependent protein kinase A (PKA) and protein kinase C (PKC) are upstream regulators of the ERK pathway in neurons. Indeed, PKA and PKC activation leads to increased excitability in hippocampal CA1 pyramidal cell dendrites, through decreasing the amplitude of the rapidly-activating, A-type K^+ current (I_A) and increasing the amplitude of back-propagating action potentials (b-APs). ERK inhibition blocks this effect of PKA and PKC activation on I_A and the b-APs in dendrites. In addition, ERK inhibition shifts the voltage-dependence of activation of I_A toward more hyperpolarizing potentials. The implication of these findings is that ERK activation leads to a depolarizing shift in the voltage dependence of I_A, and

thereby increases excitability in the dendrites. These changes are thought to be due to ERK pathway activation coupling to phosphorylation of Kv4.2 channel subunits, which are the major α-subunits of the channels underlying I_A in CA1 pyramidal cell dendrites.

Kv4.2 Channels Underlie I_A in Hippocampal Dendrites

Kv4.2 is a voltage-dependent potassium channel α-subunit that is localized to the somatodendritic regions of hippocampal neurons and contributes to I_A in the dendrites. Because of the role of I_A in reducing action potential initiation and back-propagation in the dendrites, this channel plays a major role in the regulation of postsynaptic excitability. Kv4.2 knockout mice show a complete loss of I_A in the hippocampal CA1 dendrites and have an increase in b-APs. Furthermore, the Kv4.2 knockout mice show a decreased threshold for the induction of long-term potentiation. Modulation of Kv4.2 channels can occur through multiple kinase regulatory sites, which alter channel kinetics, expression, or trafficking.

Activation of the ERK Pathway in Epilepsy

The contribution of protein kinase cascades to synaptic plasticity – particularly to LTP, learning and memory – has received significant attention. Recent studies have begun to examine the role of protein phosphorylation in neuropathology, including epilepsy. In particular, the ERK pathway has been implicated in a number of pathological processes involving the central nervous system. Modulation of ERK activation has been demonstrated following seizures and SE in rodent models in vivo and in hyperexcitability models in vitro. The ERK pathway regulates a broad range of target molecules through proline-directed serine/threonine phosphorylation. Identification of the effector molecules for the ERK pathway, under both physiologic and pathologic conditions in the nervous system, is an area of active investigation. In previous studies, we identified the potassium channel subunit Kv4.2 as a phosphorylation target of the ERK1/2 pathway. Following phosphopeptide mapping, we generated antibodies that specifically recognize Kv4.2 proteins in rat brain extracts when phosphorylated at the ERK sites. As noted above, Kv4.2 channels are a major contributor to I_A in the dendrites of hippocampal CA1 neurons, and the ERK1/2 pathway regulates I_A. Thus, our working hypothesis is that the ERK effect on I_A is via direct phosphorylation of Kv4.2 channel subunits.

Kv4.2 Alterations in Epilepsy

Potassium channelopathies on a genetic basis are associated with an epilepsy phenotype. Recently, a mutation in the Kv4.2 gene leading to a truncation of the carboxyl-terminus has been described in TLE. In addition, defects in the gene encoding an auxiliary subunit for Kv4.x channels, Kvβ2, have been described in human developmental epilepsy. These studies suggest that defects in the primary, pore-forming Kv4.2 channel subunit or an auxiliary subunit for Kv4.x channels result in increased excitability and seizures in humans. Furthermore, alterations in I_A have also been reported in human epilepsy. Thus, there may be acquired or activity-dependent alterations in Kv4.2 channels, and potentially other ion channels, that contribute to seizures and epilepsy. It has recently been shown in a heterotopia model of cortical malformations and epilepsy that a down-regulation of Kv4.2 may contribute to seizures in this model. Studies in adult rodent epilepsy models have demonstrated activity-dependent downregulation of Kv4.2 channels with associated increased dendritic excitability. These studies also demonstrated an increase in phosphorylation of Kv4.2 by ERK, which would further downregulate I_A. Following pentylenetetrazole- and kainate-induced seizures and electroconvulsive shock, there is a reduction in Kv4.2 mRNA levels in hippocampus. In the kainate model, animals that did not exhibit seizures did not have altered Kv4.2 expression.

Even though it is clear that Kv4.2 can modulate hyperexcitability and play a role in epilepsy, it is unclear whether the increase in ERK activation seen in the early phase following chemoconvulsant stimulation directly couples to Kv4.2, and whether the expression of Kv4.2 proteins is altered during this early phase of epileptogenesis. Studies in our lab have focused on this possibility.

Methods

Video-EEG analysis was used to monitor behavioral and electrographic seizure activity, and to correlate seizures and SE with ERK activation and Kv4.2 phosphorylation following convulsant stimulation (using kainate injection intraperitoneally in adult rats). At various time points following the onset of seizures and SE, the animals were sacrificed and the hippocampus rapidly subdissected. Some of the animals were allowed to survive until they developed epilepsy (3–4 months after kainate-induced SE). Video-EEG monitoring was used to confirm that these animals had developed chronic, spontaneously recurring seizures. Homogenates, total membranes, and synaptosomes were prepared from the hippocampal tissue. The samples were then used for Western blotting with antibodies that detect levels of total protein (phosphorylated and unphosphorylated) or that selectively recognize only the phosphorylated form of the protein. Commercially available antibodies were used to recognize total ERK1/2 (the dually phosphorylated activated form of ERK1/2) and total Kv4.2. For the studies

evaluating levels of ERK-phosphorylated Kv4.2 (phospho-Kv4.2), we developed antisera based on the results of phosphopeptide mapping studies.

Recent Results

An early poststimulation change in Kv4.2 channel phosphorylation and localization could produce dramatic alterations in hippocampal excitability and contribute to continuous seizure activity during SE. In the first series of studies, we examined whether early seizures and SE were associated with ERK activation and coupling to Kv4.2 phosphorylation in hippocampus. In parallel, we evaluated Kv4.2 localization and phosphorylation in the synaptosomal subcellular compartment. We found an increase in ERK activation and phosphorylation of Kv4.2 in hippocampal homogenates during kainate-induced SE compared to sham controls (**Figure 1(a)**). There was no change in total Kv4.2 levels in whole cell membrane extracts from hippocampus in either group. Next we examined ERK phosphorylation of Kv4.2 channels in hippocampal synaptosomal extracts from rats following SE. We found that after SE there is an increase in the levels of ERK phosphorylated Kv4.2 and a decrease in total Kv4.2 in hippocampal synaptosomes isolated from animals with SE compared with sham controls (**Figure 1(b)**). We predict that ERK phosphorylation of Kv4.2 channels and a decrease in the number of Kv4.2 channels postsynaptically will lead to a decrease in I_A in this region. The net result of such an alteration would be a significant increase in excitability in the hippocampal dendrites, which could contribute to alterations in neuronal network behavior (and potentially seizures) in this region.

Through these experiments we have been able to demonstrate that rapid alterations in the ERK pathway are associated with convulsant stimulation and that Kv4.2 is one candidate effector. In addition, there are associated changes in the synaptic localization of Kv4.2 channels during SE, but the mechanism underlying this effect is unknown. We have provided a figure to illustrate the effects of SE on the localization of total and phosphorylated Kv4.2 channels (**Figure 2**). We also have examined whether there are long-term alterations in Kv4.2 following kainate-induced SE. In rats with kainate-induced epilepsy, there was a downregulation of total Kv4.2 protein levels and increased ERK phosphorylated Kv4.2 (**Figure 3**), as also seen in the pilocarpine epilepsy model. These findings suggest that an *acquired* (activity-dependent) alteration in Kv4.2 channels, in part as a result of kinase-mediated events, occurs in SE and epilepsy.

Future Goals

The findings from our and other laboratories indicate that posttranslational mechanisms play an important role in

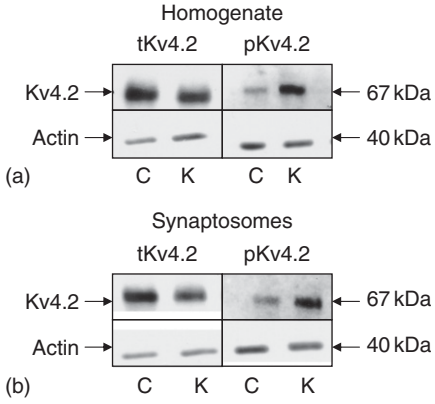

Figure 1 Status epilepticus (SE) is associated with an increase in ERK-phosphorylated Kv4.2 and a decrease in Kv4.2 protein in hippocampal synaptosomes during SE. Following 1 h of SE hippocampi were dissected and total cell (a) and crude synaptosomal (b) extracts were prepared. Western blotting was performed for ERK phosphorylated Kv4.2, total Kv4.2 and actin levels. There was an increase in phosphorylated Kv4.2 but no change in the total Kv4.2 levels using homogenates from SEK compared with control (C) (upper panel a). In crude synaptosomes there was increased ERK-phosphorylated Kv4.2 and a decrease in total Kv4.2 levels in SE (upper panel b). The actin levels were unchanged in both conditions (a & b lower panels).

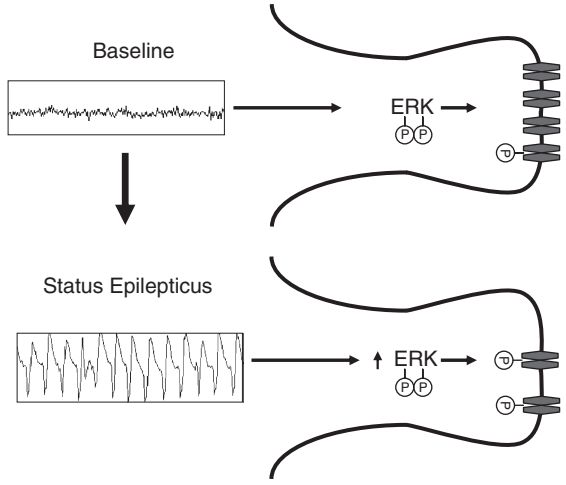

Figure 2 Model of dendritic spine with alterations in ERK activation and Kv4.2 in hippocampus during SE. Under baseline conditions in sham animals there were basal levels of ERK activation and ERK phosphorylation of Kv4.2, which was seen in total membranes and in the synaptosomal regions (top panel). After prolonged SE there was increased ERK activation in hippocampus. In addition, there was increased ERK phosphorylated Kv4.2 in hippocampus (upper panel). There was also a decrease in the level of Kv4.2 following SE, which was seen only in synaptosomes. In contrast, Kv4.2 levels in whole-cell extracts were stable, suggesting altered Kv4.2 trafficking following SE.

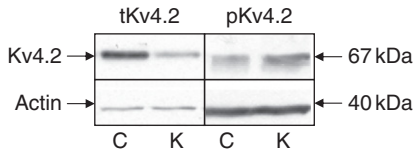

Figure 3 Hippocampal levels of ERK-phosphorylated Kv4.2 are increased and total Kv4.2 levels are decreased in epileptic animals. Following kainate-induced SE, rats developed epilepsy. Sham controls were assessed in parallel. The hippocampus from the epileptic animals (K) and sham controls (C) was removed and membrane extracts were processed for western blotting. Increased ERK-phosphorylated Kv4.2 (right upper panel) and a downregulation of total levels of Kv4.2 channels was found in hippocampal membranes (left upper panel) from epileptic animals. The actin levels were unchanged in both conditions (lower panels).

epilepsy. A number of studies have indicated that post-translational regulation of ion channels plays an important role in channel function and trafficking. In future studies, we plan to further characterize the localization changes in total and ERK-phosphorylated Kv4.2 during SE, and to evaluate whether signal transduction mechanisms play a role in the alterations in Kv4.2 trafficking. It is known that several other kinases are involved in the regulation of Kv4.2 channels in hippocampus. One possibility is that several kinase pathways converge at the point of Kv4.2 regulation, to modulate excitability in neurons during SE and possibly in epilepsy.

SE is associated with significant mortality and morbidity nationwide. Our studies are focused on understanding the cellular mechanisms that are involved in the development of prolonged, continuous seizure activity. We propose that activity-dependent alterations in ion channel regulation contribute to increased network excitability and possibly the potentiation of SE. Our studies are focused on understanding the mechanisms underlying the regulation of a particular ion channel, Kv4.2, during SE. Kv4.2 channels are critical regulators of postsynaptic excitability in the hippocampus. Thus, we predict that alteration in the phosphorylation and total levels of Kv4.2 channels during SE play a significant role in neuronal hyperexcitability and seizures. Our hope is that the findings from these studies will provide novel insights into the mechanisms involved in the regulation of Kv4.2 under physiologic and pathological conditions (such as SE), and that these studies will provide insights into the development of new interventions for the treatment of SE. Possible loci for therapeutic interventions would be at the level of Kv4.2 or the upstream kinase signaling pathways that are modulated during seizures and SE, and are involved in the regulation of Kv4.2. Some of the mechanisms that are involved in the modulation of Kv4.2 during SE may apply to other ion channels that are altered during seizures. Furthermore, these studies should provide the foundation for future investigations evaluating whether the regulatory mechanisms that are key during the early phase of SE persist in later stages of epileptogenesis and in chronic epilepsy.

Introduction

What are BK Channels?

BK channels are large-conductance, voltage, and calcium-activated potassium channels. A cartoon showing essential features of this protein is presented in **Figure 1**(**a**). The pore-forming α subunit belongs to the voltage-dependent potassium channel family. Thus, they have a typical set of six transmembrane domains (S1–S6) with charged S4 domains that moves across the electric field upon membrane depolarization and imparts energy to channel opening. Unique to BK channels, they have charged residues in S2 and S3 domains that also contribute to voltage sensing, and an additional S0 transmembrane domain. They also have intrinsic calcium binding sites in their carboxyl terminal tail that impart low affinity calcium activation. They have a potassium selectivity sequence that allows high conductance while maintaining selectivity for potassium. BK channels also assemble with a family of two-transmembrane accessory β subunits (β1–β4), through interactions in the N-terminus-S3 domain.

There are several additional features unique to BK channels that have important implications for how they regulate membrane excitability. As implied by the name, BK (Big K^+ conductance, also called MaxiK) channels have an especially large single channel conductance of $\sim$250 pS. This is in the order of 10–20 times larger than most other potassium channels (for example, Kv1.1 channel is $\sim$12 pS). The large conductance means that the opening of relatively few BK channels can have a significant impact on membrane voltage. The relevance of this is seen in vascular smooth muscle where BK channels have an established role in control of vascular tone. Smooth muscle continually gauges global calcium concentration via spontaneous calcium-induced activation of ryanodine receptors in the sarcoplasmic reticulum. As global calcium rises, the probability of ryanodine receptor opening rises to cause a transient and local release of calcium (so called 'calcium spark') that activates BK channels in the apposed plasma membrane. A single calcium spark has been estimated to activate a cluster of only $\sim$15 BK channels, that in turn hyperpolarize the membrane by greater than 20 mV. This hyperpolarization then deactivates voltage-dependent calcium channels and relaxes smooth muscle.

BK channels have the specialized ability to regulate calcium influx that is coincident with membrane depolarization. This is a unique property among potassium channels, and its biophysical basis is shown in **Figure 1**. BK channels are activated by both voltage and calcium, independently (**Figure 1**(**b**)). At a fixed voltage, increasing calcium raises channel open probability. At a fixed calcium concentration, increasing voltage also increases channel opening. However, physiological calcium rise or depolarization alone is insufficient to raise BK channels open probability to significant levels. This property is demonstrated in **Figure 1**(**c**). In nominal (nanomolar) calcium, BK channels open in a voltage-dependent manner but well outside the physiological voltage range of any cell type ($> +100$ mV). As calcium is increased to micromolar concentrations, the conductance–voltage relationship becomes shifted to physiological ranges. Fairly high calcium concentrations (e.g., 7 μM, as shown in **Figure 1**(**c**)) nevertheless still require membrane depolarization to activate significant numbers of channels. Thus, BK channels require the concerted activation by depolarization and relatively high calcium to promote significant channel openings. As a consequence, they are frequently physically and functionally colocalized with a calcium source, such as voltage-dependent calcium channels, NMDA receptors, or ryanodine receptors. By repolarizing membranes in response to coincident calcium influx and depolarization, BK channels serve as a negative feedback regulator of voltage-dependent calcium channels.

Introduction

What are BK Channels?

BK channels are large-conductance, voltage, and calcium-activated potassium channels. A cartoon showing essential features of this protein is presented in **Figure 1(a)**. The pore-forming α subunit belongs to the voltage-dependent potassium channel family. Thus, they have a typical set of six transmembrane domains (S1–S6) with charged S4 domains that moves across the electric field upon membrane depolarization and imparts energy to channel opening. Unique to BK channels, they have charged residues in S2 and S3 domains that also contribute to voltage sensing, and an additional S0 transmembrane domain. They also have intrinsic calcium binding sites in their carboxyl terminal tail that impart low affinity calcium activation. They have a potassium selectivity sequence that allows high conductance while maintaining selectivity for potassium. BK channels also assemble with a family of two-transmembrane accessory β subunits (β1–β4), through interactions in the N-terminus-S3 domain.

There are several additional features unique to BK channels that have important implications for how they regulate membrane excitability. As implied by the name, BK (Big K^+ conductance, also called MaxiK) channels have an especially large single channel conductance of ~250 pS. This is in the order of 10–20 times larger than most other potassium channels (for example, Kv1.1 channel is ~12 pS). The large conductance means that the opening of relatively few BK channels can have a significant impact on membrane voltage. The relevance of this is seen in vascular smooth muscle where BK channels have an established role in control of vascular tone. Smooth muscle continually gauges global calcium concentration via spontaneous calcium-induced activation of ryanodine receptors in the sarcoplasmic reticulum. As global calcium rises, the probability of ryanodine receptor opening rises to cause a transient and local release of calcium (so called 'calcium spark') that activates BK channels in the apposed plasma membrane. A single calcium spark has been estimated to activate a cluster of only ~15 BK channels, that in turn hyperpolarize the membrane by greater than 20 mV. This hyperpolarization then deactivates voltage-dependent calcium channels and relaxes smooth muscle.

BK channels have the specialized ability to regulate calcium influx that is coincident with membrane depolarization. This is a unique property among potassium channels, and its biophysical basis is shown in **Figure 1**. BK channels are activated by both voltage and calcium, independently (**Figure 1(b)**). At a fixed voltage, increasing calcium raises channel open probability. At a fixed calcium concentration, increasing voltage also increases channel opening. However, physiological calcium rise or depolarization alone is insufficient to raise BK channels open probability to significant levels. This property is demonstrated in **Figure 1(c)**. In nominal (nanomolar) calcium, BK channels open in a voltage-dependent manner but well outside the physiological voltage range of any cell type ($> +100$ mV). As calcium is increased to micromolar concentrations, the conductance–voltage relationship becomes shifted to physiological ranges. Fairly high calcium concentrations (e.g., 7 μM, as shown in **Figure 1(c)**) nevertheless still require membrane depolarization to activate significant numbers of channels. Thus, BK channels require the concerted activation by depolarization and relatively high calcium to promote significant channel openings. As a consequence, they are frequently physically and functionally colocalized with a calcium source, such as voltage-dependent calcium channels, NMDA receptors, or ryanodine receptors. By repolarizing membranes in response to coincident calcium influx and depolarization, BK channels serve as a negative feedback regulator of voltage-dependent calcium channels.

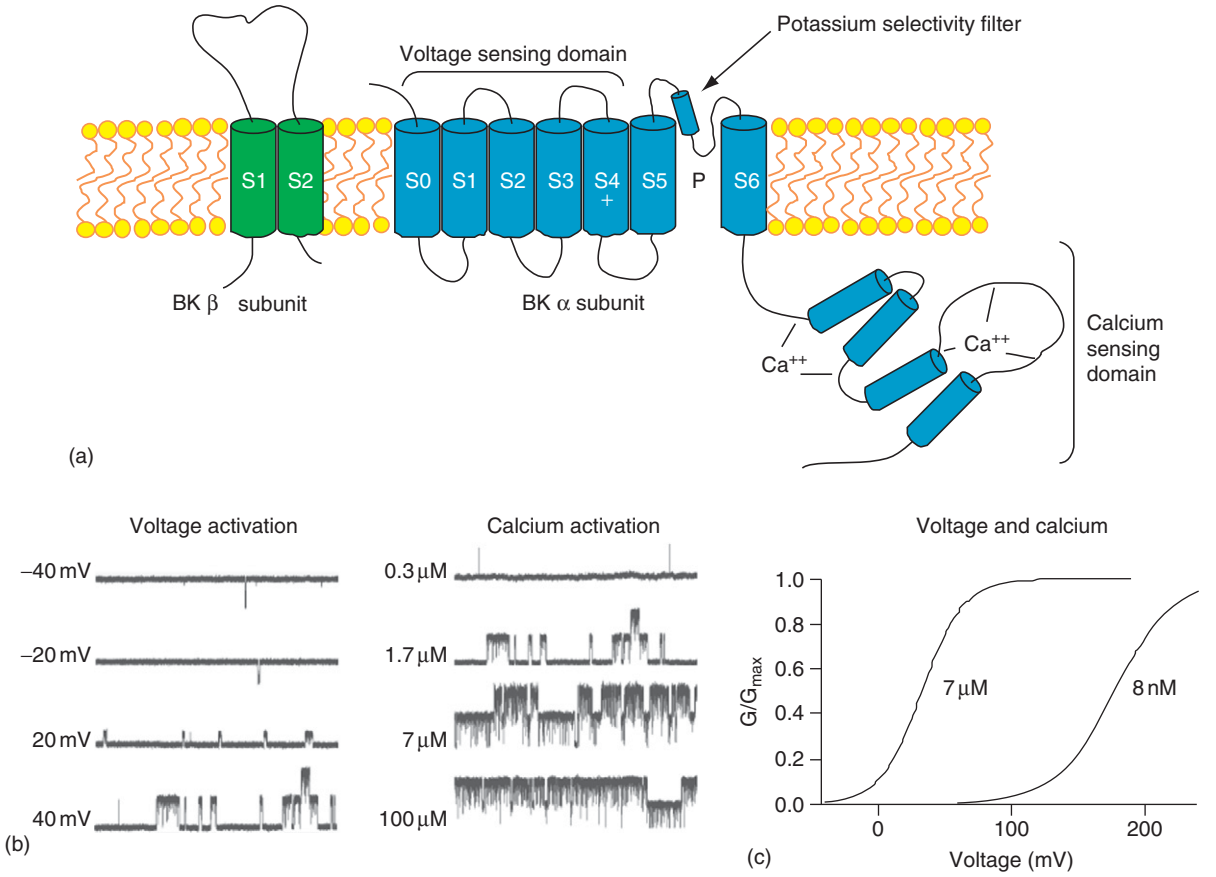

Figure 1 (a) Cartoon showing essential features of BK channels. (b) Example single channel recording of BK channels (N is 2 channels in the patch) activated by calcium or voltage. Left panel shows record traces at constant 1.7 μM internal calcium and using step potentials from −40 mV to +40 mV to activate the channel. Right panel is the same patch recorded at constant +40 mV holding potential and perfusing different buffered internal calcium. (c) BK channel steady-state normalized conductance–voltage curves for indicated calcium concentrations. High calcium shifts conductance–voltage curves to physiological voltage ranges. Conductance–voltage curves are derived from boltzman fits of mean data obtained from macroscopic currents. Currents were from mouse slo channels expressed in transfected HEK293 cells using the inside-out patch clamp configuration using high potassium concentrations (140 mM potassium outside and inside the patch).

Despite expression from a single gene, BK channels represent a diverse group of channels. This is partly mediated by a family of tissue-specific accessory subunits (β1–β4) that alter biophysical properties and pharmacology of BK channels. BK channels can be broadly classified as inactivating and non-inactivating BK channels. The β2 subunit and most splice products of the β3 subunit underlie inactivating BK channels. The non-inactivating channels are further categorized into 'type I' and 'type II' channels, based on bilayer recordings from synaptosome membrane preparations. Type I BK channels are relatively more calcium sensitive, have faster gating kinetics, and are sensitive to scorpion venoms iberiotoxin and charybdotoxin. Type II BK channels have slow gating kinetics, are less sensitive to calcium, and are insensitive to scorpion venoms. Association with the β4 subunit converts fast-gated, type I BK channels to the slow gated, iberiotoxin resistant type II BK channels. Finally, the β1 subunit slows gating and enhances BK channel activation but is predominantly expressed in smooth muscle.

BK Channel Impact on Epilepsy

Given the complexity of the nervous system, the impact of BK channels on epilepsy cannot be inferred solely from cellular neurophysiology. Before a BK channel knockout mouse was available, studies using specific blockers of BK channels indicated that reducing BK channel activity was not pro-epileptic. Injection of A-type and delayed rectifier potassium channels blockers into the brains of mice caused convulsions and seizures, whereas BK channel blockade did not. Interestingly, blocking BK channels does cause motor impairment. Consistent with the pharmacology, subsequent studies of BK channels gene knockout mice also do not demonstrate evidence of seizure activity, but do show defects in motor coordination and motor strength.

In contrast to effects of BK channel antagonists, gain-of-function of BK channel mutations have been shown to promote epilepsy. In humans, a mutation was identified

in one of the calcium binding domains of the BK channel (D434G) that is associated with epilepsy and paroxysmal movement disorders in family members that carry the allele. The epilepsy type associated with this mutation is absence, but generalized tonic-clonic seizures are occasionally seen in some individuals. Analysis of the mutation in heterologous expression systems (*Xenopus oocytes* and transfected cells) indicates that the mutation is a gain-of-function for BK channels. Activation is faster and channel steady-state openings are shifted to more negative membrane potentials. Similarly, knockout of the BK channel β4 subunit, which causes a gain-of-function of BK channels, also causes epilepsy in mice. In this case, perhaps because the β4 subunit has highest expression in the hippocampus, the seizures appear to be temporal lobe in origin, secondarily generalized, and of a non-convulsive type seizure. In both cases, the effects of the β4 knockout or D434G mutation are, perhaps paradoxically, to speed BK channel activation to rates that theoretically would allow a greater contribution of BK channels to repolarization of action potentials.

Background

BK Channel Regulation of Membrane Voltage

Because BK channels require relatively high calcium in combination with depolarization to be activated, they generally do not contribute to resting membrane potentials in neurons. Rather, BK channels are activated during the repolarization phase of an action potential, when calcium influx is greatest. They contribute to a transient outward current that sharpens the action potential and, in many neurons, also produce a transient afterhyperpolarization (fast AHP or fAHP). The fast decay of the AHP (<1 millisecond) is thought to occur because BK channels are also voltage sensitive and therefore deactivate quickly following repolarization. Although BK channels are not thought to directly regulate action potential firing frequency, they nevertheless have an important role in shaping action potential width, which impacts the relative voltage-dependent calcium channel activation and calcium influx into the cell. As will be discussed later, BK channel effects on action potential width and calcium influx may indirectly affect the recruitment of other potassium currents that control firing frequency.

It is worthwhile mentioning two other important calcium-activated potassium currents that contribute to AHPs in neurons. They have a more sustained activation and greater impact on directly regulating action potential firing rates. The decays of medium and slow AHPs (mAHP and sAHP, respectively) occur on the order tens of milliseconds to seconds, respectively. Although several channels affect the mAHP, the predominant calcium-activated channel is the small conductance, SK channel. Unlike BK channels, these channels are voltage-insensitive but have greater calcium sensitivity (submicromolar calcium). They are blocked by the bee venom, apamin. The channels that mediate the sAHP in peripheral neurons (such as enteric neurons) are the related family member, intermediate conductance (IK) calcium-activated potassium channels. However, in most central neurons, the channel underlying the sAHP is unknown.

How Do Bk Channels Increase Excitability?

Before there were indications that BK channels may have pro-epileptic effects, the precedence for a potassium channel that increases excitability was provided by the Kv3 voltage-gated potassium channels. These channels are expressed in a variety of 'fast-spiking' neurons, including inhibitory interneurons that fire action potentials at high rates with little adaptation. The Kv3 channels are high voltage activated, fast-gated potassium channels tailored for the fast-spiking rates. Their ability to quickly repolarize action potentials effectively removes sodium channel inactivation. Thus, during a spike train, action potentials can be faithfully driven at rates of 100 Hz or greater. Knockout of Kv3.2 reduces firing frequency and causes action potential failure during high current injections. As a consequence of reduced excitability in inhibitory neurons, the Kv3.2 KO mice are susceptible to seizures.

A survey of BK channel function in mammalian neurons indicates that it is also BK channels' effect on action potential firing frequency where we see effects that increase excitability. A conceptual scheme for BK channel's effect on action potential firing rates is shown in **Figure 2**. There are some common themes that emerge between different studies. One concept is that BK channel sharpening of action potentials may preclude activation of other, slower-gated potassium channels that would otherwise reduce excitability. This effect is seen in anterior pituitary somatroph neurons that require long plateau-bursts of action potentials to raise calcium to sufficient levels to evoke growth hormone release. The mechanism for plateau bursts is partly mediated by BK channel's effects on action potentials. BK channels activation in these cells reduces the height of the action potential, but is not sufficient for complete repolarization of the action potential, thereby generating the long-plateau bursts. Block of BK channels allow a larger depolarization and activation of a high-voltage activated, delayed rectifier potassium channel that sharply repolarizes the action potentials and converts plateau bursts to spikes.

In hippocampus CA1 pyramidal neurons, action potential trains progress with an early burst of spikes that is followed by spike-frequency adaptation. The early, high frequency action potential firing is promoted by the sharp repolarization and fAHP conferred by BK channels. Block of BK channels broadens action potentials and allows

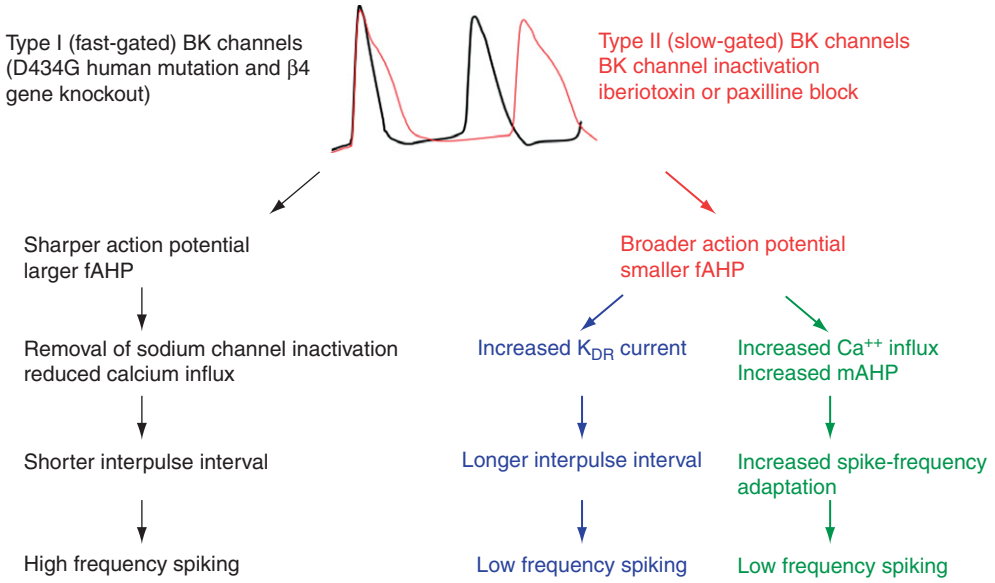

Figure 2 Scheme for BK channel effects on firing frequency. Consequences of fast-gated BK channels (black) encompassing Type I BK channels, the pro-epileptic D434G human mutation or the β4 gene knockout in mice are shown on the left. Fast-gated BK channels are effective at removing sodium channel inactivation and precluding activation of other potassium currents to enhance repetitive firing. Consequences of slow-gated (red) type II BK channels, BK channel inactivation or pharmacological block are shown on right. Slow-gated BK channels or their absence results in action potential broadening. The consequences are the recruitment of other potassium conductances such as the delayed rectifier in CA1 cells (blue scheme), or enhanced calcium influx and SK channel activation in dentate gyrus granule cells (green scheme) to reduce firing frequencies. ''Scheme for BK channels effects. ... ''has an acknowledgment that I emailed to Margaret Crick but for some reason was not forwarded to you. Please append to Figure 2 legend the following acknowledgement'' [Action potential traces (black trace is absence of iberiotoxin, red trace is with iberiotoxin block) were adapted from Gu N, Vervaeke K and Storm JF, *Journal of Physiology*, Vol. 580, No. 3, 859–882, 2007 with permission from the author and Wiley-Blackwell Publishing.'']

recruitment of a delayed-rectifier potassium current that reduces firing frequency (**Figure 2**). In addition, BK channels have a secondary effect that contributes to greater firing frequencies in CA1 cells. BK channels' ability to repolarize action potentials, and then quickly deactivate, effectively removes sodium channel inactivation without interfering with the depolarization phase of subsequent action potentials. This mechanism is ideal for supporting high frequency action potential firing and is analogous to the role that fast-gated Kv3 channels serve in fast-spiking interneurons. Indeed, in adrenal chromaffin cells, BK channel blockade also reduces firing frequencies through a mechanism that is attributed to increased sodium channel inactivation.

The examples given earlier indicate that fast-gated BK channels may be incompatible with some firing patterns that require broadened action potentials to recruit other potassium currents. The BK channel accessory β4 subunit is one example where evolution has designed a mechanism to prevent BK channel's activation during a spike. **Figure 3** demonstrates how β4 may prevent BK channel activation. Utilizing a square wave voltage stimulus (**Figure 3(a)**), we observe that BK/β4 channels have a greater than ten-fold slower activation than BK channels lacking β4 subunits. Relative to the short times scales of an action potential (<2 ms in most neurons), β4 at moderate calcium concentrations (7 μM) slows channel activation to rates that would preclude significant BK current during an action potential. Indeed, utilizing an action potential-shaped stimulus waveform (see **Figure 3(b)**), fast-gated BK channels in 7 μM calcium have a significant current, whereas BK/β4 channels do not. However, as calcium is increased to 100 μM, activation rates are similar for both channel subtypes (**Figure 3(a)**) and both can contribute to action potential repolarization (**Figure 3(b)**, right panel). Thus, the role of BK/β4 channels is strictly dependent on the local calcium environment. One may speculate that BK channels are strongly inhibited by the β4 subunit in the absence of very high calcium concentrations. However, at some sites where calcium rises to high concentrations, such as occurs at presynaptic sites, β4 would be permissive for BK channel contribution to action potential repolarization.

Methods

To investigate the role of the BK channel β4 subunit in neurons, the first exon of the β4 gene was deleted in embryonic stem cells by homologous recombination with the enhanced green fluorescent protein cDNA (eGFP). The eGFP replacement serves dual functions.

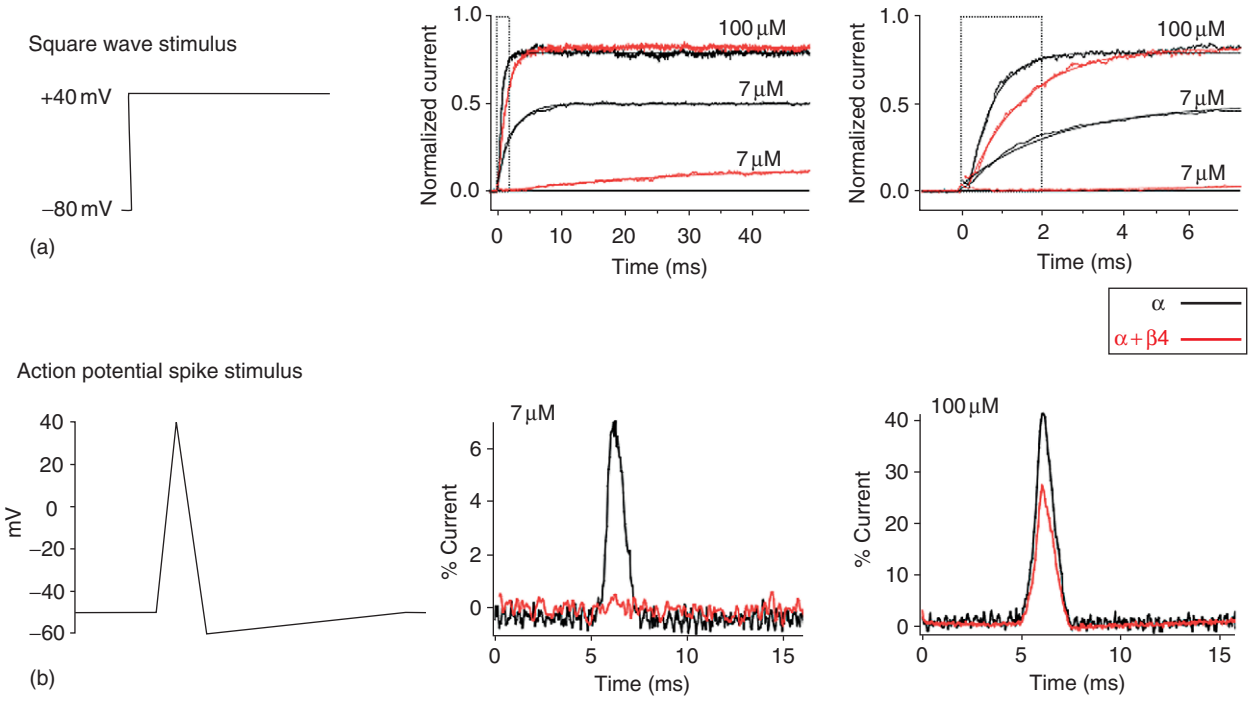

Figure 3 Effects of the β4 subunit on BK channel gating. (a) BK channel activation using a step potential to +40 mV (left panel) and resultant currents shown at two timescales (right panels). Time constants for activation in 7 μM calcium are 7.3 ± 1.7 ms for α and 244 ± 93 ms for α + β4. Time constants for activation in 100 μM calcium are 0.7 ± 0.03 ms for α and 1.5 ± 0.20 ms for α + β4 The dashed box indicates the theoretical time window for potassium currents to influence action potential repolarization. (b) BK currents (right panels) evoked by a 2.5 ms duration spike-shaped stimulus (left panel). Red traces are α + β4 and black traces α alone channels. Calcium concentrations are indicated near the traces. Currents were measured from mouse slo and mouse slo/β4 BK channels expressed in transfected HEK293 cells using the inside-out patch clamp configuration and physiological ionic concentrations.

First, it deletes a critical first exon and, by inclusion of a transcriptional terminator, precludes expression of other downstream β4 exons. In addition, the eGFP serves as a reporter for assaying distribution of the normal β4 gene expression. The gene-targeted embryonic stem cells were used to generate mice that carry the targeted β4 allele in the germline. Staining for eGFP in the transgenic mice showed that β4 was most abundant in the dentate gyrus of the hippocampus, an observation that consequently directed us to focus on these cells for further studies. As discussed above, EEG recordings indicated that β4 knockout mice had generalized, non-convulsive seizures that appeared to initiate from the temporal lobe. This feature of these mice was also consistent with the possibility that a defect in the hippocampus may contribute to the seizure phenotype.

Our study of the β4 subunit was investigated in brain slices of β4 knockout and wild type mice, using single channel recording of BK currents from excised patches and whole cell recording under current clamp conditions to observe effects on action potential firing patterns. For current clamp studies, the intracellar/pipette solution was weakly buffered to near resting calcium levels with 0.1 mM EGTA (resulting in ∼50 nM free calcium concentration) to allow calcium to accumulate during action potential firing. This technical approach allowed us to study how calcium-activated potassium currents regulate action potential shape and firing patterns in wild type and knockout granule cells.

Recent Results

The β4 Knockout as a Model for BK Channel Gain-Of-Function

Given that β4 slows BK channel activation, one may expect that the knockout would be a gain-of-function, allowing a greater BK channel activation during action potential firing. Consistent with this hypothesis, the β4 knockout indeed causes a sharpening of action potentials (**Figure 4(a)**) that is sensitive to the BK channel blocker, paxilline. In the wild type mouse, where β4 presumably reduces BK channel activation, action potentials are relatively broad and paxilline has little effect. Most importantly, the gain-of-function BK channels enhance firing frequency, and this effect can be reversed by BK channel blockade with paxilline (**Figure 4(b)**).

How does action potential broadening by β4 decrease firing frequency in the dentate gyrus? As discussed above, blocking BK channels and action potential broadening in CA1 cells secondarily recruits a slow-gated delayed

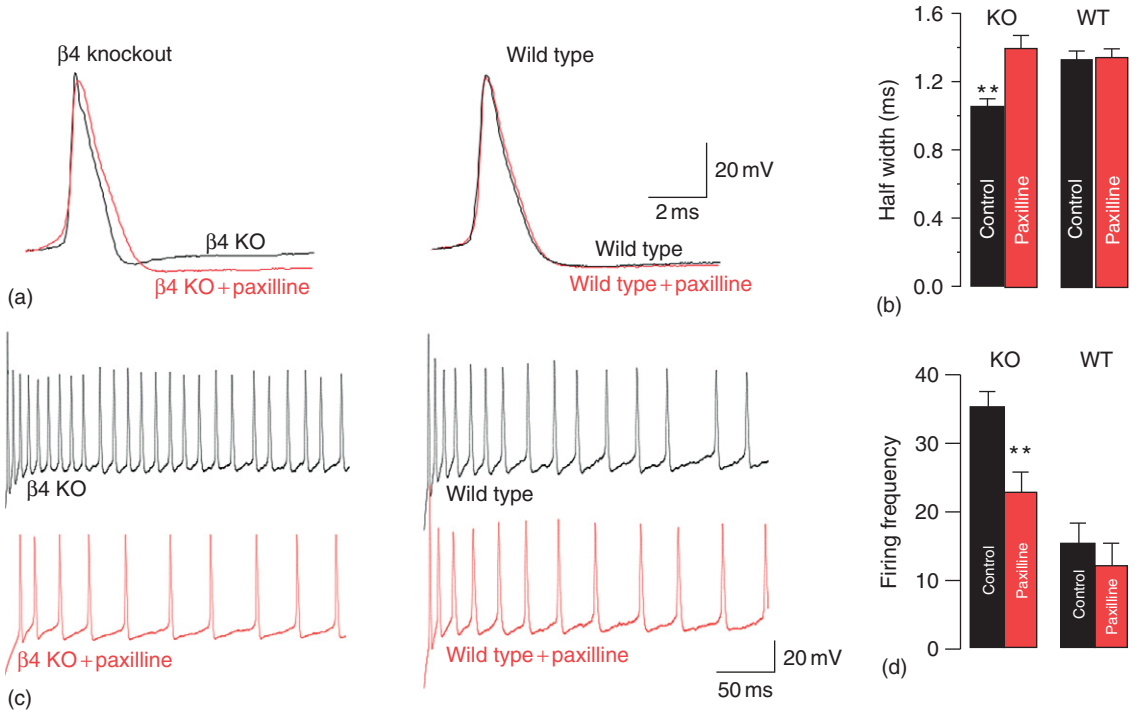

Figure 4 Firing properties of dentate gyrus granule cells indicate that gain-of-function of BK channels sharpens action potentials but increases firing frequencies. Action potentials are evoked by current clamp in the absence (black) or presence of BK channel blocker paxilline (5 μM, red). In knockout cells action potentials are sharp and have a more sustained afterhyperpolarization (a). Block of BK channels in the knockout sharpens action potentials (a, b) but increases firing frequencies (panels c and d). In wild type cells the β4 subunit reduces BK channel activation during action potential firing. This is evidenced by the fact that paxilline block has little effects on action potential waveform (a, b) or firing frequency (c, d). Representative data is shown from the 10th action potential waveforms during a 300 pA current injection. Representative firing patterns are during the first 300 ms during the trace.

rectifier potassium current that moderates spike frequency (Figure 2). In dentate gyrus granule cells, it appears that action potential broadening instead recruits SK channels and results in spike frequency adaptation. The mechanism is likely to be due to increased calcium influx during the broadened action potentials. Consistent with this hypothesis, a small concentration of cadmium, which non-selectively blocks many voltage-dependent calcium channels, increases firing frequency similar to that seen in cells from the β4 knockout/BK channel gain-of-function model (data not shown). The role of SK channels can be evaluated utilizing the SK channel blocker, apamin. In wild type neurons, apamin reduces the interpulse interval (an indicator of spike frequency adaptation) and increases firing rates (Figure 5). However in the β4 knockout, where BK channels are active, SK channel blockade does not affect the interpulse interval or firing frequency. These findings suggest a mechanism whereby β4 confers slow gating kinetics to BK channels to restrict their contribution to action potential repolarization. The broader spike width allows the necessary recruitment of other potassium currents during the interspike that moderate firing frequencies. In contrast, gain-of-function of BK channels in the β4 knockout reduces SK channel recruitment and enhances excitability.

Regulatory Mechanisms to Prevent BK Channels Activation

The human D434G mutation and the β4 gene knockout have uncovered an important glimpse into the regulation of channel expression that must underlie the finely tuned electrical properties of neurons. The relatively large potassium conductance of BK channels, unless appropriately regulated, can have antagonistic effect on activation of other potassium channels, such as delayed rectifier channels in CA1 cells or SK channels in dentate gyrus granule cells, that may otherwise reduce excitability. In hindsight, we can see how other potential regulatory mechanisms, like the β4 subunit, preclude BK channel activation during action potential spiking in neurons where β4 is not expressed. Indeed, in CA1 cells BK channels facilitate high frequency spiking only during early components of a spike train. Inactivation of BK channels at later components of the spike train, perhaps mediated by the accessory B_2 Subunit, allow action potential broadening and spike frequency adaptation. As well, an alternative splice product of BK channels that is expressed in pituitary and adrenal gland, the so called 'STREX' exon, promotes BK channel activation to similar levels as the proepileptic D434G mutation. However, expression of this

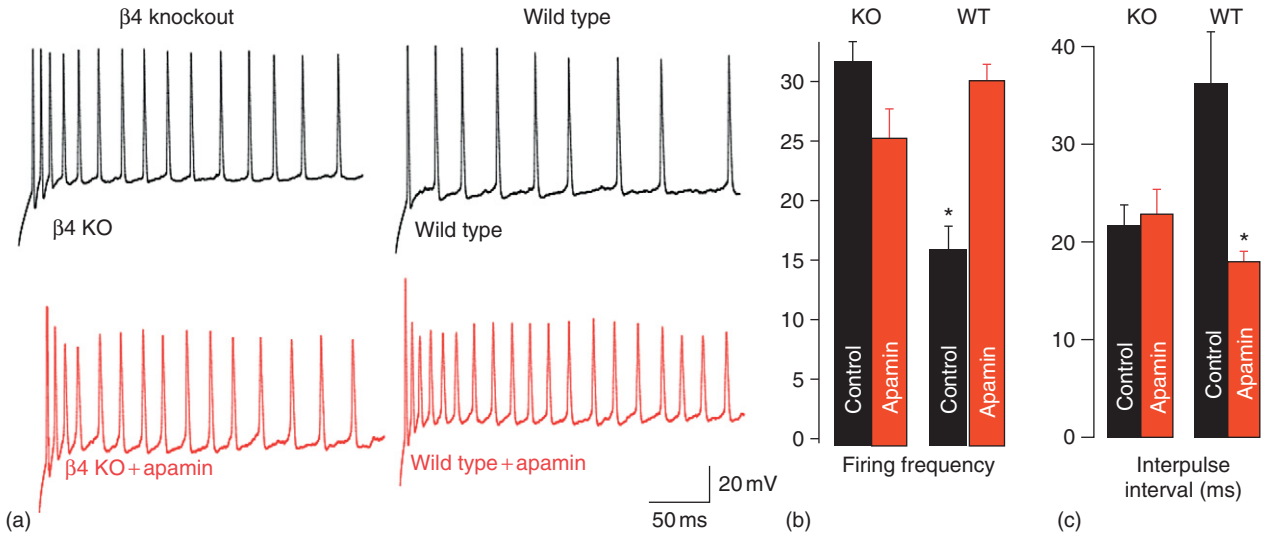

Figure 5 Loss of SK channel activation in the b4 knockout (BK channel gain-of-function) underlies increased firing frequency. The SK channel blocker apamin (100 nM) increases firing frequency in wild type neurons, (a,b) and reduces the interpulse interval (c). In BK channels gain-of-function (β4 KO), blocking SK channels is without significant effect (a–c). This suggests that the β4 KO reduces SK channel recruitment. Action potentials were evoked by a 250 pA current injection and example traces are the first 300 ms during the trace.

exon is downregulated in late neuronal development and is largely absent from most regions of the adult CNS.

From a standpoint of epilepsy, the dentate gyrus granule cells of the hippocampus have been regarded as a filter, positioned between strong excitatory input from the entorhinal cortex and the easily excited pyramidal cells of the hippocampus. The filter mechanism is attributed to strong inhibitory input from local interneurons that converge on dentate gyrus granule cells. These findings suggest that the intrinsic membrane properties of dentate gyrus granule neurons also have an important role. In this role, the β4 knockout studies have uncovered SK-type calcium-activated potassium channels as a key player. By mediating spike-frequency adaptation, SK channels reduce firing frequency and the likelihood of excitation of other cells in the hippocampus circuit. New classes of SK channel agonists indicate that this may be the case. These drugs include a low affinity agonist 1-ethyl-benzimidazolinone (1-EBIO, $EC_{50} \sim 500\,\mu M$), as well as recently identified higher affinity agonists DCEBIO ($EC_{50} = 27\,\mu M$) and NS309 ($EC_{50} = 0.6\,\mu M$). 1-EBIO is protective in a variety of rat brain slice models of epileptiform activity. In vivo effects of 1-EBIO indicate that SK channel activation affords protection against several rat seizure models (including electrically- and pentylenetetrazole-induced models), but little protection against pilocarpine-induced seizures.

Challenges for the Future

The mechanism by which BK channels negatively affect the recruitment of SK channels requires further study. The hypothesis that BK channels restrict calcium influx is not new; similar concepts have been developed in studies of smooth muscle and neurosecretory cells. SK and BK channels are frequently colocalized with specific calcium channels. We expect that this relationship occurs only in neurons where BK channels regulate a calcium influx pathway that SK channels utilize for activation. Indeed, it appears that there are examples where activation of BK channels, through leptin signaling or through BK channel agonists, reduces rather than enhances epileptiform activity of CA1 cells (in a rat brain slice model). Whether BK channel couple differently to SK channels in CA1 cells than granule cells requires further studies. Also, it is possible that leptin activation of BK channels occurs in CA3 presynaptic terminals, where BK channels have an established role in reducing excitability and neurotransmitter release.

Epilepsy is a neuronal circuit phenomenon. To cause seizures, changes in excitability must be coupled with increased synchronization within the circuit. Although this review has focused on BK channel effects on dentate gyrus granule cells, it is not certain that defects in these cells serve as the linchpin within the hippocampal circuit responsible for seizures. Future studies utilizing more sophisticated genetic techniques, such as tissue-specific and temporal-specific knockouts, will allow us to consider the role of these channels within the broader context of the neuronal circuit. This approach will allow us to address key questions, such as the followings:

- Are BK channel gain-of-function in dentate gyrus sufficient for temporal lobe epilepsy or are other cell types also involved?

- Are changes in intrinsic membrane properties sufficient to confer seizures, or do BK channels affect synaptic reorganization (such as mossy fibre sprouting) that contributes to the seizure phenotype?

From a clinical perspective, BK channels have been a target for drug design owing to their antagonist effects on calcium influx and the resultant relaxation of smooth muscle. BK channels being expressed in smooth muscle but not cardiac muscle has meant that agonists for BK channels could be used for many diseases associated with increased smooth muscle constriction (such as hypertension, incontinence and asthma) without side-effects associated with cardiac function. In the CNS, studies have investigated the use of BK channel agonist to control calcium-induced damage in neurons following stroke. However, these studies have taught us that BK potassium channel roles in the CNS are much more complex than anticipated in attempts at rational drug design. The possibility that BK channel gain-of-function may be pro-epileptic lends considerable caution to utilizing BK channel agonists that can cross the blood-brain barrier.

Sodium Channel Mutations that Cause GEFS+

A L Goldin, University of California, Irvine, CA, USA

Introduction

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominant disorder with a complex and heterogeneous clinical phenotype. Although febrile seizures occur in ~5% of all children under the age of 6 years, they are not typically associated with increased risk of epilepsy in adolescence and adulthood. In contrast, patients with GEFS+ demonstrate febrile seizures that either persist beyond 6 years of age or are associated with generalized epilepsies such as absences, myoclonic seizures, atonic seizures, and myoclonic-astatic epilepsy.

GEFS+ has been shown to result from mutations in five different ion channel genes, three of which encode subunits of the voltage-gated sodium channel.

Background

The voltage-gated sodium channel is comprised of a pore-forming α subunit that forms a fully functional channel whose properties can be modulated by association with one or more accessory subunits (β1, β2, β3, and β4). The α subunit is ~260 kDa and consists of four homologous domains termed I–IV, with six transmembrane segments called S1–S6 within each domain (**Figure 1**). The mammalian voltage-gated sodium channel α subunits are encoded by nine genes, resulting in the expression of distinct isoforms called $Na_v1.1$ through $Na_v1.9$. Four isoforms are expressed at high levels in the CNS ($Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.6$) and four isoforms are expressed at high levels in the peripheral nervous system ($Na_v1.6$, $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$). The remaining two isoforms are expressed in adult skeletal muscle ($Na_v1.4$) and in embryonic skeletal muscle and heart muscle ($Na_v1.5$).

Mutations in three different CNS sodium channel genes result in two subtypes of GEFS+. GEFS+ type 1 is caused by mutations in the *SCN1B* gene encoding the β1 subunit, and GEFS+ type 2 is caused by mutations in either the *SCN1A* gene encoding the $Na_v1.1$ α subunit or the *SCN2A* gene encoding the $Na_v1.2$ α subunit. Mutations that cause GEFS+ have been identified in two additional genes, *GBRG2* encoding the $GABA_A$ receptor γ2 subunit and *GBRD* encoding the $GABA_A$ receptor δ subunit. The majority of the known GEFS+ mutations, 13 thus far, have been identified in the *SCN1A* gene. Severe myoclonic epilepsy in infancy (SMEI), the most severe form of GEFS+, results from a haploinsufficiency of *SCN1A*, and intractable childhood epilepsy with generalized tonic–clonic seizures is caused by missense mutations in *SCN1A*.

All of the epilepsy syndromes resulting from sodium channel mutations that have been identified thus far are inherited in an autosomal dominant fashion, meaning that mutation of just one copy of the gene is sufficient to cause the syndrome. Most of the mutations involve a change in a single amino acid, so that the channel is still active but has altered functional properties. However, some of the mutations involve the insertion of a nonsense codon and thus terminate the protein early in the reading frame, resulting in complete loss of protein. Missense mutations in the *SCN1A* sodium channel gene are the most common cause of GEFS+, whereas nonsense mutations in the same gene are the most common cause of SMEI. The severity of the epileptic syndrome resulting from mutations in *SCN1A* depends on the type of mutation, with the most severe phenotype being caused by complete loss of sodium channel protein, as occurs in SMEI.

Methods

Characterization of Mutant Sodium Channels by Expression in *Xenopus* Oocytes

Because the $Na_v1.1$ sodium channel is expressed primarily in the CNS, it is not possible to directly determine the effects of mutant channels that cause GEFS+. In addition, neurons typically contain more than one

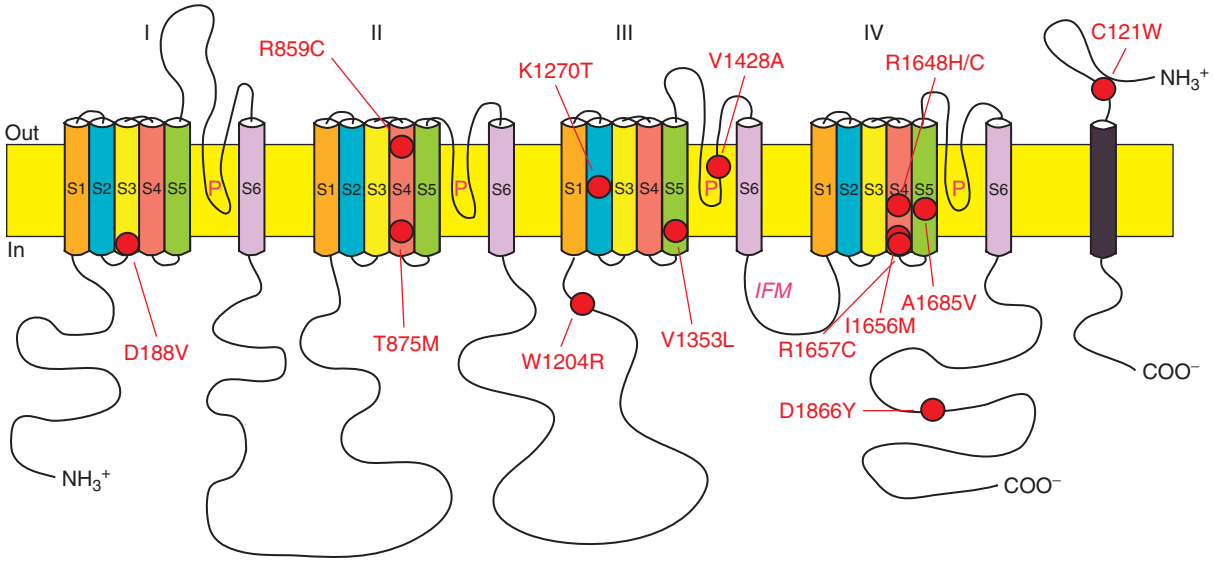

Figure 1 Schematic diagram of the voltage-gated sodium channel α and β subunits showing the positions of the mutations that cause GEFS+ (red circles). The four homologous domains in the α subunit are labeled I–IV, with each domain containing six transmembrane segments labeled S1–S6.

sodium channel isoform, making it difficult to isolate sodium currents through $Na_v1.1$. Therefore, we used a heterologous expression system to determine how the GEFS+ mutations alter sodium channel function. The cells that we used are oocytes from *Xenopus laevis* frogs, which have a number of advantages. First, the oocytes do not express any endogenous sodium channels, and so it is possible to record from the heterologous channels without contaminating currents. Second, the subunit composition can be controlled, making it possible to determine if the mutations alter the interactions between the α and β subunits. Third, there are a variety of electrophysiological recording techniques that can be used to obtain detailed information about channel activity.

We used the rodent cDNA clone for $Na_v1.1$ because our ultimate goal was to examine the function of the mutations in transgenic and knock-in mice, and the human and rat channels are 98% identical in amino acid sequence. The channels were expressed by transcription of RNA in vitro for injection into *Xenopus* oocytes, after which the electrophysiological properties of the channels were determined using the cut-open oocyte voltage-clamp. Each of the mutations was examined in the absence and presence of the β1 subunit. The various properties that were examined included the voltage-dependence of activation and inactivation, the kinetics of inactivation and recovery, use-dependent decreases in current amplitude, and slow inactivation.

Computational Model

The electrophysiological recordings provide data concerning how the mutations affect function of the sodium channel. However, the physiologically relevant property is the effect of the mutations on neuronal and network activity. To determine how the changes in sodium channel function might affect neuronal activity, we designed a computational model using the experimentally defined characteristics of the mutant sodium channels and a generic delayed rectifier potassium channel. Hodgkin–Huxley conductance-based models of spiking neurons were constructed using NEURON simulation software. The models included either wild-type or mutant channels with properties determined from the electrophysiological characterization. Sodium currents were recorded from the model neurons using protocols comparable to those used for the recordings from oocytes to assess the validity of the computational model. Current clamp simulations were then carried out to determine how the mutations might alter action potential threshold, shape, and repetitive firing properties.

Recent Results

All of the sodium channel GEFS+ mutations that have been identified thus far are missense alterations resulting in single amino acid substitutions. In addition, nearly all of them are located in or adjacent to the transmembrane or pore-forming regions of the channel (**Figure 1**), suggesting that the primary effect of the mutations is to alter the functional properties of the channel rather than to alter gene expression, protein processing, or targeting of the channel to the membrane. Our working hypothesis is that alterations in channel function lead to the seizure phenotype. To begin to test this hypothesis and determine how the alterations cause seizures, we and others have analyzed the effects of many of the GEFS+ mutations using heterologous expression systems. The results thus far suggest that most of the mutations alter different aspects of sodium channel function, and that the alterations depend on the expression system.

We have examined the effects of five different mutations in the rat $Na_v1.1$ sodium channel expressed in *Xenopus* oocytes, and each mutation altered sodium channel activity in a different manner. Some of the effects would be predicted to increase sodium channel activity, whereas others would be predicted to decrease activity. The five mutations are R859C, T875M, W1204R, R1648H, and D1866Y, and they are located throughout the sodium channel (**Figure 1**). R859C replaces a positively charged arginine with cysteine, and T875M replaces a threonine with methionine, with both located in the domain II S4 segment that comprises part of the voltage sensor for activation. W1204R replaces a hydrophobic phenylalanine with a positively charged arginine in the cytoplasmic linker between domains II and III. R1648H replaces a positively charged arginine with an uncharged histidine in the S4 voltage sensor of domain IV. Finally, D1866Y replaces a negatively charged aspartate with a tyrosine residue in the cytoplasmic carboxy-terminus of the channel.

The mutations that increased sodium channel activity are W1204R, R1648H, and D1866Y (**Table 1**). The W1204R mutation shifted the voltage-dependence of activation and inactivation in the hyperpolarized direction, causing the channel to open at more negative potentials. The R1648H mutation accelerated recovery from inactivation and decreased use-dependence, both of which would facilitate repetitive firing. The D1866Y mutation decreased modulation of the α subunit by β1, which normally causes a negative shift in the voltage-dependence of inactivation in oocytes. There was less of a shift with the mutant channel, thus increasing the magnitude of the persistent window current, an effect that would increase firing. The other two mutations (R859C and T875M) decreased sodium channel activity. The R859C mutation caused a positive shift in the voltage-dependence of sodium channel activation, slowed recovery from slow inactivation, and decreased levels of current compared with wild-type channels. The T875M mutation enhanced slow inactivation, resulting in fewer channels that are available to be activated. That each mutation

Table 1 Properties of the sodium channel mutations that cause GEFS+ type 2

Mutation	*Channel*[a]	*Cell type*[b]	*Effects*
Increased activity			
D188V	rNa$_v$1.2	HEK	↓ Use-dependence, faster recovery from slow inactivation
T875M	rNa$_v$1.1	*Xenopus* oocytes	↑ Persistence
W1204R	rNa$_v$1.1	*Xenopus* oocytes	Negative voltage-dependence
W1204R	hNa$_v$1.1	tsA201	↑ Persistence
R1648H	rNa$_v$1.1	*Xenopus* oocytes	↓ Use-dependence, faster recovery
R1648H	hNa$_v$1.1	tsA201	↑ Persistence
R1648H	hNa$_v$1.4	tsA201	Faster recovery
R1648C	rNa$_v$1.1	tsA201	↑ Persistence
D1866Y	rNa$_v$1.1	*Xenopus* oocytes	↑ Persistence
Decreased activity			
R859C	rNa$_v$1.1	*Xenopus* oocytes	Positive voltage-dependence, slower recovery from slow inactivation, ↓ current
T875M	rNa$_v$1.1	*Xenopus* oocytes	↑ Slow inactivation
T875M	hNa$_v$1.4	tsA201	↑ Fast and slow inactivation
V1353L	hNa$_v$1.1	tsA201	No sodium current
I1656M	hNa$_v$1.1	tsA201	Positive voltage-dependence
R1657C	hNa$_v$1.1	tsA201	Positive voltage-dependence, ↓ current
A1685V	hNa$_v$1.1	tsA201	No sodium current

[a]Channel in which the mutations were constructed for electrophysiological analysis. The channels are encoded by the following genes: rNa$_v$1.2, rat *Scn2a*; rNa$_v$1.1, rat *Scn1a*; hNa$_v$1.1, human *SCN1A*; hNa$_v$1.4, human *SCN4A*.
[b]Cell type in which the mutations were expressed for electrophysiological analysis.

affected a different aspect of sodium channel function suggests that multiple different alterations in sodium channel activity can cause a similar seizure phenotype.

A number of mutations have also been examined by other laboratories using expression in tsA201 cells, a human embryonic kidney (HEK) cell line, with similar findings of both increased and decreased activity (Table 1). Five mutations were observed to alter the channel in a manner consistent with increased activity. D188V in human Na$_v$1.1 was studied using HEK cells by the laboratories of Ragsdale, Dunn, and Rouleau. That mutation caused decreased use-dependence and accelerated recovery from slow inactivation, similar to our results with R1648H. The laboratories of Lehmann-Horn and Lerche observed similar effects for the R1648H mutation, which they studied in the human Na$_v$1.4 skeletal muscle channel. In contrast, the laboratory of George noted a marked increase in persistent current for the R1648H mutation, and a lesser increase in persistent current for W1204R, R1648C, and T875M. They hypothesized that the persistent current resulted in hyperexcitability and the epileptic phenotype.

However, this prediction about the effects of mutations on persistent current is not consistent with all of the data. T875M decreased sodium channel activity in our experiments and also in those of Lehmann-Horn and Lerche. In addition, four other mutations caused alterations that decreased sodium channel activity. The George laboratory observed positive shifts in the voltage-dependence of activation for I1656M and R1657C, reduced sodium current density for R1657C, and complete absence of sodium current in the heterologous system for V1353L and A1685V. Complete absence of current could be the result of a nonfunctional channel or a failure in protein trafficking to the cell membrane. That all of these mutations decreased sodium channel activity without increasing persistent current indicates that persistent current is not the general cause of seizures in GEFS+. In fact, there does not appear to be any one consistent functional consequence among the many mutations that have been characterized thus far.

Given the wide range of effects of the GEFS+ mutations, with some increasing sodium channel activity and others decreasing activity, it is extremely difficult to predict how the mutations might alter neuronal function. To begin to address this question, we used a simple computer modeling approach to gain insight into how the mutations could affect the firing of action potentials. This approach has a number of advantages. First, action potentials are dynamic events, and so the steady-state biophysical properties of sodium channels determined in heterologous systems may not combine to produce the expected outcomes in vivo. A computational model is a logical tool to predict how changes in steady-state properties might interact and alter the dynamic process of action potential generation. Second, the computer model makes it possible to include both mutant and wild-type channels in the same cell, which is important because GEFS+ is dominantly inherited. Finally, the computational model can help to guide future experiments once an animal model is developed.

To study the effects of GEFS+ mutations on action potential firing, we constructed single compartment neuronal soma models that contained Na$_v$1.1 or GEFS+ mutant sodium channels and delayed rectifier potassium channels, the minimum components necessary for the firing of an action potential. Although the interaction of the wild-type and mutant sodium channels with potassium channels could vary depending on the type of potassium channels that are present, we chose to use a simplified model containing only delayed rectifier potassium channels so that any differences in the firing of action potentials between the mutant and wild-type cells

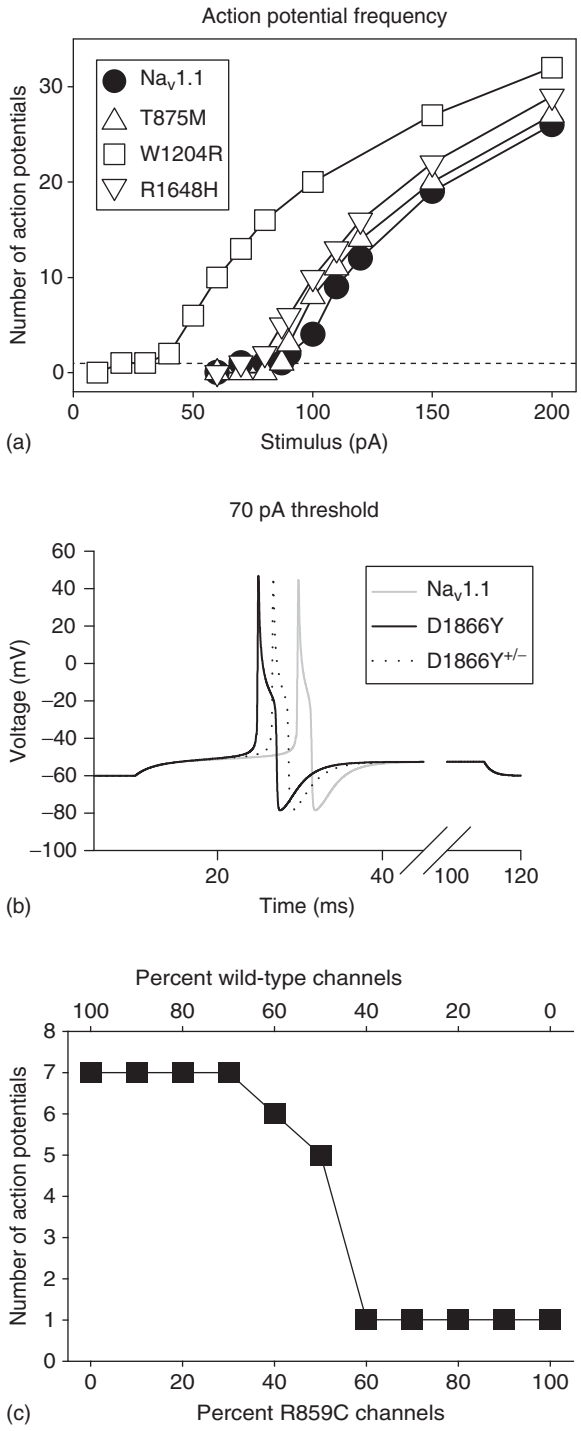

Figure 2 Effects of the GEFS+ mutations in a computational model. (a) The number of action potentials elicited by 200 ms current injections starting with 10 pA and increasing by 20 pA are shown for model neurons expressing wild-type $Na_v1.1$ (circles), T875M (up triangles), W1204R (squares), and R1648H (down triangles). (b) At the threshold stimulus for a single action potential (70 pA), the D1866Y mutant model neuron (black line) fired a single action potential with a shorter onset delay than the wild-type $Na_v1.1$ model neuron (grey line). When the population of channels was mixed in a 1:1 ratio ($D1866Y^{+/-}$, black dotted line), the mutant channels displayed a dominant effect, resulting in a shorter onset delay for firing a single action potential than would be attributed exclusively to changes in the sodium channel conductances. Passive parameters similar to the passive properties of hippocampal principal cells were adapted from previous models.

Using the NEURON simulation software, we conducted a typical input–output neurophysiology experiment on the model neurons. The model neurons were stimulated by injection of current and the resulting changes in membrane potential were generated by the computational model. Beginning with a subthreshold stimulus, we gradually increased the amplitude of the current injection and counted the number of action potentials generated to estimate the threshold for action potential firing. We observed that W1204R decreased the threshold for firing a single action potential, T875M and R859C increased the threshold, and R1648H and D1866Y did not affect the threshold. Therefore, effects on action potential threshold were not consistent with a single mechanism of pathogenesis.

We also examined the propensity of the model neurons containing mutant channels to fire multiple action potentials. Three mutations (T875M, W1204R, and R1648H) resulted in more action potentials being fired compared with a model neuron containing wild-type channels (**Figure 2(a)**). The magnitude of this effect was different for each mutation, with the most severe being W1204R and the least severe being T875M. Although the D1866Y mutation did not alter the number of action potentials fired in response to a given stimulus, it did alter the timing of those action potentials, reducing the latency to firing and the spike-to-spike interval between action potentials, thus increasing the spontaneous firing frequency (**Figure 2(b)**). In contrast, the final mutation (R859C) decreased the propensity of the model neuron to fire multiple action potentials.

Since GEFS+ is an autosomal dominant disorder, affected individuals express a mixed population of mutant and wild-type channels. Although it is difficult to vary the ratio of mutant and wild-type channels in a heterologous

would be expected based on the individual behavior of the two groups. (c) Model neurons containing a mixture of R859C mutant and wild-type channels behaved in an additive fashion. Neurons were assigned a mixed population ranging from 0% to 100% R859C mutant (100% to 0% wild-type) sodium channels, and the number of action potentials elicited during injection of 150 pA was determined and plotted versus the percentage of mutant channels. Reproduced from Spampanato J, Kearney JA, de Haan G, *et al.* (2004) A novel epilepsy mutation in the sodium channel SCN1A identifies a cytoplasmic domain for β subunit interaction. *Journal of Neuroscience* 24: 10022–10034, with permission from the Society for Neuroscience; Barela AJ, Waddy SP, Lickfett JG, *et al.* (2006) An epilepsy mutation in the sodium channel SCN1A that decreases channel excitability. *Journal of Neuroscience* 26: 2714–2723, with permission from the Society for Neuroscience.

expression system, this is a very simple experiment to perform using a computational model. When we varied the percentage of each of the mutant channels compared with the wild-type, the results depended on the mutation. D1866Y and W1204R were dominant in that a 1:1 mixture of mutant and wild-type channels demonstrated properties similar to a neuron with all mutant channels. In contrast, the other three mutations (R1648H, T875M, and R859C) each behaved in an additive fashion, so that the phenotype of a 1:1 mixture was intermediate between that of wild-type and mutant channels (**Figure 2(c)**). These results suggest that the phenotype of individuals with these mutations depends on the ratio of mutant to wild-type channels that is present in the neuron.

Although the computer modeling results suggest that there is no single mechanism of seizure pathogenesis for the GEFS+ mutations, it is difficult to extrapolate from computer modeling to the situation in vivo. The effects of the mutations on network activity depend very strongly on the specific neuronal populations in which the mutant channels are expressed, and there is evidence that $Na_v1.1$ is responsible for a substantial percentage of the total sodium current in interneurons but a very small percentage in pyramidal cells. The same biophysical alteration would have dramatically different effects on network firing if it were present in inhibitory interneurons versus excitatory pyramidal neurons. In addition, $Na_v1.1$ is expressed predominantly in the soma and dendrites of neurons, whereas action potential initiation most likely occurs at the axon hillock, so that the GEFS+ mutations may have a greater effect on signal integration rather than action potential initiation or propagation.

Future Goals

The data from heterologous expression systems and computer modeling suggest that both gain-of-function and loss-of-function mutations in the gene encoding $Na_v1.1$ can predispose the CNS to epileptogenesis. However, this conclusion assumes that the effects of the mutations in heterologous systems are a direct reflection of the effects in native neurons, which may not be the case for a number of reasons. First, sodium channels in the CNS associate with two of four accessory β subunits (β1 or β3 and β2 or β4). The specific β subunits that are present in each type of neuron could alter the properties of the sodium channels, and hence the effects of the mutations. Second, the GEFS+ mutations could alter aspects of channel processing or trafficking that may be unique to neurons, so that the physiologically relevant phenotype cannot be observed in another cell type. Third, neurons express multiple sodium channel isoforms as well as an array of other voltage- and ligand-gated ion channels. The repertoire of channels can have a dramatic effect on the properties of a mutation, as has been demonstrated by the laboratory of Waxman. They observed that a sodium channel mutation in $Na_v1.7$ causing erythermalgia made sympathetic neurons hypoexcitable, but the same mutation made sensory neurons hyperexcitable because of the presence of $Na_v1.8$ in those neurons. For these reasons, it is essential to determine the effects of the GEFS+ mutations in native neurons, which is the goal of our current research.

We are using two approaches for this purpose. First, we are using a Semliki Forest virus (SFV) vector system to obtain high efficiency expression of the sodium channels in neurons. Second, we are constructing both transgenic and knock-in mouse models expressing the GEFS+ mutations. Each approach has advantages and disadvantages.

The primary advantage of using the SFV vector system for expression of sodium channels is that SFV infects neurons with very high efficiency. In addition, it is possible to construct and analyze many different mutations because it is relatively fast to construct a viral vector with each mutation and the neurons can be easily infected. To facilitate these studies, we have inserted the coding region of $Na_v1.1$ into an SFV vector with two modifications. First, sequences encoding the red fluorescent protein (RFP) were inserted at the amino terminal end of the channel, making it possible to identify infected cells by fluorescence. Second, the channel was made relatively resistant to tetrodotoxin (TTX) by the E954Q mutation. The primary CNS sodium channels ($Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.6$) are all blocked by nanomolar concentrations of TTX, whereas channels containing the E954Q mutation are not blocked until the TTX concentration reaches millimolar levels. Therefore, we can record currents through only the mutant channels by blocking the endogenous neuronal channels with nanomolar concentrations of TTX. We have shown that SFV containing the sodium channel is efficiently expressed in primary neuronal cultures and we are now in the process of recording currents from infected cells.

A mouse model system is the most physiologically relevant approach for examining the effects of the sodium channel mutations that cause GEFS+, but it is impractical to construct mice expressing many different mutations. Therefore, we are using this approach to study a few mutations in depth by constructing both transgenic and knock-in mice. The use of transgenic mice provides some distinct advantages and disadvantages than that of knock-in mice. A major advantage of transgenic mice is that the channel can be easily modified with either a synthetic epitope or a variant of green fluorescent protein at the amino terminus and the TTX resistance mutation. Therefore, we can determine which neurons express the mutant channel, what percentage of sodium current is conducted through the mutant channel, and the biophysical effects of the mutation in isolation. The major disadvantage is that regulation is abnormal. We have mitigated

this problem by using a bacterial artificial chromosome containing the entire gene encoding $Na_v1.1$. Because the chromosome contains the entire sodium channel gene with its native promoter, expression is regulated normally. A second disadvantage of using transgenic expression is that the mutant gene is expressed in addition to the wild-type gene, so that the cells express more than two alleles. The presence of wild-type alleles should not mask the effect of the mutant allele, though, because all of the GEFS+ mutations are inherited in a dominant manner.

The major advantage of knock-in mice is that they are the most physiologically relevant model of the human syndrome – heterozygous mice express one mutant allele and one wild-type allele. A second advantage is that the dose-dependent effects of the mutation can be analyzed by studying both heterozygous and homozygous mice. The major disadvantage is that the mutant channel cannot be distinguished from the endogenous wild-type CNS channels, including $Na_v1.1$, $Na_v1.2$, and $Na_v1.6$, so that these mice cannot be used to determine which populations of neurons express the mutant channels nor to determine the biophysical properties of the mutant channels in neurons.

Our collaborator, Dr. Andrew Escayg of Emory University, has constructed both transgenic and knock-in mice expressing the R1648H mutation, and we are in the process of analyzing both lines of mice. We have used the transgenic mice to determine the relative expression levels and the biophysical properties of the mutant $Na_v1.1$ channel in dissociated cortical neurons. We are using the knock-in mice to examine the effects of the mutation on network properties by recording from hippocampal and cortical slices, which should provide insight into how the altered neuronal activity leads to synchronous firing in the population. The knock-in mice are also being used to determine the phenotypic effects on the animal by characterizing susceptibility to seizures induced by a variety of agents, including heat as a model for febrile seizures.

The data thus far concerning relative levels of expression indicate that the R1648H channel is expressed at higher levels in bipolar inhibitory cortical neurons compared with pyramidal neurons, suggesting that $Na_v1.1$ is preferentially expressed in inhibitory neurons. These findings are consistent with results obtained from two mouse models of SMEI. The Catterall laboratory observed significant loss of sodium current density in heterozygous and homozygous *Scn1a* knock-out mice in inhibitory interneurons but not in excitatory pyramidal neurons from the hippocampus. The Yamakawa laboratory noted that $Na_v1.1$ was expressed predominantly in parvalbumin-positive inhibitory interneurons in knock-in mice expressing a *Scn1a* nonsense mutation. We have also obtained preliminary data concerning the biophysical properties of R1648H mutant channels in these bipolar neurons. The most prominent effect of the mutation was increased use-dependence, leading to decreased sodium channel activity. This effect was not observed for R1648H in any of the heterologous expression systems, all of which demonstrated alterations that increased sodium channel activity.

Our current hypothesis is that loss of sodium channel activity in inhibitory neurons is a general cause of GEFS+ type 2. This hypothesis is based on a number of results. First, the $Na_v1.1$ channel is expressed preferentially in inhibitory neurons in both the cortex and hippocampus. Second, the R1648H mutation decreased sodium channel activity in inhibitory cortical neurons. Third, complete loss of one *SCN1A* allele encoding $Na_v1.1$ causes SMEI, which can be categorized as the most severe form of GEFS+. Finally, decreased inhibition has been postulated to be the cause of a number of different epilepsy syndromes. A consistent model is that loss of sodium channel activity in inhibitory neurons causes epilepsy, with the severity of the syndrome being proportional to the loss of activity. Decreased activity, such as that from missense mutations in GEFS+, causes moderate epilepsy syndromes. Complete loss of one allele, such as that from nonsense and frameshift mutations in SMEI, causes more severe epilepsy syndromes. More detailed analysis of mouse models for the syndromes resulting from sodium channel mutations should make it possible to test the validity of this model.

Introduction

Therapeutic options for management of medically refractory seizures in young children are limited. Despite the plethora of old and new anticonvulsant medications, up to one-third of children with epilepsy continue to have seizures, and many of these children take multiple medications with concurrent intolerable side effects. Alternative treatments have included the vagus nerve stimulator and dietary approaches. The ketogenic diet (KD), a high fat, low carbohydrate, adequate protein formulation, has been used since early in the twentieth century for seizure control in refractory epilepsy. Clinical studies have verified the effectiveness of the KD. In general, at least half of all patients treated with the KD will exhibit a 50% or greater reduction in seizure frequency. Despite this effectiveness, the mechanisms by which the diet works are still unknown.

Since the resurgence in clinical use of the KD in the 1990s, several laboratories have attempted to develop animal models to discern the mechanism of KD action and improve its formulation and effectiveness. In general, such models have met with modest success. Part of the challenge has been to replicate the effect of the KD in humans. However, the metabolism of rodents (the most commonly used model) differs in important ways from humans. During fasting, ketone bodies supply relatively more brain energy in humans than in rats. In the neonatal period, ketone bodies are used more by suckling rats than by humans. In addition, previous models have employed a wide variety of paradigms of seizure induction (kindling, pentylenetetrazole (PTZ), kainic acid, etc.), KD formulations, outcome measures, and assessments of metabolic parameters. Any mechanistic explanation for KD effectiveness in humans must account for certain clinical observations in animal models (**Table 1**).

When switching from a diet high in carbohydrates to one high in fats and with stringent carbohydrate restriction, the basic metabolic alteration is that fats become the primary energy source. Fat breakdown occurs in the liver, creating ketone bodies (β-hydroxybutyrate, acetoacetate, and acetone), which circulate to the brain and are taken up into cerebral tissue via specific monocarboxylate transporters. In neuronal mitochondria, ketones are metabolized to adenosine triphosphate (ATP) via the tricarboxylic acid (TCA) cycle and oxidative phosphorylation. The challenge has been to understand how this energy shift results in an anticonvulsant effect. Obviously, multiple sites exist in the relevant biochemical pathways in which seizures could be suppressed, and the mechanism (or more likely, mechanisms) by which the KD exerts an anticonvulsant effect likely involves the combination of altered energy homeostasis and regulation of membrane and synaptic excitability.

Early theories of KD mechanism focused on the involvement of ketone bodies. However, several clinical

Table 1 Criteria for an ideal animal model of the ketogenic diet

Seizure type: Broad efficacy against partial and generalized seizures
Age range: More effective at younger ages
Diet formulation: Effective with classic 3:1 and 4:1 ketogenic ratios as well as with KD modifications such as fasting, the medium-chain triglyceride diet, the Atkins diet, and the low glycemic index diet
Calorie restriction: Equally or more effective than classic KD
Ketosis: Necessary but not sufficient
Latency to effectiveness: Seizure reduction during fasting or first few days of KD initiation
Loss of seizure protection with KD discontinuation or addition of carbohydrates: Rapid (within hours)

Not all of these criteria are likely to be met in a single model and useful information can be obtained from animal models not meeting all the criteria (see text).

and experimental studies have shown that the relation between serum or urinary ketone levels and seizure control is imprecise, at best. Direct effects of ketones on neurophysiological parameters, excitatory and inhibitory neurotransmission, and ictal activity in vitro have been essentially negative, although the inclusion of glucose in the bathing medium of some brain slice experiments could have counteracted the influence of the ketones. Recent experiments have shown that, in vivo, rats on the KD or a calorie-restricted normal diet exhibit increased paired-pulse inhibition in the hippocampal dentate gyrus and increased resistance to maximal dentate activation. At present, it may be concluded that some as yet undetermined threshold level of ketosis is required and must be maintained for the KD to be maximally effective. Whether this threshold correlates with ketone levels remains unclear; the concentration of ketones at the synapse is unknown.

Other early theories included an alteration in cerebral energetics induced by the KD, which favor an increased 'energy charge' (a relative increase in the ATP/ADP ratio resulting from metabolic alterations of enzymes involved in glycolysis and the TCA). It was hypothesized that the greater availability of energy reduces cellular excitability, enhancing hyperpolarization. Another theory involved alterations in the inhibitory neurotransmitter, γ-aminobutyic acid (GABA). GABA function could be enhanced through the GABA shunt whereby glial conversion of glutamate to glutamine (a GABA precursor) is enhanced by ketosis. Ketones mimic GABA structurally and could play a direct inhibitory role on cellular excitability by activating GABA receptors or enhancing their action. KD treatment and calorie restriction increase the expression of glutamic acid decarboxylase (GAD), providing a mechanism by which GABA synthesis might increase in a patient on the KD.

Other theories have implicated the quantity or type of fat in the diet. Obviously, the KD involves large excess of fatty acids, usually of the saturated variety in the form of heavy cream or butter. Fatty acids of various chain lengths are typically included in the diet. Early clinical studies have shown a correlation between plasma lipid levels and seizure control in children on the KD. Experimental studies have likewise shown a correlation of plasma lipid levels with seizure control, independent of the level of ketosis.

A neuroprotective effect of the KD has also been proposed. The KD has been shown to increase the expression of mitochondrial uncoupling proteins and thereby reduce neuronal damage induced by formation of injurious reactive oxygen species (ROS).

In summary, there is no lack of theoretical mechanisms by which the KD can exert an anticonvulsant effect. It is doubtful that a single mechanism can account for all of the observed clinical and experimental effects.

Background

The original idea for the KD was derived from the beneficial effect of fasting on seizures. Fasting is obviously impractical except for very short-term treatment. Nevertheless the health benefits of modest calorie restriction are becoming increasingly clear and include an increased lifespan, reduced risk of cancer and cardiovascular disease, and amelioration of the degenerative effects of aging. Restriction of calorie intake can also be neuroprotective. In rats receiving kainic acid, learning defects and cellular damage are reduced when animals are placed on a calorie-restricted diet, possibly as a result of reduced oxidative stress. It is not known how calorie restriction prevents detrimental degenerative effects of aging. Multiple genes that enhance neuronal survival and plasticity are likely to be involved. It is worth exploring the possibility that calorie restriction can limit seizure occurrence.

Children on the KD are typically restricted to 75% of the recommended daily calorie allowance for their ideal weight and height. This calorie level allows linear growth but prevents significant weight gain. Calorie restriction may facilitate ketosis and exert an antiseizure effect, independent of ketosis. In children on the KD, blood glucose levels are usually in the lower end of normal, but patients are rarely hypoglycemic. Therefore, a metabolic adaptation occurs in response to the KD to maintain relatively normal glucose levels.

Recent animal studies from the laboratory of Dr. Thomas Seyfried have provided evidence that calorie restriction alone can reduce seizure occurrence. Calorie restriction increases seizure threshold in a model of genetic epilepsy (the EL mouse), which typically develop seizures at several weeks of age. By restricting calories to

85% of normal, seizure onset in EL mice was delayed by several weeks. It was postulated that the KD works by calorie restriction and altered glucose metabolism.

Another group of researchers, led by Drs. Kris Bough and Douglas Eagles, elicited seizures by tail-vein infusion of the convulsant PTZ in rats on various diets. Thresholds to generalized PTZ seizures were elevated by use of a ketogenic calorie-restricted diet to a greater extent than a normal calorie-restricted diet or a KD ad libitum. That is, rats ingesting a normal diet restricted in calories had a higher seizure threshold than did rats on a KD without calorie restriction. Subsequently, investigators showed that even a high carbohydrate calorie-restricted diet (15% normal calories) afforded PTZ seizure protection, similar to that seen in a less severely calorie-restricted KD (90% normal calories). Calorie restriction and the KD were equally effective in suppressing dentate gyrus excitability and limiting the ictal manifestations of maximal dentate activation.

Taken together, these data suggest that calorie restriction is sufficient to influence seizure threshold and may augment the effects of KD treatment. Despite the beneficial effects of calorie restriction, it should be noted that favorable effects of the KD have been achieved in animal models without using calorie restriction. Therefore, the explanation for the seizure protective effect of the KD is not a simple matter of fewer calories.

A remarkable feature of the KD is that ingestion of even a small amount of carbohydrate can rapidly result in loss ketosis and seizure recurrence in patients who were previously well-controlled on the KD. This clinical observation suggests that glycolysis and carbohydrate metabolism might promote seizure susceptibility and that inhibition or reduction of glycolytic metabolism might have anticonvulsant effects. In support of this hypothesis, we have shown (unpublished data) that isomolar substitution of glucose by alternative energy sources – e.g., pyruvate or lactate – in hippocampal slice bathing medium reduced interictal epileptic burst discharges induced by slice exposure to elevated extracellular potassium levels.

Furthermore, administration of 2-deoxy-D-glucose (2DG), which inhibits glycolysis, reduces the progression of kindling evoked by perforant path stimulation in adult rats. 2DG differs from normal glucose only by the removal of an oxygen atom from the hydroxyl group at the 2-position. 2DG is taken up by glucose transporters and is subsequently phosphorylated into 2-deoxy-D-glucose-6-phosphate (2DG-6P), which cannot be converted to fructose-6-phosphate by phosphoglucose isomerase, thereby preventing catabolism through subsequent steps of glycolysis. The trapping of 2DG-6P in cells after uptake through glucose transporters has enabled investigators to use 2DG as a metabolic tracer for glucose utilization, and its adaptation in positron emission tomography (PET) scanning and human clinical imaging.

In our previous study, intraperitoneal administration of 2DG at a dose of 250 mg kg^{-1} in rats impaired the development of kindled seizures in response to stimulation of the perforant path. The antiepileptic effects of 2DG against kindling were associated with reduction of seizure-induced increases in brain-derived neurotrophic factor (BDNF) and its receptor trkB, which are required for kindling progression. Seizure-induced increases in BDNF and trkB were prevented by 2DG through a mechanism of transcriptional repression dependent on neuron restrictive silencing factor (NRSF) and its NADH-sensitive cofactor carboxy-terminal binding protein (CtBP), which maintain a repressive chromatin environment at the BDNF and trkB promoter regions. These observations suggest that glycolytic inhibition through reduction of glycolytic flux, or inhibition by glycolytic inhibitors such as 2DG, might have anticonvulsant and antiepileptic effects. As this mechanism works through alteration of gene expression, the effect is not immediate but likely occurs over hours to days (Figure 1).

Methodology

Our laboratory has been using multiple approaches to establish the effectiveness, safety, and mechanism of 2DG action in inhibiting seizures. As indicated earlier, we have shown that 2DG is an anticonvulsant, and that it down-regulates BDNF and trkB gene expression. To evaluate the effects of 2DG on metabolism, Dr. Avtar Roopra has employed molecular techniques to study NRSF/CtBP metabolic sensing. Another current focus in our laboratory is the study of the acute anticonvulsant and chronic antiepileptic effects of 2DG in rats, in vitro and in vivo. The acute anticonvulsant actions of 2DG are assessed in vitro in rat hippocampal slices exposed to 7.5 mM extracellular potassium, 4-aminopyridine, or

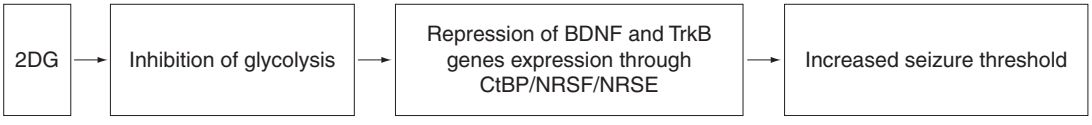

Figure 1 Simplified model for 2DG suppressive effects on kindled seizures. 2DG, 2-deoxy-D-glucose; BDNF, brain-derived neurotrophic factor; TrkB, tyrosine kinase B; CtBP, carboxy-terminal binding protein; NRSF, neuron restrictive silencing factor; NRSE, neuron-restrictive silencing element.

bicuculline. These multiple seizure induction methods are being used to investigate the effects of 2DG on interictal and ictal firing patterns in the hippocampus. In addition, we are studying several in vivo seizure models, including kindling, audiogenic seizures in Fring's mice, 6-Hz stimulation in mice, maximal electroshock seizures in rats, and seizures evoked by subcutaneous PTZ.

Results

In Vitro Anticonvulsant Effects

Removal of glucose and substitution with alternative energy sources such as lactate or pyruvate reduces high potassium-induced interictal burst firing in hippocampal area CA3 by greater than half, an effect that is reversible by restitution of glucose in the bathing solution. Therefore, glucose is necessary for maximal interictal bursting, but lactate and pyruvate are effective substitutes to maintain neural transmission.

In the CA3 hippocampal subfield of rats (postnatal age P28–40), under the conditions of high potassium exposure, addition of 10 mM 2DG reversibly decreases interictal bursts by almost 50%. Ictal bursts in the same region (in younger, P10–13 rats) were reduced markedly by the same concentration of 2DG. These seizure protective effects of 2DG are not limited to the high potassium condition; interictal bursts elicited by 10 mM bicuculline or 50–100 mM 4AP were similarly decreased by 10 mM 2DG, in a reversible fashion. Therefore, in vitro, 2DG exerts acute anticonvulsant effects on both interictal and ictal discharges, induced by a variety of convulsant agents, in the hippocampal CA3 region. It is likely that these rapid effects, occurring over minutes, are mediated by a mechanism different than the chronic effects of 2DG on kindling discussed earlier.

In Vivo Effects of 2DG

We are also investigating the anticonvulsant and antiepileptic effects of 2DG on a variety of in vivo seizure models. Garriga-Canut et al. previously showed that rats treated with 2DG and kindled from the perforant path exhibited unique anticonvulsant effects. Typically (i.e., in saline-treated rats), successive kindling stimulations lead to a gradual decrease in afterdischarge threshold (ADT). However, in 2DG-treated animals, there is a gradual *increase* in ADT as a function of afterdischarge stimulation number. This 2DG effect appears to be at least somewhat specific to the perforant path kindling paradigm, since with kindling from the olfactory bulb, both saline- and 2DG-treated animals exhibit the expected gradual decrease in ADT as a function of after discharge number (unpublished data). Although the effects of 2DG on the ADT differ according to stimulation site, 2DG slowed the rate of progression of kindled seizures evoked from both olfactory bulb and perforant path. That is, rats treated with 2DG required about 50% more afterdischarges (evoked by stimulation of the olfactory bulb) to reach the first class III, IV, or V seizure (compared with saline-treated controls). These data imply that 2DG protects against kindling epileptogenesis.

Studies in several other in vivo seizure models are underway. 2DG has anticonvulsant effects against seizures evoked by 6-Hz stimulation in mice, and against audiogenic stimulation in Fring's mice (unpublished data).

Future Goals

The goal of laboratory investigations into the mechanism of the KD is to improve its effectiveness and develop a formulation that will improve seizure control in children with refractory epilepsy. To this end, a variety of alternative diets have been used clinically, including a modified Atkins diet and a low glycemic index diet. In the Atkins diet, a state of ketosis is induced by providing high fat and little carbohydrate. Because it does not restrict calories, that diet could work by a direct effect of ketosis; the role of calories in the Atkins diet with regard to seizure control has not been elucidated. In the low glycemic index diet, the *quality* of carbohydrate rather than its amount is altered. Early clinical results show that some restriction of carbohydrates may have an anticonvulsant effect. While there are no current animal model studies of the Atkins and low glycemic index diets, such considerations have led to the current research program in which we are attempting to determine whether inhibition of glycolysis can lead to seizure reduction.

Our current experimental results are very promising, showing that inhibition of glycolysis with the glucose analog 2DG has both anticonvulsant and antiepileptic effects in a variety of animal models. A molecular explanation for these results suggests that 2DG potently reduces progression of kindling and blocks seizure-induced increases in the expression of brain-derived neurotrophic factor and its receptor, TrkB. Reduced expression of those genes is mediated by the transcription factor NRSF, which recruits the NADH-binding corepressor CtBP to generate a repressive chromatin environment around the BDNF promoter. We are now further characterizing the behavioral effects of 2DG and determining its safety profile. The cognitive and behavioral consequences of long-term 2DG treatment are being assessed using a variety of cognitive, learning and memory tests. Furthermore, physiological mechanisms by which 2DG acutely alters epileptiform burst discharges (which may be different from its longer term molecular effects on BDNF and TrkB) will be studied using electrophysiological techniques. The variable effects of 2DG on

kindling from two different brain structures raises another intriguing possibility, that metabolic activity in relation to seizure control is site-specific. Finally, alternative inhibitors at different sites within the glycolytic pathway could also be explored as possible antiseizure agents. In summary, 2DG appears to be a safe compound with anticonvulsant and antiepileptic effects, making it an exciting new potential therapy for epilepsy with novel mechanisms of action.

Published by Elsevier Ltd.

Introduction

The ketogenic diet (KD) is a high-fat, adequate-protein, low-carbohydrate diet that has been used as a treatment for epilepsy since 1921. The KD is typically administered in a 4:1 ratio of fats to carbohydrates + proteins, whereby ~90% of calories are derived from fat. Typically, the recommended daily caloric intake is reduced by ~25%. During diet treatment, the liver metabolizes fats into ketone bodies, which in place of glucose then become the primary source of metabolic fuel. Somehow, this switch in metabolism confers an anticonvulsant effect. In general, the number of seizures is reduced by half or more in approximately 50% of those who adhere to the diet. This dietary regimen must be strictly maintained, however, as even small amounts of glucose (or excessive caloric intake) diminish KD efficacy.

We have focused our studies on KD mechanisms for a variety of reasons. First, anticonvulsant drugs do not adequately control seizures for many patients with

kindling from two different brain structures raises another intriguing possibility, that metabolic activity in relation to seizure control is site-specific. Finally, alternative inhibitors at different sites within the glycolytic pathway could also be explored as possible antiseizure agents. In summary, 2DG appears to be a safe compound with anticonvulsant and antiepileptic effects, making it an exciting new potential therapy for epilepsy with novel mechanisms of action.

Anticonvulsant Mechanisms of a Ketogenic Diet

K J Bough, National Institutes of Health, Bethesda, MD, USA
R Dingledine, Emory University, Atlanta, GA, USA

Published by Elsevier Ltd.

Introduction

The ketogenic diet (KD) is a high-fat, adequate-protein, low-carbohydrate diet that has been used as a treatment for epilepsy since 1921. The KD is typically administered in a 4:1 ratio of fats to carbohydrates + proteins, whereby ~90% of calories are derived from fat. Typically, the recommended daily caloric intake is reduced by ~25%. During diet treatment, the liver metabolizes fats into ketone bodies, which in place of glucose then become the primary source of metabolic fuel. Somehow, this switch in metabolism confers an anticonvulsant effect. In general, the number of seizures is reduced by half or more in approximately 50% of those who adhere to the diet. This dietary regimen must be strictly maintained, however, as even small amounts of glucose (or excessive caloric intake) diminish KD efficacy.

We have focused our studies on KD mechanisms for a variety of reasons. First, anticonvulsant drugs do not adequately control seizures for many patients with

epilepsy and often cause unwanted side effects. Today the diet is primarily used to treat medically refractory seizures and effectively manages a wide variety of epilepsies. There are few side effects. Perhaps most importantly, however, there are experimental hints that the diet may also limit disease progression and prevent neurodegeneration. Cross comparisons of the KD anticonvulsant profile with the spectrum of activity for other AEDs suggest that the KD acts uniquely to control seizures. Thus, elucidation of KD mechanisms will likely provide unique insights into brain metabolism from which potent new treatment strategies for epilepsy and, perhaps, other neurodegenerative disorders could emerge.

Background

To begin to assess underlying mechanisms of KD, initial experimental studies defined the pharmacodynamic endpoints and when they occur. Behavioral investigations employing a variety of seizure models demonstrated that the KD acts primarily to increase seizure threshold. It thereby decreases seizure frequency but does not prevent seizure spread or attenuate convulsive activity once a seizure begins. In rodents, the KD appears to be most effective in seizures induced by $GABA_A$ antagonists, which has led to speculation that the diet may augment GABAergic inhibition. In rodents, seizure threshold reaches a zenith after 10–14 days on the diet, requiring a similarly prolonged time to return to baseline. This parallels the time course described for KD-fed patients. Although improved seizure control can be noted in patients within a day of diet onset, optimal seizure control is typically not reached until after approximately 2 weeks of sustained diet treatment.

Other studies have provided insights into key variables related to diet treatment. Collectively, both clinical and experimental work indicates that factors such as seizure type, seizure duration, diet composition (e.g., type of fats), and gender do not significantly affect treatment outcome. Although there appears to be no effect of age (at diet onset) on treatment outcome, this variable remains controversial (perhaps due to issues of compliance more than physiology). By comparison, variables such as diet ratio and the degree of caloric restriction (CR) appreciably influence the degree of seizure protection. Reducing caloric intake is the most common factor used to enhance KD efficacy. The importance of caloric intake is perhaps not surprising given that the diet originated from insights into the physiology of fasting. CR treatment itself has been shown to mitigate hyperexcitability in animal studies. In addition, seizure control is generally improved in a dose-dependent manner if the KD ratio is increased above 3:1 (to a maximal of 5:1).

Although there is no ideal model that mirrors all facets of the clinical condition, few studies have systematically explored KD. Because most investigations administered sundry high-fat ketogenic diets for different durations, induced seizures by dissimilar means, and examined animal cohorts of various ages, genera, and gender, meaningful cross comparisons have proven challenging. The vast majority of data are taken from studies employing acute seizure models. More relevant information will likely arise from studies of cellular/network hyperexcitability with concomitant alteration of spontaneous recurring seizures in multiple animal models of epilepsy.

Methods

A standard battery of behavioral tests has been implemented to characterize fully the anticonvulsant and cognitive impairments of KD treatment. Chemoconvulsant drugs have been injected into rats, mice, and rabbits to initiate seizure-like activities and establish different facets of the KD's antiepileptic efficacy. Additional behavioral tests such as Rotarod, water maze, and open field tests have been completed in both mice and rats to evaluate potential behavioral deficits in motor function and/or learning and memory following treatment with a KD.

Limited electrophysiological field recordings have been completed to assess KD-induced effects on network excitability. Field recordings have been completed both in vivo and in hippocampal tissue slices in vitro. Microarray studies have been used to assess KD-induced changes in patterns of gene expression in the hippocampus. Biochemical, histological, immunoblotting, and electrophysiological techniques were completed in parallel in an attempt to correlate transcriptional alterations with translational changes and their potential impact on synaptic function. Additional biochemical techniques (e.g., nuclear magnetic resonance imaging, gas chromatography-mass spectroscopy) have been applied to gain specific insight into the metabolic impact of ketones on neuronal and glial metabolism measured in synaptosomes, cultured astrocytes, and tissue from KD-fed or ketone-injected animals.

A putative antiepileptogenic role for the KD has also been explored. Toward this goal, maximal dentate activation (a 1-day electrical kindling protocol) was employed (while recording in vivo) to determine whether KD treatment limited the prolongation of electrical seizure duration. The antiepileptogenic actions have also been assessed following kainate-induced status epilepticus and in genetically seizure-prone EL mice. Behavioral, electrophysiological, immunohistological/histological, and molecular studies have been completed in parallel to determine the degree of KD-induced effects on traditional markers of epileptogenesis (e.g., mossy fiber sprouting), neuronal cell death, and network excitability, as well as its relation to the number of spontaneous recurring seizures.

Recent Results

Early studies of KD focused on establishing efficacy. Only following a resurgence of interest within the last decade or so have studies begun to focus on how the diet works. Several mechanistic theories have been proposed. Those that have received at least some support include (1) enhanced GABAergic inhibition, (2) modified amino acid metabolism, (3) enhanced energy metabolism, (4) diminished glycolysis, and (5) augmented noradrenergic tone. Because various low-carbohydrate KD protocols all produce some level of seizure control, it has become increasingly clear that anticonvulsant actions of the KD stem from diminished glucose and/or ketonemia. But how might this metabolic switch lead to improved seizure control?

Direct Action of Ketones

Given that ketosis is widely considered the clinical hallmark for KD success, the majority of mechanistic studies have focused on establishing a causative link between ketone bodies and seizure protection. Ketones may act directly to limit seizures. Although no acute effect of ketone bodies on neuronal $GABA_A$, AMPA, and NMDA receptors has been observed, application of either β-hydroxybutyrate or acetoacetate to rat or mouse hippocampal slices activated K_{ATP} channels and reduced the spontaneous firing rate of hippocampal neurons in an activity-dependent manner. In vivo, acute injection of acetone, acetoacetate, or ethyl-acetoacetate diminishes seizure activity in a variety of acute and chronic models of epilepsy; interestingly, however, β-hydroxybutyrate does not.

Indirect Actions of Ketones

Ketones may also act indirectly to limit hyperexcitability. This effect could occur in three main ways. First, ketones appear to improve seizure control via a modification in amino acid metabolism. Numerous studies indicate that ketones and KD treatment increase cerebral concentrations of glutamate and GABA, while decreasing aspartate levels. Because ketone body metabolism is thought to diminish the transamination of glutamate to aspartate, these data support the notion that increased glutamate concentrations would be available to enhance GABA levels and increase synaptic inhibition (**Figure 1**).

In synaptosomes, the addition of either β-hydroxybutyrate or acetoacetate increases levels of glutamate and GABA, and decreases levels of aspartate. Although elevated levels of GABA have not been observed throughout the brain, clinical studies are generally consistent with experimental findings; that is, GABA levels are elevated in patients maintained on a KD and there is a positive correlation between GABA levels and improved seizure control. Ketones and/or KD treatment also increase brain glutamine levels. It is thought that elevated astrocytic glutamine is then transported from the brain into the circulation, diminishing overall brain glutamate levels. In view of many studies indicating elevated glutamate during KD, however, this possibility seems somewhat at odds with the data.

Second, ketone bodies and KD enhance energy metabolism. Microarray studies indicate a coordinate upregulation of genes related to ATP production after KD treatment. Notably, KD also induces considerable mitochondrial biogenesis (**Figure 2**), with a parallel increase in energy reserves. For example, KD has been shown to

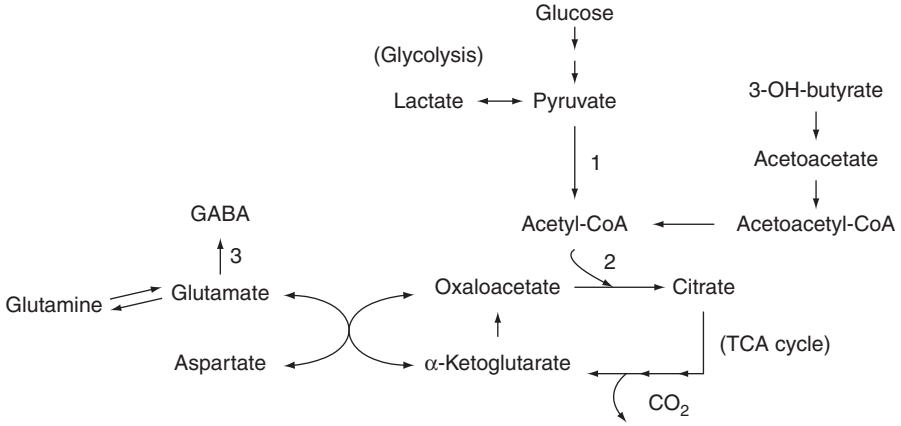

Figure 1 *Modifications in amino acid metabolism after treatment with the ketogenic diet (KD) may favor the production of GABA.*<? tfqs- As a result of a switch from D-glucose to ketone bodies (e.g., β-hydroxybutyrate and acetoacetate) as a primary energy source, a fraction of pyruvate (1) is no longer converted to acetyl-CoA. In contrast, all ketone bodies are converted to acetyl-CoA and thus enter the tricarboxylic acid (TCA) cycle (2) via citrate synthase. In the process, oxaloacetate is used preferentially within the TCA cycle to generate energy, and becomes less available for the transamination reaction of glutamate to aspartate. (3) More glutamate then becomes available for GABA synthesis via glutamic acid decarboxylase (GAD), which increases brain GABA concentrations (Adapted from Yudkoff *et al.*, 2004).

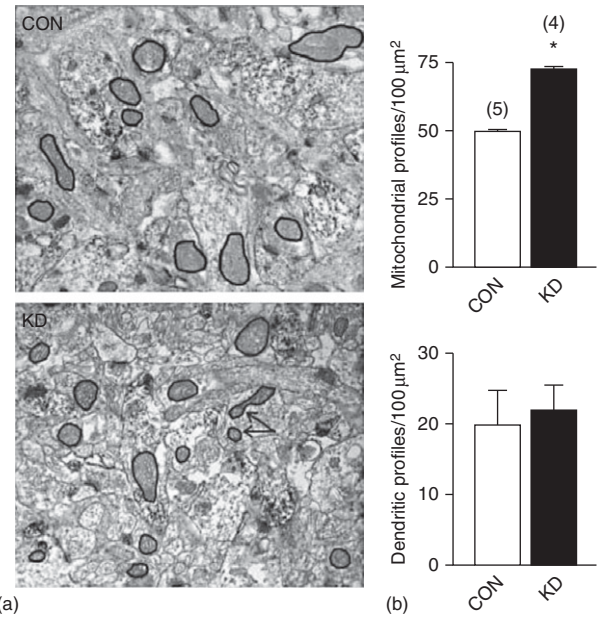

Figure 2 *Mitochondrial biogenesis in the hippocampus of rats maintained on a ketogenic diet (KD).* (a) Representative electron micrographs taken from control-(CON) or KD-fed animals (magnification 20 000; calibration bar 0.5 μm). The number of mitochondrial profiles in each micrograph was counted. An arrow indicates a single mitochondrial profile. (b) There were significantly more mitochondrial profiles in the dentate gyrus of KD-fed animals than in controls. Mitochondrial counts were taken from four KD-fed animals representing a total of 2680 μm^2 and five control rats representing 3080 μm^2. Data are presented as mean of averaged counts ± SEM per 100 μm^2 ($n = 4$ or 5). *$p < 0.001$ by *t*-test. By comparison there was no difference in the density of dendritic profiles in the same micrographs, which guards against the potential differential shrinkage of tissue in KD versus control brains (Adapted with permission from Bough *et al*., 2006).

elevate brain glycogen, boost brain ATP concentrations, and increase the PCr/Cr ratio. In accordance with this finding, tissue from KD-fed animals was more resistant to metabolic challenge with low glucose. KD-fed patients exhibited similar elevations in the PCr/Cr ratio, suggesting that similar enhancements in energy metabolism also occur clinically.

Third, ketone bodies and KD may limit neuronal dysfunction by reducing the generation of excitotoxic mitochondrial reactive oxygen species (ROS). KD increases the expression and activity of mitochondrial uncoupling proteins. Similarly, ketones diminish ROS production and increase the mitochondrial respiratory rate. In this way, the ketones produced during the KD may prevent neuronal dysfunction and help alleviate oxidative stress that could contribute to seizure onset.

Numerous studies now indicate that ketones potently diminish ROS generation and prevent neuronal cell death in a variety of in vitro models of disease. There is some evidence that KD also prevents neuronal cell loss after kainate-induced status epilepticus. Thus, ketones produced during KD may help to stabilize neuronal and/or glial metabolism to reduce hyperexcitability and limit neurodegeneration.

Of related interest is the role for norepinephrine (NE) in KD. Several lines of evidence indicate that greater noradrenergic tone increases seizure resistance. When NE-deficient (Dbh−/−) mice were treated with a KD, they failed to exhibit an anticonvulsant response, suggesting that NE was required for the anticonvulsant effects of the diet. KD may increase NE levels in hippocampus. Moreover, elevation of synaptic levels of NE (via a genetic knockout of the NE transporter) in KD-fed mice led to enhanced seizure resistance (compared to mice fed with KD alone). Together, these findings suggest that NE is a seminal component of the anticonvulsant underpinnings of the KD.

Diminished Glycolysis

The antiepileptic actions of the KD may not solely arise from ketones, however. KD treatment also diminishes significantly blood concentrations of glucose. Findings from several studies point toward a KD-induced inhibition of glycolysis. One report has recently suggested that 2-deoxygluose (2DG), an inhibitor of glycolysis, could prevent both seizures (anticonvulsant) and disease progression (antiepileptic). Injection of 2DG elevated afterdischarge threshold in the olfactory bulb of perforant path of kindled rats; it markedly reduced the progression of kindling, and it prevented seizure-induced increases in the expression of BDNF and TrkB, its cognate receptor. In vitro, epileptiform burst frequency was reduced by 20–75% in rat hippocampal slices exposed to elevated extracellular potassium. Because the activation of TrkB receptors has been integrally linked to processes of epileptogenesis, diminished glucose-induced modifications in gene expression and related modifications in hyperexcitability seem to indicate that the low-glucose KD may not only limit seizures but also prevent disease progression.

A summary of potential mechanistic pathways is depicted in **Figure 3**.

Future Goals

We have begun to define key features of efficacy, but the mechanisms of the KD remain largely unexplored. One of the foremost questions that remain to be determined is as follows: Which aspects of the KD – ketonemia or diminished glucose – are responsible for its effects? Because these two metabolic states are so tightly intertwined, it is difficult to ascertain which feature (if not both) is most critical to diet efficacy. Identification of those factor(s) of diet treatment that most significantly impact(s) its

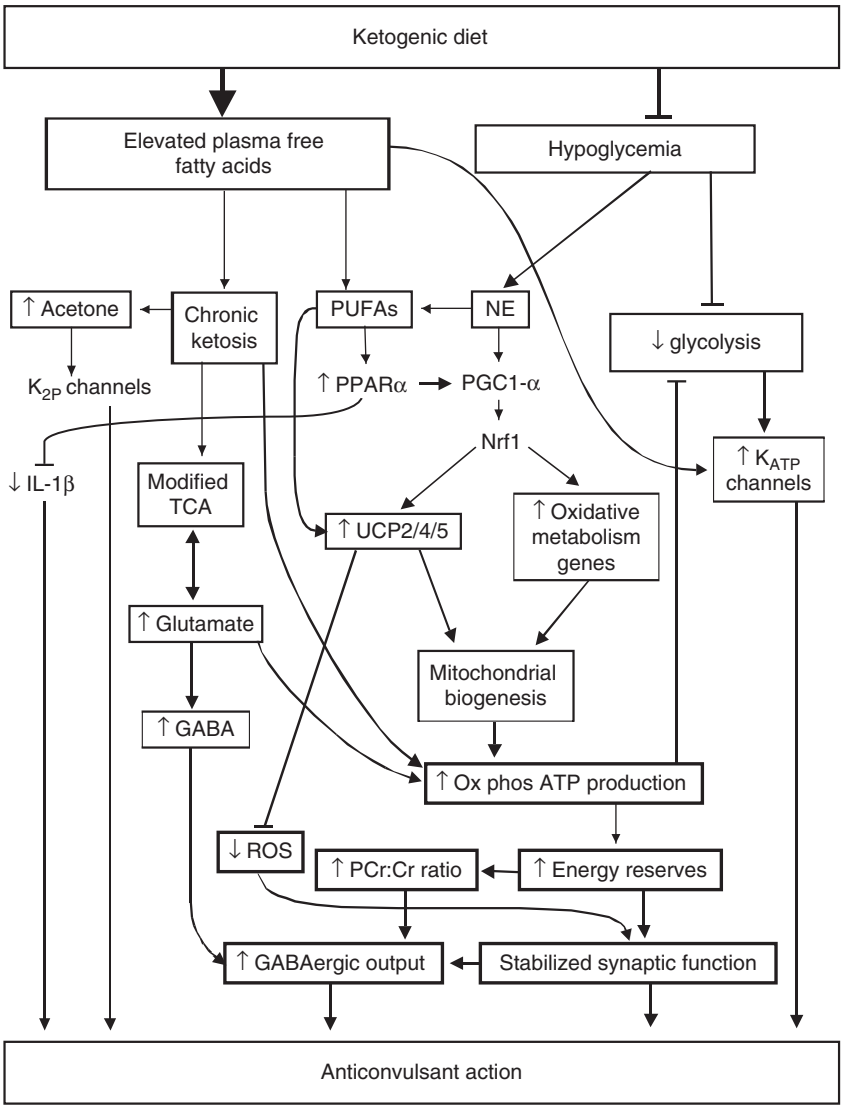

Figure 3 *Hypothetical pathways leading to the anticonvulsant effects of the ketogenic diet (KD).* Boxed variables depict findings taken from KD studies. Up (↑) or down (↓) arrows indicate the direction of the relationship between variables as a result of KD treatment. Elevated plasma free fatty acids result in chronic ketosis as fatty acids are metabolized into ketone bodies and increased concentrations of polyunsaturated fatty acids (PUFAs) in the brain. Chronic ketosis is predicted to lead to elevated levels of acetone; although not discussed in detail, acetone may activate K_{2P} channels to hyperpolarize neurons and limit neuronal excitability. Chronic ketosis is also anticipated to modify the tricarboxylic acid (TCA) cycle. This metabolically favors the production of glutamate and, subsequently, GABA synthesis in brain. PUFAs are expected to boost the activity of brain-specific uncoupling proteins (UCPs); this is expected to limit reactive oxygen species (ROS) generation to diminish neuronal dysfunction, stabilize neuronal functioning, and increase the resistance to hyperexcitability. Acting via the nuclear transcription factor peroxisome proliferator-activated receptor-α (PPARα), PUFAs would be expected to induce the expression of UCPs and coordinately upregulate several dozen genes related to oxidative energy metabolism. PPARα expression is inversely correlated with interleukin-1β (IL-1β) cytokine expression; in view of the role of IL-1β in hyperexcitability and seizure generation, diminished expression of IL-β cytokines during KD treatment could also contribute to improved seizure control. Mitochondrial biogenesis is predicted to increase ATP production capacity and enhance energy reserves, leading to stabilized synaptic function and improved seizure control. In particular, an elevated phosphocreatine/creatine (PCr/Cr) energy-reserve ratio is predicted to enhance GABAergic output, perhaps in conjunction with the ketosis-induced elevated GABA production, leading to diminished hyperexcitability. Reduced glucose coupled with elevated free fatty acids is proposed to reduce glycolytic flux during KD, which would further be feedback inhibited by high concentrations of citrate and ATP produced during KD treatment. This would activate metabolic K_{ATP} channels. Opening of K_{ATP} channels would hyperpolarize neurons and diminish neuronal excitability to contribute to the anticonvulsant nature of the KD. Reduced glucose is also expected to downregulate brain-derived neurotrophic factor (BDNF) and TrkB signaling in brain. As activation of TrkB pathways by BDNF have been shown to promote hyperexcitability and kindling, it has been suggested that these potential KD-induced effects may not only limit seizures, but also the progression of epilepsy (Adapted from Bough and Rho, 2007).

anticonvulsant action will lead to the optimization of KD treatment and more focused study of underlying mechanisms.

The 2DG model presents us with an opportunity to examine the role of low glucose in the mechanism of the KD. For example, if low glucose is a critical feature of KD treatment, then it would be of interest to see whether 2DG glycolytic inhibition recapitulates all the effects observed for the KD – i.e., a similar anticonvulsant profile, diminished hippocampal network excitability, modifications in amino acid metabolism, and enhancements in aerobic respiration (e.g., mitochondrial biogenesis).

In teasing apart a mechanistic function for ketones, we need to determine the levels of acetone, acetoacetate, and β-hydroxybutyrate in human brain during KD treatment. Despite results from many in vitro studies suggesting that ketone bodies limit (directly and/or indirectly) hyperexcitability, we do not know if the concentrations applied in many of those studies are physiologically relevant. Not only would it be of value to correlate measures of ketone levels with improved seizure control clinically, but it would help to better define the cerebrospinal fluid on which future in vitro studies could be based.

Something that was not described in great detail in the earlier discussion, but also needs to be addressed, is a putative role for hyperlipidemia during KD. Polyunsaturated fatty acids (PUFAs) such as eicosapentanoic acid (EPA) and docosahexanoic acid (DHA) modulate voltage-gated sodium channels and L-type calcium channels in hippocampal tissue. Although these PUFAs do not cross the BBB freely, plasma levels of PUFAs are increased in KD-fed children and correlate positively with improved seizure control. Thus, KD-induced hyperlipidemia may act directly to increase seizure resistance and should be explored further.

Several biochemical and molecular studies indicate that regional differences in KD effect throughout brain. Many studies have focused on hippocampus initially because of its well-defined role in epilepsy models. However, restriction of experimental studies to this one structure is clearly insufficient. Additional studies will be required to ascertain the global nature of KD effects, which in turn will help to focus future investigations.

Evidence is beginning to support several possible mechanisms consistent with the anticonvulsant action of the KD; however, all the potential mechanisms remain incompletely defined. Whereas numerous genetic, molecular, and biochemical studies indicate that KD diminishes glycolysis and enhances aerobic respiration, it remains to be determined how these metabolic alterations lead to improved seizure control during diet treatment. Given that metabolism is so closely linked to neuronal activation, a substantial area of need is the characterization of synaptic function in tissue from KD-fed animals. In view of the unique metabolic relationship between neurons and glia, these studies would help overcome a major issue in sorting out how much of a role glia may play in influencing neuronal excitability during KD. Obtaining appropriate electrophysiological recordings in vitro, however, is not without problems. As indicated earlier, glucose is thought to rapidly diminish some of the KD-induced clinical effects – but most in vitro brain slice studies use artificial cerebrospinal fluid that contains high concentrations of glucose. Thus, KD-induced changes on network and/or synaptic hyperexcitability remain largely unexplored. Whereas underlying transcriptional and translational changes should also be linked with electrophysiological modifications, of course, these changes will ultimately need to be associated with improved seizure outcome and tied together with clinical experience.

An issue of major importance is the putative antiepileptogenic role induced by KD. It is obvious that this claim will need to be corroborated in multiple models of epileptogenesis. Further characterization of disease-limiting effects and identification of KD-induced modifications of known antiepileptogenic mechanisms are needed. For example, identification of a similar diminution of BDNF and TrkB receptors, along with a concomitant decrease in spontaneous recurring seizures (as was demonstrated in the 2DG studies), would represent an important first step in confirming a putative antiepileptic role for the KD. If true, support for this effect in further studies could lead to a paradigm shift in the way we approach the treatment of epilepsy, enabling physicians to help prevent the disease, and not just treat the symptom.

Observations that the KD can have such a profound influence on so many diverse intractable epilepsies, and few side effects, underscore the importance of discovering how the diet works. The elucidation of KD mechanisms will likely provide the foundation from which we can gain an improved understanding of basic brain metabolism, its relationship to both normal and abnormal activity (e.g., seizure initiation), and susceptibility to multiple epilepsies. These insights, in turn, will likely lead to profound new treatment strategies for epilepsy and, perhaps, other neurological diseases.

Introduction

Our research focuses on the use of diet as a therapy for neurological and neurodegenerative diseases. Although epilepsy is among the oldest known neurological disorders, seizures continue to be unmanageable in many patients with epilepsy despite intensive research into antiepileptic drug (AED) development. In addition, although many available AEDs provide seizure control, their use is often associated with unanticipated and adverse side effects that diminish quality of life, particularly when used in combination as polytherapy. Regardless of whether seizures have a symptomatic or idiopathic etiology, it is our contention that epilepsy, as a neurological disorder involving dysregulated brain energy metabolism, is potentially manageable through principles of metabolic control theory (analysis). Lennox also considered disrupted energy metabolism as a focal point of epilepsy. Metabolic control theory applies principles of bioenergetics and genome flexibility for the control or management of complex phenotypes such as epilepsy. Since energy metabolism is a fundamental process that underlies all phenotypes, modification of metabolism can lead to the modification of the phenotype. Metabolic control analysis is based on the premise that compensatory genetic and biochemical networks, operating through flexible biological systems, are capable of modulating energy metabolism. Moreover, this dynamic system can potentially produce a normal phenotype through altered energy metabolism, despite the continued presence of the genetic or environmental factors that produce the epileptic phenotype. Our goal is to test this hypothesis in epileptic mice and to eventually identify underlying mechanisms.

Background

Diet Therapies for Epilepsy

Diet therapies for the control of epilepsy are as old as the disease itself, with the type or composition of the diet being adapted over time to reflect new perspectives on the etiology of epilepsy. Antiepileptic diets were used during the time of the ancient Greeks and Romans as well as during the Renaissance. These diet therapies were designed to rid the brain of toxic agents that were believed to underlie the development of epileptic seizures. It was thought that a strict diet regimen was essential for managing or curing the disease. Introduction

Our research focuses on the use of diet as a therapy for neurological and neurodegenerative diseases. Although epilepsy is among the oldest known neurological disorders, seizures continue to be unmanageable in many patients with epilepsy despite intensive research into antiepileptic drug (AED) development. In addition, although many available AEDs provide seizure control, their use is often associated with unanticipated and adverse side effects that diminish quality of life, particularly when used in combination as polytherapy. Regardless of whether seizures have a symptomatic or idiopathic etiology, it is our contention that epilepsy, as a neurological disorder involving dysregulated brain energy metabolism, is potentially manageable through principles of metabolic control theory (analysis). Lennox also considered disrupted energy metabolism as a focal point of epilepsy. Metabolic control theory applies principles of bioenergetics and genome flexibility for the control or management of complex phenotypes such as epilepsy. Since energy metabolism is a fundamental process that underlies all phenotypes, modification of metabolism can lead to the modification of the phenotype. Metabolic control analysis is based on the premise that compensatory genetic and biochemical networks, operating through flexible biological systems, are capable of modulating energy metabolism. Moreover, this dynamic system can potentially produce a normal phenotype through altered energy metabolism, despite the continued presence of the genetic or environmental factors that produce the epileptic phenotype. Our goal is to test this hypothesis in epileptic mice and to eventually identify underlying mechanisms.

Background

Diet Therapies for Epilepsy

Diet therapies for the control of epilepsy are as old as the disease itself, with the type or composition of the diet being adapted over time to reflect new perspectives on the etiology of epilepsy. Antiepileptic diets were used during the time of the ancient Greeks and Romans as well as during the Renaissance. These diet therapies were designed to rid the brain of toxic agents that were believed to underlie the development of epileptic seizures. It was thought that a strict diet regimen was essential for managing or curing the disease. These early antiepileptic diets, however, often consisted of vile concoctions of raw animal organs and extracts that induced nausea or vomiting, and were frequently administered with purgatives and enemas. Restricted food intake or reduced uptake of

nutrients over days or weeks would often be an unintended consequence of such dietary therapies. This restriction would produce the physiological conditions of fasting, during which circulating blood glucose levels are reduced and ketone levels are elevated. Hence, altered brain energy homeostasis would be expected following antiepileptic dietary therapies that lead to a change in circulating levels of glucose and ketone bodies.

Fasting and the Ketogenic Diet

Fasting has long been recognized as an effective antiepileptic therapy for a broad range of seizure disorders. Reference is often made to Biblical accounts of fasting as a cure for epileptic seizures. Biblical scholars interpret these passages to mean that the afflicted individuals could not be cured unless the *healer* engaged in prayer and fasting. Modern clinical findings indicate that fasting can significantly reduce seizure susceptibility in the majority of patients with epilepsy. Using Conklin's water-only diet, Lennox and coworkers demonstrated an impressive management of epilepsy in patients who were having as many as five seizures per day. Although seizure incidence actually increased over the first couple of days of fasting, seizure incidence decreased markedly after three days in most patients. This finding is interesting because it generally requires about three days for cerebral energy metabolism to gradually transition from glucose to ketone utilization during fasting. Seizure control through fasting was also associated with reduced blood glucose and increased blood ketone levels. When the fast was broken through food intake, seizure protection was lost in most patients. Some patients, however, remained seizure free for extended periods after fasting, indicating individual variability for the antiepileptic effects of fasting. The return of seizures was often associated with rising blood glucose levels and falling blood ketone levels.

Although effective in managing seizure disorders, periodic fasting is impractical for the long-term seizure management due largely to issues of compliance. Consequently, the high fat low carbohydrate ketogenic diet (KD) was developed to mimic the physiological effects of fasting (ketosis) without severe food restriction or starvation. The KD is effective in managing intractable seizures in children and can also be effective in managing seizure disorders in adults. In addition, the KD is effective in reducing epileptogenesis and seizures in animal models of epilepsy. Although the mechanisms by which the KD inhibits seizure susceptibility remain unresolved, alterations in brain energy metabolism are likely involved.

The role of ketone bodies (β-hydroxybutyrate and acetoacetate) and glucose in the seizure protective effects of fasting or the KD is under active investigation. Elevated plasma ketone levels have been associated with seizure protection in some studies, but not in other studies. Since ketone utilization in brain can depend on the plasma levels of ketones, glucose, and other metabolites, associations between seizure protection and plasma ketone levels may be obscured. Likewise, blood glucose levels remain constant during KD treatment in some studies, but are reduced during the treatment in other studies. Few studies have investigated the relationship between ketones, glucose, and seizure susceptibility under long-term antiepileptic diet therapies.

Caloric Restriction

Caloric restriction (CR) is a natural dietary therapy that improves health, extends longevity, and reduces the effects of neuroinflammatory diseases in humans and rodents. CR involves a reduction of total dietary energy intake while maintaining adequate levels of vitamins and minerals. In contrast to starvation, which is a pathological state, CR lowers glucose levels and raises ketone body levels within normal physiological ranges. The gradual transition in energy production from glucose to ketone bodies enhances vitality and metabolic homeostasis. We recently showed that in addition to the KD, CR alone could reduce seizure susceptibility in epileptic mice. It is important to mention that CR in the mouse is not the same physiologically as CR in humans since basal metabolic rate is about seven times greater in mice than in man. CR in mice is similar to therapeutic fasting in humans since a 40% CR in inbred C57BL/6J mice produces changes in serum lipids similar to those seen in humans following therapeutic fasting or very low calorie dieting (below 500 kcal day^{-1}). Hence, CR in mice can be an effective model system for investigating the anticonvulsant and antiepileptogenic mechanisms of therapeutic fasting in humans.

The Epileptic EL Mouse: A Natural Model of Human Idiopathic Generalized Epilepsy

Although many animal models of epilepsy can provide insight on anticonvulsant therapies, only those models that exhibit naturally recurring seizures are valuable. The epileptic EL mouse has long been recognized as a natural model of human epilepsy. Seizures in EL mice originate in or near the parietal lobe, quickly spread to the hippocampus and to other brain regions, and commence with the onset of sexual maturity (50–60 days of age). The seizures are accompanied by EEG abnormalities, vocalization, incontinence, loss of postural equilibrium, excessive salivation, and head, limb, and chewing automatisms (**Figure 1**). The seizure disorder in EL mice also models Gowers' dictum where each seizure increases the likelihood of recurrent seizures. Indeed, the EL mouse is the only known mouse model of this hallmark of progressive epilepsy. Adult EL male mice also experience a sexual dysfunction similar to that described in men with

Figure 1 Epileptic EL mouse. The EL mouse models multifactorial idiopathic epilepsy. The mouse expresses excessive salivation, and head, limb, swallowing, and chewing automatisms. The arching Straub tail is indicative of seizure spread to spinal cord. Reproduced from Seyfried TN *et al.* (2004), with permission.

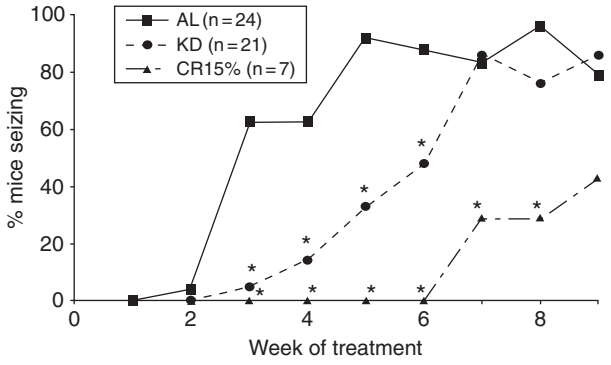

Figure 2 Influence of CR and the KD on seizure susceptibility in juvenile EL mice. Asterisks indicate that the number of mice seizing was significantly lower in the CR and KD groups than in the AL group at $^*p < 0.01$. Reprinted from Greene *et al*. (2001) Caloric restriction inhibits seizure susceptibility in epileptic EL mice by reducing blood glucose. *Epilepsia* 42(11): 1372–1378, with permission.

temporal lobe epilepsy. EL mice express abnormalities of excitatory and inhibitory neurotransmission and develop a hippocampal gliosis with seizure progression. The gliosis in EL mice, however, is not associated with obvious hippocampal neuronal loss or synaptic rearrangements (e.g., mossy fiber sprouting). Gene–environmental interactions play a significant role in the determination of seizure frequency and onset in EL mice, as is the case with multifactorial human idiopathic epilepsies. Hence, the EL mouse is a good model for evaluating the effects of dietary therapies for generalized idiopathic epilepsies.

Methods and Recent Results

Influence of the KD and CR on Seizure Susceptibility in Juvenile EL Mice

The implementation of diet therapies in mice, although simple in principle, can be difficult in practice. Prior to the initiation of diet therapy, it is essential that all mice be matched for age, weight, and sex. All mice should be individually housed and body weight along with food intake recorded 3–4 times prior to any dietary modification. Baseline blood glucose and ketone body levels should also be obtained at least once prior to diet initiation. These practices are important since any dietary manipulation can cause some mice to lose or gain weight relative to the weight they had before diet implementation, and these changes can influence data interpretation. We also found that it is better to use body weight, rather than food intake, as the independent variable when instituting CR or dietary restriction experiments. This is because physiological differences exist among individual mice for food intake even when they are matched for age, sex, and genetic background. Body weight is therefore the preferred independent variable for evaluating the physiological effects of dietary manipulations.

Our initial studies evaluated the influence of the KD on seizure onset in juvenile (about 30 days old) EL mice (Figure 2). The fat in this diet was derived from lard and the diet had a ketogenic ratio (fats: proteins + carbohydrates) of 4.75:1. The KD contained a balance of mouse nutritional ingredients and according to the manufacturer's specification (Purina or Zeigler Bros., Inc. Gardners, PA, USA), the diet delivered 6.85 kcal g^{-1} gross energy, where fat, carbohydrate, protein, and fiber comprised 90%, 0%, 10%, and 3% of the diet, respectively. The mice were deprived of food and water for 14 h prior to initiating the KD therapy. The mice in both the treatment (KD) and control (AL) arms were fed either the high fat diet or the high carbohydrate diet ad libitum (unrestricted), respectively. Mice in the AL arm received the PROLAB RMH3000 chow diet (LabDiet, Richmond, IN). This standard rodent food pellet diet (SD) contained a balance of mouse nutritional ingredients. According to the manufacturer's specification, this diet delivered 4.4 kcal g^{-1} gross energy, where fat, carbohydrate, protein, and fiber comprised 6%, 62%, 27%, and 5% of the diet, respectively. Mice in the KD treatment arm were matched for body weight throughout the study. The KD temporally delayed the onset of seizures relative to the AL group, suggesting an effect on epileptogenesis. Although the KD-fed mice had elevated blood ketone levels, glucose levels were similar in AL and KD groups. We also compared the effects of the KD with that of a calorie restricted SD arm (CR) on seizure susceptibility in the juvenile EL mice. We found that a mild 15% CR diet was more effective than the AL-fed KD in delaying seizure onset and in reducing seizure susceptibility

(Figure 2). Although body weight was about 8% lower in CR mice than in AL-SD mice, the rate of body weight gain was similar in AL-SD and CR groups. This observation is extremely important, since delay or stunting of growth is an adverse effect that can confound data interpretation. In contrast to the mice fed with KD ad libitum, which elevated plasma ketone bodies without lowering glucose levels, the CR fed mice showed elevated ketone levels with significantly lower glucose levels. Mild CR was more effective in preventing seizures than was the KD fed ad libitum. The KD may inhibit epileptogenesis in the juvenile EL mice by prolonging the preweaning period, thereby causing the brain to metabolize ketones for energy despite glucose availability. We suggest that CR enhances this antiepileptogenic effect by lowering blood glucose levels in addition to elevating blood ketone levels.

The Relationship of the KD and CR in Seizure Management in Children

The KD is most effective in reducing seizure susceptibility in children when administered with fasting or under restricted caloric intake. Clinical studies have also shown that the anticonvulsant efficacy of the KD is associated with body weight and blood glucose reductions of about 10%. Our findings in EL mice on the CR diet are consistent with these findings in humans. It is interesting that the anticonvulsant effects of the KD can be lost in patients who experience a rise in blood glucose levels, as in the case of those who gain weight on the diet or who consume carbohydrates. On the basis of our studies with EL mice, we suggest that the seizure protective effects of the KD would be best when administered in reduced amounts, so that blood glucose levels and body weight are also reduced. It is also important to recognize that consumption of the KD in unrestricted amounts is unhealthy because of the high fat content of the diet. Consumption in restricted amounts provides maximum therapeutic benefit against epilepsy while reducing the adverse effects of the high fat content of the diet.

Influence of the KD and CR on Seizure Susceptibility and Plasma Energy Metabolites in Adult EL Mice

Although the KD is used largely for the management of refractory epilepsy in children, the KD can also be effective in managing seizures in adults. In addition to evaluating the effects of the KD and CR on seizure susceptibility in juvenile EL mice, we evaluated the effects of these diet manipulations on seizure susceptibility in adult EL mice (about 210 days of age) that had already developed multiple recurrent seizures. For these studies, we reduced body weight to a similar degree (about 22%) in both the mice fed a high carbohydrate standard diet (SD) and the KD, and measured seizure susceptibility once/week over a 9-week period (Figure 3(a)). Seizure susceptibility remained high in the adult EL mice fed either the KD or SD under unrestricted feeding (UR groups) throughout the study. The KD, when administered in unrestricted amounts, was unable to significantly lower seizure susceptibility in the EL mice. In marked contrast, seizure susceptibility was significantly reduced to a similar degree in both mouse groups fed the restricted SD or the KD diets (Figure 3(b)).

Our findings clearly showed that seizure management in EL mice associated more with caloric intake than with the origin of dietary calories. We also found that seizure susceptibility was strongly correlated with blood glucose levels (Figure 3(c)). Plasma glucose levels were similarly high in both UR groups (mice exhibited high seizure susceptibility), but were similarly low in both restricted calorie groups (mice exhibited low seizure susceptibility). A less strong correlation was found, however, between seizure susceptibility and plasma ketone bodies (β-hydroxybutyrate) (Figure 3(d)). Although circulating ketone bodies were significantly elevated in the KD-UR group, the mice in this group were highly seizure susceptible. The highest plasma ketone levels were observed in the restricted KD mice, but this elevation was not associated with better seizure management relative to that found in the restricted SD mice. Finally, we used binary logistic regression analysis to determine the relationship between seizure susceptibility, plasma glucose, and plasma ketone levels in mice fed the SD or the KD. We found that regardless of diet composition, glucose could predict seizure susceptibility with a 75% degree of accuracy. As blood glucose levels dictate blood ketone levels under normal physiological conditions, glucose is the key energy metabolite for predicting seizure susceptibility in the epileptic EL mice.

Evidence that the KD Suppresses Seizure Susceptibility through CR

In contrast to the KD, CR elevates blood ketone levels naturally through a gradual reduction in blood glucose levels. Although both the KD and CR elevate blood ketone levels, circulating ketone levels alone do not explain the anticonvulsant effects of these diets in either humans or animal models. Indeed, the brain does not generally metabolize ketones for energy unless blood glucose levels are reduced. We suggest that it is the reduction of blood glucose levels together with an elevation of blood ketone levels that predicts the anticonvulsant efficacy of both the KD and CR. Blood glucose also

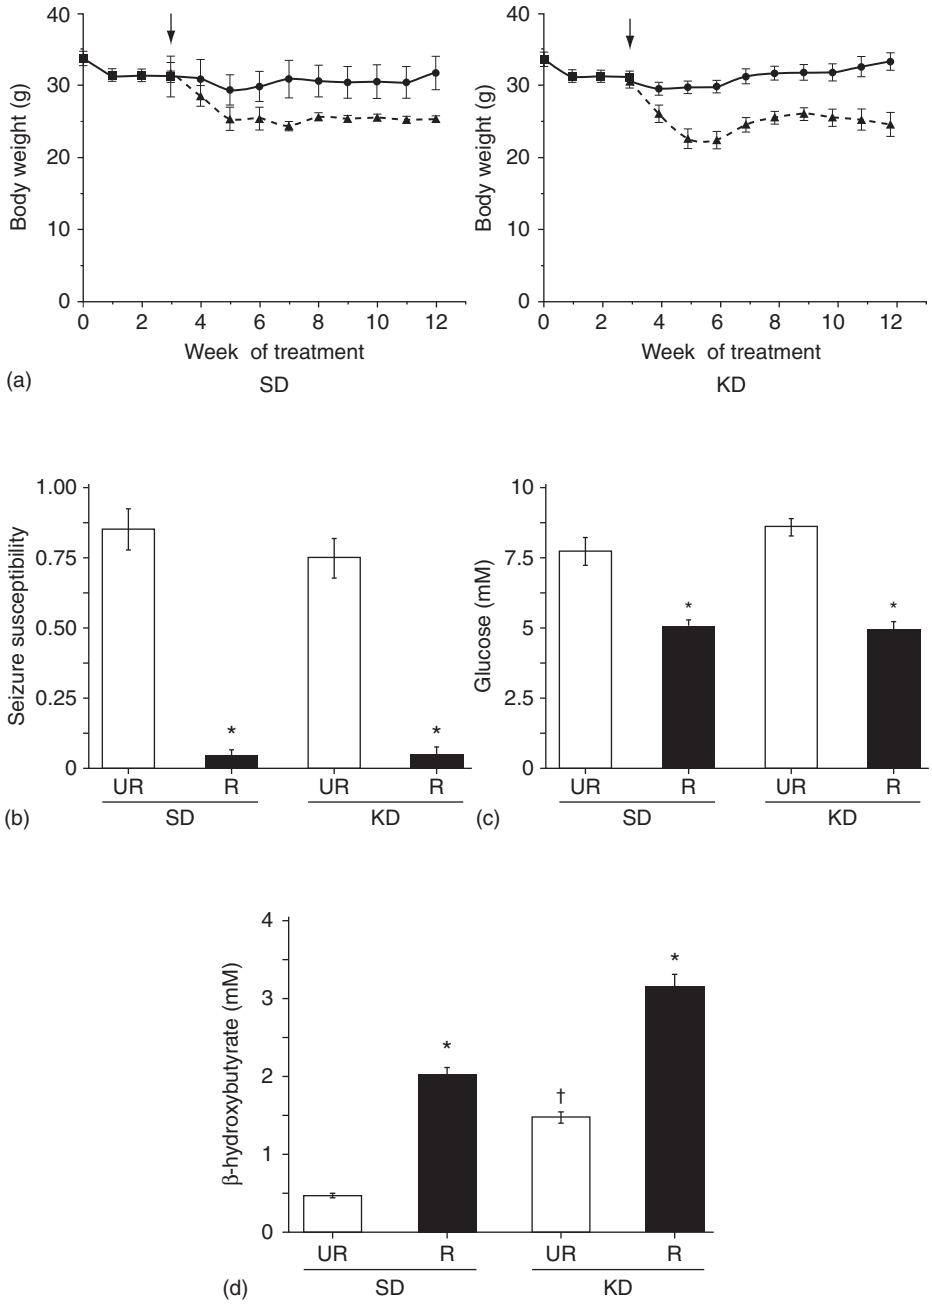

Figure 3 Influence of CR and KD on body weights (a), seizure susceptibility (b), plasma glucose levels (c), and plasma β-hydroxybutyrate levels (d) in adult EL mice. In (a), squares represent the pretrial period when all mice were fed the SD-UR. Circles and triangles represent the UR-fed and R-fed groups, respectively. The arrow indicates initiation of CR. In (b-d), the asterisks indicate that the values were significantly lower ($p < 0.001$) in the R-fed groups than in the respective UR-fed groups. The cross in (d) indicates that the plasma β-hydroxybutyrate levels were significantly higher ($p < 0.001$) in the KD-UR group than in the SD-UR group. Values were pooled from treatment weeks 5–12 (see (a)) and are expressed as the mean ± SEM ($n = 6$ mice per group). Reprinted from Mantis *et al*. (2004) Management of multifactorial idiopathic epilepsy in EL mice with caloric restriction and the ketogenic diet: Role of glucose and ketone bodies. *Nutrition and Metabolism* 1: 11, with permission.

positively correlates with susceptibility to clonic and tonic-clonic flurothyl-induced seizure in rats. High glucose may also exacerbate human seizure disorders. These observations suggest that the KD may be most effective in reducing seizure susceptibility when blood glucose levels or total calories are also restricted. The relationship of blood glucose and ketone body levels to seizure management in EL mice is illustrated in **Figure 4**.

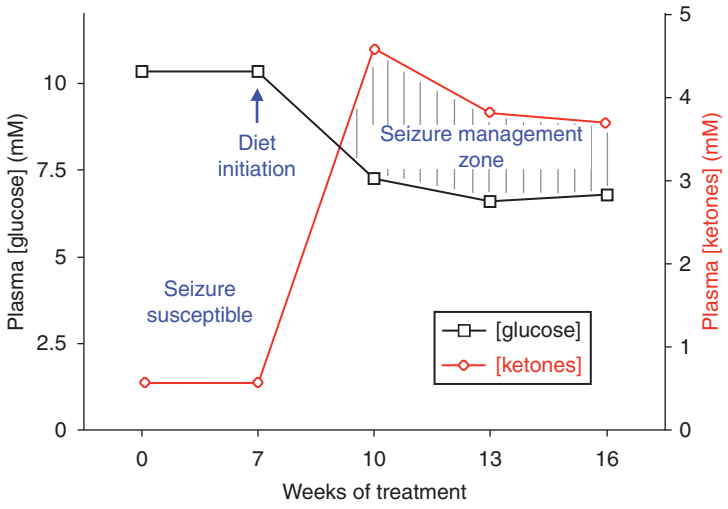

Figure 4 Relationship of circulating glucose and ketone levels to seizure management in epileptic EL mice.

The association between blood glucose levels and seizure susceptibility is less clear in humans with epilepsy than in mice with epilepsy. The reduction of body weight and restriction of calories in children on the KD implies reduced glucose levels relative to the levels prior to the initiation of the diet. In order to determine the relationship between glucose and seizure protection under the KD, it would be necessary to monitor glucose levels in children prior to the initiation of the KD. In other words, glucose levels should be monitored both before and during the KD, with each child serving as his/her own control. Body weight or weight gain measurements, however, might be more accurate predictors of diet efficacy than blood glucose levels in children. Hence, further studies with epilepsy animal models are needed to assess the relationship among blood glucose levels, body weight changes, and seizure protection with antiepileptic diets.

Perspectives on the Antiepileptic Mechanism of CR

Glucose uptake and metabolism increase more during an epileptic seizure than during any other brain activity. This increase appears to be independent of seizure etiology and occurs with either generalized or focal seizures, in either idiopathic or symptomatic epilepsies. Glycolytic energy is crucial for maintaining synaptic activity and enhanced glycolysis is associated with seizure activity. Brain lactate levels also increase significantly during seizures. The seizure-associated lactate increase reflects the rapid increase in glycolytic rate over the cerebral metabolic rate of oxygen. Pyruvate dehydrogenase fails to metabolize pyruvate to acetyl-CoA at the same rate that pyruvate is produced, thus leading to lactate accumulation. It is not yet clear, however, to what extent enhanced glycolysis is related to the cause or to the effects of seizure activity. In addition to providing immediate energy for synaptic activity enhanced brain glycolysis during seizures may be necessary to provide a rapid and large amount of ATP for maintaining or restoring neuronal membrane potentials during the seizure itself. This energy would be needed to protect the brain from glutamate toxicity and to help restore brain homeostasis (i.e., the balance of inhibitory and excitatory systems).

We suggest that CR alone, or the calorically restricted KD, inhibits seizure susceptibility by transitioning brain energy metabolism from glucose to ketone bodies. This transition could maintain brain energy homeostasis through enhanced energy production from respiration. According to Veech, ketone bodies are a 'super fuel' that provide more energy equivalents than glucose for metabolic activities. It is generally recognized that metabolic homeostasis and energy efficiency is better in the fasted state than in the 'well fed' state, when ketone bodies displace glucose as a major metabolic fuel.

We propose that epilepsy involves disruptions of brain energy homeostasis and that seizure disorders are potentially manageable through metabolic control, where a gradual transition from glucose to ketone body metabolism controls the seizure disorder by restoring energy homeostasis. Furthermore, these transitions in glucose and ketone levels occur within physiological ranges that maximize metabolic homeostasis (**Figure 4**). Transitions with a physiological range are important, since shifts that are too extreme can produce the pathological complications associated with hypoglycemia or ketoacidosis. The key to treatment is to maintain seizure management within a zone defined by a effective ratio of circulating blood glucose to ketone bodies. Since the metabolism of ketone bodies is thermodynamically more efficient than the metabolism of glucose, a transition in brain energy metabolism from

glucose to ketones will produce a homeostatic state that is capable of restoring the physiological balance of excitation and inhibition. This balance comes from more efficient activities of membrane pumps, which are major consumers of cellular ATP, and from more efficient neurotransmitter uptake, which is coupled to pump activity. The restoration of a nonepileptic (normal) phenotype can be obtained in this way, despite the continued presence of the idiopathic (genetic) or symptomatic (acquired) defects responsible for the disease. New experimental approaches involving biological system state analyses will be necessary to evaluate the mechanisms by which these gene and metabolic networks interact to manage epilepsy.

Future Goals

In summary, we propose that the metabolic management of epilepsy occurs through two distinct processes. The first involves a reduction in circulating glucose levels. The second involves an elevation in circulating ketone body levels that supply the body with energy that would otherwise not be generated during conditions of decreased glucose metabolism. These alterations would produce a shift in the neurotransmitter pools that modulate neuronal membrane potential, thus restoring the physiological balance of excitation and inhibition. This restoration of the neurotransmitter pool and membrane potential is based on the inherent genetic and metabolic flexibility of the brain to reorganize and adapt to changes in the availability of brain energy metabolites. Future goals will require identification of those neurochemical and neurophysiological changes that accompany seizure management in association with changes in glucose and ketone levels. A better understanding of the genetic and neurochemical networks of compensatory brain energy metabolism may lead to novel antiepileptic therapies that are more effective and less toxic than those currently available.

Dietary Therapies for Epilepsy

K Chapman and J M Rho, Barrow Neurologic Institute, Phoenix, AZ, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As the search for new treatments for epilepsy continues, the ketogenic diet (KD) maintains an enduring stance as an effective treatment option, notably for medically intractable patients. Since its initial use in the 1920s, at a time when few anticonvulsant medications were available, the KD has seen episodic resurgence, most recently in the 1990s. Even with the advent of more anticonvulsant medications, dietary therapy for epilepsy has continued to offer responder rates that rival or exceed the new medications. Epilepsy patients who have failed multiple antiepileptic drug trials sometimes experience dramatic responses to dietary therapy, and the KD has proven invaluable for certain epilepsy syndromes. Both clinical and basic mechanistic research in the field of dietary therapies for epilepsy continues to grow. Further, efficacious variations of the traditional KD – including the Atkins diet and low-glycemic index treatment – are being investigated and may offer useful and better-tolerated alternatives to the more restrictive classic formulation.

Background - History of the KD

The beneficial effect of fasting on seizure control had been noted as early as Hippocrates' time, with later references found in the Bible. After Jesus healed a boy with seizures, he told his disciples that the 'evil spirit' could only be exorcised with prayer and fasting. Centuries later, Rawlin Geyelin reported in 1921 that a 3-week fast was effective in treating epilepsy. His work was based on a 'water diet,' proposed by the osteopathic physician Hugh Conklin, which deprived patients of food, but allowed water for a period of 3 to 4 weeks. Geyelin reported high cure rates that persisted even after the diet was discontinued, providing the first hint of the possible anticonvulsant effects of the KD.

Based on these and other historical observations, Wilder proposed that the ketosis produced from fasting may explain the improved seizure control. He devised a diet with a fat to carbohydrate plus protein ratio of at least 3:1 (by weight) to mimic the ketosis during fasting, a formulation that is very similar to that used today. During the 1920s, Peterman at the Mayo Clinic modified the diet originally proposed by Wilder and studied its efficacy in the treatment of epilepsy. Peterman reported that 50% of patients became seizure-free with dietary therapy.

Following the introduction of phenytoin in 1938, the KD became less popular as more anticonvulsant medications became available for clinical use. The group at Johns Hopkins Hospital reinvigorated research into the diet in the 1990s with the successful treatment of Charlie, the son of a Hollywood producer. This success led to increased public awareness of the efficacy of the diet through mainstream media, and introduced the KD to many practitioners previously unfamiliar with its use. Of particular importance is the fact that the KD appeared to have considerable efficacy against seizures/epilepsies that did not respond to any of the available medical therapies. Subsequently, there has been mounting interest in optimizing clinical implementation and elucidating underlying mechanisms of the KD.

Methodological Issues

Initiation of the KD

The typical protocol used by many centers is borrowed from the experience of the Johns Hopkins group (see Table 1). Prior to initiation of the KD, patients undergo a comprehensive medical evaluation, involving a multidisciplinary team composed of a neurologist, dietician, and nursing staff, all experienced in the use of the KD. Dietary preferences and calorie counts are recorded, and this information is used to develop daily menus for each patient. Baseline laboratory studies usually include a comprehensive metabolic panel, lipid panel, and complete blood count. A careful examination of medications being taken is required, as liquid medications often contain hidden carbohydrates – which could easily break the systemic ketosis; such medications are changed to tablet forms. Encouraging families to bring to the hospital some recreational and/or educational activities for their children helps ensure a more manageable hospital stay. Several available books geared toward the lay audience address many of the questions that arise when considering or initiating the KD. Important to note, however, is the fact that the KD is fraught with certain adverse side-effects. For example, patients with an elevated urinary calcium-to-creatinine ratio may be at risk for nephrolithiasis and should be followed closely.

Patients are usually hospitalized for 4 days, although recently, outpatient initiation of the diet has been shown to be a safe and effective alternative. Hospitalization is advocated for a number of reasons, including (1) observation for hypoglycemia and other potential

Table 1 Typical regimen for initiation of the KD

Before diet
Nutrition history obtained
Minimize carbohydrate intake for 1 day
Fasting begins after dinner the evening prior to admission
Day 1
Admission to the hospital
Conversion to carbohydrate-free medications
Basic laboratory obtained if not done previously (metabolic profile, urine calcium, urine creatinine, fasting lipid profile, antiepileptic drug levels)
Check fingerstick glucose every 6 h; if <40 mg dl^{-1}, check every 2 h
If symptomatic, or glucose <25 mg dl^{-1}, give 30 ml orange juice, measure blood glucose again
Parents begin classes
At dinner, one-third of the calculated ketogenic meal given as 'eggnog'(e.g., if the full meal is calculated as 150 ml give 50 ml at this meal)
Blood glucose checks discontinue after dinner
Day 2
At breakfast and lunch, one-third of the calculated ketogenic meal given as 'eggnog'
Symptomatic ketosis (e.g., nausea, vomiting) can be relieved with small quantities of glucose
Parent classes continue
At dinner, two-thirds of the calculated meal given as 'eggnog'
Day 3
At breakfast and lunch, two-thirds of the calculated meal given as 'eggnog'
Parent classes conclude
At dinner, the first full ketogenic meal is given (not 'eggnog')
Day 4
After breakfast (full ketogenic meal), the patient is discharged home
Prescriptions written for carbohydrate-free medications, urine ketone test strips, a sugar-free, fat-soluble
Multivitamin and calcium supplements, citrate salts (if indicated)
Clinic follow-up appointment arranged

Reproduced from Hartman AL and Vining EP (2007) Clinical aspects of the ketogenic diet. *Epilepsia* 48: 31–42, with permission from Blackwell Publishing.

side-effects, (2) gradual initiation of the diet under dietary supervision to ensure that the diet is well tolerated by each patient, and (3) close personal education for the families to help with comfort level and understanding of the diet. Prior to entering the hospital, some centers advocate fasting, while other centers have found that nonfasting may allow improved tolerance of the diet and lowers the risk of dehydration.

The diet is typically calculated to yield a ketogenic ratio of 4:1 (i.e., 4 g of fat to 1 g of protein plus carbohydrate). The total calories are calculated to achieve ideal body weight, while total fluid intake is often restricted. Fluid restriction had been advocated in the belief that such restriction would enhance ketosis, and presumably seizure control. However, there is little information that fluid restriction is a necessary condition for clinical efficacy. Protein intake at 1 g per kilogram of body weight per day is provided to ensure linear growth. The diet is often started at one-third strength on day 1, and gradually increased by one-third strength each day to the full targeted ketogenic ratio. The dietician works closely with the family to individualize meals that are both palatable and also compliant with the strict requirements of the diet. Engaging children in their meal selection and preparation can help improve compliance. KetoCal (Nutricia N.A., subsidiary of SHS International, Liverpool, England) can provide the complete enteral nutritional needs for patients fed via feeding tubes, and is easily used by parents.

It is important to follow certain metabolic parameters while on the KD. Blood glucose is measured via fingerstick, three times per day, or when the patient experiences signs or symptoms of hypoglycemia. Glucose levels above 25 mg dl^{-1} are usually well tolerated and do not require treatment. If the patient becomes symptomatic or drops below 25 mg dl^{-1}, 30 mL of orange juice is generally sufficient to improve the hypoglycemia. To assess ketosis at home, family members are taught to use urinary test strips (i.e., Ketostix, Bayer AG), which specifically measure acetoacetate levels. This home intervention adds to the empowerment that families feel when administering the KD. Since urine dipstick measurements do not correlate well with ketonemia, practitioners can alternatively measure serum β-hydroxybutyrate levels to assess the degree of ketosis and compliance.

There are other important variables in the clinical management of patients. Vitamin supplementation is recommended because the diet lacks fat-soluble vitamins and calcium. Proper counseling of the family on the need for carbohydrate restriction – including consideration of the carbohydrate content of over-the-counter and prescribed liquid medications – may help prevent breakthrough seizures following loss of ketosis. If the diet is successful, patients are traditionally maintained on the KD for a minimum of 2 years (though it is unclear if early responders require such prolonged treatment), after which consideration is given to discontinuation of the diet. Patients may not respond initially, but families are encouraged to maintain the diet for at least 2–3 months before determination of failure and eventual weaning. During this initial period, modifications to the ratio of the diet may help improve seizure control.

Safety of the KD

Contrary to popular belief, the KD is not a 'natural' treatment for epilepsy, and as such, is not without side-effects. Fortunately, most side-effects are mild and can be managed successfully. These side-effects can be grouped into acute and chronic complications of the diet. Initiation of the diet forces the body's metabolism to undergo multiple systemic changes, which may be difficult for

the patient to tolerate. Gastrointestinal side-effects, such as nausea and vomiting (which can lead to dehydration), is common, particularly when the diet is initiated with fasting. Constipation is more often seen with the classic KD, while diarrhea is more common when using the medium-chain triglyceride (MCT)-oil. Laxatives to treat constipation are often needed by patients on the classic KD. Symptomatic hypoglycemia is not uncommon, but is easily treated with a glucose load (such as 30 ml of orange juice). Elevations in serum lipid levels may be seen as an early or late complication of treatment. Hypertriglyceridemia and hypercholersterolemia may occur, but often stabilize and do not require intervention. The long-term consequences of this dyslipidemia are not well understood, but a reduction in the ketogenic ratio often causes a decrease to acceptable levels. Nephrolithiasis appears to be a relatively common side-effect, seen in ~5% of patients. Alkalinization of the urine, in patients with elevated urinary calcium-to-creatinine ratios or those with a history of nephrolithiasis, can significantly reduce this risk. The relatively low protein and caloric intake of the KD may also impact the linear growth of patients, particularly younger children, and thus needs to be closely followed. Osteopenia from poor calcium absorption and increased osteoclastic activity may lead to an increased incidence of fractures. There have been rare case reports describing potentially fatal side-effects such as hepatitis, cardiomyopathy, and pancreatitis, but the cause-and-effect relationships are unclear. The KD also can provoke a secondary carnitine deficiency, as with medications such as valproic acid. As such, there has been great concern that there may be an increased susceptibility to hepatotoxicity when valproic acid is coadministered with the diet. However, this combination can be safely administered if patients are carefully followed. Overall, the side-effects of the KD are relatively mild and certain modifications and interventions can ensure increased tolerability.

Results

Efficacy of the KD

With the resurgence of interest in the KD, there are a growing number of studies evaluating clinical efficacy and tolerability, and special attention has been given toward identifying which subgroups of patients may represent more favorable responders. The Johns Hopkins experience revealed a very favorable response rate in patients with medically refractory epilepsy. Thirty-six percent of patients who were on the KD at one year exhibited a >90% reduction in seizures, and 13% were seizure-free at the 1-year follow-up mark. Seventy-two percent (8/11) of fully controlled patients remained seizure-free after discontinuing the diet. Sixteen percent (12/72) of patients who continued to have seizures at 1 year of follow-up became seizure-free at the 3–6 year follow-up time-point. An additional benefit was that 36% of children no longer took anticonvulsant medications, and another 34% took only one medication (compared with a previous mean number of medications of 1.97). These findings demonstrate the anticonvulsant efficacy of the KD, but also suggest a more enduring (and possibly, antiepileptogenic) effect.

Recently, the first randomized controlled trial of the KD in the treatment of pediatric patients with medically refractory epilepsy was completed in the United Kingdom. This study showed a statistically significant difference in responder rates between KD-treated vs. control groups. Twenty-eight children (38%) in the diet-treated group had a greater than 50% seizure reduction compared with only four (6%) controls ($p < 0.0001$).

While some larger studies have suggested that seizure type is not a predictor of treatment success, patients with complex partial seizures are less like to have an early, dramatic response to the KD. The diet has been used in a wide variety of epileptic syndromes, including Lennox–Gastaut syndrome, tuberous sclerosis complex, Landau–Kleffner syndrome, myoclonic–astatic epilepsy, Rett syndrome, and infantile spasms, often with very positive results. Dravet syndrome (severe myoclonic epilepsy of infancy) seems particularly responsive to the KD and should be considered early. Patients with glucose transporter-1 deficiency and pyruvate dehydrogenase deficiency are ideally treated with the KD, since this treatment can bypass the underlying biochemical defects. Specifically, ketone body transport and utilization through monocarboxylic acid transporters and by the tricarboxylic acid (TCA) cycle, respectively, can compensate for these metabolic deficiencies. Interestingly, despite data suggesting neuroprotective properties of the KD, Lafora body disease was not appreciably altered by such dietary intervention.

Modifications to the KD

The classic 4:1 formulation of the KD has always been hampered by the degree of carbohydrate restriction necessary to induce ketosis. This restriction has limited the palatability of the diet, and consequently its clinical use and acceptance by patients. Investigators have long sought modifications of the diet that might circumvent this problem, while retaining clinical efficacy.

The MCT Diet

The first major modification of the diet was advanced in the 1960s. Medium-chain triglycerides (MCT) were used as a supplement to the traditional KD to enhance ketosis. Medium-chain triglycerides are passively absorbed from the gastrointestinal tract and are strongly ketogenic;

they are more ketogenic than long-chain trigylcerides, and can allow for a higher carbohydrate and protein intake than the classic diet. Initiation of the MCT variation was described by Huttenlocher in 1971. Children were admitted to the hospital and started on a 50 cal day^{-1} fast for about 48 h until they became strongly ketotic. They were then started on the diet with 60% of their calories provided as MCT oil. The oil was served as milkshakes made with skim milk. The remaining calories came from protein and carbohydrate, depending on the individual tastes of the patient, to ensure the minimal daily requirements to promote growth. Four of six patients with myoclonic seizures responded well, while patients with complex partial seizures seemed to have a lower response rate. Multiple patients demonstrated a marked improvement in their electroencephalogram (EEG) and many were noted to have improved behavior and alertness. However, gastrointestinal side-effects, including cramping, nausea, and diarrhea, are commonly seen with this diet. These symptoms may improve with time or with using only small sips of the MCT oil throughout each meal, rather than ingestion all at once. Unfortunately, the traditional MCT oil diet tends to be unpalatable and can thus limit overall acceptance of this diet. Recently modified formulations employing less MCT oil content, however, have been shown to be better tolerated.

Modified Atkins Diet

In 1972, Dr. Robert Atkins introduced a modification of the classic KD to promote weight loss. His diet allows for more liberal carbohydrate content than do the classic KD; fiber and sugar alcohols are not counted toward the daily carbohydrate count, as they do not alter blood sugar levels significantly. The popularity of the Atkins diet has led to a wide variety of foods that conform to this diet and allow for greater selection. The diet does not significantly restrict protein or caloric intake as does the classic KD, and this factor can diminish weight loss as a side-effect.

The Atkins diet has been modified and implemented for the treatment of epilepsy, based on the recommendations of the Johns Hopkins group. The Atkins diet typically consists of 60% fat, 30% protein, and 10% carbohydrates by weight. When patients are started on the Atkins diet, carbohydrate content is limited to 10 g day^{-1} for the first month, corresponding to the induction phase. Urinary ketones are followed semiweekly through the use of Ketostix (see **Table 2**). Laboratory studies to evaluate baseline nutritional status are checked prior to starting the diet and are later compared with the 3 and 6 month values. Carbohydrate intake may be gradually liberalized if the child finds the diet too unpalatable. Low-carbohydrate multivitamins are also instituted, as in the classic KD. Families find that the popular book, Dr. Atkins New Diet Revolution, can answer many of their questions regarding this diet and provides useful tips and recipes.

Despite the increase in carbohydrate content, ketosis with the Atkins diet can clearly be achieved, although the degree and consistency of ketosis may be variable. In one study of epileptic patients, seizure freedom at 6 months was 20%; 35% of patients achieved a >90% reduction of seizures, and 65% of patients had a >50% reduction in seizures. This reduction in seizure frequency is especially noteworthy, given that the patient population had failed an average of 6.5 AEDs and averaged 163 seizures per week. Overall, the side-effects of the Atkins diet were typically mild and consisted primarily of gastrointestinal complaints. Further, changes in cholesterol levels were not as apparent as those seen in the classic KD.

Low-Glycemic Index Diet

In another effort to enhance the palatability of the classic KD, other researchers have advocated a diet with a low-glycemic index as an alternative. The glycemic index is a value that describes the extent to which a carbohydrate is absorbed and elevates blood glucose. This rise in blood

Table 2 Modified Atkins' diet protocol

- Copy of Dr. Atkins' New Diet Revolution provided
- Carbohydrates described in detail and restricted to 10 g day^{-1} for the first month
- Fats (e.g., 36% heavy whipping cream, oils, butter, mayonnaise) encouraged
- Clear, carbohydrate-free fluids not restricted
- Low-carbohydrate multivitamin (Unicap M) and calcium (Calcimix) supplementation prescribed
- Calendar provided to document seizures daily, urine ketones semiweekly, and weight weekly
- Medications unchanged for at least the first month, but changed if necessary to tablet or sprinkle (nonliquid) preparations
- Low-carbohydrate, store-bought products (e.g., shakes, candy bars, baking mixes) discouraged for at least the first month
- Children evaluated in clinic 1, 3, and 6 months on the diet
- Complete blood count, complete metabolic profile (SMA-20), fasting lipid profile at baseline, 3, and 6 months; urine calcium and urine creatinine obtained at 3 and 6 months

Reproduced from Kossoff EH, McGrogan JR, Bluml RM, Pillas DJ, Rubenstein JE, and Vining EP (2006) A modified Atkins diet is effective for the treatment of intractable pediatric epilepsy. *Epilepsia* 47: 421–424, with permission from Blackwell Publishing.

glucose is typically compared with the change noted following glucose absorption itself; the higher the value, the faster the carbohydrate is released into the bloodstream as glucose. In general, foods with a low-glycemic index induce a slower insulin response compared to glucose.

There are few studies describing the use of a low-glycemic index diet in epileptic patients, but the preliminary results noted by Pfeifer and colleagues are very encouraging. Four of 11 medically intractable patients (36%) became seizure-free, while another 4 experienced a >50% reduction in seizure frequency. The low-glycemic index diet caused some elevations in the β-hydroxybutyrate levels of patients, but to a degree much less than that seen with the classic KD. Overall, the diet was well tolerated, and common side-effects included somnolence and gastrointestinal discomfort. Clearly, additional studies are necessary to demonstrate the effectiveness and safety of this promising dietary therapy for epilepsy.

Mechanism(s) of Action

The mechanisms underlying the clinical effects of the KD are not readily understood, but likely involve multiple parallel (and possibly) synergistic mechanisms resulting in an anticonvulsant effect (see **Figure 1**). β-Hydroxybutyrate is the major ketone body formed by the liver during ketogenesis and is followed clinically to assess the degree of fatty acid oxidation. While clinical efficacy of the KD does not always correlate well with serum levels of ketone bodies, in animal models of acute seizures, acetoacetate and acetone have been shown to be directly anticonvulsant when administered intraperitoneally. Interestingly, β-hydroxybutyrate – which is rapidly interconverted to acetoacetate by a dehydrogenase enzyme – is ineffective in these models. Despite these tantalizing observations, in vitro experiments have failed to confirm that any ketone body can reduce neuronal hyperexcitability and/or hypersynchrony of discharge. These negative findings would suggest that the effects of the KD may not be a direct anticonvulsant effect of ketone bodies, but rather a reflection of a larger systemic adaptation – marked by ketosis – as patients shift their metabolism to reduced glycolytic flux and increased fatty acid oxidation.

Notwithstanding these negative results, ketone bodies have recently been reported to modulate the activity of cellular membrane-bound ATP-sensitive potassium (K_{ATP}) channels. K_{ATP} channels are inwardly rectifying ligand-gated receptors that link metabolic alterations to cellular membrane excitability; specifically, K_{ATP} channels are opened when intracellular ATP levels fall. It was reported that ketone bodies, in a use-dependent manner, reduced the spontaneous firing of GABAergic neurons in rat substantia nigra – a putative subcortical 'seizure gate' – by opening K_{ATP} channels. Intriguing as this finding appears, one must reconcile an inherent discrepancy when implicating K_{ATP} channels as mediators of an anticonvulsant action. It is well known that the KD can increase levels of ATP and other bioenergetic substrates through enhanced mitochondrial respiration. Since high ATP levels block K_{ATP} channel activity, it is unclear how opening of these channels be achieved by infusion of ketone bodies in the SNr.

Glucose restriction alone, however, may play an important role in an anticonvulsant action of the KD. Calorie restriction in rodents has been shown to reduce seizure susceptibility, and a lowered level of blood glucose is correlated with retardation of epileptogenesis in a genetic model of epilepsy (i.e., the El mouse). These data suggested that less readily available glucose may limit the brain's ability to generate and promote seizure activity. In further support of the glucose restriction theory, it was recently reported that fructose-1,6-bisphosphate – a biochemical intermediate that shifts cellular metabolism of glucose from glycolysis to the pentose phosphate shunt – exerted broad-spectrum anticonvulsant activity in several animal seizure models. Investigators have also demonstrated that 2-deoxyglucose – an inhibitor of phosphoglucose isomerase – potently inhibits seizure progression in the rat kindling model of temporal lobe epilepsy, and decreases the expression of brain-derived neurotrophic factor (BDNF) and its principal receptor, TrkB. These effects were linked to the induction of the transcription factor NRSF (neuron restrictive silencing factor), an important negative regulator of neuronal genes. This study indicates that pharmacological inhibition of glycolysis alone can lead to downstream physicochemical modulation of gene transcription that critically interferes with epileptogenesis (at least in the kindling model).

Polyunsaturated fatty acids (PUFAs) have also been studied intensely with respect to KD action. PUFAs are known to block voltage-gated sodium and L-type calcium channels, and hence, represent potentially important mediators of an anticonvulsant effect. Intriguingly, the KD-induced elevations in both arachidonic acid (AA, C20: 4ω-3) and docosahexaenoic acid (DHA, C22: 6ω-3) in serum and brain of patients and animals, respectively, suggesting that these substrates might exert anticonvulsant effects by inhibiting sodium and calcium channels, much like many anticonvulsant drugs. Interestingly, the rise in serum AA and DHA during KD treatment closely paralleled observed seizure control in clinical studies, but this relationship has not been consistently observed. Does dietary supplementation with PUFAs actually result in an anticonvulsant action? Unfortunately, at this time, both human and animal data addressing this question are conflicting.

Nonetheless, PUFAs may exert a neuroprotective action through upregulation of mitochondrial uncoupling protein activity and expression, which decreases the production of reactive oxygen species (ROS). Excessive ROS

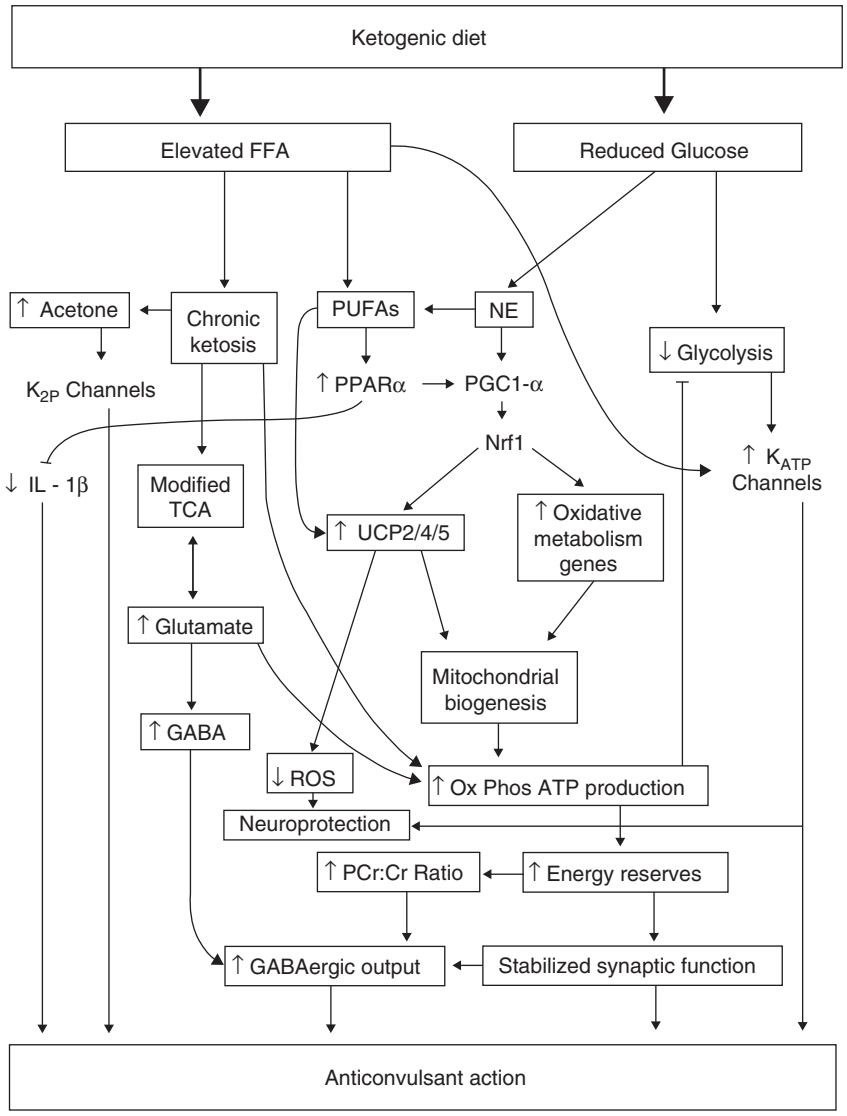

Figure 1 Hypothetical pathways leading to the anticonvulsant effects of the ketogenic diet (KD). Elevated free fatty acids (FFA) lead to chronic ketosis and increased concentrations of polyunsaturated fatty acids (PUFAs) in the brain. Chronic ketosis is predicted to lead to increased levels of acetone; this might activate K2P channels to hyperpolarize neurons and limit neuronal excitability. Chronic ketosis is also anticipated to modify the tricarboxcylic acid (TCA) cycle. This would increase glutamate and, subsequently, GABA synthesis in brain. Among several direct inhibitory actions, PUFAs boost the activity of brain-specific uncoupling proteins (UCPs). This is expected to limit ROS generation, neuronal dysfunction, and resultant neurodegeneration. Acting via the nuclear transcription factor peroxisome proliferator-activated receptor-α (PPARα), PUFAs would induce the expression of UCPs and coordinately upregulate several dozen genes related to oxidative energy metabolism. PPARα expression is inversely correlated with IL-1β cytokine expression; given the role of IL-1β in hyperexcitability and seizure generation, diminished expression of IL-β cytokines during KD treatment could lead to improved seizure control. Ultimately, PUFAs would stimulate mitochondrial biogenesis. Mitochondrial biogenesis is predicted to increase ATP production capacity and enhance energy reserves, leading to stabilized synaptic function and improved seizure control. In particular, an elevated phosphocreatine:creatine (PCr:Cr) energy-reserve ratio is predicted to enhance GABAergic output, perhaps in conjunction with the ketosis-induced elevated GABA production, leading to diminished hyperexcitability. Reduced glucose coupled with elevated free fatty acids are proposed to reduce glycolytic flux during KD, which would further be feedback inhibited by high concentrations of citrate and ATP produced during KD treatment. This would activate metabolic K_{ATP} channels. Opening of K_{ATP} channels would hyperpolarize neurons and diminish neuronal excitability to contribute to the anticonvulsant (and perhaps neuroprotective) action of the KD. Reduced glucose is also expected to downregulate brain-derived neurotrophic factor (BDNF) and trkB signaling in brain. As activation of TrkB pathways by BDNF have been shown to promote hyperexcitability and kindling, these potential KD-induced effects would be expected to limit the symptom (seizures) as well as the progression of epilepsy. Boxed variables depict findings taken from KD studies; up (↑) or down (↓) arrows indicate the direction of the relationship between variables as a result of KD treatment. Reproduced from Bough KJ and Rho JM (2007) Anticonvulsant mechanisms of the ketogenic diet. *Epilepsia* 48: 43–58, with permission from Blackwell Publishing.

levels have been implicated in a variety of neurodegenerative conditions, including Alzheimer's and Parkinson's diseases, and amyotrophic lateral sclerosis. A high-fat KD has also been reported to increase mitochondrial biogenesis and thus enhance overall availability of bioenergetic substrates (such as adenosine triphosphate or ATP), which may help stabilize cellular membrane function in the face of the metabolic stress that accompanies seizure activity. Specifically, elevations in ATP may help the functioning of the Na^+–K^+-ATPase, which would stabilize the neuronal cell membrane, hence limiting neuronal hyperexcitability and increasing the seizure threshold.

Altered neurotransmitter function may play another critical role in the anticonvulsant effects of the KD. Norepinephrine (NE) levels are increased in brains of rats fed a KD, while mice lacking the ability to produce NE (i.e., dopamine-β-hydroxylate knockout mice) lose the protective benefits of the KD in the setting of seizures acutely provoked by fluorothyl, a volatile convulsant. Perhaps most relevant to seizure control, γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the mammalian central nervous system, may also play an important role in the underlying mechanisms of the KD. Animal models of epilepsy induced by GABA antagonists have the strongest response to the KD, and the diet seems to increase GABA levels, either through increased substrate availability for GABA synthesis or through enhancing the expression of the biosynthetic enzyme, glutamic acid decarboxylase. Further supporting the GABA hypothesis of KD action, clinical studies have demonstrated increased GABA levels in the cerebrospinal fluid level of patients, as well as with magnetic resonance spectroscopy. In vivo electrophysiologic studies in rodents have revealed increased seizure threshold and decreased network hyperexcitability following treatment with a KD. Although clinical data clearly demonstrate that the KD works, the underlying anticonvulsant (and possibly antiepileptogenic) mechanisms remain elusive.

Future of the KD

The KD clearly can be effective in the treatment of intractable epilepsy patients. Accurate identification of suitable epilepsy candidates and refinement in the implementation of the diet continue to be major foci of research. The true nature of the antiepileptic effects of the diet remains unclear and it is hoped that further research may unlock alternative treatments to prevent or control epilepsy. Given the present evidence that the KD may be neuroprotective, there is growing interest into expanded uses of the diet outside of epilepsy. For example, the KD has been used to treat brain cancer, where this intervention may make certain cancers more susceptible to the effects of chemotherapy. Additionally, the wide-ranging effects of the diet may provide a useful treatment for other diseases (such as Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, and perhaps migraine) that affect the brain. Further clinical studies in these areas may unlock further insights into a multiplicity of neurological disease processes and treatments, not just within the realm of epilepsy.

Introduction

Synaptic Activity and Seizures

Glutamate, the most abundant excitatory neurotransmitter in the mammalian central nervous system (CNS), plays a central role in learning and memory formation. Fast excitatory glutamate neurotransmission is mediated by the ionotropic receptors AMPA/kainate and *N*-methyl-D-aspartate (NMDA), while the slow glutamate responses are mediated through its interaction with metabotropic receptors (mGluRs) coupled to G proteins. During seizures, release of glutamate may lead to excitotoxic neuronal damage because of an overflow of calcium in postsynaptic neurons, mediated primarily by NMDA-gated channels. In epileptogenesis, as the brain becomes prone to chronic, spontaneous seizures associated with circuitry rearrangements and individual synapse abnormalities, enhanced glutamate-mediated neurotransmission, and decreased GABA-modulated synaptic inhibition takes place. Postsynaptic events regulated by synaptic activation include enhanced phospholipase A_2 induction, which results in the cleavage of acyl chains of membrane phospholipids. Both arachidonoyl and docosahexaenoyl chains are esterified at the C_2 of the glycerol backbone of membrane phospholipids, and phospholipase A_2 cleaves that bond, releasing free arachidonic acid (AA) and free docosahexaenoic acid (DHA). The subsequent activation of other enzymes, in turn, leads to the synthesis of eicosanoids, docosanoids, and platelet-activating factor (PAF) (**Figure 1**). The bioactivity of these lipid mediators during seizures and in epileptogenesis are not well understood, as are the biochemistry, cellular, and subcellular localization of specific enzymes involved in their biosynthesis, degradation, and regulation. The complexity of these events is highlighted by the fact that there are more than 20 known phospholipases A_2. Some lipid mediators have been shown to affect the activities of ion channels, receptors, and enzymes; when released into the extracellular space, they contribute to the modulation of presynaptic neurotransmitter release/re-uptake, and/or affect other neighboring neuronal/glial cells. The significance of bioactive lipids in the intricate mesh of signaling pathways converging to the nucleus that connects upstream to downstream synaptic events is the focus of many research efforts. This article describes seizure-induced glutamate release in the activation of the hydrolysis of membrane arachidonoyl- and docosahexaenoyl-phospholipids via phospholipases A_2, which initiates pathways and/or cascades of bioactive lipids that impinge upon neurotransmission and seizure-induced brain damage.

Epileptogenesis

Mechanisms underlying kindling epileptogenesis are incompletely understood, but it is generally assumed that

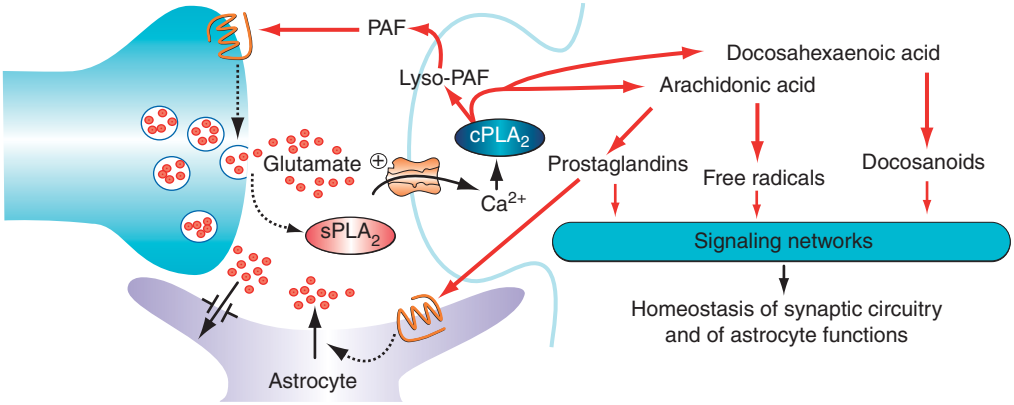

Figure 1 Bioactive lipids formed from membrane phospholipids at the synapse. In addition to pre- and postsynaptic membranes, membranes from astrocytes that surround synapses are sources of bioactive lipids. Seizures trigger glutamate release and, in turn, this activates glutamate receptors. Glutamate binds to the *N*-methyl-D-aspartate receptor and as a consequence an influx of calcium in the postsynaptic neuron occurs. Calcium-mediated activation of a PLA_2 cleaves arachidonoyl- or docosahexaenoyl-acyl chains of membrane phospholipid, releasing arachidonic acid (AA), docosahexaenoic acid (DHA), and lyso-PAF, the PAF precursor. The precise enzymes (PLA_2s, phospholipase C (PLC) followed by diacyglycerol lipase, etc.) as well as the precise localization are not well understood. Lyso-PAF is acetylated at C_2 and, in turn, forms PAF. Although PAF has a short biologic half-life, on repeated stimulus, sufficient PAF accumulates to diffuse back across the synaptic cleft. Evidence for this was provided by injecting PAF into the postsynaptic neuron and monitoring neurotransmitter release. PAF binds to its presynaptic receptor and enhances glutamate exocytosis. During synaptic plasticity events, PAF may also activate gene expression that in turn is probably involved in long-term alterations of synaptic function (not shown in this diagram). Cell surface PAF-receptor antagonists confer neuroprotection during ischemia reperfusion and inhibit PAF-induced glutamate release from hippocampal neurons and CA1 LTP formation, presumably through the same mechanism. The inhibitory effects of this antagonist on glutamate release could account in part for its neuroprotection in ischemia reperfusion. Secretory PLA_2 ($sPLA_2$) may be released from the presynaptic terminal: $sPLA_2$ binding sites are present in neurons, and $sPLA_2$ promotes active AA remodeling in neurons in culture and may also promote DHA release. DHA may also be released by $cPLA_2$. In fact, seizures increase the pool size of both arachidonic and docosahexaenoic acid. Free DHA may subsequently follow enzyme-mediated oxygenation pathways and lead to the synthesis of docosanoids (novel mediators). Free radicals would accumulate during seizures and oxidative stress. Downstream lipid signaling modulates neuronal function and survival. Synapses are intimately surrounded by astrocytes, which express glutamate transporters that remove the excitatory neurotransmitter from the vicinity of the synaptic cleft. Astrocytes also respond to prostaglandins by releasing glutamate through a Ca^{2+}-dependent mechanism. For the sake of simplicity, endocannabinoids, the CB1 receptor, and other bioactive lipids are not included. Modified from Bazan NG (2003) Synaptic lipid signaling: significance of polyunsaturated fatty acids and platelet-activating factor. *Journal of Lipid Research* 44: 2221–2233, with permission from ASBMB.

an imbalance between GABA inhibitory input and glutamate is involved. Glutamate release is thought to contribute to the reorganization of neuronal connections favoring a permanent hyperexcitable state, often associated with mossy fiber sprouting. Synthesis of new proteins is thought to form the basis for sustained seizure-induced physiological and/or pathological changes in synaptic reorganization and apoptotic/necrotic neuronal death. We postulate that seizure-induced synthesis of docosanoids, derived from docosahexaenoyl chains of phospholipids, downregulates these changes in synaptic restructuring and neuronal death.

Background

Hippocampal Kindling Epileptogenesis

Hippocampal kindling, a model of mesial temporal lobe epilepsy, is developed through repetitive stimulation of the hippocampus and leads to increased after-discharges (as measured by an electroencephalogram (EEG)) and an enduring seizure-prone state. Stimulus-induced phosphorylation of JNK, but not of p38, is enhanced in the CA1 subregion of the hippocampus of kindled animals compared to their naïve counterparts. Immunofluorescent staining confirmed this region-specific pattern of JNK activation, and revealed that reactive astrocytes mediate this effect. Astrocyte proliferation and hypertrophy, as well as upregulation of vimentin protein levels (common markers of astrogliosis), were present after four days of kindling. The consequence of these phosphorylation events suggest a selective response to aberrant synaptic activity – signaling that may modulate kindling progression and/or neuronal damage and death. Seizure-induced plasticity by electrical kindling has several limitations when compared with epilepsy. Perhaps most importantly, in most kindling models, recurrent spontaneous seizures rarely occur.

Synergy by Secretory Phospholipase A_2 ($sPLA_2$) and Glutamate on Inducing Neuronal Cell Death and Sustained AA Metabolic Changes

Secretory phospholipase A_2 ($sPLA_2$) and glutamate induce sustained changes in neuronal arachidonoyl–phospholipid

metabolism, and $sPLA_2$ plus glutamate exert synergistic mobilization of AA and subsequent neurotoxicity. Since $sPLA_2$ type II is present in synaptic vesicles, it is possible that glutamatergic neurotransmission involves the co-release of glutamate and $sPLA_2$. Thus, excitotoxicity may involve not only glutamate, as currently assumed, but may also involve $sPLA_2$ at the synaptic cleft. In this connection, it is relevant that the synthesis of PAF, a retrograde messenger of long-term potentiation (LTP), may be enhanced by $sPLA_2$ at the synapse. 'Cross-talk' between cytosolic PLA_2 ($cPLA_2$) and $sPLA_2$ has recently been suggested in signal transduction events in macrophages, and a complex interplay between glutamate-activated $cPLA_2$ and $sPLA_2$ could be envisioned at the synapse (**Figure 1**). These events remain to be defined in epileptogenesis.

Cyclooxygenase and Models of Epileptogenesis

Cyclooxygenase (COX, or prostaglandin H synthase (PGHS)), catalyzes PGH_2 synthesis from AA, the precursor of prostaglandins. COX comprises two isoforms, COX-1 (constitutive) and COX-2 (inducible). COX-2 participates in the inflammatory response, neuronal death, and neuronal hyperexcitability. Seizures activate cytosolic phospholipase A_2 ($cPLA_2$), induce expression of $cPLA_2$ and COX-2, and promote AA accumulation and PG synthesis. Free arachidonic and docosahexaenoic acids accumulate in synaptic endings isolated during seizures (**Figures 2** and **3**).

Recurrent and spontaneous seizures in epilepsy result from poorly defined cell signaling aberrations thought to include synaptic and extracellular matrix remodeling. Using a rat hippocampal kindling model, COX-2 gene expression in epileptogenesis was studied. COX-2, encoded in an early-response gene, has been shown to increase in a synaptic activity-dependent fashion and also during kainic acid-induced hippocampal damage. We found that during kindling, COX-2 induction occurred initially only in hippocampal neurons, and then spread to neocortical neurons. When rats were rekindled 34 days later, this spreading of COX-2 expression persisted. Induction of hippocampal and neocortical $cPLA_2$, an enzyme that catalyzes the release of COX-2 substrate AA, occurred after 4 days of stimulation during kindling and rekindling (**Figure 4**). Moreover the COX-2 selective inhibitor nimesulide attenuated kindling development indicating that COX-2 activity is involved in kindling epileptogenesis. Failure of nimesulide to fully inhibit kindling development may be due to an incomplete access of this drug to the COX-2 protein to achieve full inhibition or/and to redundancy of signaling pathways. COX-1, which is not inhibited by nimesulide, may synthesize an increased amount of prostaglandins due to accumulation of AA as a result of COX-2 inhibition, thereby minimizing the effect of nimesulide. The mechanism through which COX-2 inhibition slows kindling progress is not clear. However, it is likely that COX-2 inhibition may reduce synthesis of PGs and/or PAF. Both products may involve synaptic facilitation. Thus, the spreading of kindling-induced COX-2 induction from hippocampal neurons to neocortical neurons and attenuation of kindling by COX-2 inhibition suggests that kindling permanently

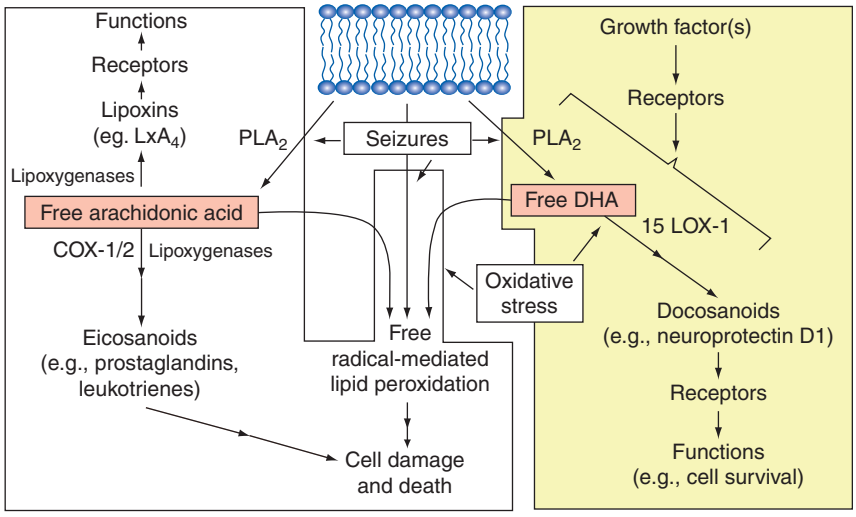

Figure 2 Fate of polyunsaturated acyl chains of membrane phospholipids. PLA_2 = phospholipase A_2. The central arrows indicate that free radical-mediated lipid peroxidation may attack esterifed arachidonoyl or docosahexaenoyl chains, as well as free arachidonic or docosahexaenoic acids (left and right arrows). The evolving lipid peroxidation products are highly reactive and promote further cell injury. On the left of the diagram, phospholipase A_2 is depicted releasing free AA and leading to the eicosanoid cascade that modulates cell functions through specific receptors. On the right side of the diagram, it is suggested that growth factor-mediated activation of the synthesis of docosanoids leads to biologically active mediators such as neuroprotectin D1, which in turn operate through receptors. Oxidative stress by itself activates both docosanoid synthesis (to counteract cytotoxic actions) and free radical-mediated lipid peroxidation.

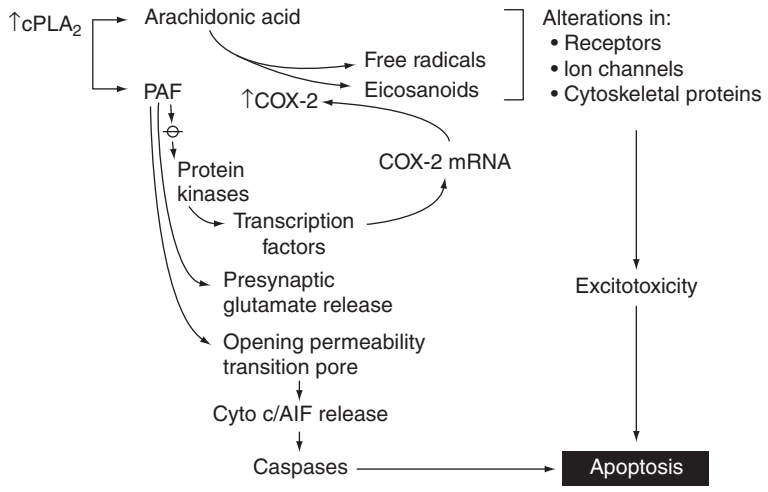

Figure 3 Involvement of phospholipid-derived second messengers in neuroexcitotoxic damage. Modified from Bazan NG, Tu B, and Rodriguez de Turco EB (2002) What synaptic lipid signaling tells us about seizure-induced damage and epileptogenesis. *Progress in Brain Research* 135: 175–185, with permission from Elsevier.

facilitates hippocampus–neocortex functional connectivity and that COX-2 is involved in epileptogenesis. We conclude that neuronal COX-2 gene induction and $cPLA_2$ activation are key signaling events in seizure-induced plasticity by kindling.

Platelet-Activating Factor

PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is another lipid mediator derived from membrane phospholipids (**Figures 1, 3,** and **5**), and is known to exert potent proinflammatory and neuromodulatory bioactivity in the CNS. Under physiological conditions, PAF participates in LTP associated with learning and memory through stimulation of its G-protein coupled receptor (PAFR). When concentrations are elevated under pathological conditions, PAF becomes neurotoxic – and is a key mediator of neuronal death following ischemia, encephalitis, epileptic seizures, meningitis, and HIV-1 dementia.

Docosahexaenoic Acid in Synaptic and Other Neural Membranes

Docosahexaenoic acid (DHA, 22:6,n-3) belongs to the essential omega-3 fatty acid family and is concentrated as an acyl group of phospholipids at synapses and in other cellular membranes of the nervous system. During postnatal development, DHA accumulates in the brain in parallel with synaptogenesis and dendrite formation (and photoreceptor biogenesis). A salient feature of DHA in the CNS is that it displays a very unusual retention ability. Only prolonged dietary deprivation of omega-3 fatty acids is effective in reducing DHA content, and only then do learning impairments or deficiencies in visual acuity occur. These functional impairments are selectively ameliorated by feeding omega-3 fatty acids. The cellular and molecular mechanisms involved in the high retention property of DHA in the nervous system are not well understood. After ingestion of food containing linolenic acid (18:3,n-3, the DHA precursor), the liver elongates and desaturates this fatty acid and, by stimuli that are not understood, releases DHA-containing phospholipids with lipoproteins into the blood stream (and to the CNS). Overall, DHA is involved in brain and retinal development, aging, memory formation, synaptic membrane function, photoreceptor biogenesis and function, and neuroprotection. Epidemiologic studies suggest that diets rich in DHA slow down cognitive impairments and progression of Alzheimer's disease. A major question to date has been: What are the molecular signaling mechanisms through which DHA confers neuroprotection? There are some suggestions that phosphatidylserine containing DHA acyl chains may be involved in the DHA bioactivity.

The free (unesterified) DHA pool size increases in the brain, and is higher in synaptosomes, of animals undergoing seizures. In bicuculline-induced status epilepticus, both free DHA and AA increase (as seen in rapidly-isolated synaptosomes), suggesting the activation of phospholipases A_2 that hydrolyze membrane phospholipids containing these polyunsaturated fatty acids. Since these membrane fatty acids are targets for free radical-mediated lipid peroxidation, and since this degradation process is engaged in cell injury, it has been suggested that these events are linked to brain damage – e.g., in brain ischemia-reperfusion and status epilepticus. Moreover, the deletion of phospholipase $A_2\alpha$, an enzyme that mediates the release of free DHA and AA, results in increased resistance to middle-cerebral artery occlusion-induced brain damage. Clearly, sustained brain injury or status epilepticus fosters an enhancement of both release of DHA, AA and lipid

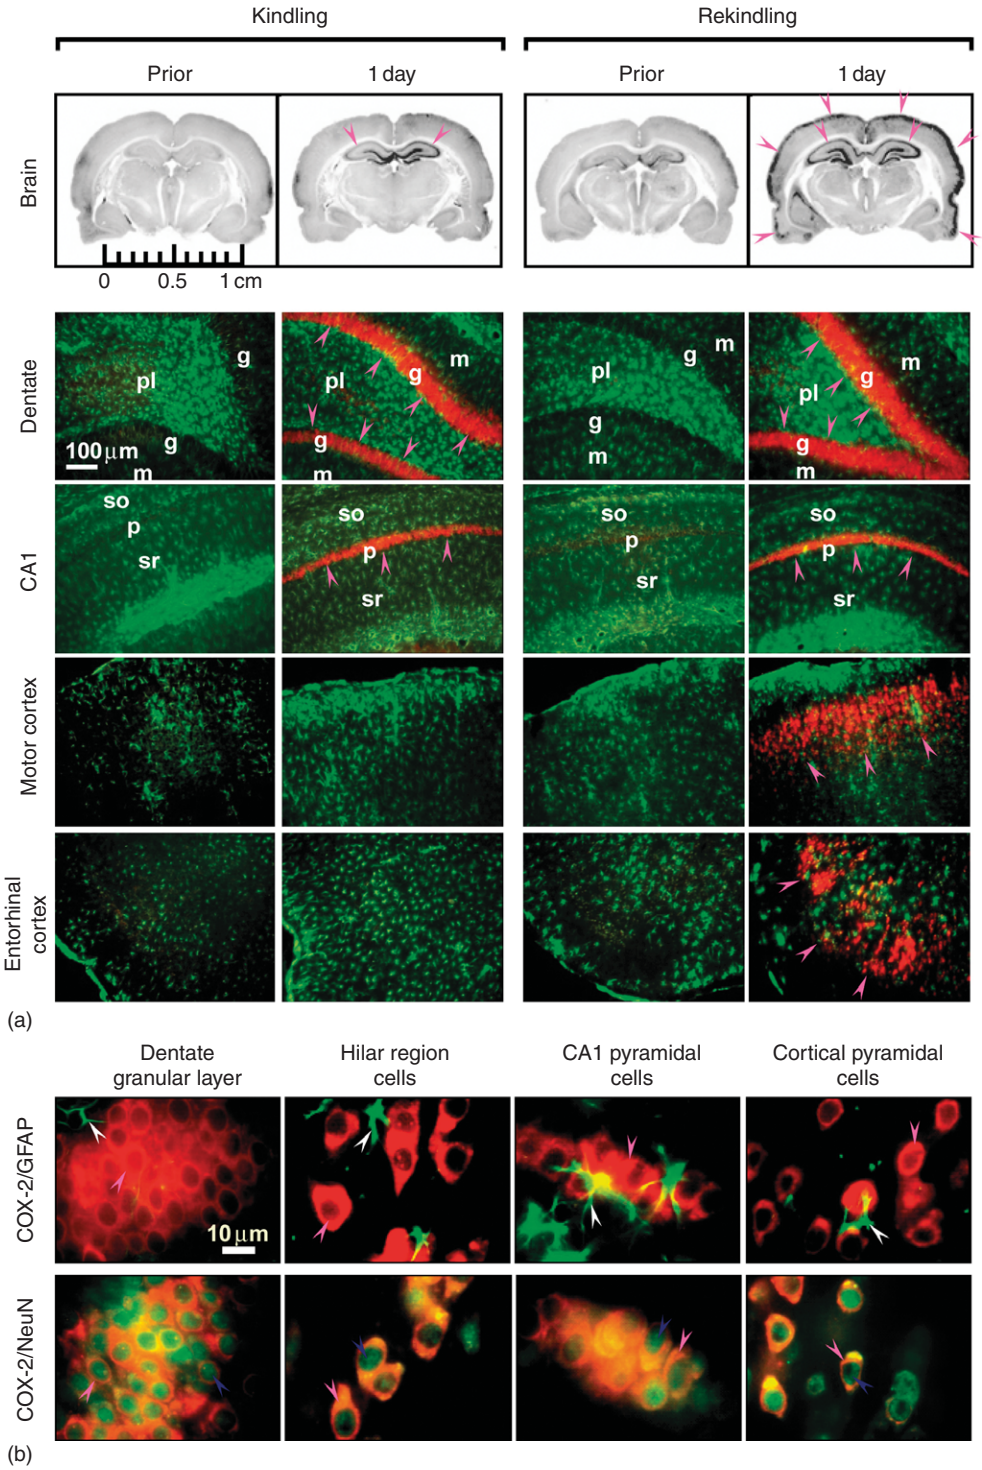

Figure 4 COX-2 induction in kindling is neuronal. (a) COX-2 immunoreactivity labeled with DAB shows low expression in controls and 1 month after kindling. After 1 day of kindling, COX-2 was induced (pink arrowheads) only in the hippocampus, while after 1 day of rekindling (34 days after kindling) the induction appears in the neocortex. Low-magnification (×100) images of COX-2 (red) and GFAP (green) double labeling showed that COX-2 immunoreactivity increased in the dentate granule cell layer and CA1 pyramidal cell layer after 1 day of kindling; however, the increase spread to the neocortex after 1 day of rekindling. g, granule cell layer; m, molecular layer; pl, polymorphic layer; p, pyramidal cell layer; sr, stratum radiatus; so, stratum oriens. (b) Higher-magnification (×1000) images of COX-2 (red)/GFAP (green) or COX-2 (red)/NeuN (green) labeling after 1 day of rekindling. The increase of COX-2 immunoreactivity is located only in cytoplasm (pink arrowheads) of neurons (blue arrowheads), and not in astroglial cells (white arrowheads). Modified from Tu B and Bazan NG (2003) Hippocampal kindling epileptogenesis upregulates neuronal cyclooxygenase-2 expression in neocortex. *Experimental Neurology* 179: 167–175, with permission from Elsevier.

peroxidation. The discovery of neuroprotectin D1 (NPD1), the finding that this lipid mediator is generated in early stages of brain ischemia-reperfusion, and the discovery of its ability to potentially inhibit ischemic brain damage, offer an alternative interpretation – that the cleavage of DHA and the subsequent synthesis of NPD1 during injury constitute a neuroprotective response (**Figure 2**). Recently, we found that NPD1 also increases in the hippocampus during seizures. In the initial phases of injury, it may be that synthesis of NPD1 is a mechanism aimed at maintaining neural cellular integrity and homeostasis.

Methods

LC–MS–MS-Based Mediator Lipidomics

Quantitative analysis of docosanoids by liquid chromatography coupled with tandem mass spectrometry (LC–MS–MS) was performed in hippocampi from mice (C57/BL-6, 20–25 g body weight) killed by head-focused microwave radiation at different time points after the onset of reperfusion. The hippocampi were rapidly dissected (20–70 mg wet tissue weight), homogenized in cold methanol, and kept under nitrogen at −80 °C until purification. Purification was performed by solid-phase extraction technique. In short, samples pre-equilibrated at pH 3.0 were loaded onto C18 columns (Varian) and eluted with 10 ml of 1% methanol in ethyl acetate (EM Science). Samples were concentrated by a nitrogen stream evaporator before LC–MS–MS analysis. Samples were loaded into a Surveyor MS pump (Thermo-Finnegan) equipped with a C18 discovery column (Supelco), 10 cm × 2.1 mm inner diameter, 5 μm internal phase. Samples were eluted in a linear gradient (100% solution A (60:40:0.01 methanol/water/acetic acid) to 100% solution B (99.99:0.01 methanol/acetic acid)) and run at a flow rate of 300 μl min^{-1} for 45 min. LC effluents were diverted to an electrospray ionization probe (ESI) on a TSQ Quantum (Thermo-Finnegan) triple quadrupole mass spectrometer running on negative ion detection mode. Docosanoid standards were used for calibration and optimization. The instrument was run on full-scan mode to detect parent ions and selected reaction monitoring for quantitative analysis to detect daughter ions simultaneously. The selected parent ions were 327 for DHA and 359 for NPD1; daughter ions were 325.1 and 297, respectively.

Kindling

Adult male Wistar rats (250–350 g, 2–3 months old) were anesthetized with 1 ml kg^{-1} anesthetic mixture (ketamine 100 mg ml^{-1} and xylazine 10 mg ml^{-1}) through intraperitoneal injection. Tripolar electrode units (Plastic One, Inc., Roanoke, VA) were used; a pair of twisted polyimide-insulated electrodes (diameter 0.2 mm, tip separation ~0.06–0.08 mm) was implanted stereotaxically in the right ventral hippocampus (from bregma: AP −3.5, ML 5.2, DV −6.5 from dura), and a ground electrode attached to a stainless-steel screw in the left frontal bone. Three more screws were cemented together with the electrode unit using dental acrylic to secure the electrode. To record secondary afterdischarge, a hexa-polar electrode unit (Plastic One, Inc.) was used. Three of the electrode tips were implanted as with the tripolar electrode units, and the remaining electrodes were implanted in the left ventral hippocampus (AP −3.5, ML −5.2, DV −6.5 from dura) and both sides of the motor cortex (AP −1.0, ML ±5.2, DV −1.5 from dura). Two weeks after surgery, kindling was achieved by stimulating rats 12 times daily for 4 days with a subconvulsive electrical stimulation (a 10-s train containing 50-Hz biphasic pulses of 1-ms width and 400-μA amplitude) at 30-min intervals. Thirty-four days later, rats were rekindled for 1 day. Seizure behaviors evoked by stimulation were graded according to Racine's Scale: stage 1, standing still, wet-dog shaking, mouth and facial movements; stage 2, head nodding or jerking; stage 3, forelimb clonus; stage 4, rearing; stage 5, falling. Behavioral seizures greater than stage 1 were considered to be convulsive. EEG was recorded through electrodes, amplified 1000 times, filtered 0.5–40 Hz (3 dB per octave), digitized at a sampling rate of 200 Hz, and analyzed using Enhanced Graphics Acquisition for Analysis software (Version 3.63.00, R. C. Electronics Inc., Santa Barbara, CA). To test afterdischarge threshold, animals were stimulated at 1-h intervals using the same parameters as in kindling stimulation except that the intensity (μA) was gradually raised as follows: 10, 20, 30, 40, 50, 60, 80, 100, 120, 160, 200, 300, 400.

Immunohistochemistry

Rats were deeply anesthetized and perfused transcardially with 200 ml 10 mM PBS (PH 7.4) and then with 200 ml fixative (4% paraformaldehyde, 15% saturated picric acid, and 10 mM PBS). The brains were removed and postfixed in fixative for 1 day. Coronal blocks (3-mm thick) were cryoprotected overnight in 30% sucrose and sectioned into 40-μm-thick slices on a cryostat. Floating slices were treated with blocking buffer (2% BSA, 2% normal goat serum, and 0.2% Triton X-100 in PBS) and incubated overnight with COX-2 antibody (1:1000, Caymen Chemicals, Inc., Ann Arbor, MI). COX-2 was labeled with avidinbiotin complexes (ABC) and visualized with diaminobenzidine tetrahydrochloride (DAB) using a rabbit ABC kit and a DAB substrate kit (Vector Laboratories, Burlingame, CA) or was labeled with Texas red conjugated anti-rabbit antibody (1:100, Caymen Chemicals, Inc.) in double immunostaining. Besides COX-2 antibody, double immunostaining used primary antibodies directed to either glial fibrillary acidic protein (GFAP, 1:200, Chemicon) or neuron-specific nuclear protein (NeuN, 1:100, Chemicon) and an antimouse

fluorescein isothiocyanate (FITC)-conjugated secondary antibody (1:100, Vector Laboratories) to label astroglial cells or neurons. Double labeling was achieved by incubating the sections with a mixture of both primary antibodies followed by incubation with a mixture containing both fluorescent secondary antibodies. COX-2 immunostaining was confirmed by blocking COX-2 labeling with a COX-2 peptide (5 μg ml^{-1}, Caymen Chemicals, Inc.). All animal-use procedures were in accordance with the *National Institutes of Health Guide for the Care and Use of Laboratory Animals* and were approved by the Louisiana State University Medical Center Institutional Animal Care and Use Committee (IACUC).

Results

DHA Effects on Excitability

Several researchers have attempted to use electrophysiological methods to characterize the actions of DHA bioactivity at the synapse. DHA added to hippocampal slices may elicit anti-epileptogenic activity. It has been proposed that DHA modulates ion channels and neurotransmitter receptors, and in turn regulates synaptic plasticity. The slice recordings have yielded conflicting observations on the effects of DHA in hippocampal slices. DHA seems to facilitate NMDA responses and block delayed-rectifier K^+ channels. As a consequence, DHA would enhance neuronal excitability and worsen seizure activity. In contrast, DHA added to neonatal rat ventricular myocytes may stabilize the neuronal membrane through suppression of voltage-gated Ca^{2+} currents and Na^+ channels. Moreover, DHA inhibits the induction of long-term depression (LTD), further supporting its potential role in learning and memory. DHA does not seem to exert actions on multiple spikes induced by bicuculline or in Mg^{2+}-free medium, indicating it does not directly interact with NMDA or non-NMDA glutamate receptors. Moreover, DHA may attenuate synaptic transmission and epileptiform activity in rat hippocampus by frequency-dependent Na^+ channel blockade. Most of these electrophysiologic studies have used added DHA at high concentrations (e.g., 50 μM). Therefore, it is important to note that in vivo, under resting conditions, brain unesterified DHA is present in undetectable amounts. The onset of seizure triggers the release of esterified DHA from phospholipids (e.g., as seen in bicuculline-induced status epilepticus, which promotes the accumulation of unesterified DHA in rapidly-isolated hippocampal synaptosomes) in the low nanomolar range.

DHA-Derived Stereospecific Neuroprotectin D1 Synthesis in the Nervous System

Early on during ischemia-reperfusion damage, enzyme-mediated oxygenation pathways are activated and a stereospecific neuroprotective mediator – neuroprotectin D1 (NPD1, 10*R*,17*S*-dihydroxy-docosa-4*Z*,7*Z*,11*E*,13*E*,15*Z*,19*Z*-hexaenoic acid) – is generated (in reinal cells and in the human brain). NPD1 was found to be reduced in Alzheimer's disease (AD) CA1, but not in other brain regions. These results open a new approach to define the significance of DHA at the synapse, and particularly in epileptogenesis, and offer a different explanation for the significant involvement of DHA in epilepsy.

PAF-Mediated Plasticity and Cell Injury

PAF plays a key role in transducing neuronal death in neurodegenerative conditions, yet therapeutic strategies targeting PAF signaling have not been successful. In rodents, PAFR is primarily expressed by activated microglia with neuronal expression restricted to subpopulations of cells in the hippocampus, notably the CA3 pyramidal cell field, cortex, and cerebellum. Presynaptic receptor-mediated PAF actions potentiate glutamergic transmission, and downstream of postsynaptic NMDA receptors, PAF is a messenger of glutamate actions that lead to gene expression and neuronal plasticity. Postsynaptic neuronal activity activates PAF synthesis, which in turn acts as a retrograde messenger, stimulating presynaptic glutamate release, thus contributing to LTP and memory formation; studies have shown that animals deficient in the PAF receptor displayed attenuated LTP. PAF-mediated effects through an intracellular receptor are linked with PAF-mediated effects on gene expression in the CNS (**Figures 3** and **5**). Electroconvulsive shock- and kainic acid-induced seizures activate early gene expression in the hippocampus, including expression of the inducible COX-2, and this induction is inhibited by PAF-receptor antagonists.

Glutamate triggers the activation of the MAPK signaling pathway, and PAF is the mediator of glutamate–NMDA activation of JNK, p38, and ERK MAPK. The MAPK cascade is also activated in the hippocampus during kainic acid-induced seizures and transient cerebral ischemia. Because PAF–MAPK activation may stimulate $cPLA_2$ and also may be upstream of PAF-induced COX-2 expression, both effects may converge in potentiating the AA cascade and eicosanoid synthesis. In addition, PAF can be the trigger for the COX-2–PGE_2–EPI receptor pathway at the nuclear level, leading to a late gene-transcription activation.

Cyclooxygenase Involvement in Epileptogenesis

Hippocampal kindling epileptogenesis selectively upregulates neuronal COX gene expression in the neocortex. COX-2 is an inducible proinflammatory protein that catalyzes prostaglandin synthesis. Interestingly, COX-2 is also present in a 'constitutive' mode in postsynaptic spines and has been linked to synaptic plasticity. The kindling-induced changes in COX-2 may reflect aberrant synaptic circuitry

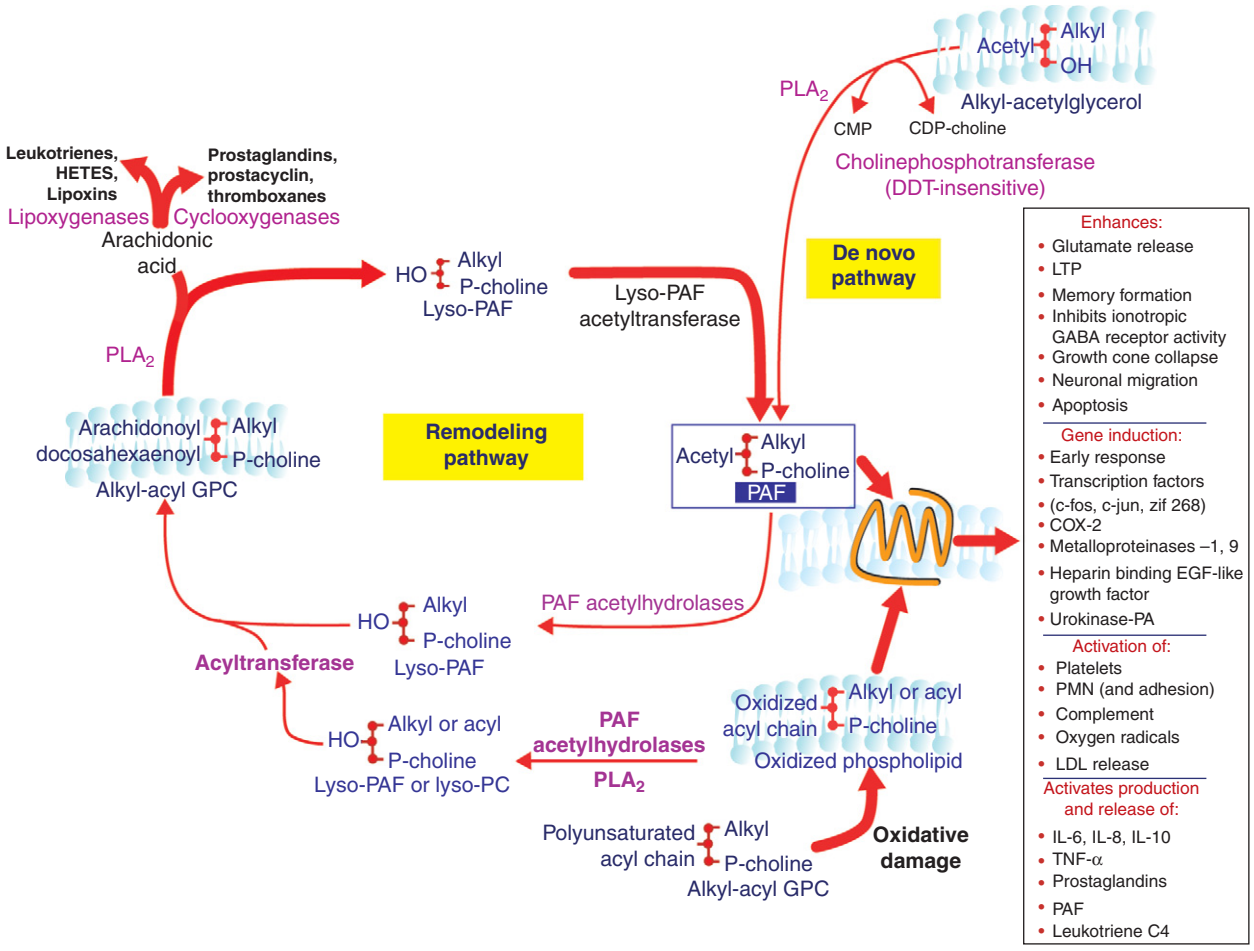

Figure 5 Seizures-stimulated PAF synthesis. In the center of this figure is the remodeling pathway or 'PAF cycle' from the membrane phospholipid PAF precursor, alkyl-acyl-glycerophosphorylcholine (GPC, on the left) to the biologically active PAF (at right). The remodeling route includes the production of lyso-PAF, which is generated from the PAF precursor alkyl-acyl-GPC either directly by the action of phospholipase A_2 or by the transfer of the *sn*-2 acyl moiety to a 'donor' lyso-plasmalogen (top), which is itself mobilized from membrane plasmalogen by phospholipase action. The de novo route of PAF synthesis (upper right) involves the direct transfer of a choline moiety to alkyl-acetylglycerol. Note that PAF acetylhydrolase (bottom) inactivates all PAF molecules, regardless of their biosynthetic route, and additionally inactivates oxidatively damaged phospholipids (shorter peroxidated acyl group at C2) that possess biological activity at the PAF receptor. Seizure activated steps are depicted with ticker red arrows. Modified from Bazan NG (2003) Synaptic lipid signaling: significance of polyunsaturated fatty acids and platelet-activating factor. *Journal of Lipid Research* 44: 2221–2233, with permission from ASBMB.

rearrangements that enhance proinflammatory signaling that, in turn, may foster neuronal excitability.

The COX-2 gene induction in neocortical neurons coincides with intensified behavioral seizures, suggesting that COX-2 induction is an indicator for neuronal seizure activity during kindling. Unlike COX-2, detectable induction of $cPLA_2$ does not occur after a single stimulation; rather, during kindling, a pattern of induction similar to that of COX-2 is found. This observation suggests that endogenous $cPLA_2$ is sufficient to deal with the free AA requirements created by newly induced COX-2 as a result of a single stimulation. Sustained COX-2 induction triggered by kindling epileptogenesis may involve additional, newly induced $cPLA_2$ to generate more free AA. Thus, it appears that only sustained epileptic activity induces $cPLA_2$. Kainic acid injected into one side of the brain causes significantly higher COX-2 induction in ipsilateral cerebral cortex than in contralateral cortex, and is associated with local kainic acid toxicity. The involvement of COX-2 induction in astrocytes by kainic acid adds to the complexity of COX-2 induction in the kainate model, introducing effects of activity in non-neuronal cell types.

Kindling induces brain COX-2 and $cPLA_2$, suggesting that released AA is converted into eicosanoids during epileptogenesis. The COX-2 inhibitor, nimesulide, attenuates kindling, supporting the hypothesis that COX-2 activity is involved in kindling epileptogenesis. Nimesulide fails to fully inhibit kindling development, perhaps because of incomplete access of this drug to the COX-2 protein to achieve full inhibition, and/or because of the 'redundancy'

of other signaling pathways with the COX-2 system. For example, COX-1, which is not inhibited by nimesulide, may synthesize an increased amount of prostaglandins (because of accumulation of AA) as a result of COX-2 inhibition, thereby minimizing the effect of nimesulide. The mechanism through which COX-2 inhibition slows kindling progress is not clear. However, it is likely that COX-2 inhibition may reduce synthesis of PGs and/or PAF (platelet-activating factor). Both lipid mediators may involve synaptic facilitation. Studies of other COX-2 inhibitors and related compounds should provide further insight into the significance of the COX-2 pathway in experimental epilepsy. In summary, COX-2 induction takes place during kindling epileptogenesis and this induction is restricted to neurons. Moreover, kindling induces $cPLA_2$, and a COX-2 inhibitor attenuates kindling development. The spread of kindling-induced COX-2 induction from hippocampal neurons to neocortical neurons, and the attenuation of kindling by COX-2 inhibition, suggest that kindling permanently facilitates hippocampus–neocortex functional connectivity and that COX-2 is involved in epileptogenesis.

Future Goals

Future studies will define the significance of omega-6- and omega-3-derived mediators in the ictal and post-ictal period. In addition, since epileptogenesis is thought to involve, in many cases, an initial injury, another goal is to define the significance of NPD1 in the initiation and progression of epileptogenesis. Some omega-6-derived mediators (e.g., prostaglandins) may represent cell-damaging signaling events, whereas others (e.g., lipoxins) are proinflammatory. Therefore, a balance between mediators derived from essential fatty acids may play a critical role in hyperexcitability and seizures. Furthermore, studies are needed for defining the significance of COX-2 at the dendritic spines, and of COX-2 induced by kindling epileptogenesis (as described here). Elucidation of the modulators of COX-2 induction will contribute to our understanding of the role of this inducible gene (and its bioactive products, prostaglandins) in synaptic circuitry function. Finally, because a balance between excitatory and inhibitory synaptic transmission is likely involved in epileptogenesis, and since GABAergic neuron dropout often is seen in models of epileptogenesis, studies should examine the possibility that NPD1 is a promoter of cell survival and plays a neuroprotective role in epilepsy.

In summary, phospholipids of excitable membranes and of other nervous system cells, including astrocytes, are richly endowed in acyl groups containing AA and DHA. Seizures, including plasticity-induced seizures, activate the cleavage of these acyl groups and their release from phospholipids. These events represent switches that open signaling pathways. The details of these signaling pathways remain to be defined, as is the determination of their significance in clinically relevant models of epilepsy.

The Emerging Role of Mitochondrial Dysfunction and Oxidative Stress in Epilepsy

M Patel and L P Liang, University of Colorado Health Sciences Center, Denver, Colorado, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

To date only a minority of epilepsy research has been focused on mitochondria. However, recent advances provide compelling evidence of mitochondrial involvement in the epilepsies. Direct mitochondrial dysfunction is associated with a small percentage of inherited epilepsies – e.g., mitochondrial encephalopathies. A role of mitochondria in acquired epilepsies, which account for ~60% of all epilepsy cases, remains to be fully explored. Temporal lobe epilepsy (TLE) is the most notable example of acquired epilepsy usually preceded by injury such as episode(s) of prolonged seizures or status epilepticus (SE), childhood febrile seizures, hypoxia, or trauma. These initial insults are thought to set in motion complex molecular, biochemical, and structural changes that culminate in the development of spontaneous recurring seizures, or 'epileptogenesis.' Since injury per se can set in motion molecular events that trigger the epileptic condition, it is important to understand the biochemical causes and consequences of epileptic seizures. Identifying these biochemical mechanisms may lead to therapies that interrupt the process of epileptogenesis.

Background

Several major features of the epileptic phenotype suggest that mitochondrial involvement may not be a mere epiphenomenon, but rather a key event contributing to the initiation and progression of TLE. Mitochondria are intimately involved in important cellular events that are leading candidate mechanisms of hyperexcitability and/or its consequences. These potential mechanisms include metabolic and bioenergetic changes associated with seizure activity, the involvement of mitochondria in the processes underlying seizure-induced cell loss (i.e., excitotoxicity and apoptosis), mitochondrial regulation of amino-acid cycling, neurotransmitter biosynthesis, and ionic homeostasis, particularly calcium buffering. Another important reason to consider mitochondrial mechanisms, particularly the involvement of oxidative stress in epilepsy, is the knowledge that the incidence of epilepsy abruptly rises with advancing age; mitochondrial oxidative stress is a leading mechanism of aging and age-related degenerative disease.

The most compelling evidence for mitochondrial (dys) function in epilepsy is the recognition that dramatic metabolic and bioenergetic changes occur following acute seizures and during different phases of chronic epilepsy (**Figure 1**). The acute consequence of seizures associated with SE is an increase in cellular glucose uptake and metabolism that is unparalleled by most conditions. Cerebral blood flow is increased to match this hypermetabolism; since the increased rate of glycolysis exceeds pyruvate utilization by pyruvate dehydrogenase, there is an increased lactate buildup. While *hyper*metabolism occurs in human epileptic foci during ictal phases (seizure episodes), *hypo*metabolism is prevalent during interictal phases (between seizure episodes). A bioenergetic defect is also evident in the measurement of ^{31}P and the loss of mitochondrial *N*-acetyl aspartate in human epileptic tissue, suggesting the involvement of mitochondria in altered neurotransmitter metabolism. Severe metabolic dysfunction characterized by biphasic abnormal NAD(P)H fluorescence transients and changes in mitochondrial membrane potential (dsm) have been observed in ex vivo preparations from both chronically epileptic rats and human subjects. The mechanisms of both hypometabolism and hypermetabolism in seizure-induced brain damage, and in subsequent development of epilepsy, need to be determined.

Introduction

Phosphorylation of synaptic receptors modulates several neurotransmission systems in the vertebrate central nervous system. It has been shown, in particular, that glutamate and γ-aminobutyric acid (GABA) ionotropic receptors can be phosphorylated on the intracellular loops of several of their subunits by known kinases. These kinases primarily phosphorylate the β or γ subunits – but not the α subunits – of the type A GABA receptor (GABA$_A$R).

A different phosphorylation mechanism was recently described for this receptor, and termed 'endogenous,' since it does not require exogenous kinase or kinase activators. The endogenous kinase must then be closely related to the receptor at the neuronal membrane. This phosphorylation mechanism prevents rundown of the GABAergic response of acutely dissociated hippocampal or cortical neurons. In the paragraphs below, we will briefly describe the characteristics of this mechanism and then show that this mechanism is deficient in the cortical zones epileptic seizures originate in patients with partial epilepsy.

Background

A New Mechanism: Glycolysis-Dependent Modulation of GABAergic Inhibition

The first step was to identify the GABA$_A$R endogenous kinase. The protein that was isolated after purification and phosphorylation tests of the receptor was not a known kinase, but rather a key glycolytic enzyme, glyceraldehyde-3-phosphate dehydrogenase (GAPDH). A kinase activity of GAPDH, independent of its role as a dehydrogenase in glycolysis, has been described in rabbit muscles, where it was shown that GAPDH autophosphorylates using glycolytic ATP and then transfers the phosphate group to other muscle proteins – thus playing the role of a kinase. We showed that GAPDH is physically associated with the receptor and is partially colocalized with GABA$_A$R α1 subunits at the plasma membrane of neurons in culture.

We also showed that local synthesis of ATP occurred in washed cerebral cortex membranes when glyceraldehyde-3P (G3P), the specific glycolytic substrate of GAPDH, was supplied. These results indicate that the enzyme that follows GAPDH in the chain of glycolytic reactions, the phosphoglycerate kinase, is also present at the neuronal membrane and that it uses the product of the reaction catalyzed by the GAPDH to produce glycolytic ATP, very likely without diffusion. The ATP is then used for GAPDH autophosphorylation, probably also without diffusion. Next, the phospho-GAPDH phosphorylates the associated GABA$_A$R on the I2 intracellular loop of its α1 subunit, at two identified serine and threonine residues. The endogenous phosphorylation of the GABA$_A$R is thus a glycolysis-dependent mechanism. These results establish a direct link between glucose metabolism and GABAergic neurotransmission (**Figure 1**).

Does GABA$_A$R endogenous phosphorylation have a functional role? We showed, on acutely dissociated pyramidal neurons from rat cortex, that any factor supporting GABA$_A$R endogenous phosphorylation retards rundown of GABA$_A$ currents in whole-cell patch-clamp recordings, and that any factor preventing GABA$_A$R endogenous phosphorylation reinforces rundown. The addition of G3P to the

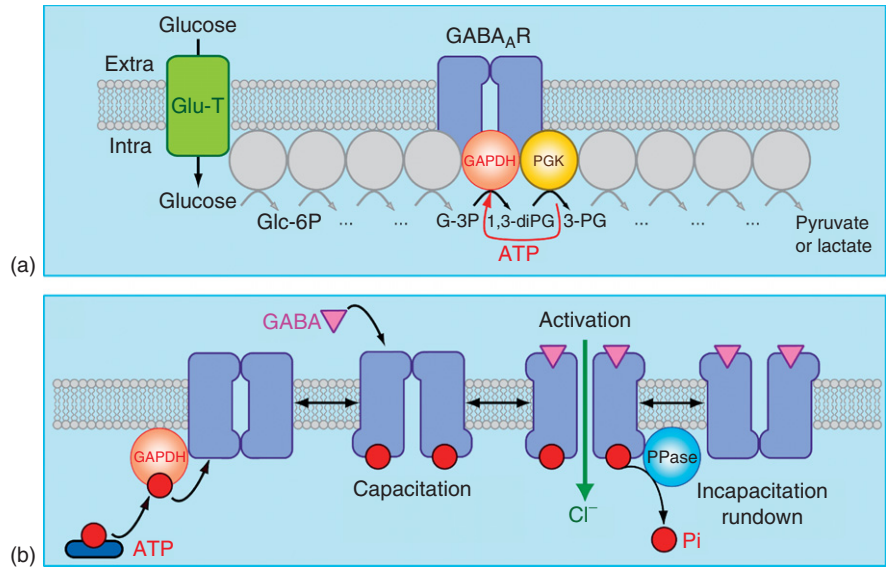

Figure 1 Glycolysis-dependent phosphorylation of $GABA_A$ receptor on the α1 subunit. The maintenance of the $GABA_AR$ in a functional state is ensured by a kinase we have identified as being a key glycolytic enzyme, glyceraldehyde-3P dehydrogenase (GAPDH), closely associated to the receptor at the plasma membrane. GAPDH fulfills successively the two following roles. (a) Glycolytic role: Once taken up by the neuron, glucose enters the glycolytic pathway whose enzymes may chain to each other for a greater efficiency. During the reaction catalysed by GAPDH, inorganic phosphate (Pi) is incorporated into the glycolytic product. At the next step, catalyzed by phosphoglycerate kinase (PGK), an ATP production occurs at the membrane. This ATP is channeled back to GAPDH allowing a supplementary role for this enzyme as the $GABA_AR$ kinase. Glu-T: glucose transporter; Glc-6P: glucose-6P; G-3P: glyceraldehyde-3P; 1,3-diPG: 1,3-diphosphoglycerate; 3-PG: 3-phosphoglycerate. (b) Endogenous kinase role: GAPDH uses the glycolytic ATP for autophosphorylation. This phospho-enzyme transfers two phosphates to the long intracytoplasmic loop of the α1 subunit of the $GABA_AR$, on identified threonine and serine residues. Such phosphorylation induces receptor 'capacitation' by allowing opening of the associated channel when GABA binds on its extracellular sites. This α1-phosphorylation is counteracted by an atypical membrane-bound phosphatase, leading to 'incapacitation' of the receptor and resulting in rundown of $GABA_A$ responses. Fast inhibition is thus fuelled by glucose consumption.

intracellular medium thus maintains the GABAergic responses over time, but a further addition of iodoacetamide – which inactivates GAPDH – rapidly induces a rundown as large as that observed in the absence of the glycolytic substrate. The endogenous glycolytic ATP produced at the neuronal plasma membrane is highly preferred to the exogenous ATP present in the patch-pipette solution.

In addition, an atypical membrane-bound phosphatase dephosphorylates the $GABA_AR$ α1 subunits and opposes endogenous phosphorylation. Addition to the intracellular medium of a phosphatase, broad-range inhibitor (orthovanadate) prevents rundown of GABAergic responses by maintaining the receptor in its phosphorylated state. Under these conditions, further addition of iodoacetamide does not alter the time course of $GABA_A$ responses. We propose that glycolysis-dependent phosphorylation maintains the $GABA_A$ currents, and that an atypical membrane phosphatase opposing the endogenous phosphorylation accounts for rundown of GABAergic currents.

Methods

Patient Populations

The study described below was performed on cortical nervous tissue excised from 50 patients (32 men and 18 women) suffering from temporal or frontal pharmacoresistant epilepsy, who underwent curative neurosurgery in the Epilepsy Centers of Sainte-Anne (Paris, France) and Pontchaillou (Rennes, France). Informed consent was given by all patients, according to the guidelines of the institutional committees. Details of the presurgical and surgical procedures have been described elsewhere (see Further Reading). Most of our samples were taken from the temporal pole of patients with epilepsy. In eleven cases, we obtained cortical tissue from nonepileptic patients, in which resection of extralesional tissue was dictated by the technical imperatives of the surgical approach to a tumor. These samples were considered as 'control' tissue.

Biochemical Studies

Washed membranes were prepared from epileptogenic and control cortex tissue excised from patients undergoing neurosurgery. Endogenous receptor phosphorylation of $GABA_AR$ was performed in presence of Mg^{2+} and $\gamma[^{33}P]$-ATP in a buffered medium at pH 7.3 (kinase or activator not added) and measured by phosphoimaging on protein electrophoresis gels (PAGE). This reaction is catalyzed by the glycolytic enzyme GAPDH, and labeling of the $GABA_AR$ α1 subunit predominates (as previously

demonstrated). The receptor endogenous phosphorylation was compared to the expression of α1 subunits quantified at the protein level by photoaffinity labeling with [^{3}H]flunitrazepam.

Functional Approach

Rundown of GABA$_A$ currents is prevented by endogenous phosphorylation. We have shown that the endogenous kinase is a glycolytic enzyme (GAPDH), and therefore we investigated the role of glycolytic factors on the rundown of GABA$_A$ responses. Whole-cell currents were recorded by repeated (1 s every 3 min) GABA (100 μM) applications on acutely dissociated pyramidal neurons from human epileptogenic and control cortex. The effects of glycolytic factors added in the pipette milieu on rundown of GABA$_A$ responses were compared with the effects obtained under standard conditions.

Recent Results

Deficiency in Endogenous Phosphorylation of GABA$_A$R in Human Epilepsy

Many reports have suggested that a deficiency of GABAergic neurotransmission may be instrumental in the triggering or the propagation of seizures in patients with epilepsy. However, our own results, as well as those of several other teams, have shown that GABAergic inhibition is functional in the nervous tissue excised (for therapeutic reasons) from the cortical zones where seizures originated in patients with epilepsy. Is there a mechanism for rapidly – and transiently – decreasing the effectiveness of inhibitory neurotransmission in these cortical zones? A mechanism involving phosphorylation-dephosphorylation cycles would have these characteristics.

We hypothesized that GABA$_A$R endogenous phosphorylation could be defective in the cortical zones where seizures originate or which are very quickly invaded by epileptic discharges. The results of our study supported this hypothesis: the phosphorylation of GABA$_A$Rs by GAPDH was significantly reduced in washed cortical membranes obtained from epileptogenic tissue than from control tissue (**Figure 2(a)**). This alteration did not result from a reduction in the expression of the α1 subunits, as shown by photoaffinity labeling with the benzodiazepine [^{3}H]flunitrazepam, but was due to an intrinsic deficiency of the endogenous phosphorylation. Indeed, immunochemical labeling showed that the expressions of α1, α2, β2/3, and γ2 GABA$_A$R subunits remained unchanged, while that of α3 subunit was decreased in the neocortex of temporal lobe epilepsy patients.

The next step was to test whether the GABA$_A$R function, as reflected in the rundown of responses recorded using the whole-cell patch-clamp technique, was altered in acutely dissociated pyramidal neurons obtained from epileptogenic cortical tissue. Rundown of the GABAergic responses was significantly faster and greater when the recordings were carried out on cortical neurons isolated from epileptogenic samples compared with the responses of neurons obtained

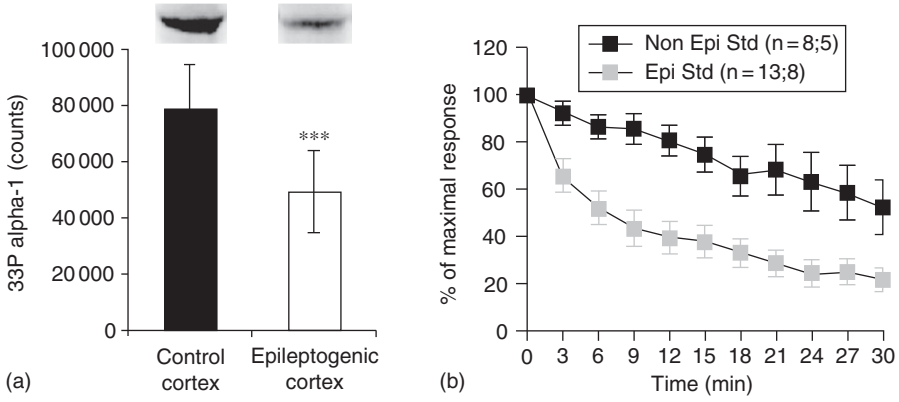

Figure 2 Endogenous phosphorylation of GABA$_A$R and GABA$_A$ currents in epileptogenic cortical tissue from patients with epilepsy and a control group. (a) Endogenous phosphorylation of GABA$_A$R α1 subunit in washed membranes prepared from epileptogenic and control tissue. *Upper part:* Autoradiography of the polyacrylamide gel after endogenous phosphorylation in a membrane preparation from tissue of a nonepileptic control patient and of an epileptic patient. The predominating ^{33}P-labeling at the 51-kDa band corresponding to the GABA$_A$R α1 subunit was clearly decreased in the tissue from epileptic patients. *Lower part:* Quantification of the ^{33}P-phosphate incorporation (in cumulated counts) into the α1 subunit of GABA$_A$R by endogenous phosphorylation of control nonepileptogenic cortex (n = 5 patients) and epileptogenic cortex (n = 23 patients); the error bars represent standard error of the mean (SEM); $P < 0.001$ for the Student's t-test (***). (b) GABA$_A$ currents measured by whole-cell patch clamp on acutely dissociated cortical neurons following GABA (100 μM) applications (for 1 s every 3 min). The responses progressively decreased (rundown) in standard condition (Std). Rundown of averaged normalized currents is compared in neurons from epileptogenic (Epi) and nonepileptogenic (NonEpi) cortex. For each curve, the parentheses indicate, respectively, the number of neurons and the number of patients; the error bars represent SEM. Modified from **Figs. 2** and **4** of Laschet JJ, Kurcewicz I, Minier F, *et al*. (2007) Dysfunction of GABA$_A$ receptor glycolysis-dependent modulation in human partial epilepsy. *Proceedings of the National Academy of Sciences USA* 104: 3472–3477.

from control tissue (Figure 2(b)). The rundown measured in the epileptogenic tissue could be reduced by adding to the pipette milieu either the glycolytic GAPDH substrate (G3P) or by inhibiting with orthovanadate, the membrane-bound phosphatase counteracting the α1-phosphorylation. Conversely, the protective effect of G3P against rundown was abolished by addition to the bath of iodoacetamide (500 μM), an irreversible inhibitor of GAPDH. The deficiency of endogenous phosphorylation thus induced considerable functional lability of the GABAergic currents. Interestingly, in the neurons dissociated from human tissue, the locally-produced glycolytic ATP (in small amounts) was very largely preferred to the ambient ATP (in large amounts) present in the patch-pipette solution.

We propose that, in the patients with partial epilepsies, any fortuitous increase in metabolic demand can induce a transient reduction in the effectiveness of inhibitory neurotransmission because of the decreased effectiveness of glycolysis-dependent phosphorylation; when a critical reduction of glycolysis-dependent phosphorylation is reached, there is a switch in the pathological cortical zone to an 'epileptic' state.

Correlations with Clinical Data

Considering the different clinical profiles in the epileptic patient group, the homogeneity of the GABAergic functional deficit is noteworthy. When the biochemical and functional results are compared with the clinical data, a few interesting observations can be made. There is a significant positive influence of age at surgery on GABAergic function, corroborated by a tendency for improvement of α1-phosphorylation. Other clinical parameters did not significantly interact with the level of deficiency. Concerning the functional GABAergic recovery by the addition G3P or orthovanadate, epilepsy duration had a positive influence only on the effect of G3P. This G3P-specific relationship may be accounted for by a gradual increase in the efficacy of energy metabolic adaptation with epilepsy duration, since a more efficient use of the glycolytic substrate may progressively occur to sustain $GABA_A$ function in long-term epilepsies.

GABAergic Deficiency and Interictal Hypometabolism

^{18}Fluoro-2-deoxyglucose positron emission tomography studies (FDG-PET) have shown that glucose utilization is decreased 10–20% during the interictal periods in the pathological cortical zones in patients with partial epilepsies. It has been suggested that hypometabolism is related to ictal discharge generation and propagation pathways. However, the relationship between this metabolic alteration and the epileptic pathology has never been fully explained. Recent reviews point out the very high energy cost related to the recycling of amino acid neurotransmitters. We propose that, in the epileptogenic tissue from patients with epilepsy, interictal hypometabolism is related to decreased effectiveness of inhibitory transmission, secondary to the deficiency of $GABA_AR$ endogenous phosphorylation. In the majority of our patients, FDG-PET studies showed that the affected zones were indeed in a hypometabolic state. A direct relationship can thus be postulated between the deficiency of glycolysis-dependent α1-phosphorylation shown in vitro and the interictal hypometabolism observed in vivo in patients with partial epilepsy.

It is doubtful that the decrease in $GABA_AR$ α1-phosphorylation per se contributes significantly to the decrease in glucose consumption. However, decreased glucose uptake should be expected as a functional consequence of the observed α1-phosphorylation deficiency on postsynaptic inhibition, if the activity of inhibitory synapses is energy consuming. It has been shown that specific activations of GABAergic inhibitory circuitry result in a marked increase in glucose consumption, as evaluated by ^{14}C-deoxyglucose uptake autoradiography (both in hippocampal slices and in the intact central auditory system). In further support of this hypothesis, FDG-PET studies have revealed that administration of a $GABA_A$ agonist increases cerebral glucose metabolism by >17% in healthy volunteers and even more in epileptic patients (by ~25% at the cortical zones where seizures originate). This GABAergic metabolic effect is of the same order of magnitude as that of the hypometabolism measured in the temporal pole of patients with partial epilepsies (as compared with healthy volunteers). It would be useful to quantify the varying degrees of hypometabolism in these patients, to determine if the degree of hypometabolism correlates with the observed GABAergic deficiencies. Unfortunately, normalization of the data in our study was not suitable for such comparisons, due to FDG-PET acquisition procedures and variability of individual hypometabolic values.

Another metabolic dysfunction, affecting mitochondrial enzymes, has been disclosed in the hippocampus of patients with epilepsy. This dysfunction may also contribute to interictal hypometabolism. An additional primary deficiency in energy metabolism would further affect $GABA_AR$ α1-phosphorylation if the glycolysis-dependent ATP production falls locally below a critical level. However, as already mentioned, the endogenous glycolytic ATP produced at the neuronal plasma membrane from glycolytic substrates is largely preferred to the ambient ATP. We propose that the deficiency of the glycolysis-dependent modulation of GABAergic inhibition can at least partially account for the interictal glucose hypometabolism. Because the α1-phosphorylation level is determined by the opposing actions of a kinase and a phosphatase, equilibrium may be reached at a lower level of α1-phosphorylation when the activity rate of GAPDH (as a kinase) is decreased or when the glycolytic

ATP is less available. The reduction in the effectiveness of endogenous phosphorylation of the $GABA_AR$ in the epileptogenic tissue should reduce the energy costs of inhibition and thus glucose consumption. It is worth noting that this view contrasts with the common opinion that an increase in the effectiveness of GABAergic inhibition produces a glucose hypometabolism by reduction of electrical neuronal activity.

Genetics of $GABA_AR$ α1 Subunit Related to Human Epilepsy

Mutation in the $GABA_A$ receptor subunit genes have been linked to several inherited forms of epilepsies. The α1 subtype is the most widely expressed of the α subunits, with expression increasing throughout development. A single mutation in the $GABA_AR$ α1 subunit was identified in a family with juvenile myoclonic epilepsy (JME), in which an alanine in the third transmembrane domain (TM3) is replaced by an aspartate (A322D). The corresponding mutation in the rat α1 subunit (A294D), expressed in HEK293 cells, reduced GABA sensitivity of the receptor, increased the deactivation rate, and slowed desensitization. However, this mutation does not concern the α1 subunit phosphorylation sites on Ser and Thr residues within the long intracytoplasmic loop (between TM3 and TM4), and therefore the mechanisms underlying this α1-related genetic disorder seem to be different from the that of $GABA_AR$ endogenous phosphorylation involved in intractable partial epilepsy.

Future Goals

Glycolysis-dependent $GABA_AR$ phosphorylation and GABAergic inhibition are deficient in cortical tissue excised from patients suffering from drug-resistant partial epilepsies. These observations have led to our hypothesized direct link between interictal hypometabolism (observed in and around the epileptogenic zones in these patients) and the epileptic pathology. Imaging, NMR spectroscopy, and modeling studies are needed to make clear such metabolic relationships.

In our study, enhancing the $GABA_AR$ endogenous phosphorylation, either by favoring the glycolytic role of GAPDH or by inhibiting receptor dephosphorylation, compensated for the GABAergic functional deficiency. This observation opens up new and promising prospects for the development of antiepileptic molecules active in drug-resistant epilepsies, which affect nearly 25% of patients with epilepsy. Two approaches should certainly be considered: (1) activating the kinase activity of GAPDH; (2) inhibiting the atypical membrane-bound phosphatase. The first approach may certainly give rise to severe side-effects, given the ubiquitous metabolic role of GAPDH. The second approach, however, appears more clinically relevant. We are presently trying to identify the membrane-bound phosphatase(s) that counteracts the $GABA_AR$ glycolysis-dependent phosphorylation. A further important step will be to design and validate specific inhibitors of the involved protein phosphatase(s), as a novel approach to developing new antiepileptic drugs.

Role of Metabolic Substrates and Acid-Base Balance in Seizures

J Velíšková and L Velíšek, Albert Einstein College of Medicine, Bronx, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As glucose is the main source of energy for neurons in the CNS, disturbances in glucose metabolism are often associated with alterations of brain function. Indeed, seizures are a common complication of diabetes mellitus, associated with either hyperglycemia or hypoglycemia. Mechanisms involved in hypoglycemic seizures are especially intriguing because low glucose levels lead to general neuronal silencing, and EEG recordings show generalized slowing of background activity with prevailing theta rhythm. Similarly in laboratory animals, insulin-induced hypoglycemia leads to generalized seizures. During severe hypoglycemia in these animals, EEG recordings (from cortex or hippocampus) prior to seizures show slowing of activity resulting in an isoelectric state – from which the seizure activity abruptly arises. As seizures start as a result of synchronized neuronal firing, it seems curious that hypoglycemic seizures appear to occur under conditions of general synaptic silencing.

Similarly, changes in acid–base balance have significant effects on neuronal excitability and seizure susceptibility. Hyperventilation leading to respiratory alkalosis is one of the diagnostic tools to evoke seizure in epileptic patients during the EEG exam. In contrast, certain antiepileptic drugs (such as acetazolamide) alter the acid–base balance of the body by inhibiting carbonic anhydrase. Accordingly, the mice deficient in carbonic anhydrase isozyme II have reduced seizure susceptibility compared with their normal littermates. Finally, moderate acidosis induced by ketogenic diet is one of the proposed anticonvulsant mechanisms of the ketogenic diet.

Background

Disturbances in Glucose Metabolism and Neuronal Excitability

Hypoglycemia is often associated with antidiabetic treatment (especially in children and during adolescence) or with other conditions such as insulinoma as well as alcoholism. Fasting or vigorous exercise seem to be predisposing factors for seizure expression during hypoglycemic crisis.

Glucose sensing in the brain

Due to the high demand of neurons for a glucose supply, the brain contains specialized 'glucosensing' neurons to regulate glucose homeostasis. These neurons change their firing rates in response to changes in glucose levels and based on this feature, two distinct populations of glucosensing neurons can be recognized: (1) Neurons that decrease their firing rates during hypoglycemia and increase their firing rates when glucose levels rise. Such neurons are called glucose responsive. (2) Neurons that increase their firing rates during hypoglycemia and decrease their firing rates when glucose levels rise. This type of neurons is called glucose sensitive.

The firing rate of neurons under metabolic stresses is regulated primarily by changes in activity of ATP/ADP-sensitive inward rectifying potassium (K_{ATP}) channels. These channels translate the metabolic state into cellular excitability. They are composed of four regulatory subunits (SUR) and four pore-forming subunits (Kir). The channel inhibition (closing) is mediated by binding of sulfonylureas or ATP to the regulatory subunit. Diazoxide or ADP binding results in the channel opening.

In the glucose responsive neurons, glucose uptake leads to an increase of the ATP/ADP ratio and K_{ATP} channels are inactivated (closed) – resulting in accumulation of intracellular K^+, membrane depolarization, and increased cell firing rate. During hypoglycemia (or other metabolic stresses such as hypoxia), the fall in the ATP/ADP ratio activates (opens) the channel and firing rates decrease due to membrane hyperpolarization. This cell hyperpolarization effect has been proposed as a neuroprotective mechanism during metabolic stress. However, it may raise the risk for global neuronal silencing and lead

membrane-associated phosphatase. *Neurochemistry International* 36: 499–506.

Introduction

As glucose is the main source of energy for neurons in the CNS, disturbances in glucose metabolism are often associated with alterations of brain function. Indeed, seizures are a common complication of diabetes mellitus, associated with either hyperglycemia or hypoglycemia. Mechanisms involved in hypoglycemic seizures are especially intriguing because low glucose levels lead to general neuronal silencing, and EEG recordings show generalized slowing of background activity with prevailing theta rhythm. Similarly in laboratory animals, insulin-induced hypoglycemia leads to generalized seizures. During severe hypoglycemia in these animals, EEG recordings (from cortex or hippocampus) prior to seizures show slowing of activity resulting in an isoelectric state – from which the seizure activity abruptly arises. As seizures start as a result of synchronized neuronal firing, it seems curious that hypoglycemic seizures appear to occur under conditions of general synaptic silencing.

Similarly, changes in acid–base balance have significant effects on neuronal excitability and seizure susceptibility. Hyperventilation leading to respiratory alkalosis is one of the diagnostic tools to evoke seizure in epileptic patients during the EEG exam. In contrast, certain antiepileptic drugs (such as acetazolamide) alter the acid–base balance of the body by inhibiting carbonic anhydrase. Accordingly, the mice deficient in carbonic anhydrase isozyme II have reduced seizure susceptibility compared with their normal littermates. Finally, moderate acidosis induced by ketogenic diet is one of the proposed anticonvulsant mechanisms of the ketogenic diet.

Background

Disturbances in Glucose Metabolism and Neuronal Excitability

Hypoglycemia is often associated with antidiabetic treatment (especially in children and during adolescence) or with other conditions such as insulinoma as well as alcoholism. Fasting or vigorous exercise seem to be predisposing factors for seizure expression during hypoglycemic crisis.

Glucose sensing in the brain

Due to the high demand of neurons for a glucose supply, the brain contains specialized 'glucosensing' neurons to regulate glucose homeostasis. These neurons change their firing rates in response to changes in glucose levels and based on this feature, two distinct populations of glucosensing neurons can be recognized: (1) Neurons that decrease their firing rates during hypoglycemia and increase their firing rates when glucose levels rise. Such neurons are called glucose responsive. (2) Neurons that increase their firing rates during hypoglycemia and decrease their firing rates when glucose levels rise. This type of neurons is called glucose sensitive.

The firing rate of neurons under metabolic stresses is regulated primarily by changes in activity of ATP/ADP-sensitive inward rectifying potassium (K_{ATP}) channels. These channels translate the metabolic state into cellular excitability. They are composed of four regulatory subunits (SUR) and four pore-forming subunits (Kir). The channel inhibition (closing) is mediated by binding of sulfonylureas or ATP to the regulatory subunit. Diazoxide or ADP binding results in the channel opening.

In the glucose responsive neurons, glucose uptake leads to an increase of the ATP/ADP ratio and K_{ATP} channels are inactivated (closed) – resulting in accumulation of intracellular K^+, membrane depolarization, and increased cell firing rate. During hypoglycemia (or other metabolic stresses such as hypoxia), the fall in the ATP/ADP ratio activates (opens) the channel and firing rates decrease due to membrane hyperpolarization. This cell hyperpolarization effect has been proposed as a neuroprotective mechanism during metabolic stress. However, it may raise the risk for global neuronal silencing and lead

to a comatose state. To reduce the rapid decline in general excitability, in some neurons the K_{ATP} channels are downregulated – as an apparent compensatory mechanism – during metabolic stress. The mechanism underlying increased firing of glucose sensitive neurons during a hypoglycemic state is not clear, but selective downregulation of the K_{ATP} channels may partially explain their somewhat paradoxical increase in firing.

Glucosensing neurons are abundant in the hypothalamus, midbrain (especially the substantia nigra), pons, and medulla.

The substantia nigra is a candidate structure involved in the hypoglycemic seizures

Our studies show that the SNR seems to be involved in hypoglycemic seizures. We found increased activity of the SNR neurons during hypoglycemic seizures. That this firing rate change may not be just 'coincidental' is suggested by the facts that: (1) The SNR plays an important role in control of generalized seizures and (2) The SNR GABAergic cells are glucosensing neurons.

1. The SNR plays an important role in seizure control: The SNR has been identified as a critical midbrain structure involved in motor control and modulation of seizures, mediated through regulation of GABAergic neurotransmission. The SNR contains mainly GABAergic neurons with high spontaneous firing rates. These neurons receive inputs from striatum directly, and also indirectly (via globus pallidus and subthalamic nucleus). The direct pathway provides GABA-mediated inhibitory effects on SNR neurons; GABA release at the striatonigral terminals or exogenous application of GABA decreases SNR neuron firing rate. The indirect pathway is excitatory, involving glutamatergic inputs from the subthalamic nucleus.

Seizures can be exacerbated when the activity of the SNR GABAergic neurons is increased. Such increase occurs when inhibitory effects of GABA on SNR neurons are decreased, or when glutamatergic excitatory drive on the SNR neurons is increased. Indeed, localized SNR microinfusions of bicuculline (a GABAA receptor antagonist) or kainic acid (AMPA/kainate receptor agonist) in the SNR have proconvulsant effects. In contrast, treatments that decrease the activity of the SNR GABAergic cells (especially in the SNR anterior) produce anticonvulsant effects. This relationship has been directly demonstrated using localized bilateral microinfusions of GABA agonists such as γ-vinyl-GABA (an irreversible GABA transaminase inhibitor that increases local GABA levels) or muscimol (a $GABA_A$ receptor agonist) into the SNR. Similarly, treatments that decrease glutamatergic neurotransmission in the SNR (infusions of AP7; an NMDA receptor antagonist) have anticonvulsant effects.

Under normal conditions, GABA inhibits the SNR neurons and decreases their high frequency of spontaneous firing, especially via activation of $GABA_A$ receptors. Thus, seizures induced by different chemoconvulsant agents under normoglycemic conditions can be attenuated by intranigral microinfusions of different $GABA_A$ receptor agonists or drugs increasing the GABA availability. However, in the case of hypoglycemic seizures, muscimol is ineffective in reducing SNR discharge rate. This failure of muscimol to prevent glucopenic seizures could be related to $GABA_A$ receptor internalization and thus to the unavailability of these receptors under conditions of metabolic stress. In contrast, intranigral microinfusions of AP7 prevents the occurrence of hypoglycemic seizures (**Figure 1**).

2. The SNR neurons are glucosensing: Studies using extracellular recordings in in vitro slices from mice showed that with decreasing glucose concentration in the artificial cerebrospinal fluid (aCSF), the SNR GABAergic neurons increased their firing rates. The SNR contains a very high density of K_{ATP} channels. The molecular structure of these SNR channels within the GABAergic neurons consists of SUR1 (high affinity receptor for sulfonylurea and ATP binding cassette superfamily) and Kir6.2 (inwardly rectifying channel operating subunit). This subunit composition endows these channels with high sensitivity to metabolic changes. The subcellular distribution of pre- or postsynaptic K_{ATP} channels is not known, but some evidence suggests that K_{ATP} channels within the SNR may be present both pre- and postsynaptically. Under

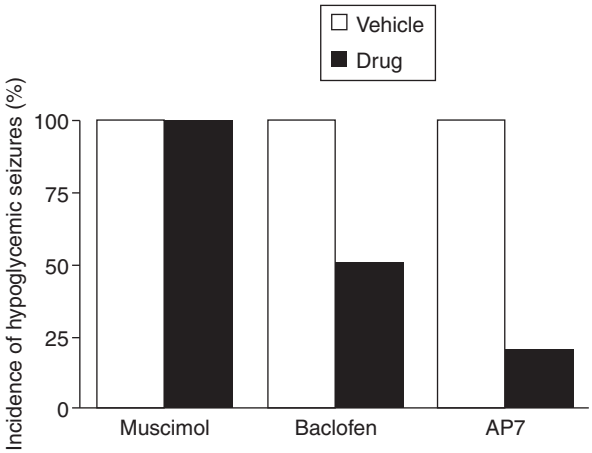

Figure 1 Incidence of hypoglycemia-induced seizures (barrel rotations) following intranigral administration of GABAergic or glutamatergic agents. The drugs or their appropriate vehicle were infused bilaterally into the SNR in a volume of 0.25 µl per side just prior to insulin injection (30 IU kg^{-1} i.p.): Muscimol (0.1 µg), baclofen (0.2 µg), AP7 (1.1 µg). Incidence of barrel rotations has been monitored. Intranigral muscimol did not affect the incidence of hypoglycemic seizures. On the other hand, both baclofen and AP7 significantly decreased the incidence of hypoglycemic seizures. These results suggest that glutamate plays an important role in the initiation of hypoglycemic seizures. The anticonvulsant effect of baclofen can be explained by its action at the presynaptic GABAB heteroreceptors located at the glutamatergic terminals originating from the subthalamic nucleus and thus suppresses glutamate release in the SNR.

metabolic stress, the SNR GABAergic neurons increase their firing rate (unlike the majority of neurons in the CNS which decrease their firing). However, the mechanism of this paradoxical effect is not well established.

Disturbances in pH Control and Neuronal Excitability

Systemic pH control

In the blood, there are four buffering systems for pH: bicarbonate, hemoglobin, protein, and phosphate. However, the buffering capacity of the latter two is small. The most important contribution to pH control in the extracellular environment belongs to the bicarbonate system, consisting of carbon dioxide (CO_2), carbonic acid (H_2CO_3), and bicarbonate (HCO_3^-). Intracellularly, proteins and phosphates are the most important buffers. The intracellular and extracellular compartments communicate with each other, using protons, bicarbonate, and oxygen modulate pH across the membrane. The capacity of the CO_2–H_2CO_3–HCO_3^- buffering system is very large because CO_2 is easily released to the atmosphere via lungs. Additional exchange with the environment is achieved via kidney acidification (H^+ excretion) of urine and, in rare cases, via gastric secretion of H^+.

Role of carbonic anhydrase

In many tissues, the interchange of pH constituents and buffers is accelerated enzymatically by carbonic anhydrase, which hydrates CO_2 to H_2CO_3. H_2CO_3 is in balance (via free dissociation) with a bicarbonate ion (H^+ and HCO_3^-). The carbonic anhydrase family consists of 12 active isozymes in humans and 13 in most other mammals. Carbonic anhydrase plays a significant role in the bicarbonate buffer system, in the proton excretion in urine, in acidification of the stomach content, and in pancreatic bicarbonate secretion, as well as in deposition of calcium in bones. There is also carbonic anhydrase in the nervous system. The principal carbonic anhydrase isozyme found intracellularly (in astroglia, oligodendrocytes, and choroids plexus is the isozyme II). In addition, CNS contains membrane-bound isozymes IV and XIV, and neuronal isozyme VII. In the CNS, carbonic anhydrase isozymes participate in fast buffering of pH transients that occur during neuronal activity.

Carbonic anhydrase inhibitors as anticonvulsants

Acetazolamide, an inhibitor of carbonic anhydrase, has anticonvulsant properties and has been approved for the treatment of epilepsy since 1953. Among newer antiepileptic drugs, anticonvulsant effects of zonisamide may be linked to its inhibitory effects on carbonic anhydrase, and topiramate has weak inhibitory effects on carbonic anhydrase activity (which, however, seems to be unrelated to its anticonvulsant effects).

Methods

Hypoglycemia-Related Experiments

P21 Sprague Dawley rats from Taconic farms have been used. Rats were sacrificed under CO_2 anesthesia, brain quickly removed from the skull, and sagittal slices (400 μm thick) containing the middle part of the SNR were cut on a vibratome in ice-cold aCSF. The aCSF composition was (in mM): 210 sucrose, 3.5 KCl, 1 $CaCl_2$, 4 $MgCl_2$, 26 $NaHCO_3$, 1.25 NaH_2PO, and 10 D-glucose. Slices were allowed to recover for at least 1 h at room temperature in aCSF containing (in mM): 124 NaCl, 2.5 KCl, 1 NaH_2PO_4, 26 $NaHCO_3$, 2 $CaCl_2$, 1.3 $MgSO_4$, and 20 glucose. During experiments, we manipulated glucose concentrations from 20 to 2 mM and added mannitol to maintain osmolarity when glucose was lowered. All solutions were saturated with 95% O_2/5% CO_2 gas mixture. Slices were transferred to the recording chamber and perfused with oxygenated aCSF at a rate of 4 ml min^{-1}. Recordings were performed at room temperature (22 °C). The pipette filling solution contained (in mM): 140 KCl, 6 NaCl, 2 $MgCl_2$, 10 HEPES, 2 Mg-ATP and the pH was adjusted to 7.3 with KOH. Whole-cell patch clamp recordings were made from electrophysiologically identified GABAergic neurons (lack of sag after negative current injection, biphasic afterhyperpolarization, and fast spiking). After recording firing frequency during a 5-min baseline period in 20 mM glucose aCSF, we switched to aCSF containing 2 mM glucose. Slices were bathed for 10 min in this glucose concentration, and firing frequency was measured in the last 10 s of each minute.

pH-Related Experiments

Carbonic anhydrase II-deficient mice

We used adult mice, in which a null mutation of the Car^{2n} locus was produced using nitrosourea. The homozygotes Car^{2n}/Car^{2n} have an absolute deficit of carbonic anhydrase II (CAII) in all tissues, including brain. These mice suffer from systemic acidosis and decreased bicarbonate levels. The mice were studied in three experiments:

1. *Susceptibility to flurothyl-induced seizures*: Flurothyl is a liquid convulsant which easily evaporates. When the gaseous form is inhaled, it produces clonic and tonic–clonic seizures. For seizure threshold testing, it is delivered to air-tight chamber using a constant rate pump (20 μl min^{-1}). The amount of flurothyl required to induce a particular seizure type can be calculated from the latency to onset of seizures.
2. Susceptibility to seizures induced by a single dose of systemically injected pentylenetetrazole. Pentylenetrazole is a convulsant drug acting on the TBPS site of the GABA receptor. After systemic injection (100 mg kg^{-1}, s.c.), it produces clonic and tonic–clonic convulsions,

sometimes with lethal ending. In this test, some of CAII-deficient mice and controls were pretreated with acetazolamide (100 mg kg^{-1}, i.p.) 30 min prior to pentylenetetrazole injection.

3. Susceptibility to audiogenic seizures, in response to a loud sound. Immature mice were 'primed' with a 5 min exposure to a 120 dB bell during a critical stage of auditory system development (postnatal day 19). They were retested – exposure to 1 min of 120 dB bell sound – at P45. In sensitized animals, this stimulus elicits tonic–clonic seizures, usually consisting of wild running, falling, a tonic phase, and then clonus of all four limbs.

pH changes in vitro

To further illustrate the effects of pH changes on seizure susceptibility, we modified pH in the extracellular environment of hippocampus–entorhinal cortex slices in vitro. Combined transversal hippocampus–entorhinal cortex slices were prepared from normal adult male rats. Epileptiform activity was induced by decreasing extracellular Mg^{2+}. This manipulation unblocks NMDA receptors and the seizure-like activity ensues. pH was changed in the extracellular environment by changing the composition of saturation gas (1.0–20.6% of CO_2, balance of oxygen, with resulting aCSF pH 7.8–6.7). For a control, we directly acidified the aCSF to pH = 6.7 using 10–12 mmol HCl. We investigated the interval between low Mg^{2+}-induced seizure-like events and their amplitudes in control aCSF, in altered pH, and after washout.

Results

Changes in Extracellular Glucose Levels Increase SNR GABAergic Neuron Firing

We evaluated the contribution of presynaptic transmitter release to hypoglycemia-induced changes in firing rate of the SNR GABAergic neurons. A decrease in extracellular glucose concentration resulted in an increase of action potential firing rate of the SNR GABAergic neurons (**Figure 2**). The increase in firing rate occurred with a delay of several minutes after the change in glucose concentration. The pipette we used to record from SNR neurons contained ATP, so that ATP presumably diffused into the impaled SNR GABAergic neurons. Thus, the K_{ATP} channels in these cells were inactivated (closed). We therefore interpreted the change in the firing rate of the SNR GABAergic neurons, under these hypoglycemic conditions, as a function of alterations in presynaptic transmitter release – i.e., as a result of an active role of the presynaptic K_{ATP} channels. Further studies, however, are needed to establish whether this effect is directly related to opening of the K_{ATP} channels at the presynaptic GABAergic terminals – leading to complete lack of GABAergic inhibition (including the tonic inhibition) on the spontaneously firing SNR GABAergic neurons, or due to an involvement of glutamate. Unlike GABAergic presynaptic terminals in the SNR, presynaptic glutamatergic terminals lack K_{ATP} channels, and thus glutamate release is not regulated by K_{ATP} channels. The possible involvement of these glutamatergic inputs in increasing SNR GABAergic neuron firing seems to be supported by in vivo data showing that bilateral intranigral microinjections of NMDA receptor antagonist AP7 significantly decreased the incidence of hypoglycemic seizures (**Figure 1**).

Seizure Susceptibility of CAII-Deficient Mice

In the flurothyl seizure model, seizures will eventually occur in all subjects. The latency to seizure is a measure of the subject's susceptibility – i.e., seizure threshold. CAII-deficient mice had an increased latency to both clonic and tonic–clonic flurothyl-induced seizures, by ~20%, compared to wild-type mice. Additionally, after tonic–clonic seizures, ~46% of wild-type mice died,

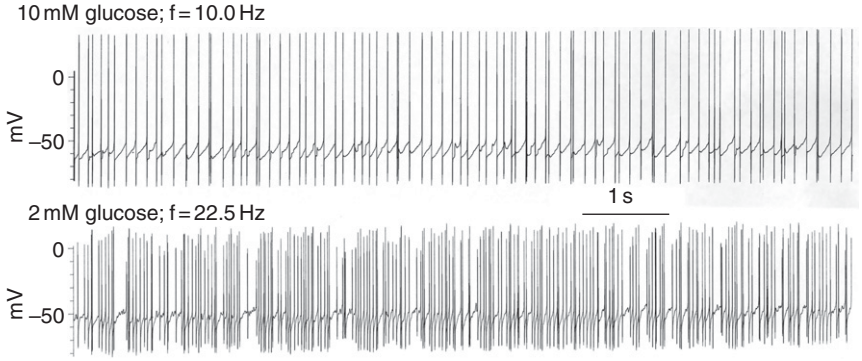

Figure 2 Whole-cell recording in a current clamp mode from an SNR GABAergic neuron. The basal average firing rate of this neuron in 10 mM glucose solution was ~10 Hz. Lowering glucose to 2 mM resulted in increase in average spontaneous firing of this neuron to 22.5 Hz.

but none of the CAII-deficient mice died. Clonic seizures induced by pentylenetetrazole developed significantly less frequently in CAII-deficient mice compared to wild-type mice (Figure 3). Additionally, pretreatment with acetazolamide in wild-type mice decreased incidence of seizures to the values found in CAII-deficient mice; pretreatment with acetazolamide did not further decrease occurrence of pentylenetetrazole seizures in CAII-deficient mice. Finally, when all mice were primed by loud sound during the critical developmental period, CAII-deficient mice experienced fewer loud sound-induced seizures in the adulthood compared to wild-type mice (Figure 3). Thus, in all seizure models, CAII-deficient mice displayed increased seizure resistance (compared to wild-type mice); this resistance was similar to the anticonvulsant effects of pretreatment with the carbonic anhydrase inhibitor acetazolamide. As the CAII-deficient mice suffer from systemic acidosis, the data suggest that systemic acidosis is associated with anticonvulsant effects.

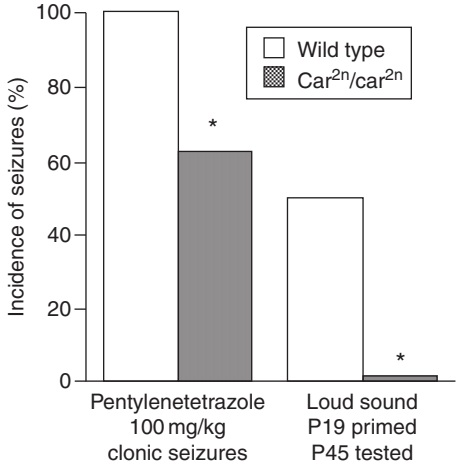

Figure 3 Incidence of clonic seizures induced by pentylenetetrazole (100 mg kg^{-1}, s.c.) and seizures evoked by loud sound after critical period priming in wild-type and Car^{2n}/Car^{2n} mice. Car^{2n}/Car^{2n} mutants demonstrated significant decrease in seizure incidence consistent with their carbonic anhydrase isozyme II deficiency. *Y*-axis: incidence in per cent. *Indicates significant difference ($P < 0.05$) compared to the wild type.

Effects of pH Changes on Seizure Susceptibility In Vitro

To test the effect of extracellular acidotic pH on epileptiform activity and seizures, we used an in vitro slice model. We induced epileptiform activity in the entorhinal cortex of combined hippocampus-entorhinal cortex slices using low Mg^{2+} and then applied aCSFs with different pH levels. When the aCSF was acidified to pH 6.7 (by either changing the oxygenation gases or by direct acidification), the interval between seizure-like events increased and the amplitude of events decreased. These effects were reversible (Table 1) and consistent with the anticonvulsant effects of extracellular acidosis, possibly working through NMDA receptor blockade.

Future Goals

The model of hypoglycemic seizures may not be relevant only to patients with metabolic disorders (diabetes mellitus or hyperinsulinism). Although it is known that a short epileptic seizure leads to increased glucose levels, a recent study showed that (in cerebral cortex) extracellular glucose levels significantly decrease in later stages of prolonged seizures. This study did not investigate the changes in extracellular glucose levels in other brain regions. The possibility exists that seizures can be maintained, and status epilepticus develops, if glucose levels decrease in structures normally responsible for seizure control or termination. This concept may have direct application to the SNR. Studies using the [^{14}C]-2-deoxyglucose (2DG) technique show that 2DG uptake is significantly increased in the SNR just prior to and during seizures – perhaps because blood

Table 1 Effects of extracellular acidification on the interval between and amplitude of low Mg^{2+}-induced seizure-like events in the medial entorhinal cortex in vitro

	pH = 6.7 achieved by pCO_2 = 20.6% in the ACSF			*pH = 6.7 achieved by direct acidification of the ACSF*		
Event parameter	Baseline pH = 7.3	pCO_2 = 20.6%, pH = 6.7	Wash pH = 7.3	Baseline pH = 7.3	pH = 6.7	Wash pH = 7.3
Interval (min)	2.59 ± 0.90	8.36 ± 2.35[a,b]	1.85 ± 0.62	5.20 ± 1.48	8.58 ± 1.28[a,b]	3.60 ± 1.07
Peak amplitude (mV)	1.92 ± 0.29	1.32 ± 0.19[a,b]	1.68 ± 0.24	1.40 ± 0.07	0.90 ± 0.04[a,b]	1.38 ± 0.14

[a]Significant difference compared to baseline ($P < 0.01$).
[b]Significant difference compared to wash ($P < 0.01$).
Interval denotes interval between individual seizure-like events. The longer the interval, the fewer seizure-like events occurred consistent with anticonvulsant effects. Decrease in the peak amplitude of the seizure-like event is also consistent with anticonvulsant effects.

flow is increased specifically in the SNR and is reflected by increased 2DG uptake. However, another explanation for the increased 2DG uptake is that there is decreased glucose availability under these conditions, which then favor 2DG uptake. Future studies should determine the details of glucose metabolism, its maintenance, and glucose transport during seizure activity.

Studies have demonstrated that extracellular pH may have multiple effects on neurons. First, proton excess inhibits NMDA receptors – perhaps the most important link between the acid–base balance and neuronal excitability. Thus, hyperventilation leads to respiratory alkalosis, which unblocks NMDA receptors and thus provokes seizures. However, there are many additional potentially pH-sensitive phenomena in the brain microenvironment, which need to be further studied. Brief acid–base transients developing during transmitter release from axonal terminals may affect the 'tone' of neurons and set the background excitability level for basic synaptic transmission. Glial cells, and especially astrocytes, significantly participate in the control of pH with their potent carbonic anhydrase and proton exchanger machinery, and therefore, pH changes may represent one means of glia-neuron communication. Extracellular pH is tightly coupled with pH maintained intracellularly; the effects of pH changes in either compartment will affect pH in the other compartment. These interactions, and their consequences for neuronal excitability, require clarification.

Seizure-Induced Metabolic and Hemodynamic Changes in the Immature Brain

A Nehlig, INSERM U 666, Strasbourg, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The use of neuroimaging is rapidly increasing, both in animal models and human neuropathology. Imaging techniques that allow for the mapping of metabolic and hemodynamic changes, and particularly, autoradiographic techniques, have been widely applied in the assessment and treatment of neurologic diseases. Measurements of ictal blood flow and interictal metabolic changes are used in most epilepsy centers as presurgical tools to locate the epileptic focus and to delineate the seizure circuit, mainly in pharmacoresistant temporal lobe epilepsy.

Application of autoradiographic techniques to animal models allows investigators to measure local cerebral metabolic rates for glucose (LCMRglcs) by the [^{14}C]2-deoxyglucose (2DG) technique, and local cerebral blood flow (LCBF) rates using the [^{14}C]iodoantipyrine (IAP) technique. These techniques map LCMRglcs or LCBF in as many regions of interest as needed, in conscious freely moving animals in experiments that manipulate physiological, pharmacological, behavioral, or pathological conditions. The spatial resolution of these techniques is sufficient to provide precise identification of the areas in which epileptic seizure leads to changes in functional activity. However, the resolution of these techniques remains regional, and most attempts to reach the cellular level with these methods have failed. Thus, there is a lack of information about the nature of the cell type (e.g., neuronal or glial) whose function/activity is affected during or after the epileptic event. A recently developed approach, combining micro-autoradiography and immunohistochemistry, has now provided that level of discrimination, so that studies can determine whether it is in neurons or astrocytes that uptake of [^{14}C]2DG is taking place. However, this technique has not yet been applied to epilepsy models. Finally, nuclear magnetic resonance spectroscopy (NMRS) with ^{13}C-labeled glucose and acetate as precursors for the neuronal and astrocytic tricarboxylic acid cycle, respectively, allows investigators to study not only metabolic activity but also the interaction between neurons and astrocytes. Again, this type of analysis can only be performed at the regional (not single cell) level. Clearly, imaging involves constant compromises between information that can be obtained at the level of the circuit, brain region, or cell type.

Background

The autoradiographic techniques for the measurement of cerebral blood flow and metabolism in the rat were first published in the late 1970s. After their initial development, they were applied to numerous paradigms, including the consequences of seizures on cerebral activity. In the immature brain, the autoradiographic techniques were used to map seizure circuits in a nonquantitative way, until methods were developed to provide in vivo quantitative data in immature rats. Indeed, quantification of brain metabolism and blood flow requires the insertion of catheters into blood vessels so as to allow the simultaneous i.v. injection of the radioactive tracer and withdrawal of arterial samples. The application of these techniques in small immature rodents was initially limited by the size and fragility of blood vessels, and by the necessity to miniaturize methods of measurements that would provide accurate data based on very limited volumes of blood (i.e., so that blood withdrawal would not compromise the physiology of the animal). More details on these techniques and their adaptation to the immature brain can be found in the Methods section.

The first studies performed in normal adult rodents showed that, in normal conditions, rates of LCBF and LCMRglcs are quite heterogeneous throughout the brain, with low rates in white matter and levels varying by as much as a factor of 4 in gray matter regions. LCBF and LCMRglcs are coupled in all brain regions; that is, the regions with the highest glucose needs have the highest blood flow in order to adjust the delivery of substrates, oxygen, and glucose to the metabolic demand. Finally, in the adult brain, glucose can be considered the sole energy substrate, and hence LCMRglcs can also be seen to provide rates of energy metabolism while both LCMRglcs and LCBF reflect cerebral functional activity.

Using these techniques (in the 1970s and 1980s), several well-known groups showed that during severe sustained seizures in the adult brain, LCMRglcs increase to very high levels, and the regions most vulnerable to the insult (i.e., showing neuronal loss) are those in which glucose use is increased to the greatest extent. Investigators showed that neuronal loss is independent of systemic factors, by carrying out these studies also in anesthetized, artificially ventilated, and well-oxygenated animals. Interestingly, during sustained seizures, LCBF and LCMRglcs

do not follow a parallel temporal evolution. While the metabolic demand and hence LCMRglcs remain elevated during long seizure periods, LCBF rates first increase greatly to match metabolic demand and then start to decrease, decreasing first to normal levels and then dropping to very low levels. Thus, the late phase of severe sustained seizures is characterized in the adult brain by a pronounced mismatch between LCBF and LCMRglcs, leading to marked relative hypoperfusion. The regions in which this mismatch takes place are vulnerable to neuronal loss; these regions are usually those with very high seizure-induced metabolic increases.

In our group, we adapted these quantitative autoradiographic techniques to the immature rat, so that we could study age-related changes in seizure circuits. We also tried to revisit, in immature brain, the issue of coupling between blood flow and metabolism in the genesis of neuronal loss. Finally, we have used ^{13}C NMRS and in situ hybridization to map the brain nutrient transporters during seizures, in order to clarify the age-specific nature of the response of the immature brain to seizures.

Methods

Autoradiography: Techniques and Limitations

LCMRglcs are measured by means of the 2DG technique, and LCBF rates are assessed using the IAP technique. Both techniques have been adapted to the adult mouse and the immature rat. The spatial resolution of these techniques is excellent, and is based on the revelation of silver grains (on autoradiographic films), which are excited by the electrons emitted from the ^{14}C-labeled molecule that has accumulated in different brain regions. The optical density of the regions of interest can be measured (e.g., on serial coronal brain sections) and compared with that of calibrated [^{14}C]-methylmethacrylate plastic standards. The final step is the calculation, by means of specific operational equations, of the relation of ^{14}C concentration to rates of cerebral glucose utilization or blood flow, in each specific brain region of interest, using an image processing system. Many software packages are now available for these procedures (including free software offered on a NIH website).

A major technical difficulty in both techniques relates to the fact that the experiments require the insertion of polyethylene catheters, usually into the femoral artery and vein, for quantification of results. The venous catheter allows for the i.v. injection (2DG) or infusion of the tracer (IAP), while the arterial catheter is needed to withdraw timed blood samples for the quantification of the temporal evolution of the specific activity of the tracer in blood. In the adult rat, the insertion of catheters does not present any technical difficulty and the volume of blood is sufficient to allow for repetitive sampling, with no significant consequences on the health status of the animals. However, in immature rats (or in mice), it was more difficult to insert the catheters; this difficulty is compounded in immature animals, where the small size of the vessels is combined with the immaturity of the vessel (especially the vein) wall. Moreover, because of the small body blood volume, it is necessary to reduce the volume and number of the samples.

The choice of the technique of interest is also limited by temporal resolution. While LCBF can be measured over very short durations ranging from 20 to 60 s, the quantification of LCMRglcs requires a 45-min period of stable metabolism, which is impossible to achieve with events like short seizures. This limitation has led some authors to use the 2DG technique to map brain metabolism during seizures in a nonquantitative manner. In this latter case, data are expressed as ratios – of the optical density of the structure of interest over that of a structure that is supposed to remain unchanged (most often the corpus callosum or the cerebellum). However, this semiquantitative approach should not be used over too short durations; longer durations are needed to minimize potential errors because of a large proportion of free 2DG present in blood and brain tissue at the time of sacrifice. When studying short events, it is preferable to choose alternate methods like the autoradiographic measurement of LCBF, which can be quantified over very short durations.

^{13}C Nuclear Magnetic Resonance Spectroscopy

The study of neuronal/astrocytic metabolism and the interactions between cell types can be studied using ^{13}C NMRS. Acetate is selectively taken up by astrocytes, while glucose is considered to be mainly metabolized by the neuronal tricarboxylic acid cycle. Thus, the simultaneous injection of ^{13}C-labeled acetate and glucose, and NMRS analysis of brain extracts, gives information on the neuronal and astrocytic metabolism in the same animal. It allows experimenters, also, to study the fluxes and exchanges of amino acid transmitters between neuronal and glial compartments. Indeed, as a result of neurotransmission, the neuronal compartment constantly loses intermediates such as glutamate and GABA that need to be rapidly cleared from the synaptic cleft. A large proportion of the two neurotransmitters is taken up by glial cells. In astrocytes, GABA and glutamate are converted to glutamine by glutamine synthetase, a glia-specific enzyme. Glutamine is shuttled back to neurons, where it is broken down to glutamate and GABA. This pathway is known as the GABA–glutamate–glutamine cycle. In this context, ^{13}C NMRS is a very useful technique for studying metabolic compartmentation, and changes in glutamate and GABA metabolism, in animal models of epilepsy as well as in human epileptic patients.

Results

In our laboratory, we have mainly focused on seizure- and epilepsy-induced changes in brain metabolism and blood flow. We have used these changes as a means of delineating the seizure circuits, and as a method of determining the vulnerability of the different brain structures, especially within the immature brain. Our interest has been focused on three types of seizures or epilepsy models: (1) primarily generalized seizures, as produced in the pentylenetetrazol (PTZ) model; (2) idiopathic generalized absence epilepsy, as seen in Genetic Absence Epilepsy Rats from Strasbourg (GAERS); and (3) temporal lobe epilepsy induced by the systemic injection of lithium and pilocarpine. In all our studies, we have focused on age-related changes in the response of the brain to, and long-term consequences of, the seizures or the epilepsy.

The Pentylenetetrazol Model of Seizures and Status Epilepticus

In the pentylenetetrazol (PTZ) model of status epilepticus (SE), induced by repetitive injections of low doses of the convulsant, the pattern of metabolic activation varies with age of the animal. At very young ages (postnatal day (PN) 10 and PN14), continuous seizures induced widespread, general activation of all brain structures. The largest metabolic increases occurred in brainstem regions, involved in seizure circuits and the control of autonomic functions essential for survival. In PN17 and PN21 rats, LCMRglcs also showed the greatest increase in most brainstem regions, but were either similar to or lower than control values in most anterior regions (Figure 1). These low values could reflect a redistribution of high levels of activity to the posterior brain regions that are critical for survival, as also reported by another group in the newborn marmoset monkey subjected to status epilepticus. Conversely, the younger (PN10 and PN14) rat brain can sustain prolonged activation without this adaptation for redistribution. Prolonged and sustained PTZ-induced seizures did not lead to brain damage in any of the 4 ages studied, but long-term decreases in LCMRglc were recorded, which reflect plasticity-induced functional changes, as also recorded by other groups in the absence of neuronal loss. Long-term functional consequences were more widespread when SE was induced at PN21 than at PN10. This difference is consistent with the widely reported higher vulnerability of the brain of the weanling compared with the suckling rat.

Metabolic Activation in a Genetic Model of Idiopathic Absence Epilepsy: The GAERS

The quantitative 2DG technique was applied to the measurement of LCMRglc in GAERS. These rats are characterized by the spontaneous occurrence of absence seizures accompanied by spike-and-wave discharges (SWD) on the EEG, occurring within a thalamocortical loop. When measured in adult rats in the basal situation (a period in which there is a mixture of ictal and interictal events), LCMRglc showed widespread increases in all brain regions – as also seen in patients with childhood absence epilepsy – although the seizure circuit is limited to a thalamocortical pathway. The metabolic increases seem to occur during the interictal phases rather than during seizures, as confirmed by continuous recording of LCBF by Laserflow Doppler. In the GAERS strain, absence seizures appear at 30–40 days postnatal. Their frequency and duration increases, up to 3–4 months of

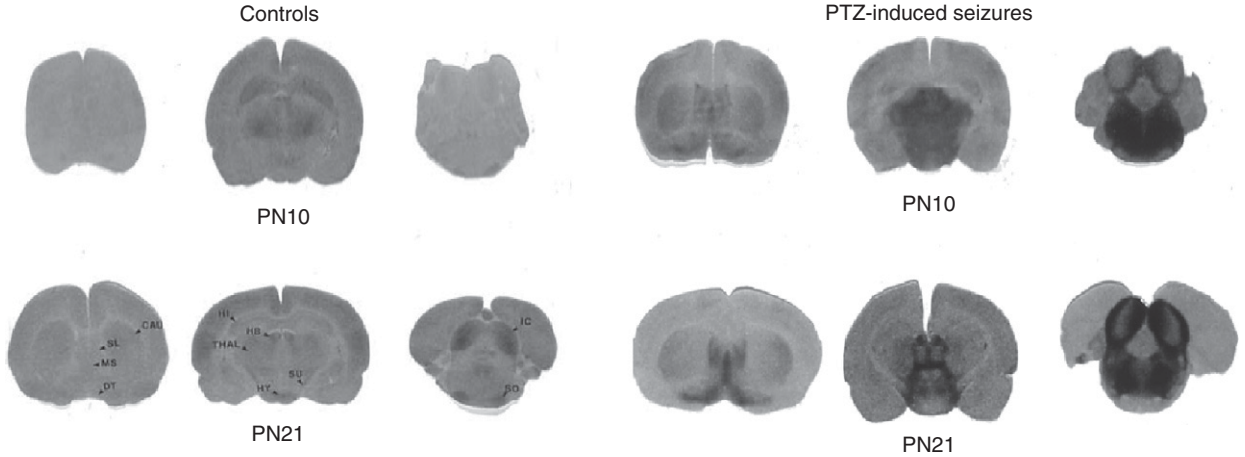

Figure 1 Age-related increases in LCMRglcs induced by prolonged pentylenetetrazol (PTZ) seizures. The response to seizures is quite homogeneous in the very immature PN10 rat brain involving mostly subcortical regions at all anteroposterior brain levels. In PN21 rats, LCMRglcs are no longer increased by seizures, even decreased compared to control levels in some forebrain regions, or regionally very heterogeneous as in thalamus. Conversely, at the brainstem level, marked metabolic increases are indicative of a redistribution of LCMRglcs in favor of vital regions mediating cardiorespiratory functions.

age, and then remains stable until the animal's death. In PN21 rats, i.e., before the occurrence of SWDs, LCMRglcs are only increased in a limited number of structures, mainly limbic regions in which SWDs are never recorded and structures belonging to the nigral system of seizure control. This finding points to the high sensitivity of limbic regions to seizure events and to cellular events preceding the occurrence of the seizure – which presumably already activate the nigral system of seizure control in these young animals.

Likewise, before the onset of SWDs, the interactions between glutamatergic neurons and astrocytes, assessed by NMRS using [1–^{13}C]glucose and [1,2–^{13}C]acetate, appear normal. In contrast, increased astrocytic metabolism takes place in adult GAERS, suggesting that astrocytic alterations could possibly be the cause of seizures. Consequently, we have hypothesized that in this rat model, seizures appear with maturation when cortical metabolism is sufficiently enhanced – and accompanied by a slight reduction in inhibitory neurotransmission, as reflected by reduced glutamine supply to GABAergic neurons.

Temporal Lobe Epilepsy: Insights from the Lithium-Pilocarpine Model

The incomplete maturation of brain structures and connections leads to age-dependent clinical seizure expression. This age-dependency is of particular relevance, since in human temporal lobe epilepsy, an initial injury occurs most often before the age of 4 years. In the lithium-pilocarpine model of SE, the initial SE induced by the chemoconvulsant leads to age-dependent neuronal loss and spontaneous seizures (or no epilepsy) after a latent phase. During SE, LCMRglcs vary with postnatal age. In PN10 rats, pilocarpine-induced SE leads to functional activation in many forebrain regions – but not in hypothalamic and thalamic nuclei. In PN21 and adult rats, increases in LCMRglc are generalized and quite dramatic in the cerebral cortex (mainly entorhinal and piriform), the hippocampus, amygdala, septum, and thalamus, while the brainstem is less activated. The largest increases occur in cortical and hippocampal regions (**Figure 2**).

Other groups have mapped LCMRglcs in immature rats subjected to kainate SE, and have emphasized the age-related maturation of the structures involved in seizure circuits. However, none of these studies was performed in a quantitative manner. In rats less than 3 weeks old, the pattern of brain activation is limited to the hippocampus and septum, reflecting the distribution of paroxysmal discharges. By the end of the third week, when kainate leads to limbic motor seizures, other regions are activated, and metabolic maps become similar to adult ones. This evolution reflects mainly the maturation of limbic circuits, which allows the propagation of seizures to extrahippocampal and subcortical sites.

The active and sustained metabolic increase associated with SE usually leads to neuronal death. In adult rats, pilocarpine-induced (and also kainate-induced) seizures lead to widespread brain damage, mainly in hippocampus, amygdala, septum, entorhinal and piriform cortex – where the largest metabolic increases are recorded. When SE is induced in rats between PN10 and PN18, the activation of a limited number of brain regions is associated with no or quite limited brain damage. In PN21 rats, neuronal loss is limited to entorhinal cortex, lateral thalamus, amygdala, and the hilus of the dentate gyrus.

There are distinct age-related differences in the long-term metabolic consequences of lithium-pilocarpine SE. In PN10 rats, in which no overt damage and no epilepsy develop, SE has no long-term metabolic consequences. Conversely, some PN21 rats and all adult rats will become epileptic after a latent phase. At these two ages, LCMRglcs are decreased during the latent and chronic phases in the hippocampus, amygdala, thalamus and

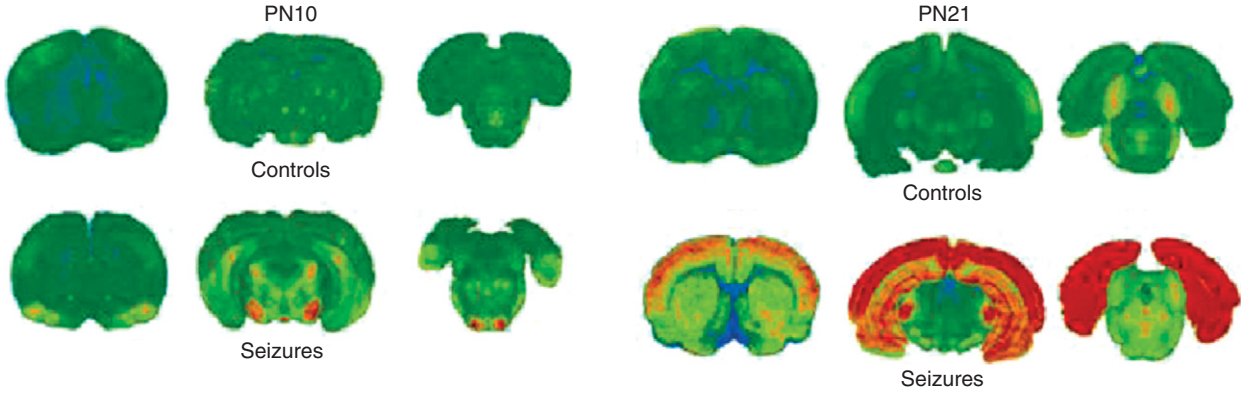

Figure 2 Age-related increases in LCMRglcs induced by prolonged lithium-pilocarpine seizures. In PN10 rats, seizures induce moderate increases in LCMRglcs compared with the response in PN21 rats. Increases are quite marked in cortical and hippocampal regions and less marked in subcortical areas. They are also more pronounced in anterior regions than in posterior regions and absent in thalamus of PN10 rats.

entorhinal cortex – even though the SE-related neuronal loss is limited to the lateral thalamus and hilus in PN21 rats. However, the most striking feature is the mismatch between the number of neurons surviving in the hilus – which is very low at both ages – and the level of metabolic activity – which is close to normal at both ages. This mismatch suggests a major role of the hilus in the initiation and maintenance of epilepsy.

Coupling Between Cerebral Blood Flow and Metabolism During Seizures and Its Relation with Neuronal Damage

In adult and immature animals and humans, LCMRglcs and LCBF are tightly coupled in most situations. In adult animals, LCBF rates and LCMRglcs usually increase to a similar degree during the early phase of seizures. In vulnerable structures undergoing neuronal damage (such as the hippocampus, cerebral cortex and thalamus), this early increase is followed by a pronounced mismatch between LCBF and LCMRglcs, the latter remaining elevated while the former is lower than the control levels (Figure 3). This mismatch can be found in the whole forebrain of both immature and adult rats, whether neuronal loss occurs or not. Hence, despite an extended flow-metabolism mismatch, neuronal loss in PN21 rats is only found in a few regions; and in PN10 rats, SE does not lead to neuronal loss. In posterior regions of the brain (i.e., brainstem), there is no mismatch between LCBF and LCMRglcs and no SE-related neuronal death at any age. Thus, in the lithium-pilocarpine model, marked hypoperfusion during SE correlates well with neuronal damage in adult rats, correlates only partly in PN21 rats, and does not correlate at all in PN10 rats. Although the mechanisms underlying the resistance of the immature brain to brain damage are unknown, the age-related differences in the consequences of the flow-metabolism mismatch calls into question the role of this mismatch in neuronal loss. These changes in cerebral functional activity are rather the consequence of SE-related cellular activation. The cellular and molecular events occurring during SE differ in nature and severity according to maturation, and these differences clearly underlie the variability in extent of neuronal death.

Transport of Nutrients Between Blood and Brain

Nutrient delivery to the brain is mediated by transporter proteins, GLUT1 and GLUT3 for glucose and mainly MCT1 and MCT2 for lactate and other monocarboxylic acids. GLUT1 and GLUT3 density is low in the immature brain and progressively increases concurrently with LCMRglcs. Conversely, the vascular expression of MCT1 peaks during suckling and declines with maturation, while nonvascular MCT1 and MCT2 stay at a constant level. Sustained seizures largely increase LCMRglcs, and a limited rate of glucose transport has been considered as a possible cause of neuronal death, especially in the immature brain. We have shown that during lithium-pilocarpine SE,

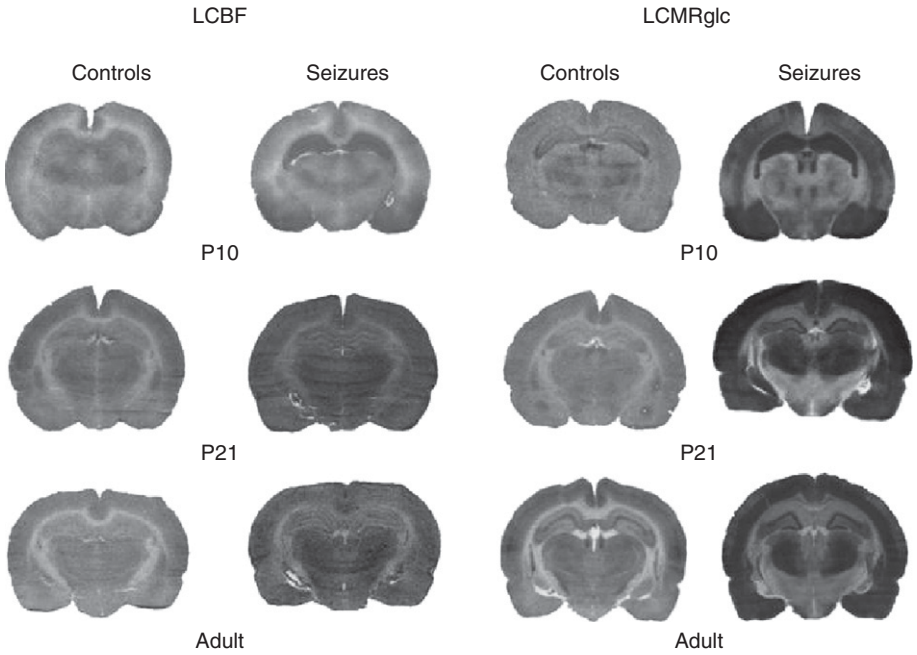

Figure 3 Age-related changes in metabolism-flow coupling induced by prolonged lithium-pilocarpine seizures. As illustrated in Figure 2, LCMRglcs increase with seizures at all ages, mainly in PN21 and adult rats while changes in LCBF rates do not match at any age the striking increases in metabolic demand leading to a mismatch between blood flow and metabolism. This seizure-induced hypoperfusion is regionally coupled with neuronal loss in adult but not immature rats.

the blood–brain barrier GLUT1 transporter undergoes widespread increases particularly in adult rats, and the neuronal GLUT3 transporter is upregulated mainly in PN10 rats. The vascular MCT1 transporter is upregulated at all ages, but 5–10 times more so in adult than in immature rats; MCT2 expression increases mainly in adult rats. Altogether, the upregulation of nutrient transporters appears to be quite well regulated to respond to the large energetic demand occurring during SE, and to the potentially large accumulation of lactate as a result of glucose metabolism that can be extruded from the brain. During the latent and chronic phases, changes in nutrient transporter expression generally reflect neuronal loss.

Future Directions

Most of the data obtained to date in the measurement of metabolic and hemodynamic changes in the immature and mature brain during seizures originate in studies using autoradiography. These techniques have proven to be very useful and to achieve a very good resolution. However, these techniques require that the experimental animal be sacrificed at each time-point studied. Therefore, the number of animals necessary to run these studies is very large, and no temporal follow-up can be conducted on the same animal. Alternative methods that would allow longitudinal tracking of pathological changes in a given animal include positron emission tomography (PET) and single photon computed emission tomography (SPECT) imaging, and functional magnetic resonance imaging (fMRI).

PET detects positron emission from selected radionucleotides. The miniaturization of PET devices has led to the development of a commercially available 'micro-PET' instrument. For the measurement of brain metabolism, [^{18}F]fluorodeoxyglucose (FDG) – which has a relatively long half-life (110 min) – is usually used. The micro-PET imaging technology has thus far had limited application to animal models of epilepsy. Micro-SPECT has been used in preclinical studies, but not yet for following blood flow changes in epileptic animals. The major limitation in the use of micro-PET and micro-SPECT in rats are their relatively poor spatial and temporal resolution. Hopefully, the resolution of both technologies will improve, and hence provide additional methods for the temporal follow-up of the evolution of seizure circuits in single animals, providing data that can be combined with the precise information obtained with autoradiography.

The fMRI technique reflects altered metabolic neuronal activity, and the method has recently been extended to the study of epilepsy in animal models. In general, fMRI measures increased blood flow as a reporter of increased neuronal activity. Blood-oxygen-level-dependent (BOLD) fMRI uses the oxygenation status of hemoglobin as the 'contrast' reporter. Altered BOLD signal changes have been reported in the thalamus and cortex after administration of γ-hydroxybutyric acid (a chemical model of absence seizures) and in a genetic strain of absence epilepsy.

Introduction

Epilepsy is a term used for several chronic neurological syndromes characterized by abnormal and inappropriate neuronal activity and synchrony. Often the neuronal synchrony is so widespread in the brain that consciousness is impaired. The particular neurons that are affected, the particular neuronal abnormalities, the particular connections that are affected, and the particular synaptic (or non-synaptic) abnormalities appear to be at least as varied as the number of named epilepsy syndromes.

The study of the basic mechanisms of epilepsy has benefited from the use of many different in vitro experimental preparations, including the intact whole-brain model and progressively more 'reduced' preparations such as brain slices, acutely dissociated neurons, neuron fragments (e.g., dendritic fragments), and single channel patch preparations. The cells in the acutely dissociated neuron preparation remain sufficiently intact for studies of many kinds of cellular activity, including action potentials, voltage-gated currents, and currents associated with activation of specific ionotropic or metabotropic receptor/transmitter systems. The acutely dissociated neuron preparation is particularly well-suited for some types of investigations that focus on the intrinsic properties of neurons or their responsiveness to activation of specific receptors. There are, in addition, several advantages to recordings from dissociated cells as compared with recordings from single neurons embedded within intact brains or brain slices or single neurons in culture. Those advantages will be discussed and exemplified in this article.

Background - The Pros and the Cons

Most studies using the acutely dissociated cell are attempts to understand the roles of ion channels in action potential generation and patterning. Such studies of ionic

The Emerging Role of Mitochondrial Dysfunction and Oxidative Stress in Epilepsy

M Patel and L P Liang, University of Colorado Health Sciences Center, Denver, Colorado, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

To date only a minority of epilepsy research has been focused on mitochondria. However, recent advances provide compelling evidence of mitochondrial involvement in the epilepsies. Direct mitochondrial dysfunction is associated with a small percentage of inherited epilepsies – e.g., mitochondrial encephalopathies. A role of mitochondria in acquired epilepsies, which account for ~60% of all epilepsy cases, remains to be fully explored. Temporal lobe epilepsy (TLE) is the most notable example of acquired epilepsy usually preceded by injury such as episode(s) of prolonged seizures or status epilepticus (SE), childhood febrile seizures, hypoxia, or trauma. These initial insults are thought to set in motion complex molecular, biochemical, and structural changes that culminate in the development of spontaneous recurring seizures, or 'epileptogenesis.' Since injury per se can set in motion molecular events that trigger the epileptic condition, it is important to understand the biochemical causes and consequences of epileptic seizures. Identifying these biochemical mechanisms may lead to therapies that interrupt the process of epileptogenesis.

Background

Several major features of the epileptic phenotype suggest that mitochondrial involvement may not be a mere epiphenomenon, but rather a key event contributing to the initiation and progression of TLE. Mitochondria are intimately involved in important cellular events that are leading candidate mechanisms of hyperexcitability and/or its consequences. These potential mechanisms include metabolic and bioenergetic changes associated with seizure activity, the involvement of mitochondria in the processes underlying seizure-induced cell loss (i.e., excitotoxicity and apoptosis), mitochondrial regulation of amino-acid cycling, neurotransmitter biosynthesis, and ionic homeostasis, particularly calcium buffering. Another important reason to consider mitochondrial mechanisms, particularly the involvement of oxidative stress in epilepsy, is the knowledge that the incidence of epilepsy abruptly rises with advancing age; mitochondrial oxidative stress is a leading mechanism of aging and age-related degenerative disease.

The most compelling evidence for mitochondrial (dys) function in epilepsy is the recognition that dramatic metabolic and bioenergetic changes occur following acute seizures and during different phases of chronic epilepsy (**Figure 1**). The acute consequence of seizures associated with SE is an increase in cellular glucose uptake and metabolism that is unparalleled by most conditions. Cerebral blood flow is increased to match this hypermetabolism; since the increased rate of glycolysis exceeds pyruvate utilization by pyruvate dehydrogenase, there is an increased lactate buildup. While *hyper*metabolism occurs in human epileptic foci during ictal phases (seizure episodes), *hypo*metabolism is prevalent during interictal phases (between seizure episodes). A bioenergetic defect is also evident in the measurement of ^{31}P and the loss of mitochondrial *N*-acetyl aspartate in human epileptic tissue, suggesting the involvement of mitochondria in altered neurotransmitter metabolism. Severe metabolic dysfunction characterized by biphasic abnormal NAD(P)H fluorescence transients and changes in mitochondrial membrane potential (dsm) have been observed in ex vivo preparations from both chronically epileptic rats and human subjects. The mechanisms of both hypometabolism and hypermetabolism in seizure-induced brain damage, and in subsequent development of epilepsy, need to be determined.

Methodological Approaches and Recent Results

Oxidative Stress and Mitochondrial Dysfunction: Acute Consequences of Epileptic Seizures

ROS and reactive nitrogen species (RNS) are thought to play important roles in diverse nervous system disorders

such as stroke, spinal cord injury, Parkinson's disease, Alzheimer's disease, Huntington's disease, Freidrich's ataxia, and amyotrophic lateral sclerosis (ALS). A role for ROS in seizure-induced neuronal death is supported in part by the observations that prolonged seizures result in increased oxidation of cellular macromolecules and compounds with antioxidant properties (superoxide dismutase (SOD) mimetics, vitamin C, spin traps, and melatonin) prevent seizure-induced pathology. Moreover, oxidative stress is thought to be an important consequence of excitotoxicity, which plays a critical role in epileptic brain damage. Finally, seizure-induced neuronal death involves overlapping processes of necrosis and apoptosis, which are strongly influenced by mitochondrial function and oxidative stress. Seizure activity initiates the mitochondrial pathway of apoptosis via involvement of proapoptotic factors, cytochrome c translocation, and caspase-3/9 activation. The following sections review the studies demonstrating oxidative stress following acute SE.

Mitochondrial ROS Production

Since reactive species are transient, unstable, and localized to cellular compartments, methodological assessment of ROS in biological systems in vivo is challenging. One approach has been the use of surrogate markers in vivo that are easily modified by ROS and are stable enough to be analyzed by reliable quantitative methods. Seizure-induced oxidative damage to susceptible targets (proteins, lipids, and DNA) has been assessed following chemoconvulsant-induced SE. The presence of a labile iron motif in the iron–sulfur (Fe–S) center of cytosolic and mitochondrial aconitase(s) renders them sensitive to O_2^- and related species, allowing the measurement of aconitase activity to serve as an index of steady-state O_2^- levels. Measurement of O_2^- production using endogenous aconitase inactivation as a surrogate marker has several advantages in that it is highly sensitive to inactivation by O_2^-, relatively specific for O_2^- and allows estimation of compartmentalized (mitochondrial or cytosolic) O_2^- production. The usefulness of aconitase inactivation is evident by the demonstration that brain and heart mitochondrial aconitase activity is drastically diminished in Sod2 homozygous knockout (Sod2−/−) mice. One disadvantage of using an endogenous marker such as aconitase is that its synthesis may be regulated, particularly during chronic studies. Since oxidative inactivation is a posttranslational event, this problem may be overcome by measurement of apoprotein levels in addition to enzyme activity. Another disadvantage is the sensitivity of aconitase to multiple reactive species; therefore, aconitase inactivation necessitates verification of the inactivating species by multiple approaches (e.g., examining mutant mice, use of specific scavengers).

In rats, kainate-induced seizures inactivate O_2^- susceptible mitochondrial aconitase but not oxidatively stable fumarase. This inactivation is specific for the mitochondrial aconitase, and not its cytosolic counterpart that is also sensitive to O_2^-, implicating mitochondria as the major site of seizure-induced O_2^- production. Maximal inactivation of mitochondrial aconitase occurs several hours after the cessation of SE (16 h post kainate injection) and at times preceding the death of susceptible hippocampal neurons. Kainate-induced mitochondrial aconitase inactivation and hippocampal neuronal loss are attenuated in transgenic mice overexpressing Sod2 and exacerbated in mice partially deficient in Sod2. Manganese (III) tetrakis (4-benzoic acid) porphyrin (MnTBAP), a broad spectrum antioxidant, protects rats against seizure-induced mitochondrial aconitase inactivation and hippocampal damage without decreasing behavioral seizure intensity or frequency. These findings support a role for mitochondrial O_2^- in hippocampal pathology produced by kainate-induced seizures. Furthermore, seizure-induced O_2^- production has been demonstrated by hydroethidium staining in the rat model of lithium/pilocarpine-induced SE. Other mitochondrial enzymes with high susceptibility to ROS include α-ketoglutarate dehydrogenase, the activity of which is also decreased following pilocarpine-induced seizures.

Lipid Peroxidation

Polyunsaturated lipids are highly susceptible to oxidation and their diverse products have been used as markers to indicate oxidative stress in vitro and in vivo. Seizure-induced lipid peroxidation has been shown to occur by the measurement of end-products such as thiobarbituric acid reactive substances and F_2-isoprostanes (F_2-IsoPs). F_2-IsoPs are a novel class of prostaglandin F_2 (PGF_2)-like compounds, produced in vivo by a noncyclooxygenase and free-radical-catalyzed mechanism involving the peroxidation of arachidonic acid. F_2-IsoPs are a validated sensitive, stable, and reliable marker of free radical-induced lipid peroxidation in vivo. Prolonged seizures produce a large increase in prostaglandin derivatives, including prostaglandin-$F_2\alpha$, a precursor of F_2-IsoP. In adult rats, kainate-induced SE produces a large subregion-specific increase in F_2-IsoP levels in the highly vulnerable CA3 region prior to cell damage. Interestingly, the dentate gyrus, a region that contains granule neurons that are resistant to kainate-induced neuronal death also shows marked increases in F_2-IsoP levels. Recently, novel products of free radical-mediated peroxidation of arachidonic acid were discovered that have a substituted tetrahydrofuran ring, which have been termed 'isofurans' (IsoFs). Interestingly, it was shown that the formation of IsoFs and F_2-IsoPs are differentially modulated by oxygen

tension; high oxygen tension favors the formation of IsoFs whereas the formation of F_2-IsoPs is favored at low oxygen tension. SE-induced IsoF formation occurs with overlapping but distinct time courses as F_2-IsoP formation in hippocampal subregions. IsoF, but not F_2-IsoP, formation coincides with other indices of mitochondrial oxidative stress. SE resulted in a transient decrease in hippocampal pO_2 measured by in vivo electron paramagnetic resonance oximetry, suggesting an early phase of seizure-induced hypoxia. Whereas SE-induced F_2-IsoP formation coincided with the peak hypoxia phase, IsoF formation coincided with the 're-oxygenation' phase. It remains to be determined whether these potentially bioactive lipid derivatives exert a cytotoxic or signaling role in response to seizure activity and if mitochondrial oxidative stress contributes to their formation.

Oxidative DNA Lesions

Seizure-induced oxidative DNA damage has been demonstrated by using the measurement of 8-hydroxy-2-deoxyguanosine (8-OHdG), an oxidatively modified guanine adduct, as an index of oxidative DNA damage. The ratio of steady-state levels of 8-OHdG to 2-deoxyguanine (2-dG) reflects oxidative DNA damage. Kainate administration in adult rats produces a large increase in the ratio of oxidized:nonoxidized bases (8-OHdG:2dG) at times preceding overt cell death, suggesting a potential role for oxidative DNA damage in the sequence of events leading to seizure-induced neuronal death. More recent studies confirm that mitochondrial, not nuclear DNA is the source of this seizure-induced change in 8-OHdG levels, as would be expected by the close proximity of mitochondrial DNA to the major source of O_2^- production, i.e., the electron transport chain (ETC), which accounts for the several fold higher oxidized DNA bases in mitochondrial DNA in comparison to nuclear DNA. Direct damage to the mitochondrial genome and base excision repair of the lesion are major consequences of increasing the steady-state levels of 8-OHdG. Recent studies in our laboratory suggest that both mtDNA damage and repair is activated by SE.

Redox Status

In addition to the measurement of oxidatively modified cellular targets as indicators of oxidative stress, another approach has been to directly determine the subcellular redox status by measuring a redox couple such as glutathione (GSH) and its disulfide (GSSG). Decreased levels of GSH have been observed in the parietooccipital region of the brain and in the plasma of epilepsy patients. Although some studies have shown decreased GSH levels in hippocampal tissue early following SE in animal models, others have reported no changes. Studies in our laboratory demonstrated a time-dependent decrease in GSH/GSSG ratios predominantly in the mitochondrial fractions compared with whole hippocampal homogenates. This decrease in GSH/GSSG ratio was accompanied by a mild increase in GSH peroxidase activity and a decrease in GSH reductase activity in hippocampal homogenates and mitochondria, respectively. Since coenzyme A (CoASH) and its disulfide with GSH (CoASSG) are primarily compartmentalized within mitochondria, their measurement in whole tissue homogenates was undertaken to overcome problems associated with GSH/GSSG measurement following subcellular fractionation. Hippocampal tissue CoASH/CoASSG ratios were decreased following kainate-induced SE; the time-course and magnitude of change paralleled mitochondrial GSH/GSSG levels. Cysteine, a rate-limiting precursor of GSH, was also decreased following SE in both hippocampal tissue homogenates and mitochondrial fractions. These changes in altered redox status provide further evidence for seizure-induced mitochondrial oxidative stress. The increased mitochondrial GSSG that was formed following SE in situ under conditions of oxidative stress may become available to exert local injury. Additionally, decreased ratios of GSH/GSSG could induce structural damage to mitochondrial membranes, changes in mitochondrial enzyme activities, and mitochondrial dysfunction.

Relationship to Neuronal Vulnerability and Age

In general, oxidative damage occurs to a greater extent in brain areas that are vulnerable to kainate-induced brain damage (hippocampal area CA3, CA1, and piriform cortex) than in resistant areas (dentate gyrus and cerebellum). Further, seizure-induced mitochondrial oxidative stress shows a strong developmental regulation, which may explain the age-related vulnerability of the brain to seizure-induced brain damage. The higher expression of uncoupling protein-2 (UCP-2) in the neonatal brain than in the adult brain was shown to be an underlying factor that renders the neonatal brain more resistant to seizure-induced free-radical production and neuronal injury. Advancing age, which renders animals more susceptible to seizure-induced mortality, also modulates the response to oxidative stress. For example, an otherwise subtoxic dose of kainate in young adult rats resulted in significant oxidative damage to aged rats.

Verification in SOD Transgenic/Knockout Mice

An additional approach for assessing the role of oxidative stress in seizure-induced brain damage is the use of SOD mutant mice. Although oxidized proteins, lipids, and DNA are useful surrogate markers for detecting the presence of oxidative stress, it is difficult to identify precisely

the reactive species and its cellular source. Hippocampal damage produced by local application of kainate in transgenic and knockout mice of the three endogenous SODs – in the cytoplasm (CuZnSOD or Sod1), mitochondria (MnSOD or Sod2), and extracellular compartment (EC-SOD or Sod3) – showed that overexpression of Sod2 (and to a lesser extent Sod3, but not Sod1) was protective. Moreover, mice overexpressing Sod2 were protected against kainate-induced mitochondrial aconitase inactivation and hippocampal cell death, whereas mice with partial Sod2 deficiency (Sod2−/+) showed exacerbation of these effects. A caveat associated with the use of mutant mice to study mechanisms of seizure-induced cell loss is the sensitivity of the genetic background strain to the injury. To circumvent this strain-sensitivity necessitates the use of intracerebral rather than systemic administration of kainic acid. Together with the demonstration that seizures inactivate mitochondrial, not cytosolic aconitase, these studies have suggested that mitochondria play a disproportionately greater role in seizure-induced O_2^- production (compared with cytosolic aconitase).

Mitochondrial Dysfunction Following Acute and Chronic SE

These studies demonstrate that prolonged seizures acutely result in oxidative damage to lipids, DNA, and susceptible proteins. However, whether oxidative stress and/or mitochondrial dysfunction occur several weeks after SE is unknown. This issue has been addressed by assessing mitochondrial dysfunction several weeks following pilocarpine-induced SE. They showed that the activities of complexes I and IV of the ETC decreased, and complex II increased, one month after piloparpine SE. These changes were accompanied by lowered mitochondrial membrane potential measured by rhodamine123 fluorescence in the CA1 and CA3 areas. The authors attributed these changes to decreased mitochondrial DNA copy number that results in down-regulation of oxidative phosphorylation (OXPHOS) enzymes encoded by mtDNA. These studies suggest that the acute effects of SE – i.e., increased mitochondrial oxidative stress – may result over time in oxidative damage to mtDNA (as suggested by increased levels of 8-OHdG) and decreased expression of mitochondrially encoded proteins required for the functioning of the ETC. Seizure-induced accumulation of oxidative mitochondrial DNA lesions and resultant somatic mtDNA mutations could, over a period of time, render the brain more susceptible to subsequent epileptic seizures, particularly in the context of advancing age. A link between mitochondrial dysfunction and epilepsy is strengthened by the finding that some patients with TLE show mitochondrial complex I deficiency in the seizure foci, which is the leading cause of increased O_2^- production and mitochondrial dysfunction in patients with Parkinson's disease. In addition to pilocarpine-induced seizures, inhibition of complex I has also been observed in homocysteic acid-induced seizures. Furthermore, ultrastructural damage to the mitochondria has been observed in the hippocampus of both kainic acid- and pilocarpine-treated epileptic rats.

Mechanistic studies assessing the role of mitochondrial functions on neuronal excitability have been attempted by measuring seizure-like events (SLEs) in hippocampal explant cultures. The SLEs, usually generated by a combination of electrical stimulation of the axons of the granule cells (i.e., the mossy fibers) and lowering the Mg^{2+} concentration in the bathing media (0 Mg^{2+}) to relieve the voltage-dependent Mg^{2+} blockade of the NMDA receptors, are associated with increased mitochondrial calcium accumulation, mitochondrial depolarization, decreased nicotinamide adenine dinucloetide [NAD(P)H] autofluoresence, and O_2^- generation. O_2^- production measured by hydroethidium progressively increases during, and with each consecutive SLE, along with increases of both cytosolic and mitochondrial calcium, thus providing a link between mitochondrial calcium, free-radical production, and neuronal death.

Mitochondrial Dysfunction and Neuronal Excitability

Although mitochondrial dysfunction is an acute consequence of epileptic seizures, whether mitochondrial dysfunction can be a causative factor in acquired epilepsies is unknown. The precedence for mitochondrial dysfunction producing epilepsy has already been established from our knowledge regarding the molecular basis of certain inherited epilepsies – i.e., the mitochondrial encephalopathies. The most prominent example of mitochondrial dysfunction causing epilepsy is the occurrence of epilepsy in mitochondrial disorders due to mutations in mitochondrial DNA (mtDNA) or nuclear DNA. For example, myoclonic epilepsy with ragged red fibers (MERRFs) is a syndrome in which a single mutation of the mitochondrially encoded $tRNA^{lys}$ results in a disorder consisting of myoclonic epilepsy and a characteristic myopathy with ragged red fibers. Defects in complex I and complex IV of mitochondrial OXPHOS are the leading mechanisms by which this mitochondrial gene mutation produces MERRF. Several normal functions of mitochondria, ranging from its bioenergetic functions to metabolic functions, can impact neuronal excitability. These include cellular ATP production, ROS formation, synthesis and metabolism of neurotransmitters, fatty-acid oxidation, calcium homeostasis, and control of apoptosis/necrotic cell death. These vital functions are closely interrelated, and which of these factors contributes to the seizures associated with mitochondrial dysfunction remains unclear.

Several common neurological insults such as hypoxia, trauma, and aging, as well as several neuronal diseases such as stroke and Alzheimer's disease render the brain susceptible to epileptic seizures. Further, although epilepsy occurs in all age groups, the incidence of epilepsy is markedly increased in the elderly. Oxidative stress and mitochondrial dysfunction is common to each of these conditions. Seizure activity can be induced by paradigms (e.g., increased oxygen tension (hyperbaric hyperoxia) and local infusion of redox-active iron salts or mitochondrial toxins) that are capable of producing mitochondrial oxidative stress and dysfunction. Thus, mitochondrial dysfunction initiated by free-radical production could contribute to lesion-induced hyperexcitabililty. In studying this relationship, mice partially deficient in Sod2 (Sod2−/+) are particularly useful because they provide a model of sublethal chronic elevation of mitochondrial O_2^- to test the hypothesis. Work from our laboratory provides experimental evidence linking mitochondrial oxidative stress with increased seizure susceptibility induced by aging, environmental stimulation, or kainate administration. Whereas Sod2−/− mice show extensive mitochondrial dysfunction and behavioral phenotypes such as ataxia and seizures before neonatal death, Sod2−/+ mice appear both biochemically and phenotypically normal at birth but develop age-related deficits consistent with chronic mitochondrial oxidative stress. A subset of Sod2−/+ mice developed spontaneous and handling-induced seizures as a function of advancing age. The age-related onset of seizures in Sod2−/+ mice correlated with increased mitochondrial oxidative stress (mitochondrial aconitase inactivation and mitochondrial, but not nuclear 8OHdG formation) and mitochondrial dysfunction as measured by O_2 utilization. Prior to the age at which spontaneous and handling-induced seizures occurred, Sod2−/+ mice showed increased susceptibility to kainate-induced seizures and hippocampal cell loss.

Although several factors associated with mitochondrial dysfunction have the ability to enhance seizure susceptibility in Sod2−/+ mice, the most likely suspects include targets sensitive to oxidative insults that raise plasma membrane excitability. We therefore examined the high affinity astroglial and neuronal glutamate transporters, based on their known sensitivity to oxidative damage and their crucial role in maintaining low levels of synaptic glutamate from reaching neurotoxic levels. Sod2−/+ mice show an age-dependent decrease in the hippocampal expression of glial glutamate transporters (GLT-1 and GLAST), which may explain the increased vulnerability of these mice to epileptic seizures. Chronic O_2^- production in the mitochondrial matrix can be rapidly converted to H_2O_2 by dismutation and Fe–S inactivation. Unlike O_2^-, H_2O_2 is freely permeable across cellular membranes and can be generated on an equimolar amount as O_2^- by oxidative inactivation of mitochondrial aconitase, which also showed parallel age-related decline in Sod2−/+ mice. H_2O_2 generated in this manner could oxidize astroglial glutamate transporters and lead to their decreased expression. These results suggest that mitochondrial oxidative stress and resultant dysfunction is sufficient to increase seizure susceptibility. Given the dependence of neurotransmitter and ion transport systems on ATP, depletion of ATP may be another important independent factor contributing to increased seizure susceptibility associated with mitochondrial dysfunction.

Therapeutic Implications and Future Challenges

Therapies for the epilepsies are largely aimed at decreasing neuronal excitability and thereby controlling the occurrence of epileptic seizures. A recent therapeutic approach is to search for antiepileptogenic, rather than antiepileptic, drugs that would target underlying processes that lead to the development of epilepsy. Testing antiepileptogenic therapies aimed at mitochondrial bioenergetics and oxidative stress pathways has, to date, been largely limited to animal studies. Clinical trials of vitamin E as an add-on therapy for refractory epilepsy have been controversial, with largely failed attempts to influence the occurrence of epileptic seizures in pediatric patients. Creatine, an endogenous guanidine, functions with phosphocreatine and a mitochondrial form of creatine kinase as a spatial energy buffer between the cytosolic and mitochondrial compartments. Administration of creatine has been shown to be protective in animal models of CNS injury, including trauma, ischemia, 3-nitropropionic acid, MPTP-induced parkinsonism, and ALS. Creatine supplementation has been effective in reducing hypoxia-induced seizures in both rats and rabbits. The clinical management of intractable epilepsies with strategies such as caloric restriction or modification – e.g., ketogenic diet – suggests the role of mitochondrial bioenergetics in the protective effects. The ketogenic diet has been shown to produce mitochondrial biogenesis, bioenergetically efficient mitochondria, and lower levels of ROS. The latter has been show to occur because of up-regulation of UCP2 in mice fed a ketogenic diet. In these experimental studies, seizure-induced brain damage and subsequent epilepsy could be inhibited by caloric restriction or a ketogenic diet. Diet modification by ketogenic diet or caloric restriction represents a nonpharmacologic strategy that decreases seizure frequency in the epileptic EL mouse. Interestingly these paradigms are also known to limit free-radical formation. Consistent with this effect, recent studies in our laboratory have shown an up-regulation of GSH biosynthesis in animals fed the ketogenic diet. Several newer antiepileptic

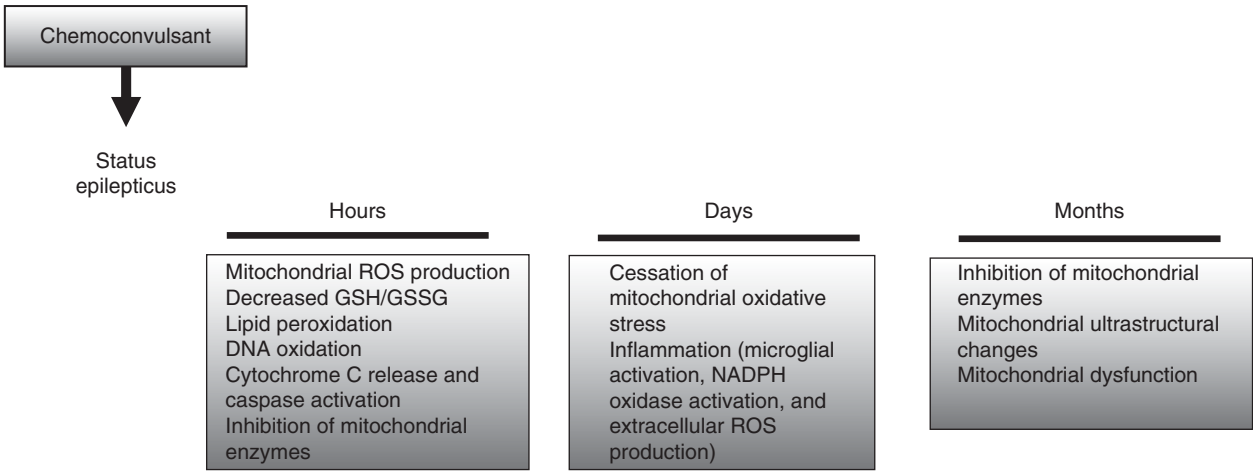

Figure 1 Documented and proposed cellular events initiated hours, days, and months following an acute episode of chemoconvulsant-induced status epilepticus. Acute and chronic biochemical events known to occur following chemoconvulsant-induced SE.

drugs such as zonisamide, topiramate, and levetiracetam inhibit mitochondrial dysfunction and/or possess antioxidant properties, raising the possibility that inhibition of mitochondrial dysfunction may in part underlie their actions.

Oxidative stress and neuronal damage induced by kainate can be ameliorated by at least two types of SOD mimetics: the manganese porphyrin, MnTBAP, and the salen compound, EUK134. However, acute administration of catalytic antioxidants does not alter chemoconvulsant-induced behavioral seizure severity. Previous generations of manganese porphyrins (e.g., MnTBAP) showed limited ability to cross the blood–brain barrier (BBB), which necessitated intracerebral administration, and it remains to be determined if newer classes that are BBB permeable, orally active, and validated in animal models of neuronal injury modulate seizure-induced injury and/or epileptogenesis. Other compounds with antioxidant properties that inhibit seizure-induced brain injury include the hormone melatonin, a nitrone spin trap, and vitamin C. It should be noted that since ROS play an important physiological role in cell signaling, their removal with antioxidants may have deleterious consequences on cellular functions during chronic administration. Although iron chelators are poorly tolerated in vivo, chelation of the mitochondrial pool may be another avenue for therapeutic intervention. One promising example is the use of HBED, a lipophilic iron chelator that penetrates mitochondria following in vivo administration and inhibits seizure-induced hippocampal injury.

Recent advances have unequivocally shown that mitochondrial dysfunction and oxidative stress are an acute consequence of seizure activity. Another exciting yet unexplored area of research is the role of RNS in neuronal excitability and epileptogenesis. The precise mechanisms by which these processes contribute to the progression of epilepsy and whether chronic improvement of mitochondrial bioenergetics has an effect on epileptogenesis remain to be determined. To develop antiepileptic (and antiepileptogenic) therapies influencing mitochondrial bioenergetics and oxidative stress, it will be important to unravel the role of mitochondrial mechanisms in the disease process (i.e., how mitochondrial defects modify neuronal excitability).

Introduction

Phosphorylation of synaptic receptors modulates several neurotransmission systems in the vertebrate central nervous system. It has been shown, in particular, that glutamate and γ-aminobutyric acid (GABA) ionotropic receptors can be phosphorylated on the intracellular loops of several of their subunits by known kinases. These kinases primarily phosphorylate the β or γ subunits – but not the α subunits – of the type A GABA receptor (GABA$_A$R).

A different phosphorylation mechanism was recently described for this receptor, and termed 'endogenous,' since it does not require exogenous kinase or kinase activators. The endogenous kinase must then be closely related to the receptor at the neuronal membrane. This phosphorylation mechanism prevents rundown of the GABAergic response of acutely dissociated hippocampal or cortical neurons. In the paragraphs below, we will briefly describe the characteristics of this mechanism and then show that this mechanism is deficient in the cortical zones epileptic seizures originate in patients with partial epilepsy.

Background

A New Mechanism: Glycolysis-Dependent Modulation of GABAergic Inhibition

The first step was to identify the GABA$_A$R endogenous kinase. The protein that was isolated after purification and phosphorylation tests of the receptor was not a known kinase, but rather a key glycolytic enzyme, glyceraldehyde-3-phosphate dehydrogenase (GAPDH). A kinase activity of GAPDH, independent of its role as a dehydrogenase in glycolysis, has been described in rabbit muscles, where it was shown that GAPDH autophosphorylates using glycolytic ATP and then transfers the phosphate group to other muscle proteins – thus playing the role of a kinase. We showed that GAPDH is physically associated with the receptor and is partially colocalized with GABA$_A$R α1 subunits at the plasma membrane of neurons in culture.

We also showed that local synthesis of ATP occurred in washed cerebral cortex membranes when glyceraldehyde-3P (G3P), the specific glycolytic substrate of GAPDH, was supplied. These results indicate that the enzyme that follows GAPDH in the chain of glycolytic reactions, the phosphoglycerate kinase, is also present at the neuronal membrane and that it uses the product of the reaction catalyzed by the GAPDH to produce glycolytic ATP, very likely without diffusion. The ATP is then used for GAPDH autophosphorylation, probably also without diffusion. Next, the phospho-GAPDH phosphorylates the associated GABA$_A$R on the I2 intracellular loop of its α1 subunit, at two identified serine and threonine residues. The endogenous phosphorylation of the GABA$_A$R is thus a glycolysis-dependent mechanism. These results establish a direct link between glucose metabolism and GABAergic neurotransmission (**Figure 1**).

Does GABA$_A$R endogenous phosphorylation have a functional role? We showed, on acutely dissociated pyramidal neurons from rat cortex, that any factor supporting GABA$_A$R endogenous phosphorylation retards rundown of GABA$_A$ currents in whole-cell patch-clamp recordings, and that any factor preventing GABA$_A$R endogenous phosphorylation reinforces rundown. Acutely Dissociated Neurons

Introduction

Epilepsy is a term used for several chronic neurological syndromes characterized by abnormal and inappropriate neuronal activity and synchrony. Often the neuronal synchrony is so widespread in the brain that consciousness is impaired. The particular neurons that are affected, the particular neuronal abnormalities, the particular connections that are affected, and the particular synaptic (or non-synaptic) abnormalities appear to be at least as varied as the number of named epilepsy syndromes.

The study of the basic mechanisms of epilepsy has benefited from the use of many different in vitro experimental preparations, including the intact whole-brain model and progressively more 'reduced' preparations such as brain slices, acutely dissociated neurons, neuron fragments (e.g., dendritic fragments), and single channel patch preparations. The cells in the acutely dissociated neuron preparation remain sufficiently intact for studies of many kinds of cellular activity, including action potentials, voltage-gated currents, and currents associated with activation of specific ionotropic or metabotropic receptor/transmitter systems. The acutely dissociated neuron preparation is particularly well-suited for some types of investigations that focus on the intrinsic properties of neurons or their responsiveness to activation of specific receptors. There are, in addition, several advantages to recordings from dissociated cells as compared with recordings from single neurons embedded within intact brains or brain slices or single neurons in culture. Those advantages will be discussed and exemplified in this article.

Background - The Pros and the Cons

Most studies using the acutely dissociated cell are attempts to understand the roles of ion channels in action potential generation and patterning. Such studies of ionic

currents in acutely dissociated cells have been useful in defining the firing patterns characteristic of principal cells and interneurons of many brain areas, to compare developmental changes in these firing properties, and to contrast 'normal' and 'abnormal' cells from the same brain region. Acutely dissociated neurons have been obtained from various animal models of interest, as well as from tissues obtained during human surgery (e.g., resections for medically-refractory epilepsy, even when tissue is removed by aspiration).

There are important technical advantages of the preparation that make possible some approaches to studying electrogenesis that are difficult or impossible to accomplish in other preparations. First, acutely dissociated cells have reduced dendritic appendages (**Figure 1**), and as such are more suitable for voltage clamp studies because space clamping is considerably improved. Second, ionic currents are more amenable to pharmacological isolation. Thus, it is possible to study the currents underlying action potential and firing pattern generation, as contributed by both the soma and proximal dendrites. Finally, the isolated cell preparation offers the cleanest access to cell contents, for studies of specific mRNA by PCR.

There are obvious disadvantages to studying the acutely dissociated cell. Cells are literally torn from the brain during the isolation process. Perhaps surprisingly, the main disadvantage is not poor cell condition. Indeed, acutely dissociated cells routinely remain viable for hours during recordings. Rather, the main disadvantage is that the partial preservation of the cell produces a distorted view of the intact cell's properties. For example, complex firing properties that depend on distributed conductances along the somato-dendritic axis are no longer available for analysis. Another important disadvantage is the absence of synaptic (or non-synaptic) neuronal connectivity. Studies of cell-to-cell interactions are limited to an analysis of transmitter action – where the dissociated cell is one of the 'cleanest' preparations.

Although it is not possible for an isolated, acutely dissociated cell to generate seizure activity, the advantages of the preparation for addressing cellular questions makes it an important complement to other methods in the study of epilepsy.

Methods

The Preparation

There are many variations in the isolation protocol. We have varied our own protocol several times. In our current protocol, we used Sprague-Dawley rats; animals of essentially any age can be used (we currently use animals that are 21–35 days old). Preparation begins by anesthetizing the animal with 2-bromo-2-chloro-1,1,-trifluoethane (halothane) and decapitating it. The brain is quickly removed from the skull by first cutting the scalp along the dorsal surface of the head, then splitting the skull and carefully removing bone and dura mater from over the dorsal surface of the brain. A small spatula is used to lift the brain from the skull as it cuts through the cranial nerves. The whole brain is placed in ice-cold artificial cerebrospinal fluid (ACSF) containing (in mM) 124 NaCl, 26 $NaHCO_3$, 3 KCl, 2 $CaCl_2$, 2 $MgCl_2$, and 10 glucose, which is bubbled with 95% O_2/5% CO_2 to maintain a pH of 7.4. Blocks of tissue, several millimeters thick, and containing the region of interest (e.g., ventral hippocampal regions cut in the horizontal plane) are cut from each hemisphere. These blocks are sectioned at 400 to 500 μm (slightly thicker than slices used for electrophysiological studies on acute slices) using a Vibratome sectioning system, and transferred to ACSF solution at room temperature. Each slice is itself then dissected to isolate a particular brain region – e.g., CA3 or subiculum. The resulting pieces of tissue are approximately 1 mm square (and the thickness of the slice). Microdissection of brain slices is a useful way to refine the isolation of a specific brain region and cell type. Microdissection of slices is relatively straightforward in hippocampal/limbic system slices, since the boundaries for many subregions are very clearly visible with a dissecting microscope.

At least one enzyme treatment (sometimes more) is used to facilitate cell dissociation. The specific enzyme, its concentration, and the duration of exposure vary considerable among the investigators using these techniques. Our current enzyme protocol for acutely dissociating cells starts with the transfer of tissue pieces (<1 cubic mm) to a small chamber containing a PIPES dissociation solution (in mM): 120 NaCl, 5 KCl, 1 $CaCl_2$, 1 $MgCl_2$, 20 PIPES, 25 Glucose, and 1 mg/ml Protease type XIV (pH 7.0 with NaOH) at temperature 31°C, where the tissue remains for 30–40 min. After enzymatic treatment, the tissue is washed three times with enzyme-free PIPES solution, and pieces remain in this solution until they are ready for dissociation. For the final step, a single piece of the enzyme-treated tissue is triturated by passing through progressively smaller tip sizes of fire-polished pipettes (approximately, 0.8, 0.4, and 0.2 mm tip diameters). The dissociated neurons are placed in an uncoated 35 mm Petri dish (Corning) containing ACSF solution bubbled with 95% O_2/5% CO_2. Cells are allowed to settle for 3–5 min by stopping the gas supply to the dish. Cellular debris can be reduced by gently replacing ACSF and allowing the cells to resettle. The petri dish is moved to the microscope stage for cell selection and recording.

Characterization of Intrinsic Neuronal Behavior

The acutely dissociated cell is an 'intermediate' preparation – more 'reduced' than a preparation involving neurons

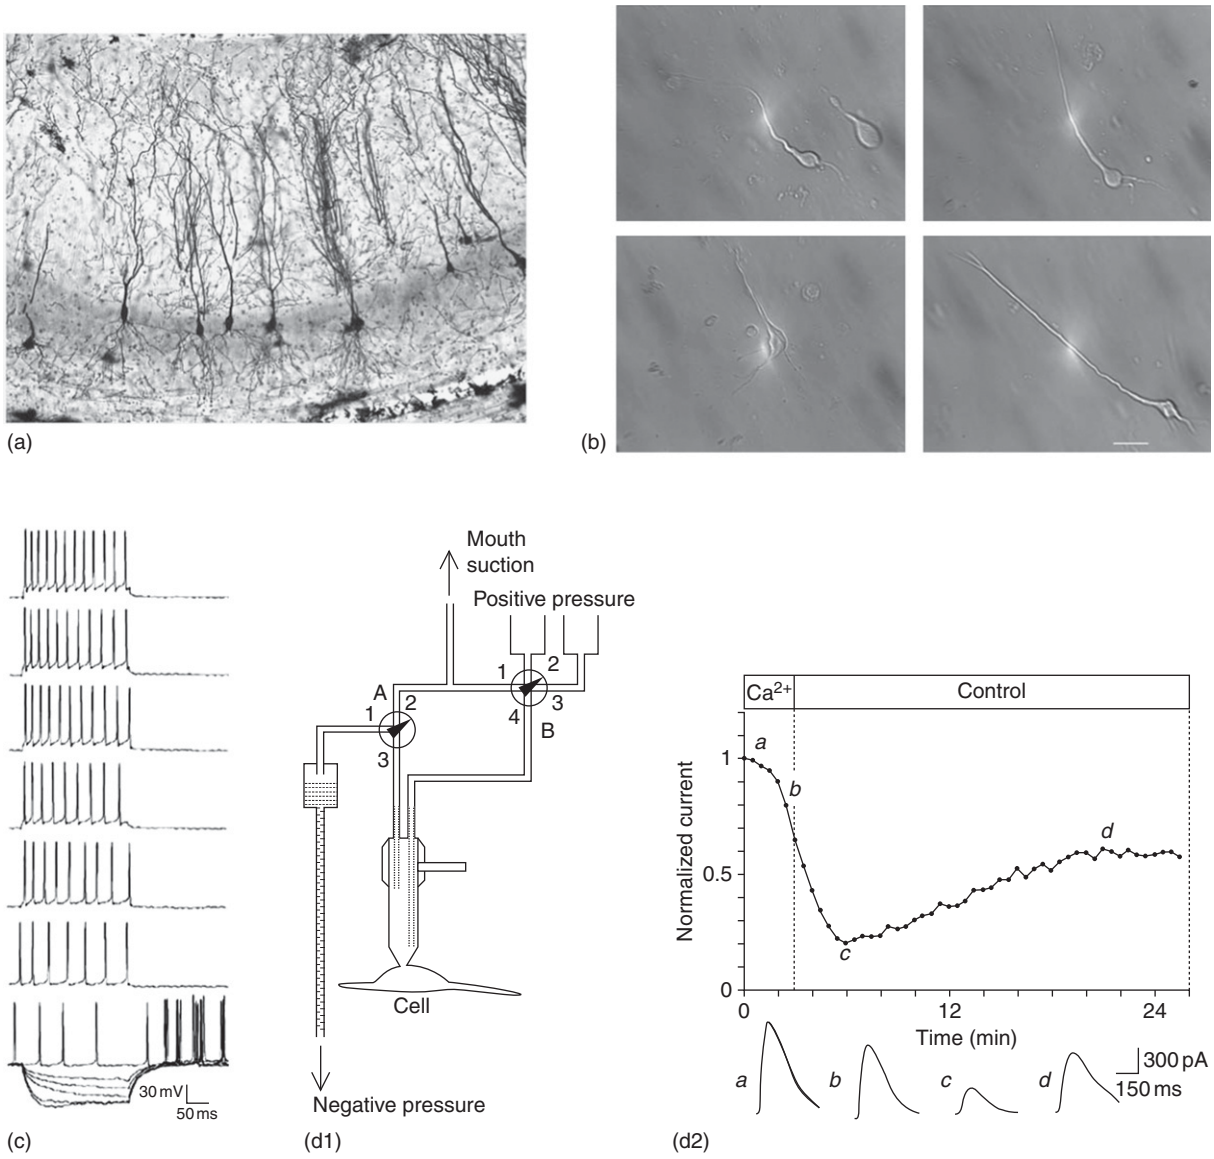

Figure 1 Examples of acutely dissociated neurons and recordings of voltage and ligand-gated currents in current-clamp and voltage-clamp configurations. (a) Golgi-stained pyramidal neurons in rat area CA1. Contrast the dendritic arbors of the intact cells (a) with the examples of acutely dissociated rat CA1 pyramidal neurons (b). (c) Current clamp recordings from area CA1 pyramidal neurons show action potential generation in response to depolarizing current steps and and voltage responses to hyperpolarizing current injection. Cell was held at −70 mV and stimualted with currents that were incremented in 50 pA steps. In part d, we illustrate the intracellular perfusion setup (d1) developed by Qiang Xiao Chen *et al.*, and an example of GABA-mediated whole cell currents (d2). The intracellular perfusion setup permits the switching of solutions inside the recording pipette and therefore inside the neuron while it is being recorded. The valve labeled B switches the perfusion solution; the valve labeled A is used to switch between mouth suction to establish the recording and steady 'pull' for perfusion. A full description of the intracellular perfusion setup is given in the publication. (d2) Effects of intracellular calcium ion concentration on GABA-A receptor-mediated whole cell currents. Top is a plot of normalized peak currents elicited by pressure ejection of GABA. Below are example current records at the labeled times. A high intracellular concentration of calcium (5×10–6 M) induces a rapid rundown of GABA-mediated currents. Switching to low intracellular calcium (1×10–8 M) reverses the rundown. Cell is voltage-clamped at −10 mV. We thank Bolek Srebro for the Golgi-stained tissue (a), and Wei-Ping Chen and Mark Stewart for the data shown in parts b and c. Both portions of part d were adapted from Chen, Stelzer, Kay, and Wong (1990) $GABA_A$ receptor function is regulated by phosphorylation in acutely dissociated guinea-pig hippocampal neurons. *J. Physiol.* (*Lond.*) 420: 207–221.

in situ (e.g., brain slices, whole brain, or even tissue culture), but more 'complete' than subcellular preparations (preparations used for all forms of frank patch recording – e.g., inside-out, outside-out, etc.). Action potential discharge properties are typically studied with current clamp techniques. Voltage-clamping methods can be used to study currents, and take advantage of the dissociated cell's relatively compact electrical structure (for effective space clamping).

Pharmacological isolation of currents is particularly effective in this preparation, since the cell's membrane is entirely exposed to the extracellular environment.

The most commonly used recording methods (we will not discuss any of these in detail here) employ low resistance pipettes for whole cell recording techniques (various configurations – whole cell mode, perforated patch mode, and cell-attached patch mode). The selection of recording configuration and pipette solution will depend on the specific goals of the study. It has been shown that the ionic composition of the low resistance pipettes can itself be a significant variable in such studies, since ingredients of the pipette solution can block some channels or substantially alter the kinetic properties of these channels. In general, to assess firing properties of neurons, the pipette solution should be 'physiological.' Alternatively, the investigator may choose a recording configuration (such as perforated patch) that will minimally alter the intracellular contents of a cell. To study particular currents, one can also use pipette solutions that will be helpful in isolating currents of interest – e.g., QX-314 to block sodium channels, or cesium ions to block potassium channels). Any study of how a particular cellular 'pathology' (such as pacemaker bursting) or a genetic mutation affecting an ion channel (channelopathy) contributes to epileptogenic mechanisms requires an understanding of the baseline characteristics of intrinsic currents of the neuron. Such measurements and comparisons can be made on cells from 'normal' and 'experimental' tissue.

A general plan for characterizing the acutely dissociated cell includes the following:

1. Determine the basic properties of a cell type by recording the cell's behavior in current-clamp mode, to define the action potential firing capabilities and patterns of the neurons. This behavior can be compared to the firing patterns of comparable cells in slices or in 'intact' preparations. Injected current (steady direct current, or brief pulses) can be used as the stimulus to evoke action potential firing.
2. Make a qualitative assessment of currents that are activated in response to hyperpolarizing or depolarizing stimuli. Determine the channels that are involved in suprathreshold activity (e.g., burst firing vs. regular spiking; various firing rates) and subthreshold changes (e.g., membrane oscillations), by testing the effects of specific channel blockers (one at a time).
3. Make a quantitative assessment of currents, using voltage-clamp techniques in the presence of drugs that will block all channels except the one you wish to study.

From a practical standpoint, experimental emphasis on a small subset of these guidelines (e.g., studies of a single current) can be used to compare cells from animals of different ages, or to compare cells from normal animals with cells from a disease model (e.g., following kainic acid treatment or kindling). In studies of neurons removed from human patients (tissue resection as part of a surgical treatment), it is difficult to establish the supra and subthreshold parameters for 'normal' cells. As such, conclusions about disease-related features of human cells are risky.

Characterization of Receptor and Channel Properties

The acutely dissociated cell cannot, by definition, be used as a model to study seizures per se. However, the preparation can be used to study abnormalities in cellular properties that contribute to seizure generation. For example, transmitter receptor agonists and antagonists, as well as ion channel blockers, can be applied to a recorded cell using any of a variety of methods: pressure ejection, iontophoresis, and bath application are all appropriate methods. The special advantage of the dissociated cell preparation is that a drug delivery device can be placed anywhere in relation to the recorded cell, and can be moved within the recording chamber without substantially disturbing the recording. This feature permits the rapid application not only of single drugs, but also of multiple drugs, to a given cell.

Results – Examples of the Preparation's Utility

Endogenous Bursting and Pacemaker Cells

One definition for a 'seizure generator' is a brain region containing 'pacemaker' neurons to drive the activity, and connectivity to the surrounding tissue to cause synchrony. While the acutely dissociated cell preparation cannot evaluate connectivity, it is ideal for the study of pacemaker properties – those intrinsic neuronal properties that lead to a burst firing pattern. These properties may be observed as properties of normal cells (physiological pacemakers), such as hippocampal CA3 pyramidal cells and subicular pyramidal cells, which have endogenous burst firing properties. We have compared properties of normal, acutely dissociated CA1 pyramidal cells in hippocampus with subicular pyramidal cells; the acutely dissociated subicular cells (by not CA1 cells) are characterized by a pattern of inward currents (when the cells are stimulated with depolarizing current) that is consistent with action potential burst generation. Burst electrogenesis in a single neuron is a complex phenomenon that appears to vary across cell types (even among closely related areas such as CA1, CA3, and subiculum) and is a key determinant of a pacemaker region.

Action potential generation, and more specifically burst electrogenesis, depend on voltage-gated sodium and calcium currents. Accordingly, these currents have been studied in various animal models of epilepsy and in

cells from human patients with epilepsy. Calcium and potassium currents have been shown to be altered in acutely dissociated neurons from rat dentate gyrus and hippocampal CA1 after kindling. Changes in calcium currents from neurons of human dentate gyrus, potassium currents from human neocortical neurons, and sodium currents from human entorhinal and subicular neurons have all been hypothesized as possibly contributing to seizure generation (or at least characterizing an epileptic brain region).

T-current and absence seizures. The acutely dissociated cell, with its advantages for voltage clamp studies of ionic currents, has been useful for evaluating the role of the transient, low-threshold (T-type) voltage-gated calcium current in absence seizures. 'Rebound' bursting in thalamic relay neurons was found to be suppressed by ethosuximide (a drug commonly used to treat absence seizures), and the acutely dissociated cell preparation was used to demonstrate that ethosuximide selectively blocks the T-current in these thalamic cells. A similar study of the T-type calcium current showed that this current is prominent in hippocampal pyramidal cells prior to postnatal day 30, but disappears after this age. Interestingly, ethosuximide did not appear to affect the T-currents in immature hippocampal CA1 pyramidal cells, suggesting that there are different subtypes of T-channels present in thalamic vs. hippocampal neurons.

Ionotropic receptor properties. The hypersynchronized activity that defines a seizure is largely dependent on glutamate receptor activation, and is prevented (at least to some extent) by synaptic inhibition. Many dissociated cell studies have been aimed at defining the properties of ionotropic receptor types, such as GABA and NMDA, as well as defining the pharmacological modulation of receptor-ion channel properties. An important aspect of these studies has been the comparison of the receptor properties of normal vs. abnormal neurons. For example, larger amplitude NMDA receptor-mediated currents were found in dentate granule cells isolated from kindled rat brains, as compared to currents in normal control granule cells. The sedative and anticonvulsant properties of drugs such as pentobarbital and phenobarbital were examined in acutely dissociated CA1 neurons in studies that contrasted the differential drug actions on calcium currents and GABA receptor-mediated currents.

Metabotropic receptor properties. The preservation of an intact cell soma in acutely dissociated cells suggests that many intracellular signaling pathways – e.g., involving g-protein coupled receptors ('metabotropic' receptors) – remain intact. Previously, it was thought that such structurally complex receptors would not survive the enzymatic action used for the cell dissociation. However, through careful monitoring of enzymatic concentration and duration of treatment, robust g-protein coupled receptor activity can be preserved. This development, together with the accessibility of the intracellular space in the acutely dissociated cell, has made it possible to characterize intracellular signaling cascades activated by these g-protein coupled receptors. Interestingly, one prominent metabotropic receptor-mediated current, the M-current, is not seen in acutely dissociated cells. This absence may be explained by the recent finding that these channels are localized near the axon hillock. The cholinergic receptors coupled to the M-current may be located on the membrane of acutely dissociated cells, but the coupled potassium channels (KCNQ) required for the M-current appear to be eliminated by the dissociation process.

Currents recorded as a consequence of receptor activation in the acutely dissociated cell preparation (as well as other preparations that employ 'bulk' drug application) will necessarily include an unknown combination of synaptic and extra-synaptic receptor-mediated channel activation. To specifically study synaptically-mediated channel activation, it is possible to preserve attached vesicle-containing boutons with the isolation of neuronal somata during the dissociation process. The dissociation process is similar to the one described above, with the critical differences being in the concentrations of calcium (0–0.2 mM) and magnesium (5 mM) salts used during the isolation and incubation steps. The procedure that maintains the attached boutons permits the investigator to observe miniature synaptic currents in a preparation that is well-suited for high resolution voltage clamp recordings.

Studies of genetic models. The genetically-altered animal is an increasingly useful tool for the neuroscientist. Channels, pumps, or signaling cascades that determine channel behavior can be studied in acutely dissociated cells in order to determine the consequences of genetic manipulations at the level of simple cell properties. The acutely dissociated cell preparation can be useful for testing the physiological consequences of altered channels in genetically engineered animals, or for evaluating altered channel behavior as a possible basis for the seizures in a diseased animal or human. This approach may be particularly useful in studying specific channelopathies that have been associated with some seizure disorders (such as Severe Myoclonic Epilepsy of Infancy).

As an adjunct to physiological studies on tissue with potential genetic abnormalities, a potentially useful manipulation is to employ single cell PCR techniques, to obtain, amplify, and identify specific genetic material (or its absence or modification, in the case of knock-out or transgenic animals) from a single cell. With the dissociated cell preparation, this process is considerably simplified since one is spared the task of aspirating the contents of a cell (the required procedure when single cell PCR is applied to neurons, e.g., in slices) because the whole cell can be processed directly, with a small risk of contamination by cellular material from other cells.

Future Directions and Conclusions

The set of tools for manipulating ion channels and other proteins in cells continues to grow. These manipulations have led to numerous insights into cellular physiology for many cell types, including neurons. Critical to our understanding specific channel or protein function is experimental access for measurements of complex cellular processes. The acutely dissociated neuron preparation offers superior access for studies of coordinated ion channel function that is required for action potential generation and changes in firing properties. It will likely continue to find utility in exploring the ever-widening spectrum of specific cellular mutations that can be produced by genetic manipulation, and as one of the most versatile tools for functional studies of human biopsy material.

We have offered some examples of how the acutely dissociated cell preparation can be useful for studying the properties of neurons (or, in theory, even glia) that may contribute to epilepsy (e.g., burst electrogenesis), for studying the changes in cells that may provide the basis for seizure activity, and for testing the effects of drugs that may act to interfere with channels and receptors that participate in epileptiform activity. As the genetic bases for cell physiology are defined, we predict that the acutely dissociated cell soma – with its intact nucleus – will be further developed into a preparation that allows the direct correlation of genetic and physiological studies. Thus, the preparation has great utility in elucidating basic properties that may be involved in seizure-related cellular behavior. Since dissociated cells cannot, in themselves, generate seizure-like 'models,' the dissociated cell approach is most powerful when applied in combination with studies of animal models or human epileptic tissue.

Introduction

A consistent theme emerging from the first century of research in neuroscience is that the brain does not respond passively to its environment. The active brain generates patterns of neural firing and produces behavior spontaneously. Likewise, the adaptive brain does not respond passively to interventions such as lesions or electrical stimulation; it reacts to the intervention and is modified in a lasting way by the experience. Not surprisingly, epilepsy is characterized by active and adaptive changes in brain function, as suggested in several preparations of experimental epilepsy. However, the progressive and adaptive nature of neural changes is not easy to track in most preparations, due to the unpredictability of, and lack of, experimental control over seizure development. A more predictable pattern of seizure development, with excellent experimental control, is found in the kindling preparation, and kindling has become the dominant preparation for studying this kind of active and lasting plasticity in experimental epilepsy. In this article we review the characteristics and potential mechanisms of kindling, with an emphasis on both enduring findings and recent developments. We start with a brief description of the discovery of kindling.

Background

Discovery of Kindling

Early investigators of the phenomenon of intracranial self-stimulation (ICSS) described the occurrence of the development of either electrographic seizures or behavioral convulsions during ICSS of sites in the forebrain. A number of early researchers interested in epilepsy also stumbled over the progressive development of seizures after repeated application of either drugs such as cocaine or focal electrical stimulation. Perhaps the clearest example of this is found in a series of studies from Jose Delgado's laboratory at Yale in the late 1950s and early 1960s, in which it was observed that behavioral seizures developed during repetitive ictal electroencephalographic (EEG) discharge. However, none of the researchers observing seizure development followed up on the observation systematically.

Graham Goddard's doctoral research in Psychology at McGill University in the early 1960s was concerned with the effects of electrical stimulation of the amygdala on conditioning in rats. Because of an equipment malfunction, repeated short trains of fairly high-intensity stimulation were accidentally delivered to the amygdala of some rats, one of which developed seizures after a few repetitions. The rat continued to display seizures even after the equipment had been repaired, and similar stimulation given to naive rats did not cause seizures. Goddard realized that it was the repeated application of stimulation that led to seizure, not the stimulation itself; after observing the phenomenon in other rats, Goddard surmised that the brain was changing in response to the repeated application of stimulation. Because stimulation initially produced no behavioral effects and the convulsions developed gradually, Goddard and his students called his phenomenon 'kindling.' They went on to show that kindling results in a state of increased susceptibility to convulsions that is long-lasting if not permanent, and that kindling can be observed in other species, including mice, cats, and monkeys. Subsequent research by the eminent neurologist Juhn Wada confirmed the occurrence of kindling in cats and primates, and first documented the development of spontaneous seizures during kindling.

Inspired by Goddard's preliminary observations, Ronald Racine carefully monitored EEG activity during kindling and convincingly demonstrated that stimulation has to elicit afterdischarge (AD) in order to kindle seizures. He found in addition that repeated stimulation significantly lowers threshold for AD in amygdala and hippocampus, and that threshold reduction persists even after a 6-week period without stimulation. The changes in threshold are localized to the area stimulated, in that there is generally no effect on thresholds measured in other limbic sites. Racine also conceived the idea of testing for transfer of both electrographic and behavioral kindling between sites in the forebrain. He found that kindling with stimulation of a limbic or cortical site results in a facilitation of subsequent kindling from other limbic or cortical sites, respectively, and that this transfer effect persists even after lesioning of the initial site of kindling. Thus transfer is not due merely to increased epileptiform output from the site of initial stimulation, but instead involves sensitization of a substrate for seizure that can be activated by multiple cortical and subcortical areas. Finally, Racine demonstrated that kindling is associated with potentiation of excitatory synaptic transmission, as discussed later.

Methods

The seminal experiments of Goddard's and Racine's groups have defined the paradigm for most subsequent research on kindling. In typical kindling studies, regardless of species, experimenters apply short trains of electrical stimulation, typically 1 or at most 2 s in duration. The waveform is usually balanced biphasic square pulses, although some experimenters apply monophasic (cathodal) pulses or sine waves. The intensity of stimulation is set at, or a fixed amount above, the threshold for triggering AD. EEG is recorded from the stimulated site and one or more additional sites, usually for 30 or more seconds before and 2 or more minutes after each stimulation.

Results

Characteristics of Kindling

Behavioral characteristics

There are at least two distinct patterns of kindling, determined by locus of stimulation: a limbic forebrain pattern and a neocortical (nonlimbic) pattern. The pattern of seizure development evoked by stimulation of limbic sites best exemplifies kindling, because it involves gradual emergence of partial seizures, hemiconvulsions, and then generalized convulsive seizures from an initially negative behavioral response. That is, early limbic ADs are associated with nonconvulsive responses, often simple behavioral arrest, and these are gradually replaced by frank convulsive movements as the AD develops and spreads, resulting in generalized seizures that become more intense with repeated stimulations. In contrast, stimulation of neocortex and several other sites (e.g., claustrum, perirhinal cortex, brainstem) typically evokes a brief forced motor response followed by a clonic or short clonic–tonic seizure. With repeated stimulations, the convulsive response often evolves to include a late-phase limbic-type generalized clonic–tonic seizure.

Electrographic characteristics

Stimulation of limbic and paleocortical sites initially triggers relatively simple ADs of short duration, low amplitude, and minimal propagation. With repeated stimulations, limbic AD dramatically increases in duration and amplitude, and it propagates widely to distant sites, many of which eventually develop patterns of AD that are independent of the stimulated site. In contrast to the striking changes in limbic or paleocortical AD during kindling, initial stimulations of the anterior or posterior neocortex or some other sites (e.g., claustrum) fail to result in any appreciable changes in the duration or amplitude of primary-site ADs. When repeated stimulation of the anterior neocortex results in the late development of generalized limbic-type seizures, however, there is an abrupt increase in the duration and amplitude of neocortical ADs associated with development of independent AD in the amygdala.

An important feature of the electrographic response during kindling is its sensitivity to the interstimulation interval. Goddard and colleagues found that seizures can reliably be kindled when stimulations are sufficiently spaced. Racine's work showed that the reliability of kindling is related to the ability of stimulation to trigger AD, with AD occurring most reliably at interstimulation intervals of 2 h or greater; stimulation at shorter intervals produces short-lasting inhibitory effects that can suppress AD or the behavioral seizures triggered by AD. These inhibitory effects of 'massed' stimulation must be taken into account in studies attempting to identify physiological, biochemical, or morphological correlates of kindling.

Neural circuitry

Numerous studies have been concerned with identifying the neural circuitry underlying kindling. A common strategy is to map the susceptibility of different sites on the assumption that sites kindling more rapidly are closer to the substrates of convulsive seizure generalization. The early research pointed to the amygdala as a highly susceptible site, and more recent work has identified high susceptibility to kindling in the piriform cortex, perirhinal cortex, claustrum, thalamic nuclei (e.g., dorsomedial nucleus, nucleus submedius), and particular nuclei in the brainstem (e.g., mesencephalic reticular formation, central gray, reticularis pontis oralis), suggesting that the limbic generalization network may be quite widespread. A second strategy is to track the patterns of seizure discharge that occur during establishment of seizures (epileptogenesis) or during the triggering of an established seizure. Another strategy is to destroy a structure implicated by its susceptibility to kindling or electrographic criteria. This approach has resulted in evidence strongly suggesting that the perirhinal cortex, piriform cortex, claustrum, and thalamus play important roles in generalization. For technical reasons, the effects of brainstem lesions have not been examined.

Interictal behavioral consequences

The behavioral consequences of kindling that are specific to the site being kindled have been examined for several decades. The results suggest, overall, that kindling produces modification of function in the structure or circuits subjected to kindling, as would be expected if kindling involves a pathological distortion of the neuronal mechanisms involved in normal plasticity. Discussion of these results are dealt elsewhere.

Mechanisms

Potential mechanisms of kindling have been investigated at the electrophysiological, morphological, and molecular levels. We provide a brief introduction to what is known to date.

Electrophysiology

Three dominant themes have emerged in this research: (1) the hypothesis that kindling-induced potentiation (KIP) of excitatory synaptic drive is the cellular mechanism of kindling; (2) the hypothesis that erosion of the synaptic inhibition mediated by GABA leads to the elaboration and spread of AD underlying kindling; and (3) the hypothesis that kindling is due to the development of the burst response, due to alterations in either network properties or cellular membranes that lead neurons to become 'epileptic.' These hypotheses are of course not mutually exclusive, and the events they postulate could either be correlated or causally related. For example, kindling could involve a shift in the balance between excitatory drive and inhibitory control, and repeated episodes of enhanced excitation and diminished inhibition could in turn lead to membrane or network changes that result in bursting in vulnerable neurons.

Kindling-induced potentiation

Prior to the first report of long-term potentiation (LTP), Racine and colleagues in the 1970s showed that kindling stimulation produces potentiation of potentials evoked in secondary sites, particularly late (presumably polysynaptic) components of the potentials. Even nonepileptogenic tetanic stimulation produces long-lasting effects that can result in facilitation of subsequent kindling, although something more than KIP seems to be required for kindling. Subsequently, Goddard and his collaborators established the paradigm of seeking correlations between kindling and changes in extracellular potentials evoked in an area connected monosynaptically to the site of kindling stimulation; the typical site of stimulation was the perforant path, and evoked potentials were monitored in the dentate gyrus. Their results, and those of others employing the same paradigm, are unfortunately inconsistent, with some studies reporting enduring KIP of both the excitatory postsynaptic potential (EPSP) and population spike (PS), others of the EPSP alone, others of the PS alone, and others of neither the EPSP nor the PS. Given the inconsistency of the results, it is clear that kindling is not reliably correlated with potentiation of monosynaptic responses evoked in the dentate gyrus.

Other studies have employed kindling stimulation at sites other than the hippocampal formation and have confirmed that KIP is not restricted to hippocampal kindling. A form of KIP occurs in the piriform cortex during olfactory bulb kindling, the persistence of which exceeds that previously described with kindling of other sites. This observation raises the possibility that KIP in the piriform lobe could be a candidate mechanism of kindling. It is not likely that these forms of extrahippocampal KIP can account for kindling, however, both because they reach maximum before kindling of behavioral seizures and because not all subjects that kindle show KIP. A plausible explanation for these findings is that KIP at the first synapse could result in sequential potentiation of successive synapses in a multisynaptic neuronal network, a process that would not necessarily be evident in the field potentials recorded at the first synapse in the system.

Disinhibition

A straightforward hypothesis for kindling, and the development of epilepsy in general, is that a physiological process results in disinhibition. Although there is considerable evidence for an inhibitory effect of noradrenaline (NA) on epileptogenesis and for an association between kindling and a decrease in NAs effects, most of the research has focused on a putative collapse of inhibition mediated by GABA. This hypothesis has been tested in numerous studies employing the paired-pulse technique to measure the strength of inhibition, where it has been found that limbic kindling produces KIP of feedback inhibition in the dentate gyrus, at both short and long interpulse intervals. Kindling also produces potentiation of feed-forward inhibition in the dentate gyrus. It is obvious that KIP of inhibition is contrary to the collapse of inhibition predicted by the GABA hypothesis. The picture is different when inhibition is measured in other sites, however. In field CA1, in particular, kindling is associated with decreased paired-pulse inhibition, and in some studies this decrease has been related to a decrease in the number of GABA-immunoreactive neurons in the hippocampus. Furthermore, research by Schinnick-Gallagher and by Leung have shown that kindling results in decreased sensitivity of a presynaptic $GABA_B$ receptor, in amygdala and hippocampus. These results suggest that disinhibition in the hippocampus, amygdala, or elsewhere might contribute in two ways to limbic kindling. First, loss of the specific subpopulation of GABAergic interneurons producing feed-forward inhibition would lead to a decrease in inhibitory postsynaptic potentials (IPSPs), thereby increasing the effects of excitatory input. Second, a long-lasting decrease in the sensitivity of presynaptic $GABA_B$ receptors would lead to increased release of glutamate or other excitatory neurotransmitters, and this action could in turn alter the systems properties of affected neural circuits such that runaway excitation would result. According to this hypothesis, disinhibition and increased excitatory drive interact profoundly, with the outcome being the development of epileptiform bursting in amygdaloid neurons.

Bursting

Bursting involves a pattern of high-frequency discharge of action potentials, usually riding on a sudden and large

(20–50 mV) depolarization of the membrane – the paroxysmal depolarizing shift (PDS) that can last for 100 ms. Interictal discharge is the EEG correlate of bursting. PDSs synchronize over a group of neurons during the transition from normal to epileptiform activity. Finally, bursting (i.e., the PDS) is the cellular behavior observed during AD triggered by a variety of treatments. Bursting is a widespread correlate of kindling that has been observed in field potential recordings and single-cell recordings, both extracellular and intracellular. Burst discharge is most prominent in the amygdala and piriform cortex, but has also been observed in the dentate gyrus, hippocampus, substantia nigra, locus coeruleus, and elsewhere. Intracellular recordings have shown that multiple action potentials typically riding on a PDS are the correlates of the bursting recorded extracellularly, similar to that observed in other forms of experimental epilepsy. Thus bursting is likely to play an important causal role in kindling, perhaps in conjunction with diminished inhibition.

The question then becomes whether the development of epileptiform bursting is a consequence of alterations in endogenous passive membrane properties of the neuron, or whether it is network driven, a distinction made by Johnston and Brown. The evidence is that kindling fails to affect passive or intrinsic membrane properties of neurons in most of the areas that have been tested, including the amygdala, piriform cortex, and hippocampus proper. In contrast, granule cells of the dentate gyrus display long-lasting changes after kindling, including increased input resistance, alterations in Ca^{2+} currents and Ca^{2+} inactivation, and evidence of enhanced participation of NMDA receptors in baseline synaptic transmission. For most sites, however, available evidence indicates that the bursting associated with kindling generally reflects epileptiform activity in a network of cells driven by synaptic transmission. This conclusion is based, in part, on the lack of evidence for alterations in intrinsic membrane properties in areas other than the dentate gyrus. If endogenous bursting is not implicated, network-driven bursting is the only likely alternative. Stronger evidence in favor of network-driven bursting is, however, available from studies investigating the effects of intracellular current injection on bursting, which have shown that the occurrence of bursting (or PDSs) after kindling is unaffected by depolarization of the membrane, suggesting that the kindling-associated bursting it is not due to endogenous bursting, which is voltage dependent. Other evidence suggests that kindled bursting in several sites, including amygdala and hippocampus, involves persistent activation of NMDA receptors. Collectively, these results support the hypothesis that kindling involves a long-lasting increase in the release of glutamate or a closely related excitatory amino acid, a mechanism that is both a cause and an effect of changes in inhibitory neurotransmission.

Morphological changes

Most investigators have found that inducing a limited number of seizures fails to produce evidence of widespread damage. Thus potential morphological substrates of kindling must be subtler than overt damage. At the light microscopic level, there has been evidence of an association of kindling with sprouting of the mossy fibers of the dentate gyrus, as seen in other preparations of experimental epilepsy and in resected tissue from patients with epilepsy. Because the mossy fibers are normally excitatory, this sprouting has been hypothesized to create aberrant excitatory loops that contribute to epileptogenesis. Contrary to the hypothesis, however, numerous studies have described dissociations between mossy fiber sprouting and kindling in several species and different kindling paradigms. Thus, for example, the time course of rapid kindling can be dissociated from mossy fiber sprouting, with generalized seizures developing well before any sprouting is evident. One interpretation of these results is that sprouting is not causally related to kindling but may be a consequence of kindling that contributes to both the intensity of kindled seizures and the behavioral comorbidities measured after kindling.

Even if mossy fiber sprouting was reliably associated with kindling, its interpretation would be clouded by recent research from the laboratory of Rafael Gutierrez. He has found that seizures are associated with an alteration of the phenotype of dentate granule cells, which give rise to the mossy fibers, such that normally excitatory glutamatergic neurons become capable of synthesizing and releasing GABA. Thus, sprouted mossy fibers may produce inhibitory as well as excitatory effects after seizures, which could explain the increased inhibitory drive seen in the dentate gyrus after kindling.

Yuri Geinisman first reported an increase in the proportion of specific, highly efficacious perforated synapses within the kindled hippocampus, at the ultrastructural level. Teskey has found that this observation generalizes to other structures, and recently reported an increase in perforated synapses in the neocortex following kindling in that area. Geinisman has published three-dimensional reconstructions that suggest that perforated synapses are, in fact, formed from nonperforated synapses, either as an endpoint of greater synaptic efficacy or as an intermediate before splitting into two separate synapses. He has also suggested that increases in the proportion of perforated synapses represent selective maintenance of a more efficacious subtype of synapse that is important for sustaining KIP. Perforated synapses may be more efficacious because of the narrower synaptic cleft between presynaptic and postsynaptic membranes at the site of the perforation and because of the additional 'edges' at the perforation sites. Perforated synapses also have ~6.5 times greater AMPA receptor density and 80% higher NMDA receptor density, and are significantly larger, than nonperforated synapses.

Molecular changes

Much of the research on possible molecular mechanisms of kindling has focused on changes in markers for neurotransmitters, and a vast literature has been generated over the past four decades. Fairly consistent results have suggested that GABAergic and noradrenergic function is diminished in areas other than the dentate gyrus, supportive of the hypothesis of disinhibition. In parallel, other molecular markers suggest that the excitatory effects of glutamate are increased, for example at NMDA receptors. Particularly striking is work by John Slevin's group showing a long-lasting increase in release of glutamate after kindling. This finding suggests that excitatory drive is increased, which might result in increased network-maintained bursting. James McNamara and colleagues have reported that conditional deletion of the trkB receptor for BDNF in mice results in the complete abolition of kindling, suggesting that particular neurotrophins are critical for epileptogenesis. The group of mice showing the effect comprised only four animals, however, and acceptance of the results awaits replication in another laboratory.

There are large species differences in susceptibility to kindling, suggestive of an important role for genetic mechanisms. For example, rats develop generalized seizures fairly quickly, whereas guinea-pigs are extremely resistant to seizure generalization. Similarly, during kindling, baboons develop bisynchronous and bisymmetrical primary generalized seizures, both triggered and spontaneous, whereas macaques develop only asynchronous and asymmetrical secondary generalized seizures and fail to show spontaneous seizures. A very promising approach to genetic determinants of susceptibility to kindling is being conducted by Dan McIntyre and colleagues. They have been examining molecular differences between the fast and slow kindling strains of rat, originally developed by Racine through inbreeding based on their rate of amygdaloid kindling. The fast strain requires only half as many stimulations and the slow strain requires up to three times more stimulations as 'normal' Long-Evans rats to kindle. Fast rats are more susceptible to the convulsant effects of GABA antagonists, and slow rats are more susceptible to the depressant effects of GABA agonists, suggesting that GABAergic transmission may be altered in the strains. In confirmation, fast rats show underexpression of the adult form of the $\alpha 1$ subunit of the $GABA_A$ receptor, and overexpression of neonatal forms of α subunits; and the reverse pattern is found in slow rats. Thus, enhanced susceptibility to kindling is, in this preparation, associated with developmental abnormalities in inhibitory mechanisms and this immaturity is, in turn, reflected functionally in differences in miniature IPSCs in the perirhinal cortex. McIntyre's ongoing research is mapping out differences in gene expression in the fast and slow strains, and should provide additional insight into key mechanisms.

In other recent research concerned with changes in gene expression associated with kindling, Corcoran and his colleagues have been using microarray analysis to compare expression of genes after hippocampal kindling and after amygdaloid kindling, with the view to identifying the gene changes possibly related to the behavioral consequences specific to kindling of that site. Ontological analysis of amygdaloid kindled tissue reveals significant enrichment in expression of categories of genes related to cytoskeletal reorganization and biogenesis, cation transport, glutamatergic neurotransmission, and neurogenesis. Hippocampal kindled tissue also displays enrichment in expression of genes related to cytoskeleton reorganization and biogenesis and cation transport, and unique enrichment in transcription factor activity and GTPase-mediated signal transduction. Slevin's group has been using proteomics to examine changes in proteins, the product of gene expression, after kindling. Kindling is associated with significant increases in the catalytic subunits and decreases in the regulatory subunit of the mitochondrial ATP synthase complex, and with large increases in the subunits of the synaptic vesicle H^+-ATPase involved in transmitter uptake. Thus, at the molecular level, both energy metabolism and transmitter uptake show a long-lasting increase in kindled tissue.

Conclusions and Future Goals

Kindling is one of the most dramatic and enduring changes in brain activity produced by focal electrical stimulation. It is a function of the repeated induction of AD, which grows, propagates, and triggers the development of behavioral seizures. The permanence of the kindled increase in seizure susceptibility suggests that dramatic reorganization of neural structure and function is involved, and research into mechanism has been pursued at the molecular, electrophysiological, and morphological levels.

Although much has been learned about the characteristics and mechanisms of kindling, much more remains to be learned. For example, kindling results in several morphological changes, but none can yet be viewed as convincingly accounting for the permanent change in seizure susceptibility underlying kindling. Furthermore, many laboratories are working to identify possible molecular substrates of kindling. Analysis of the epigenetic changes associated with kindling is particularly promising, and may provide important insights into the fundamental mechanisms of epileptogenesis. Additional characterization of the behavioral consequences of kindling should help us to understand the comorbidities of the clinical epilepsies, and future research should address the intriguing possibility that molecular or other interventions will be able to dissociate the behavioral changes consequent to kindling from the induced epileptic state. Finally, notwithstanding the provocative results of

preliminary studies and anecdotal reports, a key question remains as yet unanswered: Do kindling-like events underlie the occurrence of some kinds of epilepsy in humans?

The 'engram' of kindling (in Goddard's terminology) has not yet been identified conclusively, but there is every reason to expect that investigation of kindling will continue to generate insight into fundamental mechanisms of the brain's active responses to change in its environment, as well as into epilepsy and epileptogenesis.

Introduction

Scientific understanding of the complex circuits involved in epileptogenesis and seizures has traditionally been obtained through the use of animal models, culture systems, and numerous other experimental approaches. In the past several decades, however, computational modeling has become an increasingly useful tool for studying and understanding neuronal network structure and function. In epilepsy research, such models have been employed to investigate the role of specific pathologies in epileptogenesis, in conjunction with experimental work or as stand-alone modeling studies. These models vary greatly in both scope (e.g., a given model can range from simulations of the effect of mutations on specific ion channels to representations of entire brain areas and their associated connectivity)

and complexity (e.g., models can consist of simple integrate-and-fire neurons, or they can incorporate realistic channels and conductances, combined with detailed three-dimensional reconstructions of their anatomical features). While each specific model is uniquely suited to answering a particular question, understanding the intricacies of complex pathological states such as epileptogenesis requires approaches that combine complex single cells into large networks with a broad scope. Fortunately, the extraordinary increases in computational power over the last 10 years have made this type of approach quite feasible. This article will illustrate how complex single-cell models, derived from and replicating experimental data, can be combined into large-scale networks to yield substantial increases in our understanding of the relationships between structure and function of large, pathologically relevant brain areas such as the dentate gyrus in the hippocampus.

Background

The dentate gyrus in the mammalian brain is composed of a complex neuronal circuit that is thought to serve as a gate for activity propagation throughout the limbic system. Following repetitive seizures, head trauma, and ischemia, the dentate gyrus undergoes marked structural reorganization, primarily due to loss of hilar cells and the occurrence of mossy fiber (granule cell axon) sprouting, the hallmarks of seizure-induced end-folium sclerosis in temporal lobe epilepsy. Within the resulting, fundamentally transformed dentate gyrus microcircuit, there are simultaneously ongoing alterations in intrinsic cellular and synaptic properties, prompting the question of how to study the impact of network structural changes in isolation.

Computational modeling offers a unique tool to help isolate and demonstrate the effects of individual pathologies, allowing for the implementation of only structural changes in the network while leaving intrinsic neuronal and synaptic properties unaltered. Several studies (see Further Readings) have examined potential epileptogenic roles for enhanced synchronization and activity propagation in small-world network architectures using idealized model networks. However, to model processes involved in epileptogenesis, and to make confident experimental predictions, model networks must be strongly data-driven and include detailed structural and functional properties.

In this article, we discuss results from research employing a complete 1:1 scale structural model of the rat dentate gyrus (over 1 million nodes with full connectivity), as well as a 1:20 scale functional model composed of more than 50 000 multi-compartmental neurons, representing four different excitatory and inhibitory cell types, each reliably reproducing firing properties from electrophysiological experiments. The latter model is made possible by the incorporation of numerous realistic ion channel mechanisms, complete with biologically accurate kinetics, densities, and distributions. The structures of these dentate networks can be characterized using tools from graph theory. These tools have recently been employed in studies of real world networks such as the electric power grid, the internet, and the *C. elegans* worm nervous system. Initially, we determine for the first time the topological characteristics of the healthy dentate gyrus structural model as well as the subsequent topological changes during epileptogenesis. Subsequently, we determine the functional relevance of these topological changes, leading to an intriguing demonstration of hyperexcitability arising exclusively from structural alterations in a realistic neuronal network.

Methods – Implementation of Dentate Network Models

Vast amounts of information about the dentate gyrus, detailing cell types and numbers, connectivity, and intrinsic single cell and synaptic properties, have been collected in the past decade, allowing for the construction of the realistic models discussed in this article. While a summary of the model components and their implementation is provided in this section, the interested reader should refer to the papers listed under 'Further Reading' for a detailed discussion of the experimental justification of model components based on the published literature. The models themselves are available from the ModelDB database, located online at http://senselab.med.yale.edu/senselab/modeldb/.

A Purely Structural Model

The structural model of the dentate gyrus is a complete 1:1 scale representation containing eight distinct and well-described cell types: granule cells, mossy cells, basket cells, axo-axonic cells, MOPP cells (molecular layer cells projecting to the perforant path termination zone), HICAP cells (hilar cells projecting to the commissural-associational pathway termination zone), HIPP cells (hilar cells projecting to the perforant path termination zone), and IS (interneuron-specific) cells (see connectivity diagram in **Figure 1(a)**). The cell numbers and connectivity of each neuron type were determined from published data and are indicated in **Table 1**. The connectivity is displayed as the numbers of postsynaptic targets within a population that a single presynaptic neuron of a given type innervates (e.g., looking at the third row, second column of **Table 1**, a single basket cell innervates approximately 1250 granule cells; mean and ranges are indicated).

Not only the number of connections made by a presynaptic cell, but also the distributions of these connections along the dentate septo-temporal axis, are very

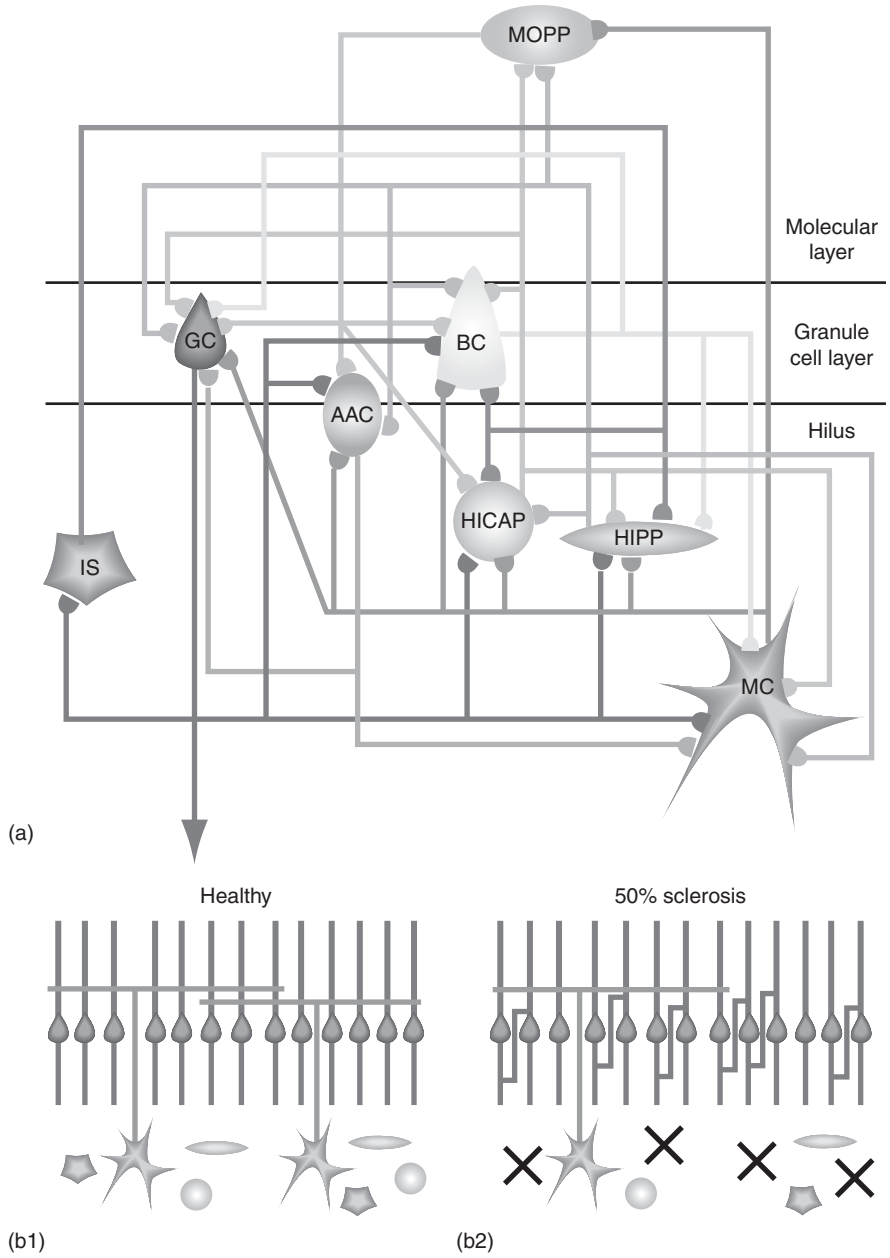

Figure 1 Basic circuitry of the dentate gyrus and the network alterations during sclerosis. (*a*) Schematic representation of connectivity of the eight major cell types in the healthy dentate gyrus (GC: granule cell; BC: basket cell; MC: mossy cell; AAC; axo-axonic cells; MOPP: molecular layer interneurons projecting to the perforant path termination zone; HIPP: hilar interneurons projecting to the perforant path termination zone; HICAP: hilar interneurons projecting to the commissural-associational pathway termination zone and IS: interneuron specific cells). The diagram shows the location of different cell types within the three layers of the dentate gyrus, but does not indicate the actual axonal connection topography (implemented in structural and functional dentate models) or the specific location of the synapses on the post-synaptic cell (implemented in the functional network models). (b1) Diagram of the excitatory connections in the healthy dentate gyrus (only granule cells and hilar neurons are shown). Note that the mossy fibers (granule cell axons) do not make connections with other granule cells in the healthy network. (b2) Diagram of the dentate gyrus at 50% sclerosis indicating the loss (represented as large X-s) of half the of hilar neuron populations, and the 50% sprouting of mossy fiber connections to other granule cells (note that this is a simplified representation: all granule cell axons sprouted new contacts in both structural and functional models of sclerosis). Used with permission from *The Journal of Neurophysiology*.

important for an accurate representation of network structure. In the model, single or double Gaussian distributions were fitted to average axonal distributions determined from published in vivo single cell fills from the literature (**Figure 2**). All cell types were distributed evenly in 100 bins along a simulated 6 mm strip of dentate gyrus, and the cell-to-cell connectivity was determined probabilistically based on the fitted axonal distributions.

Table 1 Connectivity matrix for the healthy dentate gyrus

	Granule cells	*Mossy Cells*	*Basket cells*	*Axo-axonic cells*	*MOPP cells*	*HIPP cells*	*HICAP cells*	*IS cells*

(3000)	X	X	5–10	X	X	5–10	5–10	100–800

Numbers and connectivity values for granule cells, mossy cells, basket cells, axo-axonic cells, molecular layer interneurons projecting to the perforant path termination zone (MOPP), hilar interneurons projecting to the perforant path termination zone (HIPP), hilar interneurons projecting to the commissural-associational pathway termination zone (HICAP), and interneuron specific cells (IS) were estimated from published data. Connectivity is listed as the number of connections from a single presynaptic neuron (column 1) to a postsynaptic population (corresponding rows). The mean number of connections implemented in the graph theoretical calculations is indicated in italic. However, small world structure was preserved even if the extreme low or the extreme high estimates (ranges given below mean values) were used for the calculation of L and C. Used with permission from *The Journal of Neurophysiology*.

The structural model was represented as a 'graph' in the computer, detailing 'nodes' (representing individual cells) and the 'links' (representing synapses) connecting them. Each node represented a unique single cell in the biological dentate gyrus and its complete connectivity. This representation resulted in a graph with more than 1 billion directed synaptic links connecting over 1 million nodes.

Adding Functionality

The approach for implementing the functional model network was similar to that described for the structural model above; however, some important differences stand out: The functional model only represented four cell types (granule cells, mossy cells, basket cells, and HIPP cells) with sufficient electrophysiological data available to implement faithful representations of their firing characteristics in single cell models. These four cell types comprised the granule and mossy cells (the only excitatory cell types in the dentate gyrus) and two major (i.e., numerically dominant and functionally important) types of interneurons – the parvalbumin and somatostatin-positive interneurons. Furthermore, the functional model is a 1:20 scale representation of the dentate, rather than 1:1 representation implemented in the structural model. This reduced model is due to constraints imposed by available computational resources. Even with downscaling, the number of represented cells remains extremely large (with over 50 000 multicompartmental model neurons), allowing the network to maintain the topological characteristics of the full scale model (see below). Finally, the functional model network includes active, biophysically realistic model neurons connected with weighted synapses, each accurately reproducing a number of input-output characteristics determined experimentally.

Implementation of Sclerosis

'End-folium' sclerosis (subsequently termed 'sclerosis') comprises several pathological changes occurring in the dentate gyrus, including hilar cell loss, mossy fiber sprouting, and gliosis. For investigating alterations of the neuronal network architecture, hilar cell loss and mossy fiber sprouting are the primary determinants, and thus these two factors were implemented in the model and will be referred to as sclerosis in this article.

To allow for the implementation of progressive sclerosis in the network, maximal sclerosis was defined as (1) complete hilar cell loss (i.e., loss of all hilar interneurons and all mossy cells) and (2) simultaneous maximal mossy fiber sprouting (as reported in the literature, an average of 275 new contacts per granule cell – in this model represented exclusively as the addition of previously nonexistent granule cell-to-granule cell connections). Subsequently, any intermediate level of sclerosis could be represented as a simple percentage of this maximum. For example, at 50% sclerosis, 50% of mossy cells and hilar interneurons were lost, and 50% of the maximum number of mossy fiber contacts was added (schematically shown in **Figure 1(b)**).

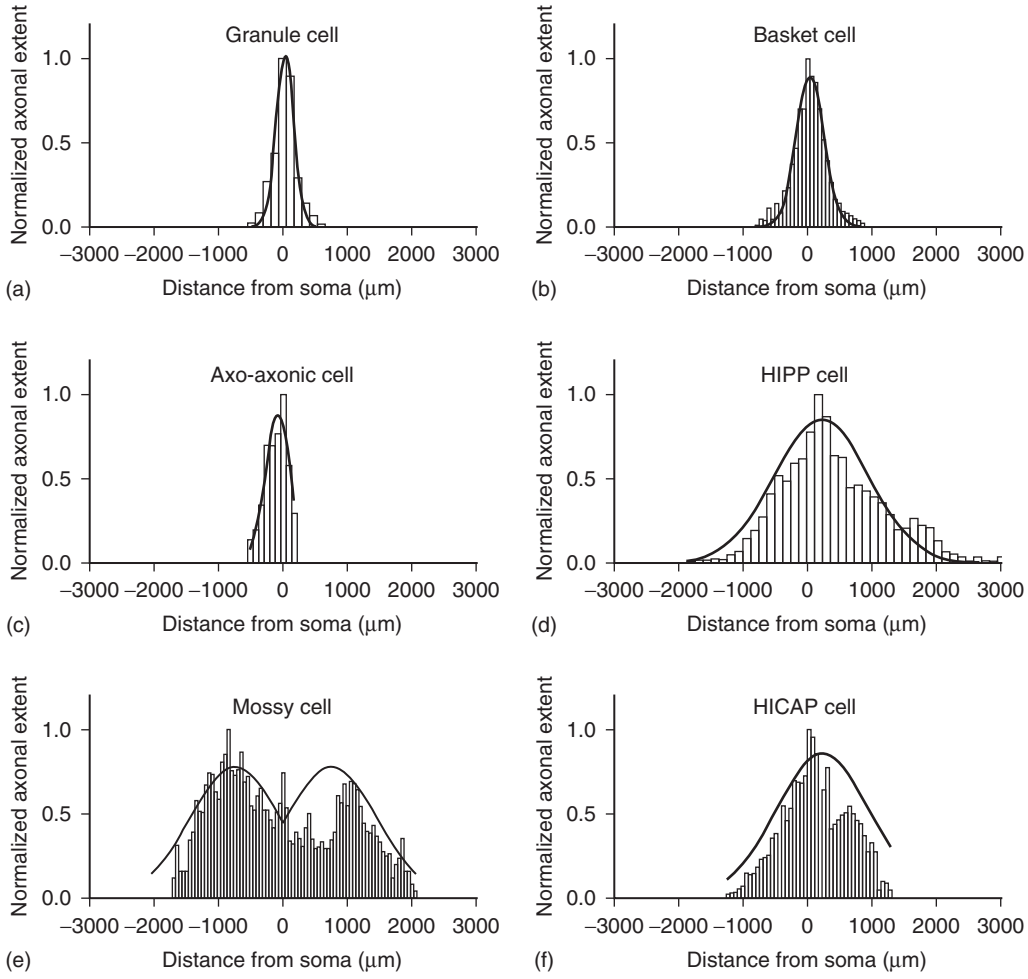

Figure 2 Gaussian fits to distributions of axonal branch lengths from experimental in vivo fills used in model connectivity. (a) Graph of the averaged axonal distribution from 13 granule cells and the fitted Gaussian distribution. (b) Fitted septo-temporal distribution of axonal length of a reconstructed basket cell. (c) Fitted axonal distribution of a CA1 axo-axonic cell. (d) Averaged axonal distributions of 3 HIPP cells from gerbil and the corresponding Gaussian fit. (e) Fitted averaged axonal distributions of 3 mossy cells with a characteristic bimodal pattern of distribution. (f) Septo-temporal distribution of the axonal lengths of a HICAP neuron and the fitted Gaussian. In all graphs, the septal pole of the dentate gyrus is to the left (negative coordinates) with the soma positioned at zero. Used with permission from *The Journal of Neurophysiology*.

Structural and functional calculations were performed at increments of 10% of maximal sclerosis in both the structural and functional models.

Results – Structural and Functional Characterization of the Networks

Topological Assessment of the Structural Network

Two measures originally employed to assess the structure of the nervous system of the worm *C. elegans* were used to characterize the network topology of the healthy and sclerotic dentate: The average path length, L, and the average clustering coefficient, C. The average path length is defined as the average number of steps required to move from any node to any other node in the network, and thus measures the global connectivity of a network. The average clustering coefficient is a measure of local connectivity, defined as the average fraction of all possible connections between 'postsynaptic' nodes, of each node, that are actually present. These topological measures, C and L, can perhaps be best understood in the context of a social network: C measures the probability that any two friends of a given person also know each other. L measures how many steps in a chain of friends would be necessary to connect two randomly selected people in the network.

Based on these two topological measures, networks can be divided into three classes: (1) Regular, with a long path length and large clustering coefficient (**Figure 3(a)**; high local connectivity, low global connectivity); (2) Random, with a short path length and small clustering coefficient

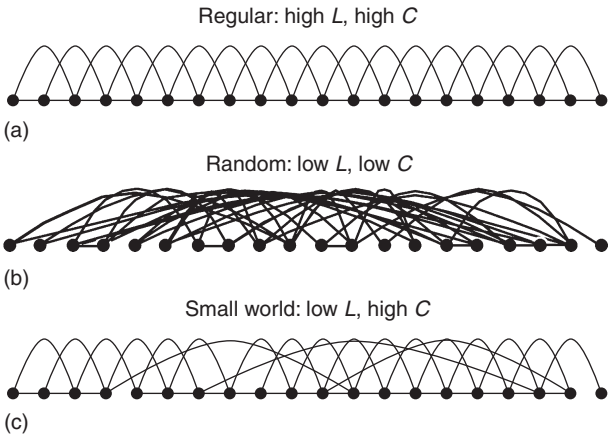

Figure 3 Diagrams of three basic network types. (a) A network with regular topology. All nodes in a regular network form nearest neighbor connections, leading to strong local interconnectedness (high clustering coefficient *C*), but also demanding a large number of steps to move from a given starting point to any other node in the network (high average path length *L*). (b) A network with random topology. A random network has no spatial constraints on the connectivity distribution of individual nodes, leading to a low average *L* but at the same time a low *C*. (c) A network with 'small world' topology. Randomly reconnecting even a few local projections in a regular network topology to distal nodes results in the emergence of a network with 'small world' topology, displaying a high *C* along with a low average *L*. Used with permission from *The Journal of Neurophysiology*.

(**Figure 3(b)**; low local connectivity, high global connectivity); and (3) Small World, with a short path length and large clustering coefficient (**Figure 3(c)**).

The small world network (**Figure 3(c)**) is a unique intermediate between the random and regular graphs, combining a high degree of local connectivity with a number of long range connections, resulting in a both locally and globally well-connected network.

While L and C values are clearly important for network classification, it is difficult to understand topological alterations during sclerosis in terms of their absolute values, as the size of the network and number of connections change with progressive sclerosis. Rather, it is important to use a random network of equivalent size, with an equivalent number of connections as a reference. Using the ratios of C/C_{random} and L/L_{random} normalizes each network to the reference and allows a direct characterization of the randomness (or lack thereof) of its topological features. Both absolute values and these normalized ratios will be illustrated in the present article; however the ratios are most meaningful in terms of comparing networks with different degrees of sclerosis.

The Dentate Gyrus is a Small World Network

Initially, the structure of the healthy or control (also referred to as the model at 0% sclerosis) structural network was established. Remarkably, considering the more than 1 million nodes represented, the average path length was very low ($L = 2.68$, marked ○ in **Figure 4(a)**), meaning that any two neurons on average are separated by fewer than 3 synapses in the dentate gyrus. This is remarkably close to the average path length of the *C. elegans* nervous system (2.65), which has only 282 nodes, a full four orders of magnitude smaller than the dentate gyrus!

When comparing the average path length of the control dentate network to an equivalent random graph, the L/L_{random} ratio obtained was very close to one (1.19; horizontal dotted line in **Figure 4(c)**). This value indicates a globally extremely well-connected control dentate network, with the average path length only slightly increased over the case of a random network- and could perhaps indicate that the neural network of the dentate gyrus simply is a random graph. However, when comparing the calculated clustering coefficient to the clustering of an equivalent random graph, this possible 'equivalence' was clearly not the case. Specifically, the calculated high ratio of C/C_{random} demonstrated a high degree of local connectivity ($C/C_{\text{random}} = 0.026751/0.001135 = 24.7$; horizontal dotted line in **Figure 4(d)**; the absolute value for C in the control network is marked with a ○ in **Figure 4(b)**). Together with the high degree of global connectivity, this ($L \sim L_{\text{random}}$ and $C \gg C_{\text{random}}$) indicates that the dentate gyrus has a small world network topology.

Small World Characteristics are Initially Enhanced, then Transformed during Sclerosis

Similar to the characterization of the control dentate graph, calculations were performed for networks during progressive sclerosis. Maximal sclerosis resulted in a dramatic loss of connections in the network (953 198 800 links are removed out of a total of 1 287 363 500, 74% reduction), while the number of nodes changed minimally (48 000 hilar cells are lost out of 1 064 000 total cells, only 4.5% reduction). Despite the massive loss of connections (due to the loss of richly connected hilar mossy cells and interneurons, which is only slightly compensated by relatively sparse mossy fiber sprouting), the structural graph calculations revealed that L did not significantly increase until beyond 90% sclerosis (solid black line in **Figure 4(a)**). Furthermore, the ratio L/L_{random} surprisingly decreased below the control value during submaximal sclerosis (solid black line in **Figure 4(c)**; control value indicated by horizontal, dotted line in **Figure 4(c)**), suggesting a more globally well-connected graph. Calculation of the clustering coefficient demonstrated similar results, with the ratio C/C_{random} increasing and remaining above the control value until approximately 90% sclerosis (solid black line in **Figure 4(d)**; control marked with

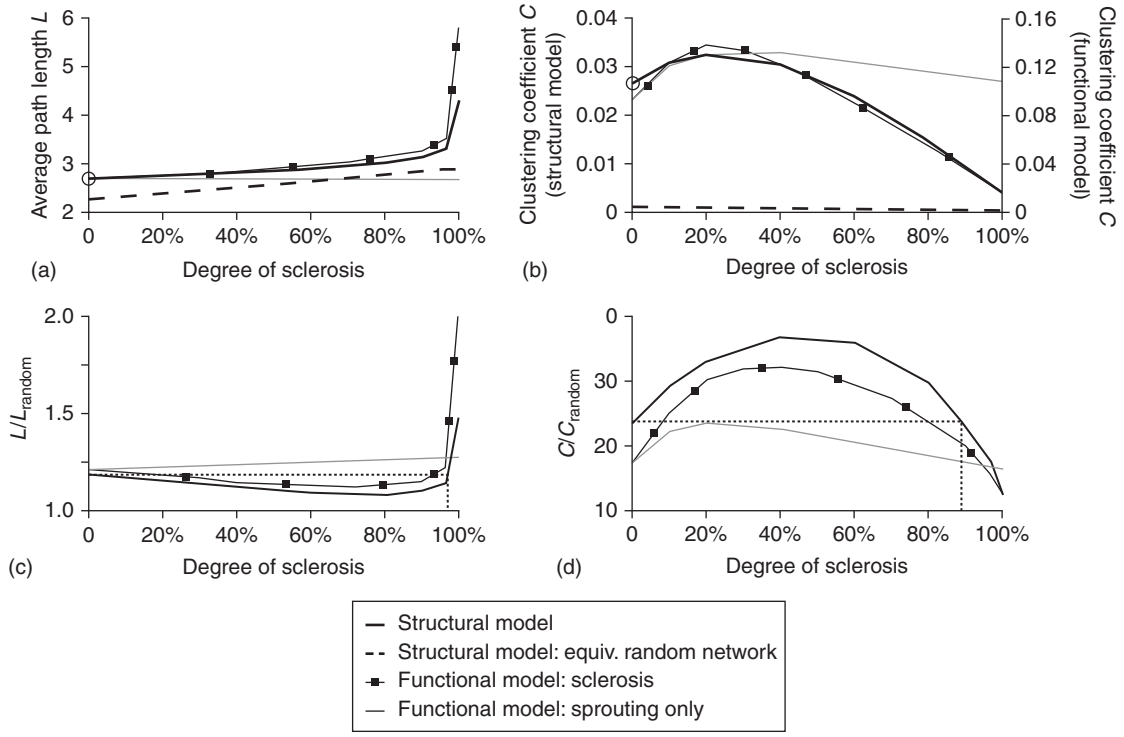

Figure 4 *L* and *C* changes during sclerosis for the different models of the dentate gyrus. (a,c) Alterations of the average path length *L* with sclerosis; (b,d) Alterations of the clustering coefficient *C* with sclerosis. Legend in a also applies to (b,d). Legend in e also applies to f. Solid black lines in a–d: 1:1 structural models; Solid black lines in e–f: graphs of the isolated excitatory/inhibitory networks. Black lines with squares: Structural graph of the 1:20 functional model during sclerosis; Gray lines: Structural graph of the 1:20 functional model network during sprouting only. Dashed black lines in a,b: Equivalent random graphs of the 1:1 structural models. (a,b) Changes in *L* and *C* of the different dentate graphs. The values of *L* and *C* for the healthy (i.e., at 0% sclerosis) full scale structural model dentate gyrus are indicated by '○' on the *y*-axis. (c,d) The relative *L* ($=L/L_{random}$, from panel a) and relative *C* ($=C/C_{random}$, from panel b) changes during sclerosis. In panels c and d, the relative *L* and *C* for the 1:1 structural model of the healthy dentate graph are indicated by dotted horizontal lines. The vertical dotted lines indicate the degree of sclerosis at which the relative *L* exceeds, and the relative *C* decreases below the values for the healthy control graph. Note that the changes of the relative *L* and *C* during sclerosis in the structural model of the 1:20 functional model network (50 000+ nodes; black lines with squares) closely resemble those in the 1:1 full-scale structural model (over 1 million nodes; solid black lines). Note that panel b has two *y* axes. Used with permission from *The Journal of Neurophysiology*.

dotted horizontal line in Figure 4(d)). Taken together, these changes demonstrate a surprising enhancement of small world characteristics at sub-maximal sclerosis, with improved global and local connectivity.

Beyond 90% sclerosis, the absolute value of *L* increased rapidly (solid black line in Figure 4(a)), with the ratio L/L_{random} surpassing the control value at 96.6% sclerosis (vertical dotted line in Figure 4(c)). Furthermore, at approximately 90% sclerosis, the C/C_{random} ratio decreased below the control value (vertical dotted line in Figure 4(d)). Since both a short path length and a large clustering coefficient are required to confer a network with small world structure, the greatly increased path length and decreased clustering coefficient (albeit still high compared to an equivalent random network) indicated a transformation of network topology from a small world into a more regular network structure (high *L*, high *C*) at maximal sclerosis.

Mechanisms of the Biphasic Structural Alterations

In order to understand the factors underlying the described biphasic transformation of dentate network topology during progressive sclerosis (i.e., the initial enhancement of small world properties followed by a transition to a more regular network structure), the excitatory and inhibitory parts of the dentate gyrus graph were studied in isolation.

The behavior of the isolated excitatory graph (granule and mossy cells alone; solid black lines in Figure 5) closely resembled the findings from the complete dentate graph (solid black lines in Figure 4). As described for the complete graph, the average path length remained low during submaximal sclerosis and increased rapidly above 90% sclerosis, while the changes in clustering coefficient displayed the earlier described biphasic pattern

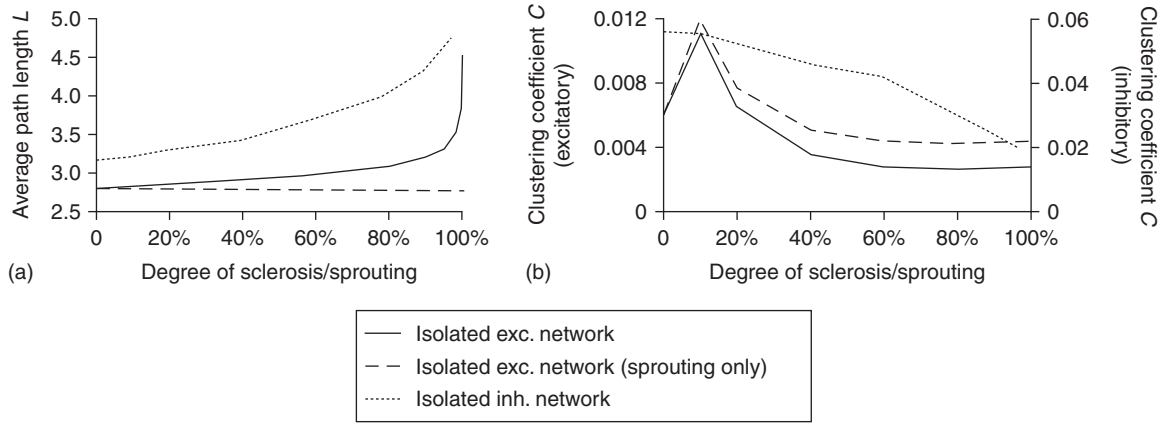

Figure 5 Changes in *L* and *C* during sclerosis for the isolated excitatory and inhibitory graphs. (a,b) Alterations in *L* and *C* for graphs of the isolated excitatory and inhibitory networks during sclerosis, and graphs of the isolated excitatory networks with sprouting alone (no mossy cell loss). Dotted lines: Alterations in *L* and *C* for inhibitory graphs following hilar interneuron loss; solid lines: excitatory graphs (granule and mossy cells); dashed lines: excitatory graphs with mossy fiber sprouting in the absence of mossy cell loss. Note that panel b has two y axes. Used with permission from *The Journal of Neurophysiology*.

as sclerosis progressed. This pattern of change suggests that loss of long range connections resulting from mossy cell loss, and addition of new recurrent granule cell connections through mossy fiber sprouting, govern the biphasic changes described in the complete graph. Further analysis incorporating mossy fiber sprouting in the absence of hilar cell loss showed no significant effect on path length in the isolated excitatory graph (dashed line in **Figure 5(a)**), emphasizing the fact that surviving long range connections provided by mossy cells are the main determinant of *L*. Conversely, the clustering coefficient still displayed a biphasic pattern when hilar cell loss was omitted (dashed line in **Figure 5(b)**), pointing to mossy fiber sprouting as the determining factor for the alterations in C. In the isolated inhibitory network, sclerosis simply resulted in loss of interneurons and an increasingly sparse network, with monotonically increasing L and monotonically decreasing *C* (dotted lines in **Figure 5**).

In summary, two primary factors govern the biphasic topological alterations of the dentate network during sclerosis: During sub-maximal sclerosis, mossy fiber sprouting maintains a high degree of local connectivity and indirectly connects granule cells to surviving mossy cells, conserving the relatively low *L*. With severe sclerosis, the main factor switches to the loss of long-range projecting hilar neurons, particularly the mossy cells, when the increased local connectivity created by mossy fiber sprouting no longer adequately compensates for the massive loss of long distance connections. This latter condition leads to the dramatic increase in average path, and transition of network structure from a small world to a more regular, lattice-like structure.

Characterization of the Functional Network

To understand the functional impact in temporal lobe epilepsy of the described topological changes during sclerosis, the activity in the described network architectures was analyzed in the 1:20 scale functional model of the dentate gyrus previously introduced. The use of a computational model here allows for a dissociation of structural alterations from underlying cellular or synaptic modifications confounding such investigations in experimental preparations.

At first, a structural graph of the 1:20 scale functional model was constructed, and *L* and *C* calculations during sclerosis were performed as in the full scale model. These calculations verified that the structural alterations in the 1:20 scale graph closely resembled those of the full scale graph, with biphasic changes retained for both *L* and *C* (lines with squares in **Figure 4**; compare with solid black lines).

Activity in the functional model network was stimulated by a single, simulated perforant path input to 5000 granule cells, 10 mossy cells, and 50 basket cells in the centrally located bins of the network, 5 ms after simulation start. The resulting activity of the functional network was quantified using four different measures: (1) Duration of granule cell firing (the time between the first and the last granule cell action potential in the network); (2) Average number of action potentials per granule cell; (3) Time until action potentials were fired in granule cells at the edges of the network, furthest from the stimulation point (i.e., latency to full network activity); and (4) Synchrony of granule cell action potential firing assessed by an established coherence measure.

Network Activity Mirrors the Biphasic Structural Alterations

Built from detailed, biophysically realistic single cell models reliably reproducing electrophysiologically determined firing properties, the healthy functional model network showed limited firing in response to a single perforant

path input (**Figure 6(a)**), in accordance with experimental data, and it became increasingly hyperexcitable up to approximately 80% sclerosis (**Figure 6(b–e)**). However, surprisingly, hyperexcitability in the functional model network actually decreased at levels of sclerosis exceeding 80% (**Figure 6(f)**). This pattern of hyperexcitability in the functional network followed the same biphasic pattern seen in the structural network, and the functional effects were solely due to structural network alterations. During submaximal sclerosis and small world structural enhancement, hyperexcitability increased, while hyperexcitability decreased when the network transitioned to a more regular structure.

As previously described, network activity was quantified by four different measures (**Figure 7**); the biphasic structural changes in the network during sclerosis were mirrored by both the maximal activity duration and mean number of action potentials per granule cell, as well as the latency to full network activation (solid black lines in **Figure 7(a–c)**). Synchrony of granule cell firing was assessed both locally (within 0.12 mm along the virtual dentate strip; dashed black lines in **Figure 7(d)**) and globally (up to 2.5 mm separated sampled granule cells; solid black lines in **Figure 7(d)**). While local and global synchrony measures were similar at moderate levels of sclerosis (40–60%), global synchrony subsequently decreased with severe (>60%) sclerosis, while local synchrony increased substantially. These data demonstrate that sclerosis leads to a fundamentally transformed microcircuit where biphasic patterns of activity changes follow biphasic structural changes in network architecture.

To ensure that network activity levels did not simply follow changes in levels of granule cell synaptic input, the net excitatory and inhibitory conductances were calculated at each level of sclerosis (**Figure 8**). However, as both net excitatory and inhibitory peak conductance declined in a monotonic fashion with progressive sclerosis (black lines,

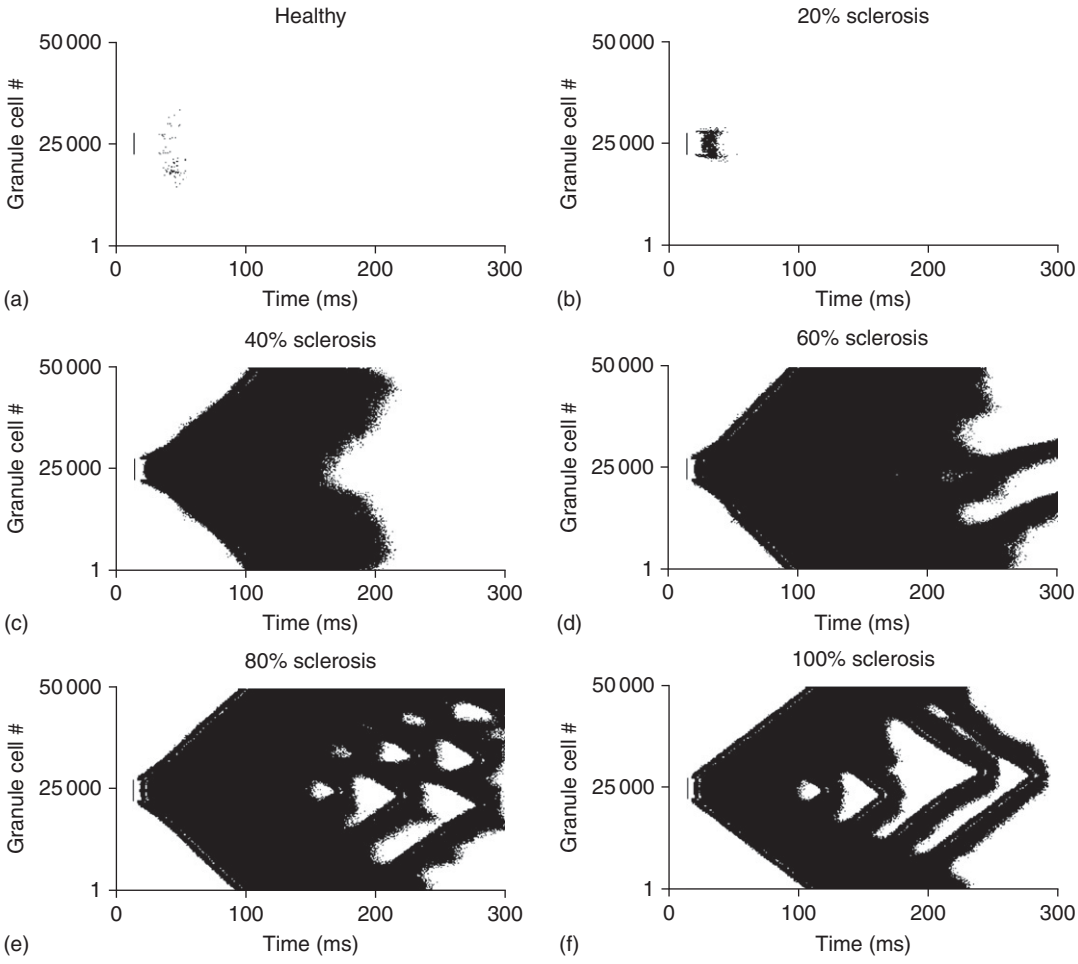

Figure 6 Impact of sclerosis-related topological changes on granule cell firing in functional model networks. (a–f) Raster plots show the first 300 ms of granule cell action potential firing in the functional model network (Granule cells #1–#50 000, plotted on the *y*-axis) for increasing degrees of sclerosis. Activity was initiated by a simulated, single shock stimulation of the perforant path input to granule cells #22 500–#27 499 along with 10 mossy cells and 50 basket cells (co-localized with the stimulated granule cells) at $t = 5$. Note that peak hyperactivity was observed at less than maximal (80%) sclerosis (see quantification in **Figure 7a–d**). Used with permission from *The Journal of Neurophysiology*.

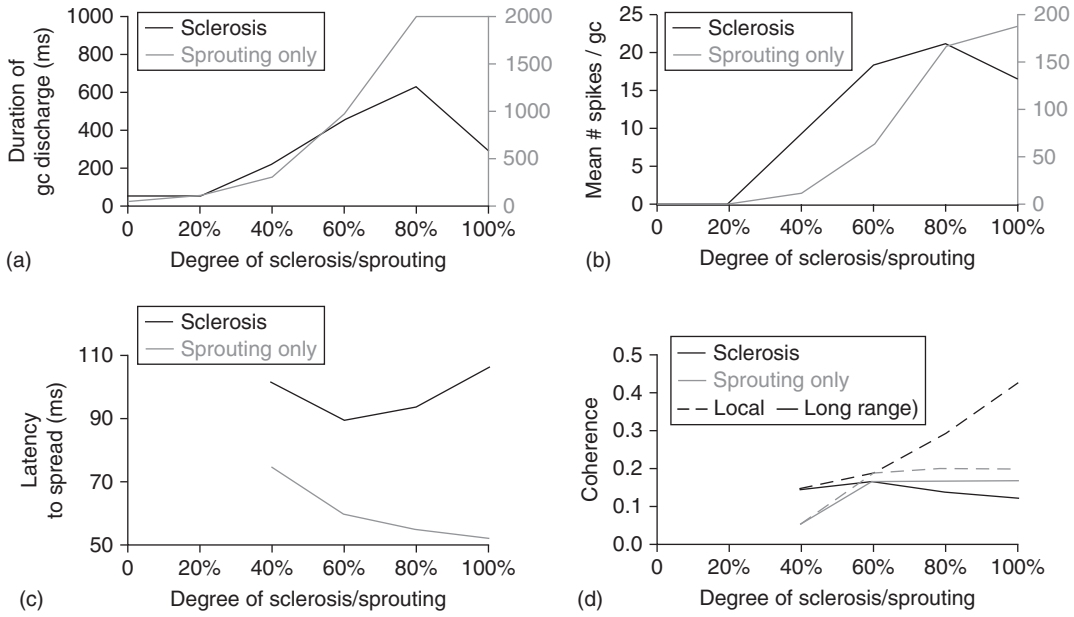

Figure 7 Biphasic changes in functional model network activity during sclerosis, but not during sprouting without hilar neuron loss. Black lines: sclerosis; Gray lines: sprouting without hilar cell loss. (a) Maximal duration of perforant path stimulation-evoked granule cell firing as a function of sclerosis or sprouting without hilar cell loss (note that at 80% and 100% sprouting in the sprouting only case, granule cell firing persisted beyond 2000 ms). (b) Mean number of spikes fired by each granule cell during sclerosis or sprouting alone. (c) Latency to granule cell firing in all 100 bins (only quantified at degrees of sclerosis/sprouting with persistent activity in all bins). (d) Local (dashed line, all-to-all comparison of action potential firing in granule cells #25 000–#25 999) and long range (solid line, pair-wise comparison of the activity in granule cells #25 000–#25 999 to granule cells #45 000–#45 999) coherence of granule action potential firing in the period from 100 ms to 200 ms (only quantified at degrees of sclerosis/sprouting with persistent activity in all bins). Used with permission from *The Journal of Neurophysiology*.

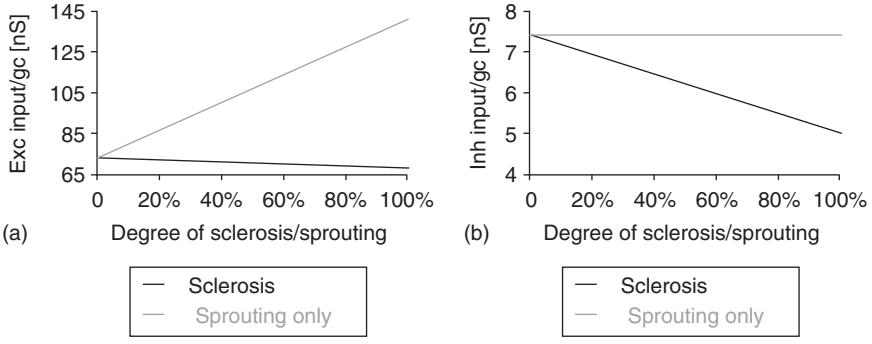

Figure 8 Changes in peak conductance onto granule cells during sclerosis or sprouting without hilar cell loss. (a,b) The average total peak conductance of excitatory (a) and inhibitory (b) synapses onto a model granule cell during sclerosis or sprouting alone. Note that the absence of biphasic changes in **Figure 7(a–d)** during sprouting without hilar cell loss follows the monotonic increase in excitatory drive seen in panel a (gray line). Used with permission from *The Journal of Neurophysiology*.

Figure 8), this pattern could not have been solely responsible for the observed biphasic activity changes.

Activity in Networks with Sprouting but No Cell Loss

Following the approach previously used in determining the mechanism of network structural alterations, the roles of L and C in determining functional network activity were examined using a functional model with sprouting in the absence of cell loss (**Figure 9**). This model provided the opportunity to determine whether biphasic changes in the clustering coefficient could account for biphasic changes in network excitability in the absence of a biphasic change in path length. Again, the structural changes in a 1:20 scale sprouting-only network were determined to ensure biphasic changes in C were accompanied by a stable L (gray lines, **Figure 4**).

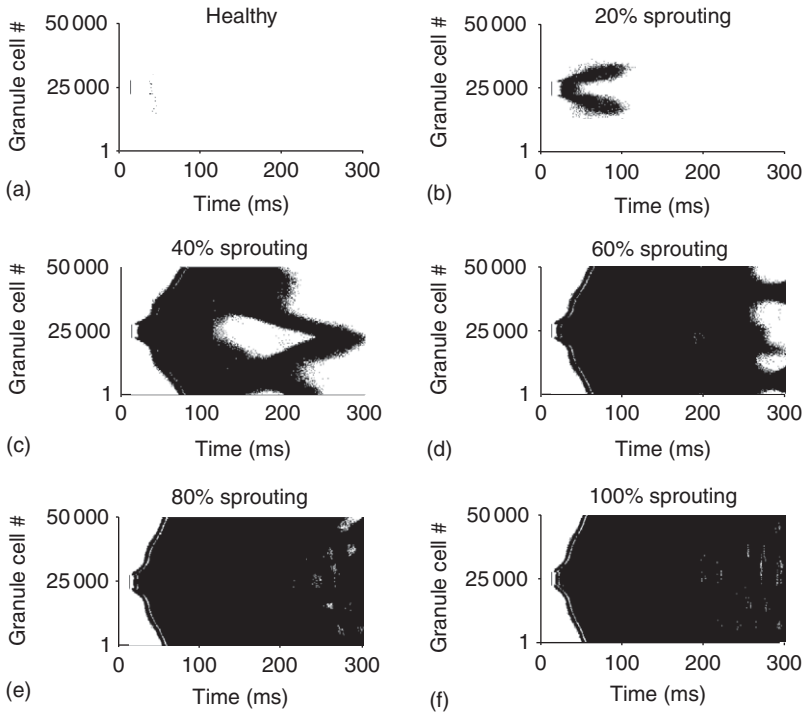

Figure 9 Functional impact on network activity of sprouting in the absence of hilar cell loss. (a–f) Raster plots of granule cell action potential firing in the functional model networks during progressive mossy fiber sprouting. Network activity was initiated as described for **Figure 6**. Note that maximal hyperactivity occurred at maximal sprouting (see **Figure 7(a–d)** for quantification). Used with permission from *The Journal of Neurophysiology*.

Contrasting the activity determined in the sclerotic functional networks described above, all four activity measures showed monotonous changes with increasing sprouting alone in the functional model (gray lines, **Figure 7**), in spite of the remaining biphasic change in clustering coefficient. However, a quantification of the net inhibitory and excitatory drive to the granule cells (**Figure 8**, gray lines) suggested the firing properties in the sprouting-only network simply reflected a monotonic increase in granule cell excitatory drive (68 nS increase per granule cell from 0% to 100% sprouting; gray line in **Figure 8(a)**).

These results demonstrate that both the sprouting and cell loss, initially enhancing small world network properties and subsequently causing the transition to a more regular network structure, are required for the biphasic activity changes seen in the functional model.

Conclusions and Future Directions

The presently discussed study had five major findings: (1) The dentate gyrus network has a small world structure; (2) Moderate sclerosis enhances the small world network characteristics of the dentate gyrus (i.e., L/L_{rand} decreases and C/C_{rand} increases), but severe sclerosis induces a transition to a more regular network structure (L rises rapidly and C declines). (3) Calculations with isolated excitatory and inhibitory networks determined the different roles of hilar cell loss and mossy fiber sprouting in the biphasic structural and functional alterations described. During moderate sclerosis, mossy fiber sprouting compensates for the loss of long range mossy cell connections and enhances small world features, by indirectly connecting granule cells to spared mossy cells. However, at severe sclerosis, hilar neuron loss defines network topology, as mossy fiber sprouting cannot compensate for the maximal loss of long distance connections. (4) Simulations in the functional network model demonstrated that network excitability closely mirrors changes in network topology, with enhanced small world features resulting in network hyperexcitability. With severe sclerosis, however, there is a decrease in hyperexcitability at the transition to a more regular network structure. (5) Simulations of functional sprouting-only networks determined that biphasic changes in the clustering coefficient alone are insufficient to reproduce the biphasic changes in network activity. The increase in relative path length at severe sclerosis caused by maximal loss of hilar neurons results in diminished network excitability, indicating that a small number of surviving, long distance projecting mossy cells can maintain a hyperexcitable dentate gyrus circuit.

The combination of a large number of local and long range connections in a small world network confers the capacity for both fast local computations and efficient

long-range signal relays. In fact, several studies have demonstrated both fast signal propagation and long range synchronization in small world networks. In agreement with these studies, the presently discussed enhancement of small world characteristics of the sub-maximally sclerotic dentate gyrus was accompanied by increasing hyperexcitability and activity propagation. This enhancement of small world structure was made possible by mossy fiber sprouting compensating the massive loss of long distance connections during sclerosis. However, this compensation also led to an increased clustering coefficient and enhanced network hyperexcitability – both very serious and potentially disastrous changes contributing to epileptogenesis.

The surprising decrease of hyperexcitability at maximal sclerosis, caused by the transition of network architecture from an enhanced small world topology to a more regular structure following the loss of the final hilar cells, is in agreement with experimental observations in both epileptic animals and humans. In particular, it is worth noting that studies quantifying hilar cell loss in animal models of epilepsy never report 100% cell loss, and cell counts in surgically removed specimens from pharmacologically intractable human temporal lobe epilepsy patients show a maximal loss of approximately 80% of hilar cells. Interestingly, this number coincides perfectly with maximal hyperexcitability in the functional model networks, observed at 80% sclerosis.

The findings described in this article demonstrate that structural alterations in disease states are crucial for determining neural network function, and computational modeling studies provide a unique way of isolating the impact of multiple pathological changes in epileptogenesis. With the presently established model, the functional effect of, for example, experimentally determined specific changes in intrinsic cellular and synaptic properties can be tested, with only structural changes as the control state. Thus, modeling will continue to be very important for understanding the relative importance of specific pathologies in epilepsy, and potentially help guide efforts towards identifying the optimal targets of improved treatment strategies.

Ictogenesis in the In Vitro Isolated Guinea Pig Brain

Introduction and Background

The epileptic condition is characterized by the abrupt occurrence of seizures, usually without prodromic warning. One of the experimental strategies used to understand epilepsy aims at investigating the mechanisms that control the genesis of a seizure – i.e., the events that regulate the transition from the interictal and the ictal state. These mechanisms are still not well characterized and may be specific for different types of epilepsies. Animal models are used to reproduce epileptic discharges and to study the network, cellular, and subcellular alterations that generate seizures. Since the accessibility to brain tissue is limited in the in vivo condition, in vitro experimental models have been developed to analyze systemic and molecular changes associated with epilepsy.

Excessive and hypersynchronous neuronal activity can be precipitated by several means in in vitro preparations. The complexity of in vitro preparations varies from the very simple (cell cultures), to the complex (slices), to the very complex, in which the entire brain or parts of it are functionally preserved. According to their complexity, different in vitro models produce epileptic-like activities that approximate the patterns observed in human focal epilepsies. In the 1980s, an in vitro preparation of the whole brain of the guinea pig was developed in the laboratory of Rodolfo Llinas. The functional and structural preservation of brain structures in this preparation has been analyzed in detail by further studies performed by several laboratories. More recently, acute conditions that mimic brain diseases have been reproduced in the isolated guinea pig brain. Several studies have demonstrated that seizure-like activity can be generated in this preparation by acute application of proconvulsive compounds.

In the last 20 years, ictal discharges in the human temporal lobe have been recorded with invasive intracranial electrodes, implanted in the temporal region of patients suffering from drug-resistant temporal lobe epilepsy. This presurgical diagnostic procedure aims at identifying the epileptogenic area that can be surgically removed to cure epilepsy. One of the prevalent patterns observed at seizure onset in these patients is the appearance of fast activity at 15–30 Hz in the hippocampus and entorhinal cortex; this pattern is usually preceded by a brief enhancement of interictal spiking in these regions. The present article shows that a similar pattern of seizure initiation can be reproduced in the in vitro isolated guinea pig brain.

Methods

Young adult guinea pigs, from 2 weeks to 2 months of age, are commonly used. The implementation of the procedure on older animals prolongs the time required for brain isolation and affects the viability of the preparation. Animals are deeply anesthetized with a sublethal dose of sodium thiopental (80–120 mg kg^{-1}) before starting the dissection. Surgery begins when trigeminal reflex cannot be elicited bilaterally. Thoracotomy is performed to cannulate the aorta at its emergence from the left ventricle, and the animal is perfused with a cold (10 °C) oxygenated (95% O_2, 5% CO_2) solution composed of 126 mmol l^{-1} NaCl, 3 mmol l^{-1} KCl, 1.2 mmol l^{-1} KH_2PO_4, 1.3 mmol l^{-1} $MgSO_4$, 2.4 mmol l^{-1} $CaCl_2$, 26 mmol l^{-1} $NaHCO_3$, 15 mmol l^{-1} glucose, 2.1 mmol l^{-1} HEPES, and 3% dextran (MW 70 000, pH = 7.1). This procedure reduces brain temperature to 15 °C within 3 min. After 3 min of perfusion, brains are carefully dissected out, transferred to a recording chamber, and perfused via a peristaltic pump (Minipulse 3, Gilson, France) with the aforementioned solution (7 ml min^{-1}, pH = 7.3, 15 °C) through a polyethylene cannula inserted in the basilar artery. Brain temperature is raised slowly to 32 °C (over the course of 1 h) before starting the electrophysiological experiment. The brain is positioned with its ventral surface upward, to access the basilar artery for cannulation.

Extracellular recordings were simultaneously obtained with NaCl-filled micropipettes (5–8 μm tip diameter, 5–10 MΩ resistance) positioned in the piriform cortex (PC), in the medial and lateral entorhinal cortex (EC), and in the hippocampus (subfield CA1). Signals were amplified using a multichannel amplifier (Biomedical Engineering, Thornwood, NY) and were digitized via an AT-MIO-64E3 National A/D Board (National Instrument, Milan, Italy). Data were acquired and analyzed with a custom-made software (ELPHO©) developed in Labview by Vadym Gnatkovsky.

The viability of isolated brains was tested by recording the responses evoked in the olfactory–limbic cortex by stimulation of the lateral olfactory tract. Stimuli were delivered through an isolation unit driven by a Grass S88 pulse generator (Grass Telefactor S88, USA). Stimulating and recording electrodes were positioned in the isolated brains under direct visual control with a stereoscopic microscope.

Drugs such as the muscarinic receptor agonist, pilocarpine (100 μmol l^{-1}, 800 μmol l^{-1}, 10–13 mmol l^{-1};

Sigma, St. Louis, MO, USA), histamine, the $GABA_A$ receptor antagonist bicuculline (50 µmol l^{-1}), and kainic acid (4 µmol l^{-1}) were dissolved in the perfusate and were applied through the resident arterial system.

Results

The results reported here demonstrate that complex patterns of epileptiform activity can be generated in the in vitro isolated brain preparation by acute treatment with proconvulsive compounds. Brief (3 min) arterial perfusion of the isolated brain with 50 µmol l^{-1} bicuculline induces a prevalent pattern observed in 80% of the experiments, characterized by the initial appearance of interictal spikes in the piriform cortex (asterisks in Figure 1) that propagate to the lateral part of the EC (the target structure of PC neurons). In 50% of the experiments, these spikes propagate further into the hippocampal region. By evaluating the time delays between the subsequent appearances of interictal spikes along the piriform–entorhinal–hippocampal pathway, we have concluded that a polysynaptic pathway is responsible for the propagation of the interictal spikes that originate in the PC.

A few seconds before the onset of an ictal discharge, a secondary "focus" of interictal spikes, independent from the PC spikes, is activated in the medial and caudal part of the entorhinal cortex (med EC) and in the hippocampus (arrowheads in Figure 1).

In the illustrated experiment, one of these spikes is followed by a discharge pattern switch that correlates with the onset of an all-or-none ictal event, characterized by the appearance of a prolonged sequence of fast activity at 15–25 Hz in the CA1 region of the hippocampus and in the medial EC (Figure 1(a)). In different experiments, this fast activity was initiated from either one of these

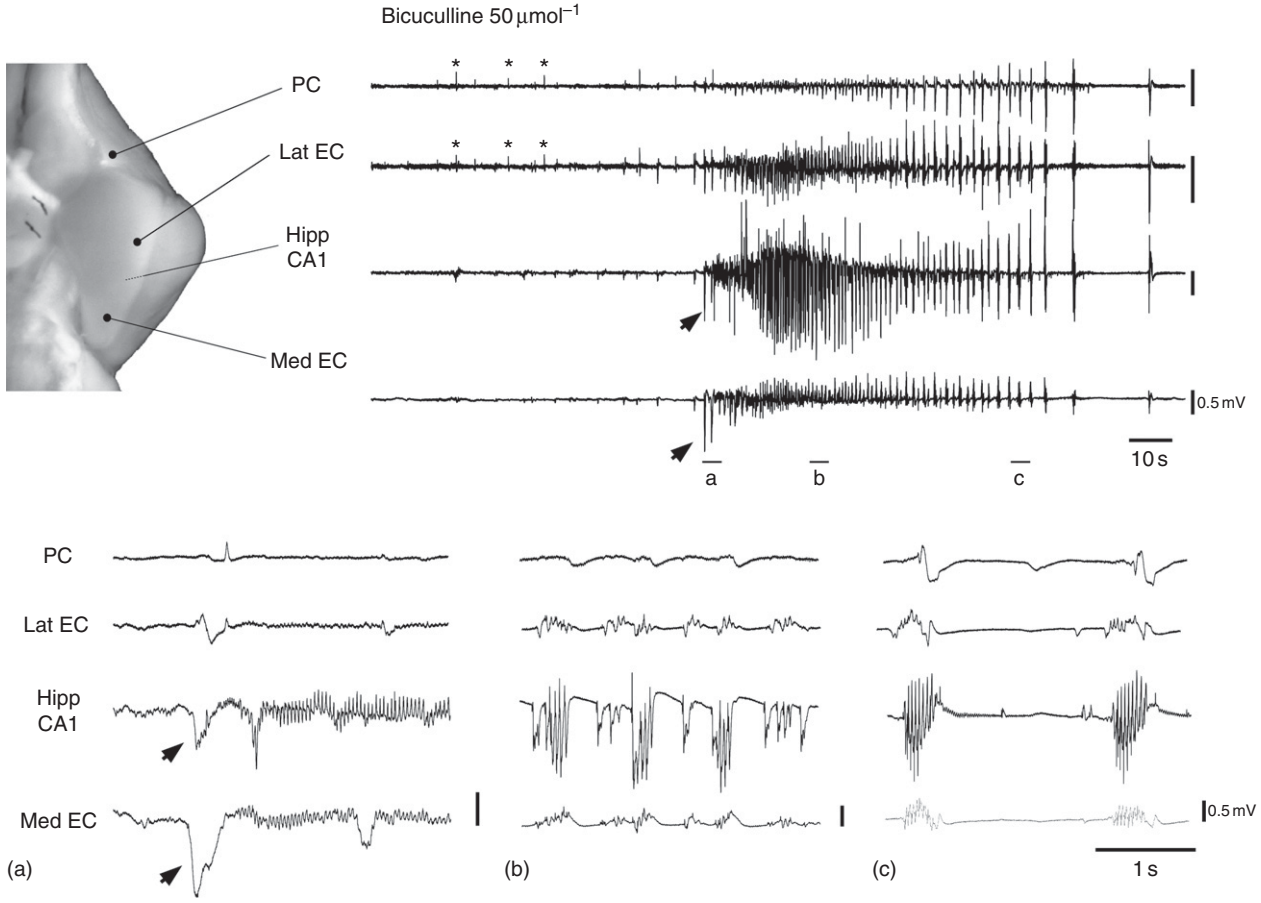

Figure 1 Epileptiform activity generated by a 3-min arterial perfusion of 50 mmol l^{-1} bicuculline in the in vitro isolated brain preparation. The positions of the recording electrodes in the piriform cortex (PC), lateral (lat EC) and medial entorhinal cortex (med EC), and in the CA1 subfield of the hippocampus (hipp CA1) of one hemisphere are illustrated in the panel on the left. Interictal spikes (asterisks) are generated in the PC and propagate to the lat EC. Just ahead of the seizure in the hipp and med EC, large-amplitude interictal spikes (arrowheads) were observed. To enhance visual correlation between activities at different recording sites, slow potentials in all traces were filtered by a 1 Hz high pass filter. Expansions of the recordings at seizure onset, during irregular bursting and during the late-ictal regular bursting (marked by a, b and c, respectively) are shown in the lower part of the figure. Note that fast activity at 15–25 Hz is generated in the med EC and hipp only. Toward the end of the seizure bursting, afterdischarges propagate to more rostral regions.

two regions. Since the recordings were performed from discrete regions within this wide area, no definitive indication on the structure that generates the fast activity can be gained from these experiments. Fast activity at seizure onset remains confined to the hippocampal–medial EC region and does not propagate to the lateral EC and to the PC. Fast activity persists for 3–10 s and is followed by an irregular population bursting pattern (**Figure 1(b)**) that becomes progressively more regular and entrains the lateral EC (**Figure 1(c)**). Late ictal bursting propagates to distant cortical regions, such as the PC, where it may generate secondary interictal spikes (**Figure 1(c)**) or burst responses. Seizures are followed by a postictal depression.

The pattern of activity described earlier was consistently observed during brief and incomplete disinhibition of the whole isolated guinea pig brain with the $GABA_A$ receptor antagonist, bicuculline. A study based on paired-pulse stimulation (not shown) confirmed that inhibition efficacy is reduced only by 20% when this seizure-like activity starts. To verify whether such seizure-onset pattern is specific to bicuculline, other proconvulsive drugs were tested in the in vitro isolated brain. Arterial perfusion of the glutamate receptor agonist kainic acid ($4\,\mu mol\,l^{-1}$) and of the muscarinic receptor agonist pilocarpine ($800\,\mu mol\,l^{-1}$) were examined. As shown in **Figure 2(a)**, kainic acid induced within few minutes of perfusion a clear ictal discharge that also initiated with fast activity (in the 15–25 Hz range) in the medial EC and in the hippocampus. The appearance of this activity correlated with a DC shift of the extracellular trace that typically marks seizure initiation. Pilocarpine alone was not able to induce epileptiform activity, unless the permeability of the blood–brain barrier is enhanced by coperfusion of compounds such as histamine ($100\,\mu mol\,l^{-1}$; **Figure 2(b)**) or bradykinin. In these latter conditions, seizure-like events were consistently observed. Also in these experiments, seizure onset was characterized by the appearance of fast activity (at 15–25 Hz), coupled with a DC shift in the trace, in both the medial EC and the hippocampus. Both kainic acid and pilocarpine + histamine perfusion induced interictal spikes before the onset of an ictal discharge.

These experiments demonstrate that seizure-like activity in the hippocampal–entorhinal area is characterized by the appearance of a sequence of fast activity in the frequency range of the fast activity observed in the same regions in human TLE. The seizure-onset pattern is the same when different proepileptic agents, with different mechanisms of action, are utilized. These findings demonstrate that in an in vitro preparation in which the connectivity between brain areas is functionally preserved, temporal lobe seizure activity is quite stereotyped at onset, suggesting the existence of a prevalent and peculiar pattern generated by the hippocampal–entorhinal network.

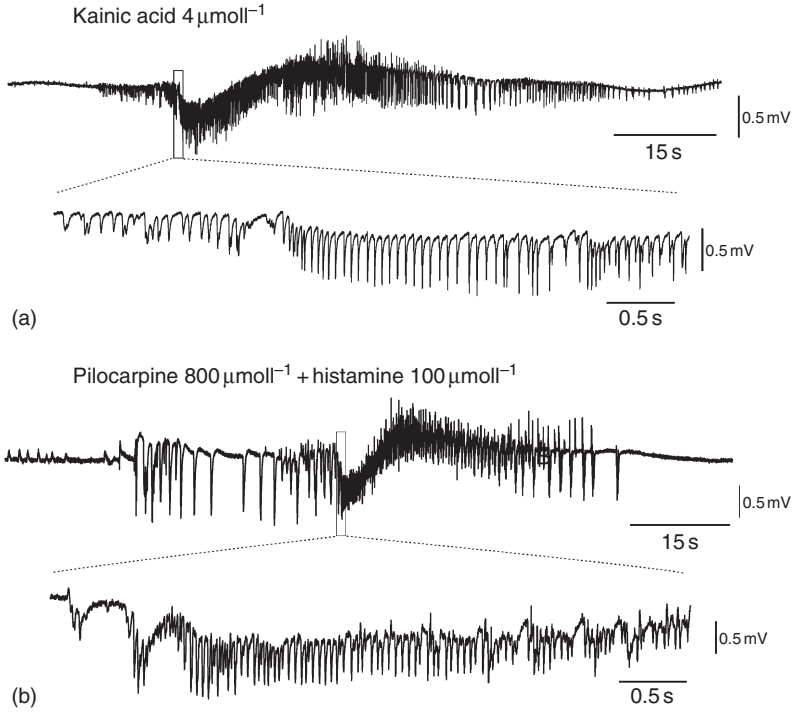

Figure 2 Ictal events recorded in the medial EC during arterial perfusion of kainic acid (a) or pilocarpine and histamine (b) in the in vitro isolated guinea pig brain. Expansions of the recordings at seizure onset are illustrated in the lower part of each panel. High pass filter was 0.02 Hz in these experiments.

Future Goals

The present data, and several reports published in the last 10 years on acute ictogenesis in the in vitro isolated guinea pig brain, demonstrate that this preparation is suitable to study system physiology of the temporal region in conditions of enhanced excitability. This experimental preparation represents a close-to-in vivo condition, but maintains the advantages of an in vitro preparation in terms of mechanical stability, accessibility to different brain regions, pharmacological manipulations, etc. As in other in vitro preparations, intracellular recordings with sharp electrodes can be obtained from principal cortical neurons and putative interneurons in the isolated guinea pig brain. This approach offers the possibility to identify the role of morphologically identified subpopulations of neurons during the interictal and ictal discharges described above. Modification of extracellular ion concentration (such as potassium and protons, i.e., pH) can also be measured in the isolated guinea pig brain during seizure activity. Laminar profiles of extracellular field activity, and current source density analysis of laminar profiles, are currently utilized in our laboratory to analyze evoked potentials and spontaneous event generated in the isolated brain. Finally, optical imaging of the activity-dependent signals generated by voltage-sensitive dyes perfused into the isolated brain has been used to map the tangential propagation of brain activity in the parahippocampal region. The combined use of these techniques can be used to analyze the role of individual variables (extracellular ions, single neuron activity, pH, networks) and their reciprocal interactions in the generation of network and structure-specific interictal–ictal patterns. In addition, further studies in the isolated guinea pig brain preparation will allow us to understand the complex interactions between different cortical (and subcortical) structures, and between hemispheres, in a condition of functional preservation of brain connectivity.

So far, the isolated guinea pig brain has been used to study acute ictogenesis. The in vitro maintenance of an entire adult brain relies on the existence of a good anatomical communication between the vertebrobasilar arterial system and the carotid system. The in vitro perfusion of the guinea pig brain is accomplished via a single access – the basilar artery. In the guinea pig (as well as in other lagomorph, such as the rabbit, but not in the rat and the mouse), the basilar artery bifurcates into two large posterior communicating arteries that allow a proper perfusion of the rostral part of the brain served by the carotid system. In rat and mice, cannulation of the basilar artery is practicable, but the posterior communicating arteries have a small size and do not allow a sufficient perfusate flow into the brain regions supplied by the carotids, via the anterior and medial cerebral arteries. Therefore, the brain of rodents such as rats and mice – in which most models of acquired or genetic-based epilepsy have been developed – cannot be studied using this in vitro in toto preparation. Therefore, to study a whole chronic epileptic brain in vitro, we need to develop chronic models in the guinea pig. A temporal lobe epilepsy model in the guinea pig is presently in development in our laboratory, with the objective of studying the cellular, homeostatic, and network mechanisms that regulate the generation of spontaneous epileptiform discharges in a chronic model of focal temporal lobe epilepsy.

The data reported here support an observation that is well known to clinical neurophysiologists – i.e., that the electroencephalographic correlate of seizure onset in focal epilepsies is the appearance of fast activity. This pattern has been confirmed by intracranial recordings performed in patients with temporal lobe (but also neocortical) epilepsy resistant to the pharmacological treatment, in presurgical evaluation for the excision of the epileptogenic area. Several reports indicated that one of the prevalent patterns of seizure initiation in mesial temporal lobe epilepsy is fast activity, at 15–30 Hz, that may be anticipated by the occurrence of large-amplitude EEG spikes. The reproduction of a similar pattern in homologous brain regions of the in vitro isolated guinea pig brain provides us with an opportunity to identify the mechanisms of seizure generation in the entorhinal cortex–hippocampus. On the basis of on these studies, more specific and detailed hypotheses on the mechanisms that initiate seizure activity in the mesial temporal lobe should be formulated and tested.

Kindling: A Phenomenon of Seizure-Induced Plasticity and a Model of Focal and Limbic Epilepsy

Introduction

Kindling is a specific form of seizure-induced, activity-dependent plasticity which is associated with repeated episodic network synchronization. As an example of activity-induced modification of neuronal and circuit function, kindling shares the common feature of activity-induced long-term change in neural function with other phenomena of activity-dependent plasticity such as long-term potentiation (LTP) and developmental activity-dependent plasticity. However, the distinctive feature that distinguishes kindling from these other activity-dependent phenomena is its association with repeated episodic network synchronization and seizures.

Kindling of limbic structures has been regarded as a model of limbic or temporal lobe epilepsy (TLE). As the cumulative permanent effects of repeated episodic network synchronization eventually result in spontaneous seizures, limbic kindling has features of slowly developing epileptogenesis, and has been used for decades to investigate how repeated seizures modify neural pathways and contribute to the histopathological alterations underlying chronic TLE. The kindling model is also pertinent to understanding how seizure-induced plasticity and repeated seizures can contribute to development of increasingly severe seizures, and provides an opportunity to investigate the underlying neurobiology leading to intractable epilepsy. This latter aspect of kindling has been used to study how the adverse effects of repeated seizures can be modified by therapeutic agents. The well-controlled, gradually evolving chronic epileptogenic process that occurs during kindling has been exploited to study the progression of molecular, cellular, and circuit modifications that are a consequence of repeated seizures. More recently, the kindling model has been used to evaluate novel drugs that may be effective at slowing or stopping the progression of epileptogenesis.

Background

The phenomenon of kindling was initially recognized serendipitously in 1969, by Graham Goddard, during experiments investigating the effects of hippocampal stimulation on a learning task in awake, freely-moving rats. Subsequently, many investigators have used kindling to study a variety of plasticity-related phenomena, at both the electrophysiological and the behavioral/clinical levels. Kindling has been induced in a variety of animal species, with stimulation in many different brain regions. Kindling with stimulation in limbic areas of the brain has been most common, particularly from the amygdala. Clinical responses to limbic seizures were described and classified by Racine according to a scale that is based on severity of the evoked clinical phenomena. Seizure-like activity develops, associated with stereotypic behaviors, as follows: (i) behavioral arrest, eye closure, vibrissae twitching, sniffing; (ii) facial clonus and head bobbing; (iii) unilateral forelimb clonus; (iv) rearing with continued forelimb clonus (bilateral); and (v) rearing with loss of motor control and falling.

Kindling provides the investigator with an opportunity to test hypotheses during a slowly evolving process of epileptogenesis under rigorous and graded control. This

Introduction

Kindling is a specific form of seizure-induced, activity-dependent plasticity which is associated with repeated episodic network synchronization. As an example of activity-induced modification of neuronal and circuit function, kindling shares the common feature of activity-induced long-term change in neural function with other phenomena of activity-dependent plasticity such as long-term potentiation (LTP) and developmental activity-dependent plasticity. However, the distinctive feature that distinguishes kindling from these other activity-dependent phenomena is its association with repeated episodic network synchronization and seizures.

Kindling of limbic structures has been regarded as a model of limbic or temporal lobe epilepsy (TLE). As the cumulative permanent effects of repeated episodic network synchronization eventually result in spontaneous seizures, limbic kindling has features of slowly developing epileptogenesis, and has been used for decades to investigate how repeated seizures modify neural pathways and contribute to the histopathological alterations underlying chronic TLE. The kindling model is also pertinent to understanding how seizure-induced plasticity and repeated seizures can contribute to development of increasingly severe seizures, and provides an opportunity to investigate the underlying neurobiology leading to intractable epilepsy. This latter aspect of kindling has been used to study how the adverse effects of repeated seizures can be modified by therapeutic agents. The well-controlled, gradually evolving chronic epileptogenic process that occurs during kindling has been exploited to study the progression of molecular, cellular, and circuit modifications that are a consequence of repeated seizures. More recently, the kindling model has been used to evaluate novel drugs that may be effective at slowing or stopping the progression of epileptogenesis.

Background

The phenomenon of kindling was initially recognized serendipitously in 1969, by Graham Goddard, during experiments investigating the effects of hippocampal stimulation on a learning task in awake, freely-moving rats. Subsequently, many investigators have used kindling to study a variety of plasticity-related phenomena, at both the electrophysiological and the behavioral/clinical levels. Kindling has been induced in a variety of animal species, with stimulation in many different brain regions. Kindling with stimulation in limbic areas of the brain has been most common, particularly from the amygdala. Clinical responses to limbic seizures were described and classified by Racine according to a scale that is based on severity of the evoked clinical phenomena. Seizure-like activity develops, associated with stereotypic behaviors, as follows: (i) behavioral arrest, eye closure, vibrissae twitching, sniffing; (ii) facial clonus and head bobbing; (iii) unilateral forelimb clonus; (iv) rearing with continued forelimb clonus (bilateral); and (v) rearing with loss of motor control and falling.

Kindling provides the investigator with an opportunity to test hypotheses during a slowly evolving process of epileptogenesis under rigorous and graded control. This

control of epileptogenesis arises from the ability of the experimenter to determine the number of stimulations or evoked episodes of network synchronization to reach a particular stage of behavioral seizures, and to use the number and timing of stimulations as an experimental variable under rigorous control throughout the chronic kindling process. The episodic network synchronization and afterdischarges (ADs) required for kindling progression, and the eventual emergence of spontaneous seizures, can be elicited via stimulation through chronically implanted electrodes. Stimulation intensities that are initially subconvulsant for eliciting ADs in naïve animals dependably evoke overt secondarily generalized seizures in a fully kindled animal.

Experimental and Methodological Details

Kindled seizures can be induced by any method of stimulation that elicits network synchronization accompanied by ADs. Kindled seizures are typically evoked by electrical stimulation, consisting of trains of pulses 1–2 s in duration. Within the train, the pulses – typically 1.0 ms constant current biphasic pulses – are delivered at 25–150 Hz. Stimulation trains of 60 Hz were initially identified as particularly effective in evoking kindled seizures. Biphasic constant current square wave pulses are generally preferred to minimize possible chronic tissue changes induced by repeated stimulation at the electrode site, but constant voltage and sine wave pulses are also effective. Most kindling protocols use the lowest stimulation intensity that evokes an AD.

The evoked kindled seizures gradually evolve through predictable behavioral stages from partial or focal seizures (classes I–III) to secondary generalized tonic–clonic seizures (class V). For experimental purposes, the behavior observed in classes I, II, and III are compared with the complex partial or limbic seizures found in human epilepsies. The more severe seizures (i.e., classes IV and V) are consistent with secondary generalized seizures (Table 1). Once the animals begin to have class V seizures, they are considered fully kindled. The number of ADs required to evoke the first class V seizure is a highly reliable measure of the rate of kindling progression and varies as a function of stimulation site. As kindling progresses, there is a gradual reduction in the stimulation intensity required to evoke an AD and behavioral seizure, and the repeated evoked seizures induce permanent life-long increases in susceptibility to additional seizures.

Table 1 Classification of kindled seizures

Seizure Class (from Racine, 1972)	*Behavioral Manifestation*	*International Classification of Seizures (from Gastaut, 1970)*
Class 1	Mouth and facial movements	Partial
Class 2	Head nodding	Partial
Class 3	Forelimb clonus	Partial or secondary generalized
Class 4	Rearing	Secondary generalized
Class 5	Rearing and falling	Secondary generalized

In a given animal species, the rate of kindling development to the stage of class V seizures is remarkably consistent, as a function of the site of stimulation. The interstimulus interval that optimizes the rate of kindling progression appears to be under strict control, as repeated brief stimulus trains applied 1–2 times daily (~8–24-h intervals) most reliably induce the gradually evolving behavioral and electrographic seizures and permanently increased susceptibility to additional seizures. 'Massed' stimulation, which refers to delivery of stimulus trains at short intervals, can inhibit kindling development. However, protocols have also been developed that group stimulations more closely than 1–2 per day and still produce permanent increased seizure susceptibility and spontaneous seizures. Although these so-called 'rapid' kindling protocols induce permanent functional modifications, the alterations induced by the different protocols may not be identical in all respects. With sufficient repetition of the evoked seizures (using the conventional once or twice daily stimulation protocol), spontaneous seizures are observed; this kindling stage usually requires 90–100 evoked seizures. At this stage of the kindling process, epilepsy (defined as chronic susceptibility to spontaneous seizures) has been induced.

Although electrical stimulation is most commonly used to evoke kindled seizures, repeated application of chemoconvulsants such as pentylenetetrazol, carbacol, cocaine, bicuculline – any agent that elicits network synchronization accompanied by ADs – also induces kindling. Both focal and generalized application of chemoconvulsants will induce kindling. The regions and pathways of the central nervous system that demonstrate kindling in response to electrical stimulation are diverse, and include neocortex, subcortical regions, limbic system, and brainstem (Table 2). Limbic structures appear to be particularly vulnerable, with fastest rates of kindling (defined by the number or ADs required to elicit a class V seizure) observed with stimulation of the perirhinal cortex > olfactory bulb > amygdala > entorhinal cortex > hippocampus. It is presumed that the rate of kindling, which is remarkably consistent for a given site of stimulation, is a reflection of an evolving sequence of activity-induced neuronal and cellular alterations that gradually propagate into the motor system circuitry underlying evoked secondarily generalized tonic–clonic (class V) seizures. The progression and permanence of kindling in neural pathways 'transfers' across sites

Table 2 Brain regions susceptible to kindling

Brain region	*Mean number of stimuli required to induce first convulsion*	*Relative susceptibility of structure to kindling*
Amygdala	15	More vulnerable to kindling
Globus pallidus	22	
Pyriform cortex	24	
Olfactory area	29	
Anterior limbic field	29	
Entorhinal cortex	37	
Olfactory bulb	44	
Septal area	55	
Preoptic area	63	
Caudate-putamen	74	Less vulnerable to kindling
Hippocampus	77

as well as across methods of induction, and kindling can be induced in species ranging from amphibians to nonhuman primates (Table 3). For all of these reasons, kindling is most appropriately regarded as a phenomenon of seizure-induced plasticity.
